Abstract

Endoscopic therapies for lesions of the duodenum are technically more difficult than those for lesions of the other parts of the gastrointestinal tract due to the anatomical features of the duodenum, and the incidence rate of complications such as perforation and bleeding is also higher. These aforementioned trends were especially noticeable for the case of duodenal endoscopic submucosal dissection (ESD). The indication for ESD of duodenal tumors should be determined by assessment of the histopathology, macroscopic morphology, and diameter of the tumors. The three types of candidate lesions for endoscopic therapy are adenoma, carcinoma, and neuroendocrine tumors. For applying endoscopic therapies to duodenal lesions, accurate preoperative histopathological diagnosis is necessary. The most important technical issue in duodenal ESD is the submucosal dissection process. In duodenal ESD, a short needle-type knife is suitable for the mucosal incision and submucosal dissection processes, and the Small-caliber-tip Transparent hood is an important tool. After endoscopic therapies, the wound should be closed by clipping in order to prevent complications such as secondary hemorrhage and delayed perforation. At present, the criteria for selection between ESD and EMR vary among institutions. The indications for ESD should be carefully considered. Duodenal ESD should have limitations, such as the need for its being performed by experts with abundant experience in performing the procedure.

INTRODUCTION

Endoscopic submucosal dissection (ESD) is widely recognized as an effective treatment strategy for early gastric cancer[1,2]. In recent years, the indications for ESD have been expanded to include lesions of the esophagus and the large intestine[3-5]. Although there are several reports of ESD performed for non-ampullary duodenal tumors[6-8], the indication of ESD for the treatment of these tumors remains controversial, because the procedure is technically difficult and associated with a high incidence rate of complications[1]. While ESD may be indicated for non-ampullary duodenal tumors, including adenomas, carcinomas, and neuroendocrine tumors (NET), there is the need to determine whether ESD or endoscopic mucosal resection (EMR) might be optimal. At present, the criteria for selection between ESD and EMR vary among institutions.

In order to determine whether ESD is indicated for duodenal tumors, examination of the site, size, and macroscopic and histological morphology of the tumors is necessary. Development of guidelines for ESD of duodenal lesions (duodenal ESD) is awaited.

DIFFICULTY IN DUODENAL ESD

The duodenum is curved in the shape of a letter C and divided into four portions. The first portion is covered by the peritoneum and is mobile, whereas the second and third portions are dorsally fixed by the peritoneum and located in the retroperitoneum. These portions are immobile. The duodenal wall is thin, which consists of the mucosal, submucosal, proper muscle, and subserosal layers, starting from the lumen inward. At the outermost layer, the anterior aspect of the duodenal wall (peritoneal cavity aspect) is covered by serosa (peritoneum), while the posterior aspect is connected with the retroperitoneum. There are numerous mucosal folds on the internal surface of the duodenum, except in the first portion. The surface of the folds carries many villi which function to absorb nutrients, *etc*. In the duodenal lumen from the second portion downward, a number of circular folds (Kerckring's folds) composed of the mucosa and submucosa are arranged perpendicular to the long axis. Duodenal glands (Brunner's glands), which produce alkaline fluid rich in mucus, are distributed in the submucosa.

In endoscopic therapies for lesions of the duodenum, the maneuverability of the endoscope is poor due to the anatomical features. Moreover, because of the presence of the folds and Brunner's glands, it is more difficult to achieve sufficient bulging by local injection into the submucosa, as compared with the case in other parts of the gastrointestinal tract, and the duration of bulge of the submucosa is also short. Furthermore, because the duodenal wall is thin, the incidence rate of complications such as bleeding and perforation is high. Especially, duodenal ESD is technically difficult, often takes long time to perform, and is associated with a high risk of perforation[6]. Thus, it would seem that duodenal ESD should be performed by operators skilled in safe and reliable techniques for ESD of at least lesions of the stomach, esophagus, and large intestine.

SELECTION OF ENDOSCOPIC THERAPIES FOR LESIONS IN THE DUODENUM

The indication for ESD of duodenal tumors should be determined by assessment of the histopathology, macroscopic morphology, and diameter of the tumors. The three types of candidate lesions for endoscopic therapy are adenoma, carcinoma, and NET.

In the case of duodenal tumors, unlike tumors of the stomach and the large intestine, it is often difficult to differentiate between benign and malignant tumors on the basis of the macroscopic endoscopic findings alone. Thus, histopathological diagnosis is basically essential. However, the high risk of development of fibrosis in the submucosa occurring after biopsy reportedly makes endoscopic therapy difficult[9]. While magnifying endoscopy with narrow-band imaging has frequently been reported to be useful for qualitative diagnosis of early esophageal[10,11], gastric[12,13], and colorectal cancers[14], it is also useful for qualitative diagnosis of superficial non-ampullary duodenal epithelial tumors[15]. For depressed-type lesions, because fibrosis is likely to occur after biopsy, optical biopsy using magnifying endoscopy with narrow-band imaging has been reported to be more effective than tissue biopsy[16].

Endoscopic therapies for duodenal adenomas

Duodenal adenomas have the potential for malignant transformation[17,18]. Especially, those that are 2 cm or more in diameter and adenomas showing high-grade dysplasia on histopathology show a high likelihood of becoming malignant[19-21], and resection is preferable for such lesions. On the other hand, there is a report that low-grade adenomas measuring less than 1 cm in diameter remained low-grade lesions even at 2 years after the first diagnosis[22]. EMR of duodenal tumors has been reported to be safe and useful and to be associated with a favorable long-term prognosis[23-29].

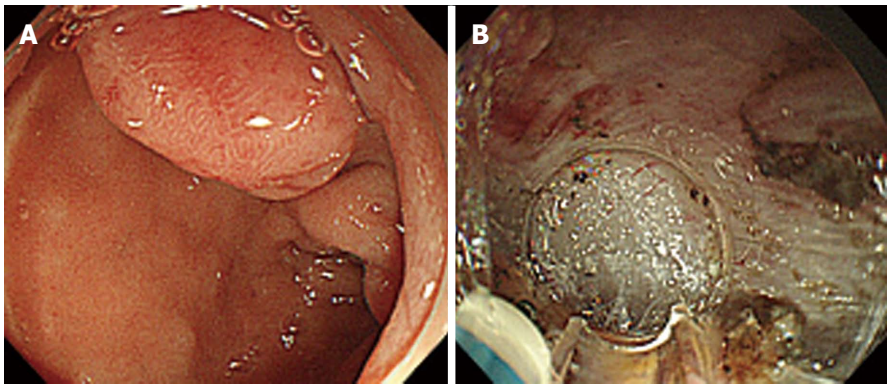

Figure 1 Endoscopic submucosal dissection of a neuroendocrine tumors in the superior duodenal bulb. A: A protruded-type tumor 0.9 cm × 0.9 cm in size was identified; B: We performed a submucosal dissection. The tip of a knife is perpendicularly oriented to the dissection surface.

In addition, piecemeal resection of adenomas is acceptable. Thus, EMR seems to be preferable for the treatment of duodenal tumors. However, a study showed that the preoperative pathological diagnosis was adenoma in 3 of 4 cancer patients who underwent EMR[30], and accurate preoperative diagnosis is necessary. At our institution, endoscopic therapy is not selected for patients with low-grade adenomas measuring less than 1 cm in diameter; instead, such patients are followed up with regular endoscopy. We select endoscopic therapies for adenomas that are at least 1 cm in diameter or show a tendency to grow, those that are histopathologically diagnosed as low-grade adenoma, but appear red and are macroscopically suspected as cancer, *etc.*

Endoscopic therapies for duodenal cancer

In a study of 128 lesions of early duodenal cancer for which surgery or endoscopic polypectomy was performed, it was reported that none of the cases of intramucosal carcinoma showed lymph node metastasis[31]. Thus, endoscopic therapies should be considered for well-differentiated noninvasive carcinomas not showing submucosal invasion. The complete remission rate after EMR for duodenal tumors ranges from 63% to 97%[24-39]. Lesions measuring 2 cm or more in diameter are likely to require piecemeal resection[23,29], and the persistence and recurrence rates are higher after piecemeal resection than after *en bloc* resection[16,29]. Complete (R0) resection is more frequently achieved by ESD than by EMR[16,30]. Furthermore, *en bloc* resection enables accurate histopathological assessment of deep and lateral surgical margins[33]. Thus, it seems preferable to perform EMR for lesions that can be resected *en bloc* by EMR and to perform ESD for lesions in which EMR is expected to result in piecemeal resection.

Endoscopic therapies for duodenal NET

The common sites of NET are the ileum, appendix, and rectum[34], and NET originating from the duodenum accounts for less than 5% of NET[35-38]. While according to one previously reported retrospective study, no recurrence was observed after local excision in any patients with tumors measuring less than 2 cm in diameter[39], another report indicated that lymph node metastasis was observed in 13% of patients with tumors measuring less than 1 cm in diameter[40]. No consensus has been reached on the association between tumor diameter and the likelihood of lymph node metastasis. Burke *et al*[41] reported the following three risk factors as being predictive of metastasis: tumor invasion to the muscle layer, tumor diameter 2 cm or more, and the presence of mitotic figures[41]. Zyromski *et al*[39] also reported that in cases of tumors measuring less than 2 cm in diameter, no metastasis was observed, regardless of the depth of invasion, recommending endoscopic therapies for tumors measuring less than 1 cm in diameter, and open transduodenal local excision for those measuring 1 to 2 cm in diameter[39]. There are reports that endoscopic resection is safe, minimally invasive, and effective for patients with tumors measuring less than 1 cm in diameter that are not identified by EUS as invading the muscle layer[42]. Although EMR may be well applicable in tumors measuring less than 1 cm in diameter invading the superficial layers of the submucosa, especially lesions with polypoid morphology, ESD may be useful for lesions that are difficult to resect *en bloc* by EMR. However, when the lower margin of a tumor lesion is widely attached to the muscle layer, ESD is associated with an extremely high risk of perforation, and the histopathological diagnosis of the deep surgical margin is also slightly uncertain; thus, surgical treatment should be considered for such cases[7].

TECHNICAL KNOW-HOW OF METHODS OF DUODENAL ESD

The most important technical issue in duodenal ESD is the submucosal dissection process, and it is common to encounter difficulties during submucosal dissection, such as when the tip of a knife is perpendicularly oriented to the dissection surface (Figure 1). In

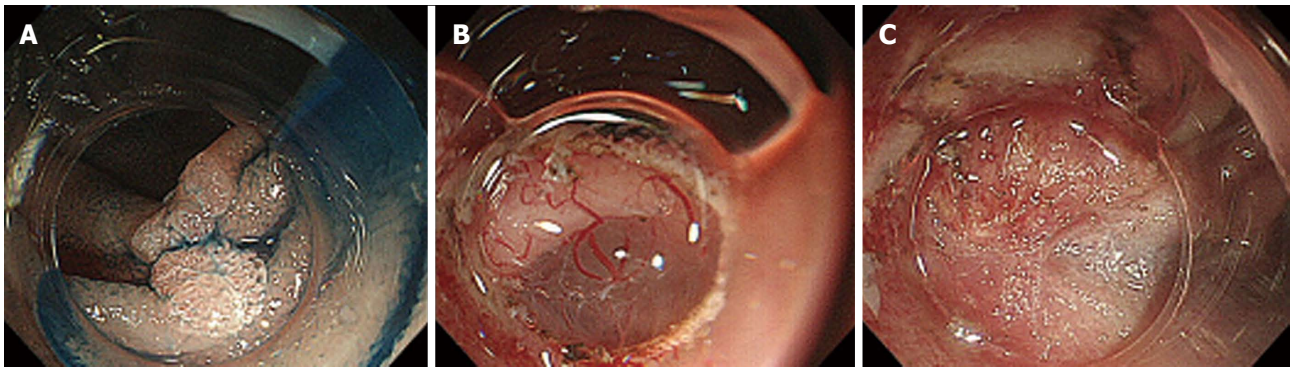

Figure 2 Endoscopic submucosal dissection of an adenoma in the descending part of the duodenum. A: A depressed type tumor 1.2 cm × 1.2 cm in size was identified; B: After incising the oral side of the lesion, we slightly detached it to form a mucosal flap; C: A severe submucosal fibrosis was found.

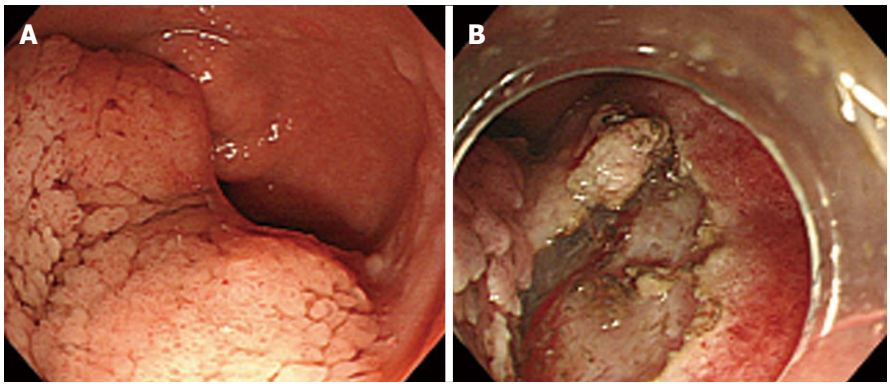

Figure 3 Endoscopic submucosal dissection of an adenoma in the anterior duodenal bulb. A: A flat-elevated type tumor 6.0 cm × 5.0 cm in size was identified; B: We performed submucosal dissection using the ST hood.

duodenal ESD, a short needle-type knife is suitable for the mucosal incision and submucosal dissection processes. The authors use the Dual knife (Olympus, Tokyo, Japan). Moreover, for the submucosal dissection process, the Small-caliber-tip Transparent (ST) hood (Fujifilm, Tokyo, Japan) is an important tool[6]. One of the important aspects of the procedure is to ensure a space for the ST hood to be placed directly under a lesion by incising the oral side of the lesion and slightly detaching it to form a mucosal flap in the early stage (Figure 2). This is the key for the success of the procedure. When a lesion is detached from the anterior wall, the tip of a knife is likely to be perpendicularly oriented to the dissection surface. Under such a situation, the authors make direct visualization of the submucosa easy using the ST hood and apply electrical current while keeping the knife slightly pressed on the lesion (Figure 3) or while the tissue to be detached is hooked and pulled toward the scope by the Hook knife (Olympus, Tokyo, Japan). When the submucosa is detached, it is important to leave as much submucosa on the dissection surface as possible in order not to expose the surface of the muscle layer. Moreover, because there is also a possibility of perforation due to an attachment of the knife such as ST hood, it seems preferable to slightly press the attachment on the dissection surface. The tips for ESD of lesions in the second portion of the duodenum are to push and pull the endoscope and control the intraduodenal air volume. In the third portion of the duodenum, the maneuverability of a scope is poor, and it is essential to check the maneuverability before the operation. If the maneuverability is poor, double-balloon enteroscopy may be useful[43].

Control of bleeding during the procedure is a key to the success of duodenal ESD. It is important to recognize the blood vessels and coagulate them before cutting. Hemostatic forceps should be slightly pulled away from the muscle layer before coagulation to prevent electrical injury of the thin muscle layer[43]. In addition, bipolar coagulation forceps are effective to prevent and restrain hemorrhage.

Because of the high incidence rate of complications caused by duodenal ESD, we have used carbon dioxide insufflation during the ESD. Carbon dioxide insufflation has been reported to be useful for early esophageal[44] and gastric ESD[45]. In addition, a system for ensuring backup by the surgical department may be essential when the procedure is performed. At our institution, in an effort to provide safer treatment, duodenal ESD has been performed under general anesthesia in the operating room since 2010.

Meanwhile, there are also difficult situations encountered during EMR of duodenal lesions. In EMR of lesions in the first portion of the duodenum, the pyloric ring may pose an obstacle to snaring. Moreover, because a lesion relatively often extends over several folds in the second portion, where the space between the folds is small, it may be difficult to ensure snaring in EMR lesions in the second portion of the duodenum.

AFTER DUODENAL ESD

At our institution, intravenous injection of a proton pump inhibitor is started on the day of the ESD, and intravenous cephem antibiotics are administered for approximately 3 d. A blood test is performed on the day after the ESD. If complications such as perforation do not occur, a rice gruel diet is started approximately 3 d after the ESD. Yamamoto suggests taking the fasting period a few days longer in duodenal ESD than other ESDs[43]. During the hospitalization, endoscopy is not performed to check for the formation of ulcers after ESD. If no complications occur, the patients are usually discharged within one week after the operation.

COMPLICATION OF DUODENAL ESD

The most common complication of endoscopic therapies for duodenal lesions is bleeding, which, in general, occurs within 24 h after the operation. The frequency of bleeding after EMR of adenomas ranges from 4% to 33%[23-28]. The frequency of bleeding after ESD ranges from 6.7% to 22.2%[6,30]. The incidence rate of perforation complicating duodenal ESD ranges from 21% to 35.7%[6,46,47], which is extremely high as compared to that of perforation complicating gastric ESD, which ranges from 1.2% to 3.6%[48-50]. Moreover, attention should be paid not only to intraoperative perforation, but also delayed perforation due to exposure to bile or pancreatic juice[6]. As compared to that in patients undergoing EMR, the incidence rate of perforation is significantly higher in those undergoing ESD, and the duration of postoperative hospital stay is also significantly longer[30]. If patients complain of abdominal pain or fever after procedure, they should be checked for their abdominal tenderness and free air in the abdomen by computerized tomography. Thus, the wound should be closed by clipping in order to prevent complications such as secondary hemorrhage and delayed perforation[46,51]. However, in some patients with lesions located in the first portion of the duodenum, closure of the wound by clipping may be difficult, and there is a report of patients in whom perforation occurred after closure of the wound by clipping[52]. In such patients, coverage of the wound with polyglycolic acid sheets (Neoveil; Gunze Ltd., Kyoto, Japan) and fibrin glue (Bolheal; Kaketsuden, Kumamoto, Japan) as a substitute to closure of wound by clipping may be effective for the prevention of delayed perforation[52].

SURGERY FOR NON-AMPULLARY DUODENAL TUMORS

At present, the frequency of complications of duodenal ESD is high, even in institutions with experts in endoscopic therapies. Unlike gastric ESD, it is more difficult to popularize the use of duodenal ESD around the world. Therefore, ESD for duodenal lesions should be performed at limited institutions with abundant experience in performing the procedure. There is also a report that surgery is preferable for lesions exceeding 20 mm in major axis[16]. It is necessary to always keep in mind surgery as one of the treatment options, and endoscopic therapies should not be insisted upon.

Recently, there have been an increasing number of institutions where endoscopists and surgeons cooperatively perform Laparoscopy and Endoscopy Cooperative Surgery (LECS). In a study conducted on 22 patients undergoing LECS for duodenal tumors, the mean tumor diameter was 13.3 mm; the mean diameter of the resected specimens was 28.9 mm; the mean operative time was 133 min; and the duration of postoperative hospital stay was 15.1 d. Complications were observed in 5 patients, 3 (13.6%) of whom had asymptomatic minor leakage. All patients recovered with conservative therapy, and no serious complications were encountered in this study[53].

LONG-TERM PROGNOSIS

In regard to the long-term prognosis, according to one study with a mean follow-up period of 10 mo, no recurrence was observed in any of the 16 patients treated by duodenal ESD, while recurrence was observed in one of the 31 patients undergoing duodenal EMR[30]. Another study also reported that no recurrence was observed with a mean follow-up period of 48 mo in any of the 37 patients treated by ESD for duodenal tumors measuring 20 mm in diameter[54]. Further accumulation of cases may be needed to clarify the long-term prognosis.

Abstract

Gastric adenocarcinoma generally culminates *via* the inflammation-metaplasia-dysplasia-carcinoma sequence progression. The prevalence of gastric adenomas shows marked geographic variation. Recently, the rate of diagnosis of low-grade dysplasia (LGD) has increased due to increased use of upper endoscopy. Many investigators have reported that gastric high-grade dysplasia has high potential for malignancy and should be removed; however, the treatment for gastric LGD remains controversial. Although the risk of LGD progression to invasive carcinoma has been reported to be inconsistent, progression has been observed during follow-up. Additionally, the rate of upgraded diagnosis in biopsy-proven LGD is high. Therefore, endoscopic resection (ER) may be useful in the treatment and diagnosis of LGD, especially if lesions are found to have risk factors for upgraded histology after ER, such as large size, surface erythema or depressed morphology. Fatal complications in endoscopic submucosal dissection (ESD) are extremely low and its therapeutic and diagnostic outcomes are excellent. Therefore, ESD should be applied preferentially instead of endoscopic mucosal resection.

Key words: Intraepithelial neoplasia; Low-grade dysplasia; Adenoma; Endoscopic resection; Endoscopic submucosal dissection

Core tip: According to the guideline, endoscopic resection or follow-up is recommended for noninvasive category 3 low-grade dysplasias (LGDs), while category 4 lesions such as high-grade dysplasia, non-invasive carcinoma and intramucosal carcinoma should be removed by local resection. However, as LGD has a relatively high underdiagnosis rate and rarely contains submucosal cancer, a follow-up strategy might result in the opportunity for endoscopic therapy being missed. Furthermore, repeated endoscopic examinations with biopsies might impose a psychological and financial burden on the patient. Based on its efficacy and safety, the use of endoscopic submucosal dissection as a primary procedure for LGD should be considered.

INTRODUCTION

Gastric cancer (GC) is the fourth-most common cancer and the second-leading cause of cancer-related deaths worldwide, and is especially prevalent in Asia-Pacific countries, including South Korea[1]. In general, gastric adenocarcinoma culminates *via* the inflammation-metaplasia-dysplasia-carcinoma sequence progression, which is described as the Correa cascade of multi-step gastric carcinogenesis[2]. Gastric atrophy and intestinal metaplasia are lesions that confer a high risk for the development of gastric adenocarcinoma, and gastric epithelial dysplasia (GED) is considered the penultimate stage of gastric carcinogenesis[3,4]. Understanding the clinicopathological characteristics of GC is important for prevention. Along with the increasing number of endoscopies performed, the detection of precancerous lesions has increased in clinical practice[5].

The prevalence of gastric adenomas shows marked geographic variation. The reported prevalence is approximately 0.5%-3.75% in western countries and approximately 9%-20% in Asian countries where the prevalence of GC is high[6-8]. Some precancerous lesions progress to adenocarcinoma, whereas others remain unchanged for an extended period of time[9,10]. Furthermore, irrespective of used classification, several studies have demonstrated inter-observer variation in the histological assessment of GED[11-13]. Therefore, it is difficult to establish coincident international guidelines for the management of such lesions.

This review discusses the current optimal strategies for managing gastric low-grade dysplasia (LGD). In preparation for this review, we searched for epidemiological studies, clinical studies, meta-analyses and published guidelines related to GED in the Medline and PubMed databases. The search was performed using index words related to LGD ("gastric epithelial dysplasia" or "low grade dysplasia" or "gastric adenoma" or "gastric dysplasia") and treatment ("endoscopic resection" or "endoscopic submucosal dissection").

DEFINITION

Dysplasia is defined as an unequivocally neoplastic but non-invasive lesion, distinguished from regenerative changes[14]. Used initially to define inflammatory bowel diseases, the term is currently applied throughout the gastrointestinal tract and other organs. Grundmann[15] first used the term gastric dysplasia, and the World Health Organization (WHO) defined dysplasia as cellular atypia, abnormal differentiation and disorganized architecture[4,6]. Conventionally, dysplasia was a term used to describe flat or depressed lesions, whereas adenoma described raised circumscribed lesions that were either sessile or pedunculated. Therefore, a WHO committee defined adenoma as a circumscribed benign neoplasm composed of tubular and/or villous structures lined by dysplastic epithelium. On the other hand, Lewin[16] defined adenoma as a circumscribed lesion unassociated with underlying inflammation whether pedunculated, sessile, flat or depressed; and dysplasia was defined as a benign neoplastic lesion associated with underlying inflammation. However, most clinicians use these terms widely without distinction between adenoma and dysplasia in clinical practice.

Although the biological potential of GED as a precancerous lesion is clear, the classification of these lesions has been controversial in the diagnostic approach. For example, Japanese studies have referred to these lesions as borderline (Group 3 or 4), while the terms gastric adenoma or dysplasia have been used widely in Western countries (Table 1)[12,17]. Because dysplasia implies carcinoma in Japan, pathologists are reluctant to use the term gastric adenoma with LGD[18]. Furthermore, intraepithelial gastric neoplasias are classified into adenoma or carcinoma with low and high-grade cytological atypia[19]. Therefore, the term adenoma with low-grade atypia has been substituted for dysplasia in Japan. From the Japanese viewpoint, gastric adenoma with LGD diagnosed using western criteria include typical adenomas of the small intestinal type and tubular structures, and are thus diagnosed as carcinoma without invasion in Japan[18]. The Vienna classification for GED was proposed as a consensus between western and Asian countries (Table 1)[11,20]. In this classification, dysplastic lesions without invasion of the lamina propria are placed as category 3 or 4 according to the degree of cytologic atypia or architectural complexity[9,11]. Category 3 is a non-invasive low-grade neoplasia, also known as low-grade adenoma/dysplasia. Currently, the WHO recommends the terminology of non-invasive low-grade and high-grade intraepithelial neoplasia and defines carcinoma as invasion into the lamina propria or beyond[21].

NATURAL HISTORY

Although several studies have addressed the risk of carcinoma in GED[22-24], its natural course remains unclear. A large cohort study from the Netherlands suggested that the risk of progression to cancer within 10 years was 3.9% in individuals with LGD[25]. The differences among previous studies regarding the natural course of LGD are due primarily to the differences in diagnostic criteria including the classification and grading (Table 1). Additional reasons for these differences include sampling error in forceps biopsy, discrepancies between forceps biopsy and endoscopic resection (ER), and variations in the rate of malignant transformation. As mentioned earlier, noninvasive intramucosal neoplastic lesions with high-grade cellular and architectural atypia are termed intramucosal carcinoma in Japan, whereas the same lesions are diagnosed as high-grade dysplasia (HGD) by most pathologists in western countries[26]. Under these definitions, lesions diagnosed as gastric adenomas in

Table 1 Common reporting classifications of gastric epithelial neoplasia

Vienna classification[11,20]	WHO[21]	JGCA[19]
Negative for neoplasia/dysplasia		Group 1; Normal tissue or non-neoplastic lesion
Indefinite for neoplasia/dysplasia		Group 2; Material for which diagnosis of neoplastic or non-neoplastic lesion is difficult
Noninvasive neoplasia, low grade (low-grade adenoma/dysplasia)	Low-grade intraepithelial neoplasia	Group 3; Adenoma
Noninvasive neoplasia, high grade	High-grade intraepithelial neoplasia	
High grade adenoma/dysplasia		Group 4; Neoplastic lesion that is suspected to be carcinoma
Noninvasive carcinoma		Group 5; Carcinoma
Suspicious of invasive carcinoma		
Invasive carcinoma	Carcinoma	

WHO: World Health Organization; JGCA: Japanese Gastric Cancer Association.

Japan rarely progress to cancer[18]. Yamada *et al*[27] reported follow-up data for 48 gastric adenomas (38 LGD and 10 HGD) with a median of 4.7 years. During the follow-up period, 37 (97%) LGD lesions showed no histological change, while the remaining lesions progressed to HGD. However, this description of an indolent natural course may have been influenced by selection bias and the use of different LGD classifications in Japan. LGD lesions with invasive carcinoma were more likely to be excluded at the time of the first biopsy. Additionally, a substantial number of patients were excluded since they underwent ER or surgery due to a larger lesion or greater malignant potential. Therefore, half of the patients (19/38) in the study had lesions < 0.5 cm, with most lesions (76.3%, 29/38) measuring < 1 cm. This selection bias may influence a favorable LGD prognosis[28]. In contrast, Rugge *et al*[29] performed a prospective long-term follow-up study to evaluate the clinicopathological behavior of GED. A total of 118 gastric non-invasive neoplasias, including 90 LGDs, were followed for a mean of 52 mo. Among 90 LGDs, 48 (53.3%) were no longer detectable and 28 (31.1%) were unchanged; however, 14 (15.5%) LGDs evolved into HGD and GC.

To date, few studies have determined the predictors for malignant transformation of GEDs[30-32]. Gastric inflammation is a well-known risk factor for gastric carcinoma[33,34]. Correa[2] postulated that chronic gastritis may lead to intestinal metaplasia and atrophy, and that these lesions should be considered a GC risk factor as they are frequently found to be closely related to cancer. In a study that evaluated the endoscopic, pathological and immunophenotypic differences in LGD and HGD lesions according to the revised Vienna classification, Jung *et al*[32] determined that the size, color change and ulceration of the lesion, as well as gastritis score of the surrounding mucosa and positive expression of MUC6, were risk factors for malignant transformation. Because of the use of different diagnostic criteria and ethical reason, it is difficult to confirm a consistent natural history of LGD at present. Recent observational studies have indicated that the cancer progression risk of LGD is relatively low[27,29]. Nonetheless, it is possible that LGD can progress to invasive carcinoma[24,29,35]. Therefore, further studies are needed to understand the natural course of LGD to determine the most effective management option for follow-up treatment.

DISCREPANCIES BETWEEN BIOPSY AND ER

The endoscopic forceps biopsy (EFB) is crucial for grading pre-neoplastic gastric lesions and determining an appropriate treatment strategy. Because EFB specimens are not representative of the entire lesion, significant histologic discrepancies have been found between diagnoses based on EFB and subsequent ER (Figure 1). Recent advances in technology such as image-enhanced endoscopy with narrow-band imaging have led to improvements in the diagnostic accuracy of gastric lesions. However, the discrepancy between pre-endoscopic and post-ER diagnoses remains a concern[36]. Several studies have indicated that pretreatment EFB is inadequate for obtaining a correct diagnosis. We retrospectively reviewed 285 lesions that were initially diagnosed as LGD by EFB[37]. After ER, 46 LGDs (16.1%) showed an upgraded histology: 22 HGD (7.7%) and 24 differentiated adenocarcinoma (8.4%)[37]. In another study from South Korea, Kim *et al*[38] reported that the histologic discrepancy rate was 18.7% (51/273) in LGDs detected using forceps biopsy. Among 51 upgraded lesions, 24 lesions (8.8%) were upgraded to a diagnosis of adenocarcinoma.

Discrepancies in EFB and ER diagnoses contribute to the suboptimal treatment of biopsy-proven LGDs. Therefore, it is essential to identify the risk factors affecting these discrepancies for the proper management of LGD. We found that a lesion size ⩾ 2 cm, surface erythema and a depressed-type lesion were significant predictors of upgraded LGDs. Several studies have reported similar results regarding the endoscopic risk factors for histologic discrepancies in patients with LGD (Figure 2). Kim *et al*[38] reported that lesion size and the presence of spontaneous bleeding were significant factors predicting an upgraded histology after ER; in contrast, the presence of whitish discoloration was a significant negative factor. In a different retrospective

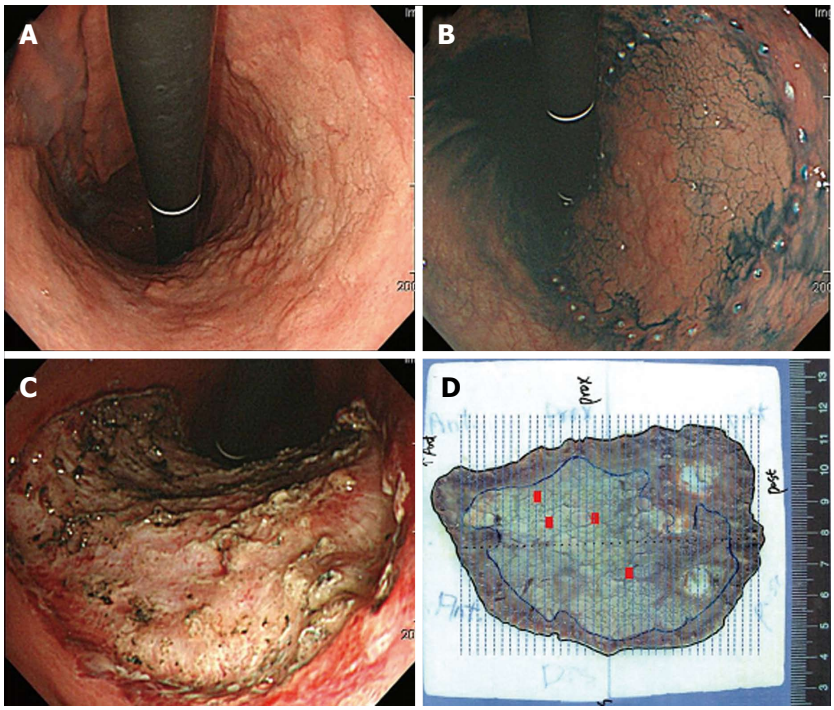

Figure 1 A lesion with a histologic upgraded from extended low-grade dysplasia to adenocarcinoma following endoscopic submucosal dissection. A: White light endoscopy reveals a large elevated mucosal lesion with nodularity in the lesser curvature side of the body. This lesion was diagnosed as LGD by the endoscopic forceps biopsy; B: This lesion is removed by ESD; C: A large mucosal defect is noted over the gastric body after ESD; D: Mapping of the resected specimen. The tumor size is 75 mm, focal cancer lesions (red bar) mixed with LGD are evident. The lateral and vertical margins are free from tumor. LGD: Low-grade dysplasia; ESD: Endoscopic submucosal dissection.

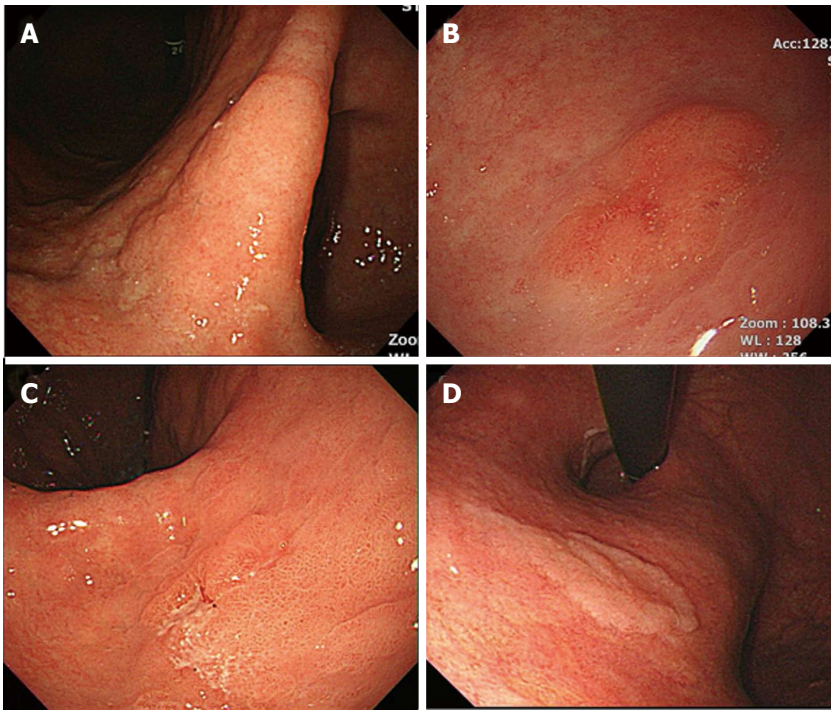

Figure 2 Endoscopic images of biopsy-proven low-grade dysplasia. A-C: lesion size > 2 cm (A), surface erythema (B), and depressed appearance (C) are endoscopic risk factors for an upgraded histology after endoscopic resection; D: In contrast, the presence of whitish discoloration was a negative factor.

study, Cho *et al*[28] demonstrated that a lesion size ⩾ 1 cm, depressed morphology, and erythema were significantly associated with HGD and carcinoma. In a study from Japan[39], a lesion size > 2 cm and depressed appearance were significant independent factors suggesting cancer. To summarize, lesions of larger size and morphology with surface erythema and depression in biopsy-proven LGDs were predictive of an upgraded histology after ER. Therefore, when selecting treatment methods for these lesions, the collection method of the suspected malignant foci should be taken into consideration. ER should be considered for diagnostic and therapeutic purposes in lesions with these risk factors.

MANAGEMENT

In developing a therapeutic plan for LGD management, it is important to identify LGDs that have histological and classical risk factors for GC progression. In South Korea, ERs-including endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD)-are performed widely for the treatment of gastric adenoma, in which early GC and gastric adenoma

are prevalent. According to the revised Vienna classification, ER or follow-up is recommended for noninvasive category 3 LGD lesions, while category 4 lesions such as HGD, non-invasive carcinoma and intramucosal carcinoma should be removed by endoscopic or surgical resection[20]. Some investigators have suggested regular endoscopic surveillance with repetitive biopsy, while others have proposed ER for accurate diagnosis and treatment of LGDs. As mentioned earlier, various factors account for these discrepancies, including differences in diagnostic criteria, inconsistent results among studies of the natural course in LGD, and histologic discrepancies in EFB and ER.

Recent advances in endoscopic techniques have enabled the removal and histological diagnosis of most intra-mucosal lesions regardless of size, shape and location in the stomach[40]. However, performing resections in all patients with LGDs with relatively low malignant potential may lead to significant increases in cost, procedure time, risk of complication, and requirement for advanced technical skills. Although EMR is an easily and rapidly applicable method for therapeutic and diagnostic modalities, it has some limitations. Conventional EMR techniques are unreliable for lesion > 2 cm in diameter due to high rates of positive lateral and/or deep resection margins[41,42]. Even in lesions < 2 cm, the complete resection rate with EMR was 33%-76%[43,44]. Lesion factors, such as tumor size and location, contribute to the difficulty of en bloc resection. To overcome these problems, the development of ESD has allowed complete resection regardless of tumor size and location. In a meta-analysis[45], ESD was significantly more effective than EMR for en bloc resection, complete resection, curative resection and local recurrence. Whereas intra-operative bleeding, perforation risk, and operation time were significantly greater for ESD, overall bleeding risk and all-cause mortality did not differ significantly between ESD and EMR. One meta-analysis[46] showed that procedure-related bleeding (OR = 2.2, 95%CI: 1.58-30.7) and perforation rates (OR = 4.09, 95%CI: 2.47-6.80) during ESD were much higher compared with those for EMR. However, these were not statistically significant in another meta-analysis including 12 studies[45]. Both studies[45,46] showed that ESD was more time-consuming.

Several studies have evaluated endoscopic techniques as a treatment for LGD. Kim *et al*[47] compared the therapeutic outcomes of ESD and EMR in histologically confirmed LGD cases. The en bloc resection rate was significantly lower in the EMR groups (31.1%) compared with the ESD group (75.0%) (P < 0.001). However, no significant difference was observed in the prevalence of remnant lesion or recurrence rate (P = 0.911). On the other hand, Choi *et al*[48] reported a 96.1% complete resection rate using ESD, and the local recurrence rate was 1.4% in patients with biopsy-proven LGD. In this study, no patient had perforation and four (1.4%) patients had significant post-ESD bleeding that was treatable by endoscopic intervention. A multicenter study by the Osaka University ESD study group[49] analyzed a total of 468 subjects with GED. The results showed that the complete en bloc resection rate was 97%, and the incidences of post-ESD bleeding, perforation and serious complication were 5.5%, 4.7% and 0.43%, respectively. Miyamoto *et al*[50] reported that tumor size and location of the lesion are important factors that affect the success rate of en bloc resection. Because not all lesions can be resected en bloc for technical difficulty, another treatment option such as ablation therapy should be considered for the treatment of LGDs[51].

As LGD has a relatively high underdiagnosis rate and rarely contains submucosal cancer, a follow-up strategy might result in the opportunity for endoscopic therapy being missed[49]. Furthermore, repeated endoscopic examinations with biopsies might impose a psychological and financial burden on the patient. Based on its efficacy and safety, the use of ESD as a primary procedure for LGD should be considered.

CONCLUSION

The increased use of upper endoscopy has resulted in increased diagnosis of gastric adenoma. Although many investigators have suggested that gastric HGD should be removed due to its high potential for malignancy[20], the treatment of gastric LGD remains controversial. Although previous studies have reported inconsistent results regarding the risk of LGD progression to invasive carcinoma, such progression can occur during follow-up. Additionally, the rate of upgraded diagnosis in biopsy-proven LGDs is high. Considering these results, the use of ER might enhance treatment and diagnosis, especially of lesions with risk factors such as large size, surface erythema or depressed morphology. Furthermore, the incidence of fatal complications of ESD has been extremely low, with excellent therapeutic and diagnostic outcomes. Therefore, ESD should be applied in preference to EMR.

Abstract

AIM: To investigate long-term re-bleeding events after a negative capsule endoscopy in patients with obscure gastrointestinal bleeding (OGIB) and the risk factors associated with the procedure.

METHODS: Patients referred to Hospital Egas Moniz (Lisboa, Portugal) between January 2006 and October 2012 with OGIB and a negative capsule endoscopy were retrospectively analyzed. The following study variables were included: demographic data, comorbidities, bleeding-related drug use, hemoglobin level, indication for capsule endoscopy, post procedure details, work-up and follow-up. Re-bleeding rates and associated factors were assessed using a Cox proportional hazard analysis. The Kaplan-Meier method was used to estimate the cumulative incidence of re-bleeding at 1, 3 and 5 years, and the differences between factors were evaluated.

RESULTS: The study population consisted of 640 patients referred for OGIB investigation. Wireless capsule endoscopy was deemed negative in 113 patients (17.7%). A total of 64.6% of the population was female, and the median age was 69 years. The median follow-up was forty-eight months (interquartile range 24-60). Re-bleeding occurred in 27.4% of the cases. The median time to re-bleeding was fifteen months (interquartile range 2-33). In 22.6% (n = 7) of the population, small-bowel angiodysplasia was identified as the culprit lesion. A univariate analysis showed that age > 65 years old, chronic kidney disease, aortic stenosis, anticoagulant use and overt OGIB were risk factors for re-bleeding; however, on a multivariate analysis, there were no risk factors for re-bleeding. The cumulative risk of re-bleeding at 1, 3 and 5 years of follow-up was 12.9%, 25.6% and 31.5%, respectively.

Patients who presented with overt OGIB tended to re-bleed sooner (median time for re-bleeding: 8.5 mo *vs* 22 mo).

CONCLUSION: Patients with OGIB despite a negative capsule endoscopy have a significant re-bleeding risk; therefore, these patients require an extended follow-up strategy.

Key words: Capsule endoscopy; Gastrointestinal hemorrhage; Anemia; Angiodysplasia; Risk factors

Core tip: This study describes a large cohort of patients with obscure gastrointestinal bleeding in whom the first capsule endoscopy was negative. Re-bleeding events, risk factors and causes were analyzed. A significant risk of re-bleeding was observed; however, independent predictors for re-bleeding were not identified. Re-bleeding due to small-bowel angiodysplasia was a frequent occurrence; therefore, these patients require an extended follow-up strategy, perhaps involving repeated endoscopic procedures if re-bleeding occurs.

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) represents approximately 5% of all gastrointestinal bleeding cases and, in most cases, the culprit lesion located in the small-bowel[1]. OGIB is defined as bleeding from the gastrointestinal tract that persists or recurs without an obvious source, as assessed by esophagogastroduodenoscopy (EGD), colonoscopy and radiologic evaluation of the small-bowel[1]. OGIB is classified as either occult or overt; occult OGIB is characterized by iron deficiency anemia (IDA) with or without a positive fecal occult blood test[1,2], and overt OGIB is characterized by clinically perceptible bleeding that recurs or persists despite negative initial endoscopic (EGD and colonoscopy) and radiologic evaluations. Wireless capsule endoscopy (WCE) is a cost-effective investigation in patients with OGIB[3]. In one study, after a WCE evaluation, there was a significant reduction in hospitalizations, additional investigations and units of blood transfused compared to before WCE[4]. Currently, OGIB is the main indication for a capsule endoscopy study. A myriad of studies have analyzed and compared the diagnostic yield (*vs* other techniques)[5-7] and clinical impact of a positive WCE study on patient outcome[8]. Still, a negative WCE study remains a clinical challenge, and little is known about the long-term follow-up of such patients. Therefore, many questions persist about the "protective effect" of a negative WCE study on future re-bleeding events. To date, there are some conflicting data about the re-bleeding rates and predictive factors linked to a re-bleeding event, and in addition, the median follow-up period varies substantially among studies[9-15]. The aim of this study is to assess the long-term outcome (especially re-bleeding events) after a negative WCE study in patients referred for OGIB investigation and risk factors associated with a re-bleeding event.

MATERIALS AND METHODS

We present a retrospective, observational cohort, single center study. Clinical data were obtained from medical records of all patients referred to our tertiary referral hospital - Endoscopy Unit (Hospital Egas Moniz, Centro Hospitalar Lisboa Ocidental, Lisboa) - to undergo a WCE for OGIB investigation between January 2006 and October 2012. All of the patients presented with overt or occult gastrointestinal bleeding according to guidelines[1]. All patients had at least one negative EGD and ileo-colonoscopy before referral for WCE. After signing a written informed consent, every patient underwent a WCE with a PillCam SB (R) (M2A, from January 2006) or SB2© (since June 2007) capsule endoscopy system (Given Imaging, Yoqneam, Israel) according to the standard protocols[16]. All the procedures were performed in an outpatient setting. Since January 2008, a small-bowel purgative preparation with a 2-L polyethylene glycol solution before WCE was introduced in our protocol. Simethicone was also used on a routine basis before all procedures. Two hours after taking the capsule, patients received a clear liquid diet and, two hours later, a light meal, as recommended in the standard protocol. Eight hours after WCE, the patients returned to the Endoscopy Unit, the data recorder was removed, and images were downloaded. The recordings were independently reviewed by four experienced gastroenterologists (Chagas C, Couto G, Santos S, Bispo M) at 8-10 frames per second using the Rapid® Reader. When possible, the colon was also observed. The WCE findings were classified into three types based on the Saurin classification[17,18] as follows: lesions considered to have a high potential for bleeding (P2); lesions with uncertain bleeding potential (P1); and lesions with no bleeding potential (P0). Positive WCE studies were defined as examinations that identified one or more P1 or P2 lesions, whereas those that identified only P0 or no abnormal lesions were regarded as negative WCE studies. Exclusion criteria were as follows: concomitant or not non-gastrointestinal blood loss (hematuria, hemoptyses and gynecological blood loss), incomplete exams (not

NSAID: Non-steroidal anti-inflammatory drugs; SSRI: Selective serotonin reuptake inhibitor; OGIB: Obscure gastrointestinal bleeding; [Hb]: Serum hemoglobin; WCE: Wireless capsule endoscopy; IQR: Interquartile range; RBC: Red blood cells.

reaching the ileocecal valve), poor preparation (as dictated by the examiner) and less than twelve months of follow-up. Negative WCE cases were selected and analyzed. A re-bleeding event was defined as occult re-bleeding [a decrease in 20 g/L of [Hb] - (serum hemoglobin) from the patient baseline] or overt re-bleeding (melena, hematochezia). Cases of re-bleeding due to non-small-bowel pathology (*e.g.*, peptic ulcer disease, erosive esophagitis/gastritis/duodenitis, gastroesophageal varices, colorectal carcinoma, *etc.*) detected during follow-up were excluded from further analysis. The median follow-up for all patients strictly monitored for re-bleeding was forty-eight months (interquartile range 24-60). Study variables included the following: demographic data (patient age and gender), comorbidities (chronic kidney disease, aortic stenosis, prior diagnosis of angiodysplasia), relevant medication [use of anticoagulant, antiplatelet agent/s, nonsteroidal anti-inflammatory drugs (NSAIDs), selective serotonin reuptake inhibitors (SSRIs)], hemoglobin level prior to WCE, indication for WCE (occult or overt - melena/hematochezia OGIB), time from OGIB detection to WCE procedure, post procedure details and follow-up [type of treatment for bleeding, hospital admissions (especially for anemia and/or recurrent gastrointestinal bleeding), blood transfusions, need for iron supplementation, additional endoscopies and surgery, re-bleeding causes (if determined) and patient status at the end of follow-up (on-going investigation or treated successfully)].

Statistical analysis

The Statistical Package for Social Science (version 20.0; SPSS Inc., Chicago, IL, United States) was used for all statistical analysis. Continuous variables are expressed as the mean ± SD or median (interquartile range) as appropriate. Qualitative and quantitative differences between subgroups were analyzed using the χ^2 test or Fisher's exact test for categorical parameters and Student's *t* test or Mann-Whitney test for continuous parameters as appropriate. Univariate and multivariate analyses by Cox proportional hazards regression model was performed to identify factors associated with re-bleeding. After the univariate analysis, variables with a $P < 0.05$ were entered in the multivariate analysis. Effect sizes are expressed as hazard ratios (HRs) and 95%CIs. The Kaplan-Meier method was used to estimate the cumulative incidence of re-bleeding at 1, 3 and 5- years of follow-up, and differences between factors were evaluated using the log-rank test. All statistical tests were 2 sided. Statistical significance was set at $P < 0.05$.

RESULTS

Patient characteristics

During the follow-up period, 640 patients were referred for OGIB investigation. In 113 exams (17.7%), the WCE could not find the culprit lesion and was deemed negative (P0 lesions or no abnormal findings). A summary of baseline characteristics is displayed in Table 1. Among the studied population, 73 patients were female (64.6%), with a median age of 69 years old (interquartile range 56-79); 62.8% (*n* = 71) of the patients were > 65 years old. Forty-five patients (39.8%) were taking bleeding-related drugs (single anti-platelet agent: *n* = 19 (16.8%); anticoagulant: *n* = 8 (7.1%); double anti-platelet agent: *n* = 6 (5.3%); non-steroidal anti-inflammatory (NSAIDs): *n* = 8 (7.1%); SSRI: *n* = 4 (3.5%). Thirty-five out of 113 (31%) presented with overt obscure bleeding (overt OGIB) - melena (*n* = 22; 19.5%) and hematochezia (*n* = 13; 11.5%).

Follow-up

The median follow-up was forty-eight months (interquartile range 24-60). After the exclusion of re-bleeding cases due to non-small-bowel pathology, re-bleeding from the small-bowel (or unknown origin) occurred in thirty-one out of 113 negative WCE studies (27.4%). The median time from index negative WCE

Variable	All	Non re-bleeders	Re-bleeders	*P*
Age (years old)	67 ± 15	65 ± 15	72 ± 11	0.007
Gender (M/F)	40/73	27/55	13/18	0.386
OGIB presentation (*n*)				
Occult	79	61	18	0.067
Overt	34	21	13	
[Hb] (median)	86	86	79	0.143
Anticoagulant use (*n*)	11	4	7	0.009
Small-bowel Transit time (median)	253	253.5	251.5	0.650

Values are presented in mean ± SD unless stated otherwise. M/F: Male/female; OGIB: Obscure gastrointestinal bleeding; [Hb]: Serum hemoglobin.

to the re-bleeding episode was 15 mo (interquartile range 2-33). Figure 1 provides data regarding endoscopic investigations in patients who re-bled and the associated causes. Among the re-bleeding cases, 29 (94%), were submitted to at least one additional endoscopic procedure. In ten re-bleeding cases (32%), the culprit lesion was/remains unknown; in thirteen cases (42%) an angiodysplasia (small-bowel *n* = 7, colon *n* = 3, stomach *n* = 3) was identified on a subsequent study. Half of the repeated WCE visualized a previously unrecognized small-bowel angiodysplasia. Of those who re-bled from a small-bowel angiodysplasia (*n* = 7), three (all P2 lesions; 43%) were submitted to argon-plasma thermocoagulation (APC) *via* deep enteroscopy (one patient received one APC session, one received two APC sessions and the other patient had to be submitted to five APC sessions), with complete resolution of the gastrointestinal bleeding. Among the total re-bleeding population, five patients (16%) received specific medical therapy (proton pump inhibitor and/or NSAIDs or anticoagulant withdrawal), three patients (9.7%) received non-specific medical therapy (iron supplementation or blood transfusions), and twenty patients (64.5%) did not receive any type of treatment.

Overall, at the end of the follow-up period, twenty-four patients with re-bleeding (77.4%) were considered successfully treated [*i.e.*, despite the re-bleeding event they were asymptomatic, did not require a blood transfusion or iron supplementation and had a normal (Hb) level]. Seven patients (22.6%) remain under close follow-up (requiring regular iron supplementation, blood transfusions).

Risk factor analysis and risk of re-bleeding

A comparison of baseline characteristics between re-bleeders *vs* non re-bleeders is summarized in Table 2. The results of univariate and multivariate analyses regarding factors associated with re-bleeding in patients with a negative WCE are summarized in Table 3. According to a univariate analysis, age > 65 years old, chronic kidney disease, aortic stenosis, anticoagulant use and overt OGIB were detected as factors associated with a significant risk of re-bleeding after a negative WCE. After subjecting the previous variables to a multivariate analysis using a Cox proportional hazards regression model, none of the previously identified factors were able to independently predict future re-bleeding events.

The overall cumulative risk of re-bleeding at 1, 3 and 5-year of follow-up was 12.9%, 25.6% and 31.5%, respectively (Figure 2). To perform a comprehensive analysis, a subgroup comparison between those who initially presented with occult OGIB vs overt OGIB is summarized in Table 4. The overt group tended to re-bleed sooner than the occult group (median time until re-bleeding event: 8.5 mo *vs* 22 mo; *P* = 0.257); however, re-bleeding rates between these two groups were not significantly different (Figure 3; *P* = 0.099).

DISCUSSION

Capsule endoscopy revolutionized the world of gastrointestinal endoscopy, mainly OGIB, by allowing the gastroenterologist to identify the possible cause of OGIB and enhance a directional or specific treatment.

Table 3 Univariate and Multivariate analysis *via* Cox proportional hazard regression model: Re-bleeding risk factors in patients with obscure gastrointestinal bleeding and a negative capsule endoscopy

Variables	Univariate analysis			Multivariate analysis		
	HR	95%CI	*P*	HR	95%CI	*P*

Capsule endoscopy is a safe and effective technology in the evaluation of small-bowel pathology[1]. Whether a positive or negative WCE study impacts patient outcome remains ill defined. Two recent studies failed to demonstrate that a higher diagnostic yield is related to an improved outcome in patients with OGIB[19,20]. Moreover, on a recent nationwide study by Min *et al*[8], the authors concluded that WCE did not have a significant impact on the long-term outcome of patients with OGIB. Some studies analyzed the long-term outcome defining the occurrence of a re-bleeding event as a primary outcome[9-12,14,15,21]. In the paramount study of Lai *et al*[9], patients with a negative WCE study (n = 18) displayed a low re-bleeding rate (5.6%) when followed for twelve months (median). Another study by Macdonald *et al*[10] that analyzed 49 patients with OGIB (median follow-up = 17 mo) demonstrated a higher re-bleeding rate in this subgroup (negative WCE) of patients (11%) and, when assessing risk factors associated with re-bleeding, identified anticoagulant use as the only independent predictor. Therefore, these first two studies claimed a low re-bleeding probability in patients whose first WCE study was negative, thus advising an expectant approach. Thereafter, it has been postulated that a negative WCE result predicts a favorable prognosis in patients with OGIB and a low risk of re-bleeding. Later, a study by Park *et al*[12] with 51 patients followed for thirty-two months demonstrated a re-bleeding rate of 35.7% in WCE negative patients. Hence, the authors recommended a close follow-up of these patients for at least 2 years. Moreover, two of the most recent studies[14,19] report re-bleeding rates of 23% and 33%, respectively. Additionally, it has been demonstrated that there are no significant difference in the cumulative re-bleeding rates between patients with positive *vs* negative WCE findings[8,12,14].

In the present study, we focused on and followed 113 patients referred for OGIB investigation with a negative WCE. Similar to previous recent retrospective cohort studies[12,14], we demonstrated high re-bleeding rates (27.4%) in this group of patients when followed for longer periods (> 12 mo). Studies that reported lower re-bleeding rates had shorter follow-up periods[9,10,15,22]. To optimize the definition of the risk, we set the minimum follow-up period at 12 mo, and we obtained a median follow-up period of 48 mo (4 years). In approximately 1/3 of the re-bleeders, the culprit lesion remained unknown (*i.e.*, persistently negative endoscopic studies), and when identified, angiodysplasia was the most frequent lesion (42%), mainly small-bowel angiodysplasia (53.8% of all the missed angiodysplasia), which is in line with a previous report[23]. One explanation for these findings might be that some angiodysplasias were missed in the first WCE (although some lesions may have developed after the index WCE). In addition, the natural history of such vascular lesions remains unclear, and their dynamic nature makes them hard to demonstrate consistently. Additionally, it is important to note that knowing that there is a positive correlation between diagnostic yield and small-bowel transit time (SBTT), especially in OGIB[24], as presented in Table 4, SBTT did not differ between re-bleeders and non-re-bleeders; therefore, it is unlikely that re-bleeders had a higher rate of important missed lesions than non-re-bleeders.

In Western countries, angiodysplasia seems to be more frequent than in Asia, and this might be another explanation for the lower re-bleeding rates observed across some of the Asian studies, where small-bowel ulcers dominate the OGIB etiology[8,22]. In patients with recurrent OGIB or IDA who had a negative WCE, a repeat WCE revealed the presence of angiodysplasia in up to 29% of patients (75% of all findings) and led to changes in patient management in two small studies[25,26], which is in line with our data.

Similarly to previous studies[14,15] our median time until re-bleeding was 15 mo, which strengthens the importance of closely following these patients in the first 2 years after index WCE and seemingly over the 3rd year, as our interquartile range for re-bleeding was between 2 and 33 mo. Although the results were not statistically significant (Figure 3; Log-Rank test =

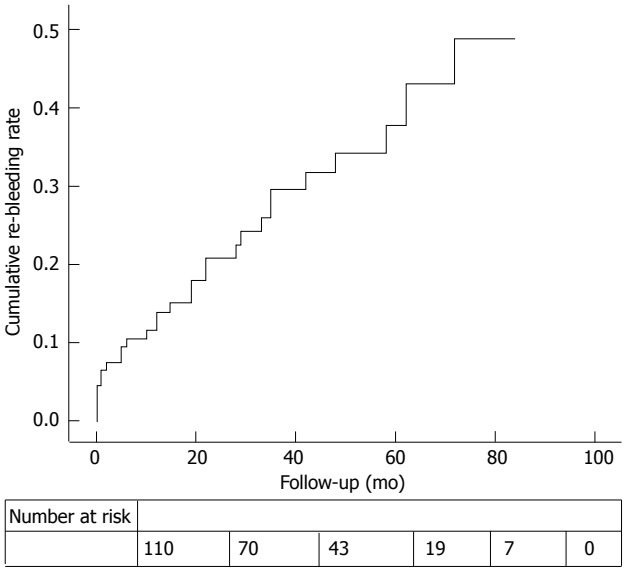

Figure 2 Kaplan-Meier curve showing cumulative re-bleeding rates in the study population.

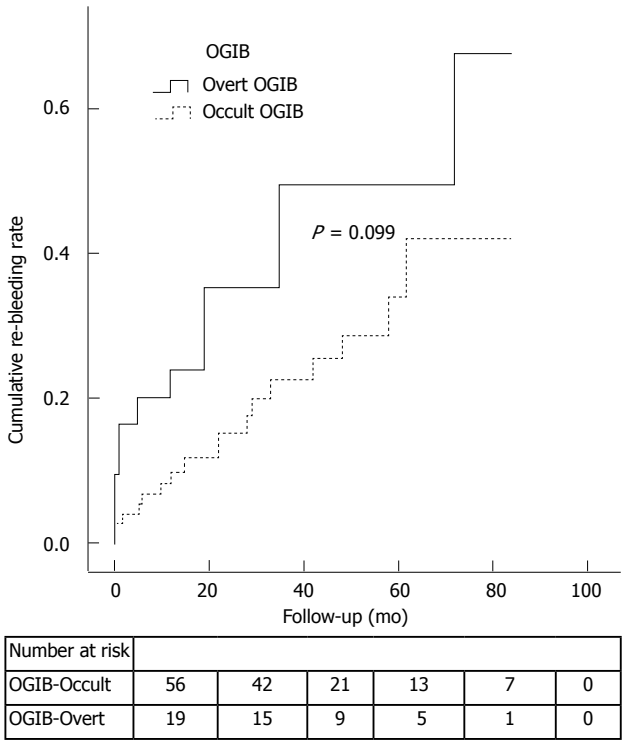

Figure 3 Kaplan-Meier curve showing cumulative rebleeding rates after a negative capsule endoscopy according to initial obscure gastrointestinal bleeding presentation (Log-Rank = 0.099). OGIB: Obscure gastrointestinal bleeding.

0.099), when the subgroups of patients presenting with occult and overt OGIB were analyzed separately, we observed that patients who presented with overt OGIB, in contrast with the occult group, tended to re-bleed sooner (median time until re-bleeding = 8.5 mo *vs* 22 mo).

Previous studies pinpointed anticoagulant intake[10,14] as an independent risk factor for re-bleeding, regardless of WCE results. Others[15] identified younger age (< 65 years old) and the onset of bleeding as independent risk factors for re-bleeding after a negative WCE. Consistent with another recent study[23], our results showed that in a univariate analysis, patients who re-bled were older (HR = 3.599; 95%CI: 1.364-9.501; *P* = 0.010). One explanation is that the prevalence of angiodysplasia (the most frequent re-bleeding lesion in most studies) is known to be higher in older individuals[1], making them a group prone to re-bleeding. It is also known that the incidence of small-bowel vascular lesions (mainly angiodysplasia) in patients with chronic kidney disease is high[27-29], thus making them more likely to re-bleed, as shown in an univariate analysis (HR = 3.498; 95%CI: 1.265-9.671; *P* = 0.016). In our study, as demonstrated previously[14], taking anticoagulants is an important risk factor for re-bleeding (HR = 3.903; 95%CI: 1.542-9.875; *P* = 0.004). Another interesting finding was that even though patients who presented with an overt OGIB tended to re-bleed more than those who presented with occult OGIB (HR = 2.104; 95%CI: 1.011-4.380; *P* = 0.047), a statistically significant difference could

not be found between the groups (Figure 3). Patients with aortic stenosis may have a higher prevalence of angiodysplasia (condition also known as Heyde Syndrome) through the gastrointestinal tract[30,31]. In patients with aortic stenosis, the tendency to harbor angiodysplasia in the gut may pose an elevated risk of re-bleeding events. In this study, there was a trend towards more re-bleeding events in these patients (HR = 4.159; 95%CI: 1.412-12.247; *P* = 0.010). However, when all of these factors were pooled on a multivariate analysis, their statistical significance became null.

Our study limitations were the following: (1) the data were collected from a single tertiary referral hospital and the study had a retrospective design; (2) some of the patients included are followed at other institutions; thus, some follow-up data are missing; and (3) we focused only on patients referred for OGIB with a negative WCE. A comparison of re-bleeding rates with positive WCE cases would have been interesting; however, in a recent study[8], it was demonstrated that re-bleeding rates between positive and negative WCE cases were not significantly different. A leverage point of our study was the very long-term post procedure follow-up period and the relatively large number of patients included.

In conclusion, patients with OGIB with a negative WCE have a significant re-bleeding risk (27.4%), and a follow-up strategy is recommended. In this study, predictive factors for re-bleeding events could not be found using a multivariate analysis; however, a tendency was demonstrated (older age, chronic kidney disease, aortic stenosis, anticoagulants use and overt OGIB), and in future series, a tailored approach/surveillance may be required. Prospective observational studies addressing this topic with long-term follow-up are urgently needed.

COMMENTS

Background

Obscure gastrointestinal bleeding (OGIB) is defined as occult or overt gastrointestinal bleeding of unknown origin that persists or recurs after initial negative endoscopic evaluation (esophagogastroduodenoscopy and colonoscopy). OGIB represents approximately 5% of all gastrointestinal bleeding cases, and the culprit lesion is located in the small-bowel in most instances. Angiodysplasias of the small-bowel account for 30% to 40% of OGIB. Wireless capsule endoscopy (WCE) is a safe and well-accepted technology that enables visualization of the small-bowel.

Research frontiers

A negative (WCE) study remains a clinical challenge, and little is known about the long-term follow-up of such patients. The "protective effect" of a negative WCE study on future re-bleeding events remains controversial. To date, there are some conflicting data about the re-bleeding rates and predictive factors linked to a re-bleeding event, and in addition, median follow-up period varies among studies.

Innovations and breakthroughs

In a retrospective analysis, the authors evaluated the long-term re-bleeding events after a negative WCE in patients referred for OGIB. In a concrete and relatively large cohort from a tertiary center in Europe with long-term follow-up (48 mo), it was found that patients with OGIB, despite a negative WCE, have a significant re-bleeding rate (27.4%). Small-bowel angiodysplasia was the most frequent re-bleeding related lesion (22.6%). The median time from index negative WCE to the re-bleeding episode was fifteen months. After a multivariate analysis, there were no independent predictors for re-bleeding.

Applications

This study suggests that patients with OGIB and a first negative WCE should have an extended follow-up. Although independent predictors for re-bleeding were not found, physicians should recognize some important risk factors for re-bleeding (older age, chronic kidney disease, aortic stenosis, anticoagulants use and overt OGIB) and consider further endoscopic investigations if re-bleeding occurs.

Terminology

OGIB is defined as bleeding from the gastrointestinal tract that persists or recurs without an obvious source being discovered by esophagogastroduodenoscopy, colonoscopy and radiologic evaluation of the small-bowel. Small-bowel capsule endoscopy uses a wireless miniature (pill sized) encapsulated video camera designed to visualize the entire small-bowel.

Peer-review

In a retrospective analysis the authors evaluated the long-term re-bleeding events after a negative wireless capsule endoscopy in patients referred for obscure gastrointestinal bleeding. They found that patients with obscure gastrointestinal bleeding, despite a negative capsule endoscopy, during a 48 mo mo follow-up period have a significant re-bleeding rate (27.4%). They concluded that there are no reliable risk factors that can predict a future re-bleeding event in these patients. The topic is interesting and suitable for publication.

Abstract

AIM: To compare n-butyl-2-cyanoacrylate, iso-amyl-2-cyanoacrylate and a mixture of 72% chromated glycerin with hypertonic glucose solution in management of gastric varices.

METHODS: Ninety patients with gastric varices presented to Endoscopy Unit of Ain Shams University Hospital were included. They were randomly allocated into three groups; each group included 30 patients treated with intravariceal sclerosant injections in biweekly sessions till complete obturation of gastric varices; Group I (n-butyl-2-cyanoacrylate; Histoacryl®), Group II (iso-amyl-2-cyanoacrylate; Amcrylate®) and Group III (mixture of 72% chromated glycerin; Scleremo® with glucose solution 25%). All the procedures were performed electively without active bleeding. Recruited patients were followed up for 3 mo.

RESULTS: 26% of Scleremo group had bleeding during puncture *vs* 3.3% in each of the other two groups with significant difference, ($P < 0.05$). None of Scleremo group had needle obstruction *vs* 13.3% in each of the other two groups with no significant difference, ($P > 0.05$). Rebleeding occurred in 13.3% of Histoacryl and Amcrylate groups *vs* 0% in Scleremo group with no significant difference. The in hospital mortality was 6.6% in both Histoacryl and Amcrylate groups, while it was 0% in Scleremo group with no significant difference. In the first and second sessions, the amount of Scleremo needed for obturation was significantly high, while the

amount of Histoacryl was significantly low. Scleremo was the less costly of the two treatments.

CONCLUSION: All used sclerosant substances showed efficacy and success in management of gastric varices with no significant differences except in total amount, cost and bleeding during puncture.

Key words: Gastric varices; N-butyl-2-cyanoacrylate; Iso-amyl-2-cyanoacrylate; Hypertonic glucose solution; 72% chromated glycerin

Core tip: We compared n-butyl-2-cyanoacrylate (Histoacryl®), iso-amyl-2-cyanoacrylate (Amcrylate®) and a mixture of 72% chromated glycerin (Scleremo®) with hypertonic glucose solution (25%) in management of gastric varices. The study included 90 patients who were randomly allocated into three groups, and each group included 30 patients treated with sclerosant injections in biweekly sessions till complete obturation: Group Ⅰ (Histoacryl®), Group Ⅱ (Amcrylate®) and Group Ⅲ (Scleremo® with Glucose 25%). Patients were followed up for 3 mo. We concluded that all used sclerosants showed efficacy and success in management of gastric varices, without significant differences, except in total amount, cost and bleeding during puncture.

N-butyl-2-cyanoacrylate, iso-amyl-2-cyanoacrylate and hypertonic glucose with 72% chromated glycerin in gastric varices. *World J Gastrointest Endosc* 2015; 7(4): 411-416 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i4/411.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i4.411

INTRODUCTION

Varices occur in approximately 50% of cirrhotic patients[1,2]. Gastric varices (GV) are less common than esophageal varices (EV), with a prevalence of approximately 20% in patients with portal hypertension[3], and about 15%-25% of GV bleed during the patient's lifetime[4,5].

The management of GV has not been well studied as that of EV. Both the evaluation and treatment of GV are still controversial[6,7].

Cyanoacrylates are synthetic glues that rapidly polymerize on contact with water or blood[8]. Injection therapy with cyanoacrylates is now considered to be the first-line endoscopic intervention for bleeding GV and for the secondary prevention of gastric variceal bleeding[9].

N-butyl-2-cyanoacrylate (Histoacryl®; Germany) has been used extensively in endoscopic therapy for the last 10 years. Another N-butyl-2-cyanoacrylate (Glubran®; Italy) was recently approved for endoscopic use in Europe[10].

Scleremo, a compound of 72% chromated glycerin, is a polyalcohol that is often considered to be a sclerosant chemical irritant, as it causes cell surface protein denaturation leading to thrombo-fibrosis[11]. The compound is commonly used in Europe, but it has not been approved by the FDA for use in the United States[12].

This work aimed at comparing n-butyl-2-cyanoacrylate (Histoacryl®), iso-amyl-2-cyanoacrylate (Amcrylate®) and a mixture of 72% chromated glycerin (Scleremo®) with a hypertonic glucose solution (25%) in the management of GV in Egyptian patients.

MATERIALS AND METHODS

Patients and methods

This prospective randomized study was conducted on ninety patients who presented with GV at the Endoscopy Unit of Ain Shams University Hospital. Patients with non-variceal causes of upper gastrointestinal bleeding and those with severe co-morbidities were excluded.

The patients were randomly allocated into three groups. Each group included 30 patients who were treated with sclerosant injections in biweekly sessions until the complete obturation of the GV was achieved, with follow-up of 3 mo: (1) Group Ⅰ (Histoacryl® Group); (2) Group Ⅱ (Amcrylate® Group); and (3) Group Ⅲ (Scleremo® with Glucose 25% Group).

The three groups were matched for age, gender, cause of liver cirrhosis (viral hepatitis B or C), Child score and endoscopic findings (including the number, grade of the EV and the size of GV).

All of the included patients underwent: (1) a complete clinical evaluation; (2) laboratory investigations: CBC, liver profile, viral markers (HBs Ag, HB core Ab, HCV Ab) using the ELISA technique; (3) child classification according to the modified Child Pugh's criteria[13]; (4) abdominal ultrasonography for liver and spleen size, portal vein diameter and ascites; (5) upper gastrointestinal endoscopy using the Pentax video endoscope EG 3440. The EV were classified according to their size at the gastroesophageal junction into 4 grades according to Westaby *et al*[14]; The GV were classified into either gastro-EV or isolated GV according to Sarin *et al*[15]; and (6) therapeutic interventions: The intravariceal injection technique was performed according to Soehendra *et al*[16].

The Histoacryl® was diluted as 0.5 mL histoacryl: 0.8 mL lipidol as a contrast agent to dilute the adhesive material to fill the entire varix and to prevent rapid hardening and the obstruction of the needle. The mixture was injected slowly to minimize the risk of embolization and was followed by the injection of 2 mL of distilled water. The first ml of water was injected to force the material into the varix, and the second ml was injected during the withdrawal of the needle to prevent its obstruction[8].

The Amcrylate® was injected slowly followed by injection of 2 mL distilled water without mixing with any other substances[17].

The Scleremo® was mixed with glucose 25% in a ratio of 1:1. The mixture was injected very slowly and with the waiting for moments inside the variceal lumen after injection to give enough time for the sclerosing material to be in contact with the vessel wall. There was no need for an injection of distilled water[11].

Informed consent was obtained from all of the included patients, and the study protocol was approved by the ethical guidelines committee.

All of the procedures were performed electively, without active bleeding. The patients who had bleeding that occurred immediately or after the procedure were treated with additional injections.

The primary end point of this study was the obturation of the GV. The secondary endpoint was the occurrence of bleeding, whether from the puncture site during or immediately after the injection or delayed bleeding (in-hospital or after discharge) and mortality.

Statistical analysis

The statistical review of the study was performed by a biomedical statistician.

The quantitative variables are presented as the mean and the SD. An unpaired (*t*) test was used for the comparisons.

The qualitative variables are presented as numbers and percentages. The χ^2 test was used for the comparisons.

A value of $P < 0.05$ was considered to be statistically significant (S), $P < 0.01$ was considered to be highly significant (HS), and $P > 0.05$ was considered to be non-significant (NS).

RESULTS

This study included 90 Egyptian patients with chronic liver disease. There were 58 males (64.4%, mean age: 50.88 ± 9.08 years) and 32 females (35.6%, mean age: 49.28 ± 8.11 years). A total of 74 patients (82.2%) had hepatitis C virus (HCV), 12 patients (13.3%) had hepatitis B virus (HBV), and 4 patients (4.4%) had both HCV and HBV. According to the Child-Pugh classification, 18 patients (20%) were class A, 36 patients (40%) were class B, and 36 patients (40%) were class C.

The recruited patients were randomly allocated into three groups that were matched for age, gender, cause of chronic liver disease, Child score and endoscopic findings. Each group included 30 patients who were treated with sclerosant injections in biweekly sessions until the complete obturation of GV was achieved. The groups consisted of Group Ⅰ (the Histoacryl® Group), Group Ⅱ (the Amcrylate® Group) and Group Ⅲ (the Scleremo® with glucose 25% Group).

There were non-significant ($P > 0.05$) differences among the 3 groups regarding previous bleeding or previous sclerotherapy for EVs (93.3%, 66.6% and 93.3%, for Groups Ⅰ, Ⅱ, and Ⅲ, respectively) as shown in Table 1.

Table 1 Previous bleeding and previous sclerotherapy for esophageal varices in the 3 groups *n* (%)

		Histoacryl	Amcrylate	Scleremo with glucose	χ^2	*P* value
Previous bleeding	None	2 (6.6)	10 (33.3)	2 (6.6)	11.6	> 0.05 (NS)
	Once	20 (66.6)	8 (26.6)	20 (66.6)		
	Twice	2 (6.6)	8 (26.6)	4 (13.3)		
	3 times	2 (6.6)	0 (0)	0 (0)		
	4 times	4 (13.3)	4 (13.3)	4 (13.3)		
Previous sclerotherapy for EV	None	2 (6.6)	10 (33.3)	2 (6.6)	16.5	> 0.05 (NS)
	Once	6 (20)	6 (20)	0 (0)		
	Twice	6 (20)	0 (0)	4 (13.3)		
	3 times	2 (6.6)	6 (20)	8 (26.6)		
	4 times	14 (46.6)	6 (20)	16 (53.3)		

EV: Esophageal varices; NS: Non-significant.

The endoscopic findings for the 3 studied groups are shown in Table 2. There were non-significant differences among the 3 groups for the location, the size of the GV and associated EV ($P > 0.05$).

Table 3 shows the non-significant differences among the 3 groups regarding the rate of the obturation of the GV ($P > 0.05$). In the first month, the rate of the obturation was 66.6%, 53.3% and 46.6%; in the second month, the rate of the obturation was 86.6%, 80% and 73.3% and in the third month, the rate of the obturation was 93.3%, 93.3% and 100% in the Histoacryl, Amcrylate and Scleremo groups, respectively.

Regarding the number of sessions needed for the obturation of the GV; in the Histoacryl group, 33.3% of the patients needed one session and 66.6% needed two sessions. In the Amcrylate group, 26.6% of the patients needed one session, 70% needed two sessions and 3.3% needed three sessions. In the Scleremo group, 20% of the patients needed one session, 66.6% needed two sessions and 13.3% needed three sessions.

The amount of the sclerosant used per session is shown in Table 4. In the first and second sessions, a significantly high amount of Scleremo was used compared with the Amcrylate and Histoacryl ($P < 0.05$). In the third session, there was insignificant differences among the amounts of the 3 sclerosant materials used ($P > 0.05$).

Regarding problems with the endoscopy, eight patients (26.6%) in the Scleremo group had bleeding of their GV during the puncture compared with one patient (3.3%) in each of the other two groups, with a significant difference ($P < 0.05$). None of the patients in the Scleremo group had needle obstructions during the injections compared with four patients (13.3%) in each of the other two groups, with non-significant differences ($P > 0.05$).

Table 2 Endoscopic findings among the 3 studied groups *n* (%)

		Histoacryl	Amcrylate	Scleremo with glucose	χ^2	*P* value
Site of GV	Fundal	24 (80)	22 (73.3)	18 (60)	1.514	> 0.05
	Cardiac	6 (20)	8 (26.6)	12 (40)		(NS)
Size of GV	L	10 (33.3)	12 (40)	8 (26.6)	2.68	> 0.05
	M	12 (40)	16 (53.3)	14 (46.6)		(NS)
	S	8 (26.6)	2 (6.6)	8 (26.6)		
Associated EV	No EV	2 (6.6)	6 (20)	0 (0)	7.85	> 0.05
	Grade II EV	10 (33.3)	4 (13.3)	6 (20)		(NS)
	Grade III EV	14 (46.6)	16 (53.3)	18 (60)		
	Grade IV EV	4 (13.3)	4 (13.3)	6 (20)		

GV: Gastric varices; EV: Esophageal varices; L: Large tortuous varices; M: Medium nodular varices; S: Small straight varices; NS: Non-significant.

Table 3 Outcomes of gastric varices for rates of obturation and number of sessions *n* (%)

		Histoacryl	Amcrylate	Scleremo with glucose	χ^2	*P* value
Obturation of varices	1st month	20 (66.6)	16 (53.3)	14 (46.6)	1.4	> 0.05
	2nd month	26 (86.6)	24 (80)	22 (73.3)		(NS)
	3rd month	28 (93.3)	28 (93.3)	30 (100)		
No. of sessions	One	10 (33.3)	8 (26.6)	6 (20)	2.5	> 0.05
	Two	20 (66.6)	21 (70)	20 (66.6)		(NS)
	Three	0 (0)	1 (3.3)	4 (13.3)		

GV: Gastric varices; NS: Non-significant.

Bleeding in the Scleremo group during the puncture was controlled by injecting more of the sclerosing mixture and leaving the needle in the puncture site for few minutes to allow time for the blood to clot and occlusion of the puncture to occur. In 2 of the cases in the Scleremo group (Child C) this maneuver failed to stop the bleeding, and an injection of Histoacryl was used to control the bleeding.

Rebleeding (within 5 d of the injection) occurred in 4 cases (13.3%) in both the Histoacryl and the Amcrylate groups, while no cases (0%) of rebleeding were recorded in the Scleremo group, with a non-significant difference ($P > 0.05$).

Two of the patients (6.6%) in each of the Histoacryl and Amcrylate groups died in the hospital 2 d after the injection (due to hepatic comas), while the mortality rate in the Scleremo group was 0%, with a non-significant difference ($P > 0.05$).

There were insignificant ($P > 0.05$) differences among the 3 groups in complications in the form of chest pain (6.6%, 6.6% and 13.3%) in the Histoacryl, Amcrylate and Scleremo groups, respectively, transient dysphagia (13.3%) in the Amcrylate group only, low grade fever in the Histoacryl group only (6.6%); and ulceration in both the Histoacryl and Amcrylate groups only (13.3% *vs* 6.6%).

Regarding the total cost of the sclerosant materials used in the current study, Scleremo was the least costly compared with the Histoacryl and Amcrylate, as shown in Table 5.

Table 4 Total amount of sclerosant used per session

	Histoacryl	Amcrylate	Scleremo with glucose	*P* value
1st session	42 cc	80 cc	126 cc	< 0.05 (S)
2nd session	20 cc	28 cc	74 cc	< 0.05 (S)
3rd session	0	2 cc	10 cc	> 0.05 (NS)

S: Significant; NS: Non-significant.

Table 5 Amount of sclerosants and their cost

	Histoacryl	Amcrylate	Scleremo with glucose
Amount of one ampoule	0.5 cc	0.5 cc	5.0 cc
Total used amount	62 cc	110 cc	210 cc
No. of all injected ampoules	124	220	42
Cost of one ampoule	88 EGP (14.6 USD)	44 EGP (7.3 USD)	15 EGP (2.5 USD)
Cost of all injected ampoules	10912 EGP (1809 USD)	9680 EGP (1605 USD)	630 EGP (104.5 USD)

EGP: Egyptian Pound; USD: United States Dollar.

DISCUSSION

In contrast to the treatment of EV, the endoscopic treatment of GV is still controversial[18]. Treatment options for GV that have been studied in prospective trials include injections of cyanoacrylate-based tissue adhesives, alcohol, sclerosants, and band ligation[3,4,19-21]. The results from this limited number of small studies had varying success rates and were uncontrolled, making it difficult to draw definitive conclusions about their efficacy or the superiority of one therapy over another[22].

The purpose of this prospective randomized study was to compare the efficacy of n-butyl-2-cyanoacrylate (Histoacryl)®, iso-amyl-2-cyanoacrylate (Amcrylate)® and a mixture of 72% chromated glycerin (Scleremo)® with a hypertonic glucose solution (25%) in the management of GV in Egyptian patients.

The present work shows the obturation of varices in all of the groups, with no significant differences ($P > 0.05$) after three months of follow-up. We observed that the obturation of the GV occurred sooner and with fewer sessions in both the Histoacryl and Amcrylate groups than in the Scleremo group. Similarly, it has been previously reported that glue injections had achieved variceal eradication in approximately 75% of patients (range: 50%-100%)[3].

In comparison with the other types of sclerosants that were used in previous studies, obliteration was achieved in only 32% of the sodium tetradecyl sulphate group and 81% of the hypertonic (50%) glucose water group ($P < 0.05$) in the study of Chang *et al*[7].

The Scleremo (72% chromated glycerin) was useful

primarily in the sclerosis of small vessels. Its principal advantage is that it rarely causes extravasation necrosis; its viscosity also allows maximum surface contact time and avoids the risk of an oily base causing the formation of an embolus. The main problems with Scleremo are that it is difficult to work with because it is extremely viscous, that it can be quite painful on injection, and that the chromate moiety is highly allergic[12].

To our knowledge, there is no previous Egyptian study that addresses the efficacy of Scleremo in the management of GV. In the current study, Scleremo with glucose 25% was characterized as being more economical, with a clean and smooth endoscopic field of vision and fewer side effects. However, bleeding from the puncture site, specific dealing during the injection, its high amount and number of sessions required and a delay in the obturation of the varices were its disadvantages.

El-Wakil[11] investigated the efficacy of Scleremo in the management of bleeding EV and demonstrated that the rate of the eradication of EV in the Scleremo group was 75% in comparison with 60% in the Ethanolamine Oleate group.

In the present study, none of the patients in the Scleremo group had needle obstruction during the injection in comparison with four patients (13.3%) in each of the other two groups, with a non-significant difference ($P > 0.05$). Chang *et al*[7] reported the frequent obstruction of the injection needle when using Histoacryl during the treatment of active gastric variceal bleeding, although it achieved a nearly 100% success rate for the initial hemostasis.

In the current study, rebleeding occurred in 4 cases (13.3%) in both the Histoacryl and Amcrylate groups, while no cases (0%) were recorded in the Scleremo group, with an insignificant difference. Previous studies of glue injections for GV have shown a rebleeding rate ranging from 23%-50%[3,21].

In the current study, the mortality rate was (6.6%) in both the Histoacryl and the Amcrylate group compared with 0% in the Scleremo group, with a non-significant difference.

El-Wakil[11] reported that the mortality rate was 5% in the Ethanoleamine Oleate group, while no fatalities were reported in the Scleremo group during the management of bleeding EV.

Kind *et al*[23] treated 174 cirrhotic patients who had actively bleeding GV with cyanoacrylate and then by weekly sessions until their varices were eradicated. The hemostasis, early rebleeding and hospital mortality rates after the cyanoacrylate treatment were 97.1%, 15.5% and 19.5%, respectively. In approximately 75% of the patients, the GV were successfully obliterated.

In the present work, all of the groups reported some minor complications, with non-significant differences among them, in the form of chest pain (6.6%, 6.6% and 13.3%) for the Histoacryl, Amcrylate and Scleremo groups, respectively, transient dysphagia in the Amcrylate group only (13.3%), low grade fever in the Histoacryl group only (6.6%) and ulceration in both the Histoacryl and Amcrylate groups only (13.3% *vs* 6.6%).

It has been previously reported by Ljubicic *et al*[24] that fever, retrosternal discomfort and dysphagia frequently occur with Histoacryl injections and usually resolve within 48 h.

In the study of El-Wakil[11], the Scleremo showed fewer complications than Ethanoleamine Oleate in the form of chest pain (15% *vs* 40%), transient dysphagia (15% *vs* 40%) and low grade fever (5% *vs* 20%). A large post-sclerotherapy ulcer occurred in (10%) of patients in the Ethanolamine Oleate group, while no ulcers were reported in the Scleremo group.

All of the sclerosant substances that we used (Histoacryl, Amcrylate and Scleremo with glucose 25%) showed both efficacy and success in the management of GV, with no significant differences among them except in the total amount required, their cost and incidences of bleeding during the puncture; however, they did vary in their superiority in some aspects.

The authors gratefully acknowledge all of their colleagues for their contributions.

COMMENTS

Background

The endoscopic treatment of gastric varices (GV) is still a matter of debate. Treatment options for GV that have been studied in prospective trials include the injection of cyanoacrylate-based tissue adhesives, alcohol and sclerosants. The results from this limited number of small studies had varying success rates and were uncontrolled, making it difficult to draw definitive conclusions about their efficacy or the superiority of one therapy over another.

Research frontiers

Cyanoacrylates are synthetic glues that rapidly polymerize on contact with water or blood. Scleremo, a compound of 72% chromated glycerin, is a polyalcohol that is considered to be a chemical irritant sclerosant that causes cell surface protein denaturation leading to thrombo-fibrosis. The authors compared n-butyl-2-cyanoacrylate (Histoacryl®), iso-amyl-2-cyanoacrylate (Amcrylate®) and a mixture of 72% chromated glycerin (Scleremo®) with hypertonic glucose solution (25%) in the management of GV. All of the sclerosants showed efficacy and success in the management of GV; they differ in the total amount required, cost and the occurrence of bleeding during the puncture.

Innovations and breakthroughs

This is the first Egyptian study that addresses the efficacy of Scleremo® in the management of GV; it is characterized as being economical and clean, with a smooth endoscopic field of vision and few side effects.

Applications

This study may represent a future strategy for the use of a mixture of 72% chromated glycerin (Scleremo®) with a hypertonic glucose solution (25%) in the management of GV.

Terminology

Variceal obturation employs the injection of sclerosant substances leading to the plugging and thrombosis of the varices and an immediate cast of the vessel, followed by the consequent sloughing of the cast after 1-2 wk.

Peer-review

This is a well-researched and well-written article that will be of interest to the readers and will add to the literature on the management of this condition. The endoscopic treatment of GV is still a matter of debate, and controversy exists

on their evaluation and possible pharmacologic and endoscopic treatment. Additionally, Scleremo appears to be the least costly alternative.

Abstract

AIM: To summarize the clinical impact of a formal training for the effectiveness and safety of endoscopic submucosal dissection for gastrointestinal cancer.

METHODS: We searched databases including PubMed, EMBASE and the Cochrane Library and Science citation Index updated to August 2014 to include eligible articles. In the Meta-analysis, the main outcome measurements were *en bloc* resection rate, local recurrence rate (R0) and the incidence of procedure-related complications (perforation, bleeding).

RESULTS: *En bloc* resection was high for both, dissecting stomach tumors with an overall percentage of 93.2% (95%CI: 90.5-95.8) and dissecting colorectal tumors with an overall percentage of 89.4% (95%CI: 85.1-93.7). Although the number of studies reporting R0 resection (the dissected specimen was revealed free of tumor in both vertical and lateral margins) was small, the overall estimates for R0 resection were 81.4% (95%CI: 72-90.8) for stomach and 85.9% (95%CI: 77.5-95.5) for colorectal tumors, respectively. The analysis showed that the percentage of immediate perforation and bleeding were very low; 4.96 (95%CI: 3.6-6.3) and 1.4% (95%CI: 0.8-1.9) for colorectal tumors and 3.1% (95%CI: 2.0-4.1) and 4.8% (95%CI: 2.8-6.7) for stomach tumors, respectively.

CONCLUSION: In order to obtain the same rate of success of the analyzed studies it is a necessity to create training centers in the western countries during the "several years" of gastroenterology residence first only to teach EGC diagnose and second only to train endoscopic submucosal dissection.

Key words: Endoscopic submucosal dissection; Training

Core tip: Endoscopic submucosal dissection (ESD) has gained widespread use in Asia because of a well-

documented higher *en bloc* and curative resection rates for early neoplastic gastrointestinal lesions. Unfortunately, ESD has not been yet widespread in the West due to remain the very flat learning curve and lack of training resources. In Asia, ESD skills are acquired in the time-honored mentor/apprentice model over a period of few years. Although, there is a great heterogeneity in the medical literature reports about training and learning curve of ESD. In this meta analysis we had analyzed the results from these training centers reports. Because technical maturation often requires measurable standard to achieve.

Impact of formal training in endoscopic submucosal dissection for early gastrointestinal cancer: A systematic review and a meta-analysis. *World J Gastrointest Endosc* 2015; 7(4): 417-428 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i4/417.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i4.417

INTRODUCTION

There are few training centers around the world in which an endoscopy fellow can be trained in the ESD technique. There is probably only a formal ESD training program in Asian countries (Japan, South Korea and China). As ESD is a highly technical and demanding minimal invasive procedure, endoscopists require training before performing the procedure. The operator must possess a good understanding of all aspects of ESD: full knowledge of early GI lesions, the endoscopes, EUS, ESD knives, electro surgical unit parameters, injection agents, sedation, complications and other aspects.

In Asian countries like Japan, South Korea and China, gastrointestinal intraepithelial neoplasm is more prevalent than in Western countries. Accordingly, most medical institutions in Japan provide training (in a stepwise manner): initially, endoscopists participate as an assistant, starting with ESD in the gastric antrum or the rectum with a supervisor, then in the proximal stomach, the colon or the esophagus. In contrast, in Western countries, cases of early gastrointestinal lesions are less diagnosed, resulting in a slow introduction of the ESD technique. Efforts are currently underway to change this situation. Possible solutions to improve training and experience are the use of animal models and the establishment of training centers. Further, deficiencies in training and experience can now be more rapidly overcome as a result of new technologies. As described above, new advances have led to devices that are easy to handle, making it simpler for beginners to perform ESD. Devices with scissors and forceps, like the Clutch Cutter or other covered devices, are easier to use, leading to fewer complications (*e.g*., perforation), although the procedure time is longer than those with non-covered devices. The other new approach in ESD, the use of mesna (2-mercaptoethanesulfonate sodium), may also make submucosal dissection safer and faster.

MATERIALS AND METHODS

Data sources and searches

We searched databases including PubMed, EMBASE and the Cochrane Library and Science citation Index updated to August 2014 to identify related articles in English language that review Endoscopic submucosal dissection training[1-121]. All bibliographies were indentified in the reference lists and were analyzed separately by two experts in ESD during the selection process. The initial searching Medical Subject Headings *(MeSH)* used were "Endoscopic submucosal dissection", afterwards "Endoscopic submucosal dissection training" and finally the articles that does not analyze the operation time, *en bloc* resection rate, local recurrence rate and the incidence of procedure-related complications were excluded (Figure 1A).

Study selection

The inclusion and exclusion criteria are shown in Table 1.

Data extraction and quality assessment

Data were extracted with a predefined MeSH criteria by one investigator and confirmed by the others according to a data extraction form. The following data were collected: year of publication, first author, country, number of participants, site of the lesions and lesions in each group, tumor size and endpoints (*en bloc* resection rate, local recurrence rate, and complications). The definitions of the endpoints were: (1) site of resection; (2) *en bloc* -removal in one piece without fragmentation; (3) local recurrencte rate - during the follow-up an histological diagnosis of tumor at the resected site; (4) operation time - from marking to complete resection; and (5) rate of complications - related bleeding or perforation incidence.

Statistical analysis

Meta-analysis: The statistical review of the study was performed by a biomedical statician of the Infectology department from the National Institute of Medical Sciences and Nutrition S.Z. (Mexico). The DerSimonian/Laird random effects model was used due to expected heterogeneity among studies. Statistical heterogeneity was assessed using the Higgins I^2 test. For the Higgins test, I^2 < 25% indicates low heterogeneity, 25%-50% moderate and > 50% severe heterogeneity. Preplanned analyses included analyses limited to studies including resection of stomach tumors and colorectal tumors using endoscopic submucosal dissection. Data quality assurance and data analysis were conducted using Stata™ 12.0

(Statistics/Data analysis Special Edition; Statacorp, College Station, Texas, United States). All statistical test in the analysis were two-sided and were conducted with α = 0.05 (95%CI).

RESULTS

Study selection

A total of 1853 were retrieved with the MeSH "endoscopic submucosal dissection" to estimate the potential studies for the meta-analysis. Afterwards, we refine the search including the word training with the MeSH "endoscopic submucosal dissection training" and 1733 were excluded. In the remaining 120 potential studies 71 were excluded because of the exclusion criteria in Table 1[1-12,14-16,18-28,30-33,35-40,42-50,52-62,64-82,95-114].

From the 49 remaining studies 32 were included in the meta-analysis. All of these 32 studies were in human patients respective case/control studies, not randomized controlled trials.

En bloc resection rate (Figures 1B and C)

The present analysis shows that the percentage of *en bloc* resection was high for both, dissecting stomach tumors with an overall percentage of 93.2% (95%CI: 90.5-95.8) and dissecting colorectal tumors with an overall percentage of 89.4% (95%CI: 85.1-93.7).

Local recurrence rate (Figures 1D and E)

Although the number of studies reporting R0 resection (the dissected specimen was revealed free of tumor in both vertical and lateral margins) was small, the overall estimates for R0 resection were 81.4% (95%CI: 72-90.8) and 85.9% (95%CI: 77.5-95.5) for stomach and colorectal tumors, respectively.

Procedure-related complications

Data for procedure-related complications were

Table 1 Inclusion and exclusion criteria

Inclusion criteria	Exclusion criteria
ESD in patients	Case report

(R0) and the incidence of procedure-related complications	Review
(perforation, bleeding)	Letters to editor
Written in English	Insufficient data
	Guidelines

ESD: Endoscopic submucosal dissection.

reported in all of the studies included in the meta-analysis. The analysis showed that the percentage of immediate perforation and bleeding were very low.

Perforation rate (Figures 1F and G)

The perforation rate was 3.1% (95%CI: 2.0-4.1) for stomach tumors and 4.96 (95%CI: 3.6-6.3) for colorectal tumors. In most studies, late perforation and bleeding was not reported and thus not included in the current analysis.

Bleeding rate (Figures 1H and I)

The bleeding rate was 4.8% (95%CI: 2.8-6.7) for stomach tumors and 1.4% (95%CI: 0.8-1.9) for colorectal tumors.

Finally, the last 17 studies were in animal models and even though they were not included in the meta-analysis, we resume them in a table that contains: author, year, type of animal model, number of patients, organ and main conclusion (Table 2)[13,17,29,34,41,51,63,83,94,96,115-121].

DISCUSSION

To our knowledge, this systematic review and meta-analysis is the first to analyze the impact of a formal training in ESD for early gastrointestinal cancer. Probably there are ESD formal training centers only in the Asian countries (Japan, China and South Korea). For the above reason almost 100% of the analyzed studies were from Asia. All the studies included in our analysis were done in a formal ESD training setting although most of them does not include the number of trainees and/or a comparison between preceptees *vs* experts and thus not included in the current analysis. The present study shows that the percentage of *en bloc* resection was high for both, dissecting stomach and colorectal tumors. Even with a small number of studies reporting R0 resection (the dissected specimen was revealed free of tumor in both vertical and lateral margins), the overall estimates for R0 resection were 81.4% (95%CI: 72-90.8) and 85.9% (95%CI: 77.5-95.5) for stomach and colorectal tumors respectively. The analysis also showed that the percentage of immediate perforation and bleeding were very low. ESD was developed in Japan in the year 1999 to preserve intact gastrointestinal function and for *en bloc* resection of lesions larger than 2 cm. ESD also has made it possible to resects early gastrointestinal tumors even with large submucosal fibrosis or ulcerative scars in an *en bloc* fashion and it has gradually gained acceptance as a standard treatment for these tumors. The ESD era began with pioneers trained in Japan on South Korea (2003-now) and in China (2006-now) rapidly gaining expertise and acceptance. Hotta *et al*[77] reported that 80 procedures must be carried out to acquire skill at ESD. In order to acquire this skill all the procedures even in animal models must be carried out under supervision of ESD experts and with availability of all the equipment and high trained team. Because this is not just a fact of endoscopic skills but of knowledge, technology and team work. This procedure should never be trained in an experimental ("not supervised by an ESD expert") fashion with animal models just focusing on the dissection technique without firstly make a good analysis of the borders and deepness of the early gastrointestinal cancer (EGC) lesion invasion under an expert supervision. Probably the lack of research, diagnose and case series of early gastrointestinal cancer lesions in the Western countries are due to a lack of formal training centers firstly with certified EGC experts and afterwards ESD experts. In order to obtain the same rate of success of the analyzed studies it is a necessity to create training centers in the western countries during the "several years" of gastroenterology residence first only to teach EGC diagnose and second only to train ESD. In the same manner that the medical techniques should never anticipate the clinic, nor the endoscopic skills, nor the technology or both could substitute tutorial training by an expert.

Although, there is a great heterogeneity in the medical literature reports about training and learning curve of ESD. In this meta analysis we had analyzed the results only from the formal training centers reports. The results presented in the literature that can be included in our meta analysis to clarify the training efficacy concerning the procedure length, completeness and complications such as *En bloc* resection rate, Local recurrence rate, Procedure-related complications, Perforation and Bleeding rate were included. But unfortunately, we can only assume that the procedure was done in a formal training center, such as the one in which some of the authors had been trained. Even when there are very detailed description of the learning curve specially in the Japanese and European reports there is a great heterogeneity of the numeric information presented and thus cannot be included in a meta analysis. There is not uniform information if the procedure was done by a trainee with/without supervision. Also, the analyzed issues in each report has great heterogeneity

Table 2 Endoscopic submucosal dissection studies in animal models

Ref.	Year	Model	*n*	Organ	Main conclusion
González *et al*[17]	2013	Porcine	30	Stomach	A sequential ESD training program of a unique endoscopist contributed to learning ESD for its subsequent application in humans, yielding good results in efficacy and safety
Takizawa *et al*[13]	2013	Porcine	30	Colon	Large mucosal target sites in the rectum and distal colon could be safely removed *en bloc* by means of a hybrid technique, SEMR, with blunt submucosal balloon dissection
Moss *et al*[115]	2012	Porcine	10	Colon	HK-ESD with SG submucosal injection is superior to CSI-EMR for *en bloc* excision of 50 mm diameter lesions. The technique is rapidly learn
Gostout *et al*[41]	2012	Porcine	16	Rectum and colon	Large mucosal target sites in the rectum and distal colon can be safely removed *en bloc* by means of a hybrid technique, ie, submucosal endoscopy with mucosal resection, combining elements of ESD with our SEMF method
Kumano *et al*[117]	2012	Porcine	24	Esophagus	PCH permits more reliable ESD of the esophagus without complications than do SH and HS
Balogh *et al*[51]	2012	Porcine	15	Esophagus	Training in live pig models could help endoscopists to overcome the learning curve and minimize the risk of complications before starting the procedure in humans Reduction in the resection time and low risk of complications, especially bleeding, could be achieved by the application of a flush knife
Tanaka *et al*[63]	2012	Porcine *ex vivo*	10	stomach	*Ex vivo* training model was helpful to endoscopists with experience in gastric ESD in acquiring the basic skills for performing esophageal ESD
Parra-Blanco *et al*[29]	2011	Porcine	18	Stomach	A Clip-band traction technique is feasible, safe, effective, and relatively inexpensive gastric ESD
Von Renteln *et al*[118]	2011	Porcine	12	Stomach	Submucosal mesna injection did not affect ESD procedure times but was associated with a trend toward a lower incidence of intraprocedural bleeding
Tanimoto *et al*[94]	2011	Canine	10	Esophagus	ECE-ESD training is feasible in canine models for postgraduate endoscopy fellows
Hon *et al*[96]	2010	Porcine	10	Colon	Technical proficiency improved by repetition. This setup may be a promising training model for endoscopists working in areas with a low incidence of early gastric cancer
Von Renteln *et al*[119]	2010	Porcine	12	Stomach	The flexible Maryland dissector was demonstrated to be efficient, safe, and feasible for facilitating gastric ESD
Parra-Blanco *et al*[34]	2010	Porcine	30	Esophagus stomach	Training in animal models could help endoscopists overcome the learning curve before starting ESD in humans
Moss *et al*[116]	2010	Porcine	10	Colon	CSI-EMR with submucosal injection of succinylated gelatin is safe and superior to conventional EMR.With experience, total procedure duration is comparable
Von Delius *et al*[120]	2008	Porcine	10	Stomach	PMT-ESD is feasible and safe. With the use of PA-ES, mucosal pieces of various sizes can be resected *en bloc* in gastric locations that are difficult to access by flexible endoscopy alone
Yamasaki *et al*[121]	2006	Porcine	2	Stomach	ESD by submucosal injection of viscous SCMC solution appeared to be an easy, safe, and technically efficient method for dissection of gastric lesions
Neuhaus *et al*[83]	2006	Porcine	17	Stomach	The R-scope (double channel endoscope) facilitated ESD of large gastric areas. Procedure is technically demanding and time-consuming, with a high risk of perforation may be related to an insufficient volume of solution being injected submucosally

HK: Hybrid knife; ESD: Endoscopic submucosal dissection; CSI-EMR: Circumferential submucosal incision endoscopic mucosal resection; SEMF: Mucosal safety valve flap; HS: Hypertonic saline solution; PCH: Photocrosslinkable chitosan hydrogel; SFC: Submucosal fluid cushion; SH: Sodium hyaluronate; ECE: *En bloc* circumferential esophageal; PA-ES: Percutaneously assisted endoscopic surgery; PMT-ESD: PEG-minitrocar ESD; SCMC: Sodium carboxymethylcellulose.

(animal model, human, periods of time, *etc.*) and the results are presented for example in ranges but not in mean ± SD. Because technical maturation often requires measurable standard to achieve. As this procedure become more standardized in the Western countries we can also be able to make more precise comparisons between training centers and learning curve. There are no shortcuts and probably we have to find out the way to establish training centers with the same training scheme as the Asian countries if we are expecting to have similar rates of success, but as always time will say.

COMMENTS

Background

Endoscopic submucosal dissection (ESD) was originally developed to preserve intact gastrointestinal function after *en bloc* resection of early GI cancer lesions larger than 2 cm.

Research frontiers

This systematic review and meta-analysis is the first to analyze the impact of a formal training in ESD for early gastrointestinal cancer.

Innovations and breakthroughs

Authors designed the meta-analysis to systematically evaluate the ESD formal training impact in the early gastrointestinal cancer regarding *en bloc* resection rate, local recurrence rate and procedure-related complications rate.

Applications

The conclusions of this meta-analysis can help the endoscopists to select the right tool to treat early gastrointestinal cancer lesions.

Terminology

ESD is a newly developed technique in which submucosal dissection is carried out using an electrocautery knife to acquire a single-piece specimen, it is developed for *en bloc* removal of large (> 2 cm) GI tract lesions.

Peer-review

This paper is intereting and valuable because technical maturation often requires measurable standard to achieve.

Abstract

A 45-year-old man of Middle Eastern origin, morbid obese, with a body mass index of 39 had an intra-gastric balloon, filled with 500 mL of saline/methylene blue and intended as definite therapy, inserted some 8 wk previously. He was admitted to the emergency department with abdominal cramps. An ultrasound of the abdomen was performed in ER which confirmed the balloon to be in place without any abnormality. He was discharged home on symptomatic medication. Patient remains symptomatic therefore he reported back to ER 2 d later. Computed tomography scan was performed this time for further evaluation which revealed a metallic ring present in the small bowel while the intra-gastric balloon was in its proper position. There was no clinical or radiological sign of intestinal obstruction. Patient was hospitalized for observation and conservative management. The following night, patient experienced sudden and severe abdominal pain, therefore an X-ray of the abdomen in erect position was done, which showed free air under the right dome of diaphragm. Patient was transferred to O.R for emergency laparotomy. There were two small perforations identified at the site of the metallic ring entrapment. The ring was removed and the perforations were repaired. Due to increasing prevalence of obesity and advances in modalities for its management, physicians should be aware of treatment options, their benefits, complications and clinical presentation of the known complications. Physicians need to be updated to approach these complications within time, to avoid life-threatening situations caused by these appliances.

Key words: Spatz adjustable balloon; Intragastric balloon; Morbid obesity; Safety ring; Perforation

Core tip: Because the rare reported unexpected complications that the balloon safety ring which designed to prevent its complication it was by it self the cause of

serious complication. The u/s confirmation of balloon position was miss leading so radiographic images was essential when there is suspicious.

INTRODUCTION

Obesity is a major health problem, and is challenging the modern world. Its distribution is insidious throughout the world. Because it is a major risk factor for many potential life-threatening conditions, different invasive and non-invasive therapeutic techniques are being used to help the individuals suffering from obesity return to a healthy life.

Among these modalities, intra-gastric balloons are gaining popularity because of their efficacy, safety, and technical ease, as shown by some studies[1,2]. Moreover, it has been recommended as a weight reduction adjuvant before bariatric surgery, and before all kinds of planned surgery in morbidly obese persons; to reduce life-threatening co-morbidities and reduction of surgical risk[3,4].

Most of the reported serious complications with the newer generation of balloons take place 6 mo after placement of the balloon[5]. Here, we are reporting a case of small bowel perforation, secondary to break down and migration of the safety ring of an adjustable intra-gastric balloon (Spatz) that happened 8 wk after its insertion.

CASE REPORT

A 45-year-old man was brought to the emergency department with a history of abdominal cramps, on and off, for a few days, associated with anorexia and nausea. Patient had a history of saline filled adjustable intra-gastric balloon placement for the management of obesity 8 wk ago. Initial investigations including an ultrasound abdomen were unremarkable for any complication or pathology. Symptomatic treatment trial was unsuccessful and patient remained symptomatic, therefore, he reported back to ER.

He was in mild distress this time, but stable hemodynamically. Although his abdomen was soft and bowel sounds were active, a new onset mild generalized abdominal tenderness was noticed on clinical examination, therefore an abdominal computed tomography (CT) scan was planned which later reported the presence of a metallic ring (foreign body) in the small bowel without any sign of perforation or obstruction, while the adjustable balloon was in place (Figure 1).

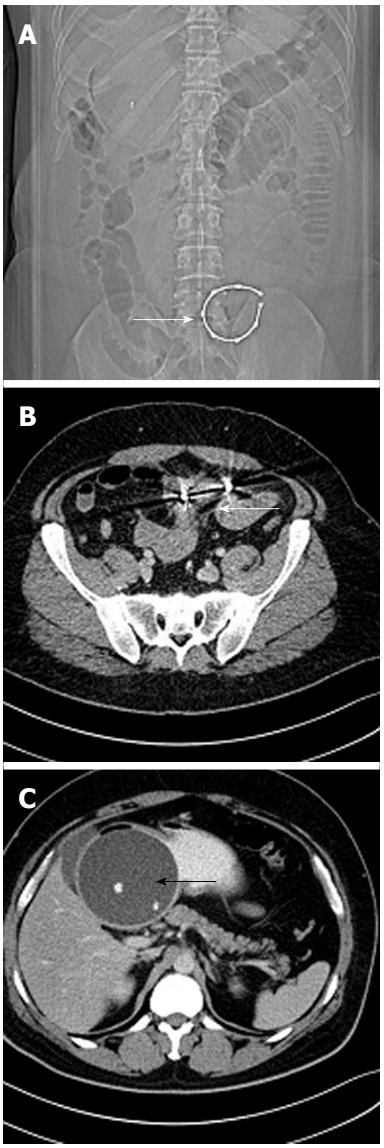

Figure 1 Abdominal computed tomography scan showing the safety ring migrated to the small bowel (A and B) (white arrows) and (C) the balloon was in the stomach (black arrow).

Patient was admitted for observation, advised null per oral, and started on intra-venous fluid. He becomes completely asymptomatic on conservative management. Next morning, patient underwent an upper gastrointestinal endoscopy. Balloon was seen in place but the safety ring was not seen in position, nor was it present in gastric cavity. Therefore, balloon was retrieved. Patient was stable clinically till night when he experienced a sudden and severe abdominal pain.

Plain X-ray film of abdomen was taken that revealed the presence of free air under the right dome of the diaphragm. Surgical team was informed immediately. Mean while NG tube was placed and IV antibiotics were initiated. Patient was transferred to the operation room for an emergency laparotomy. A 10 cm mid-line incision was given small bowel was examined.

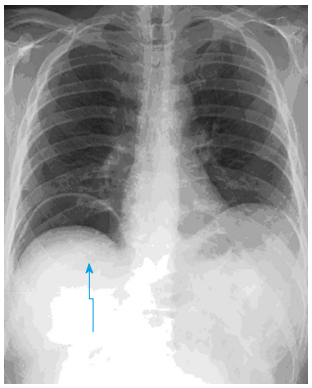

Figure 2 Free air under the diaphragm.

Two perforations were identified in distal jejunum at the site of ring entrapment. Small incision was made at the site of perforation and metallic ring was extracted followed by a successful primary repair of small bowel. Figure 2 shows free air under the diaphragm. Figure 3 shows endoscopic and gross eye views of both balloon and its broken ring after extraction.

DISCUSSION

Intra-gastric balloons were introduced in the early 1980s for the management of morbid obesity. These IGBs have attracted physicians since their first use[6].

Initial results were promising for this less invasive procedure in comparison with surgery for the treatment of morbid obesity[7-9]. Some published results reveal an average weight loss of 11-15 kg within 6 mo[10-13]. Standard IGBs are having significant undesired effects, *e.g.*, nausea or vomiting, and significant abdominal discomfort in initial phase. Balloon deflation and distal migration that may lead to bowel obstruction and a physical adaptation indicated by lack of further weight loss effects by these IGBs[14-17]. Complications of balloon insertion constitutes a diagnostic challenge because majority of patients were presented with non-specific abdominal pain, nausea or vomiting[18-23].

Spatz adjustable balloon system (SPATZ-ABS) is a vibrant bariatric therapy with significantly improved implantation time, having an adjustable size balloon according to desired weight, and a safety ring that prevents distal migration of device in case of rupture of balloon[24].

In our case, the safety ring was detached from the rest of the system and migrated down to the jejunum while the balloon remains in the stomach. It was retrieved endoscopically. The jejunal perforation caused by migration of the safety ring was managed by emergency surgery. This complication was unexpected as there was no clinical sign of intestinal obstruction. Ultrasonography alone was also not helpful in identifying this complication by SPATZ-ABS.

Because of non-specific clinical presentation and inadequacy of ultrasonography alone, we suggest that whenever there is suspicion of a balloon related complication, a combination of plain abdominal X-ray, ultrasound, an upper GI endoscopy and/or CT scan will be an appropriate approach for early detection and management of complication.

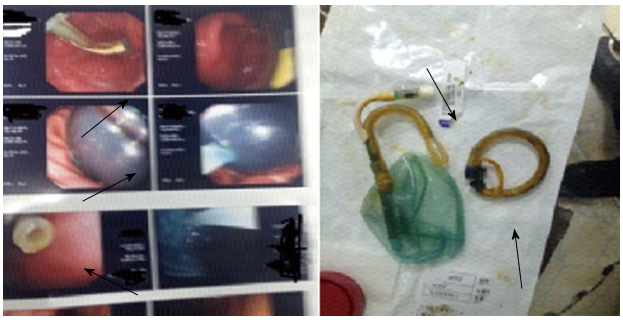

Figure 3 Endoscopic and gross eye views of both balloon and its broken ring after extraction.

COMMENTS

Case characteristics

A 45-year-old patient with history of intragastric Bio enteric balloon, experienced a recurrent cramp and abdominal pain, which became severe when perforation occurs.

Clinical diagnosis

No significant clinical signs, but when perforation occurs there was abdominal tenderness.

Differential diagnosis

Potential perforated duodenal ulcer, acute pancreatitis, acute intestinal obstruction or biliary colic.

Laboratory diagnosis

The CBC, LFT, KFT, and coagulation profile were all within normal parameters.

Imaging diagnosis

U/S abdominal was normal, computed tomography abdominal the ring was migrated down to the small bowel, when perforation occurred X-ray of the abdominal area showed free air under right dome of the diaphragm.

Pathological diagnosis

A pathology sample was not tested, but during surgery two small perforations were closed by sutures.

Treatment

NPO, endoscopic removal of the balloon, Laparotomy for repair of perforation, Pethedin inj, Paracetamol inj, Cefotoxim inj, Metronidazol infusion and *iv* fluid.

Related reports

From this case, any abdominal pain in a patient with an intragastric balloon should be taken seriously, and potential complications managed early.

Peer-review

This case report should be published.

Abstract

More than a century has elapsed since the identification of *Clostridia* neurotoxins as the cause of paralytic diseases. *Clostridium botulinum* is a heterogeneous group of Gram-positive, rod-shaped, spore-forming, obligate anaerobic bacteria that produce a potent neurotoxin. Eight different *Clostridium botulinum* neurotoxins have been described (A-H) and 5 of those cause disease in humans. These toxins cause paralysis by blocking the presynaptic release of acetylcholine at the neuromuscular junction. Advantage can be taken of this blockade to alleviate muscle spams due to excessive neural activity of central origin or to weaken a muscle for treatment purposes. In therapeutic applications, minute quantities of botulinum neurotoxin type A are injected directly into selected muscles. The Food and Drug Administration first approved botulinum toxin (BT) type A in 1989 for the treatment of strabismus and blepharospasm associated with dystonia in patients 12 years of age or older. Ever since, therapeutic applications of BT have expanded to other systems, including the gastrointestinal tract. Although only a single fatality has been reported to our knowledge with use of BT for gastroenterological conditions, there are significant complications ranging from minor pain, rash and allergic reactions to pneumothorax, bowel perforation and significant paralysis of tissues surrounding the injection (including vocal cord paralysis and dysphagia). This editorial describes the clinical experience and evidence for the use BT in gastrointestinal motility disorders in children.

Key words: Botulinum toxin; Gastrointestinal motility disorders; Children; Swallowing disorders; Gastroparesis; Defecation disorders

Core tip: *Clostridium botulinum* toxin has been used to alleviate symptoms associated to muscle spams due to excessive neural activity of central origin or to weaken a muscle for treatment purposes. In therapeutic applications, minute quantities of botulinum neurotoxin type A are injected directly into selected muscles. Ever since, therapeutic applications of botulinum toxin have expanded to other systems, including the gastrointestinal tract. This editorial presents the current evidence and evaluates the clinical experience for the use of botulinum

toxin in gastrointestinal motility disorders in children.

Arbizu RA, Rodriguez L. Use of *Clostridium botulinum* toxin in gastrointestinal motility disorders in children. *World J Gastrointest Endosc* 2015; 7(5): 433-437 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/433.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.433

SWALLOWING DISORDERS

Cricopharyngeal achalasia

Cricopharyngeal achalasia is characterized by abnormal relaxation of the upper esophageal sphincter associated to abnormal coordination with pharyngeal contraction resulting in oropharyngeal dysphagia and at times resulting in aspiration. The disorder has been treated with medications, dilatations, botulinum toxin (BT) and myectomy. BT has been reported as safe and effective in patients with cricopharyngeal achalasia[1-3], particularly in those who failed medical therapy and are poor surgical candidates, as a diagnostic tool in complex cases[3], to alleviate symptoms until surgery can be safely performed[4] and to provide relief for residual symptoms after myotomy[5] with minimal side effects reported. In our experience the potential complications with the use of BT in cricopharyngeal achalasia can be important so we recommend its use for experienced hands, particularly ENT surgeons.

Esophageal achalasia

Esophageal achalasia is a disease of unknown etiology characterized by loss of esophageal peristalsis and failure of the lower esophageal sphincter (LES) to relax with swallowing. Decrease in nitric oxide synthase containing nerve fibers and interstitial cells of Cajal in the distal esophagus have been proposed as potential causes[6]. It is an uncommon condition in pediatrics and has an estimated incidence that ranges from 0.11-0.18/100000 children per year[7,8]. Symptoms vary with age of presentation. Progressive dysphagia, vomiting and regurgitation are common complaints in older children[9]. Initial diagnostic studies include barium swallow and upper endoscopy, but esophageal manometry is considered to the gold standard test for diagnosis and will provide diagnostic certainty in approximately 90% of the cases[10,11]. The goal of treatment in children with achalasia is to improve bolus transport across the LES by reducing the pressure at that level. Current treatment options include pharmacotherapy, pneumatic dilation, surgery or injection of BT and recently the Peroral Endoscopic Myotomy[12]. BT is endoscopically injected at the LES with a sclerotherapy needle in 4 different quadrants. The short-term efficacy of BT in treating esophageal achalasia has been well established in adults. Multiple double blind placebo controlled studies have revealed BT to be safe and effective in reducing symptoms and improving esophageal clearance in adults with esophageal achalasia[13]. It has been described to be as effective as pneumatic dilation[14-17] and comparable to surgical myotomy[18] in the short term (< 6 mo). It has been reported to improve residual symptoms after myotomy and pneumatic dilations[19]. It has been recommended primarily in those who are poor surgical candidates resulting in important symptomatic response[20]. BT has also been used as a diagnostic tool in cases where diagnosis of achalasia is not clear and to indicate definitive therapy[21]. Most of the information of BT use in children is found as case reports and case series. Most authors reported a short-lived (2-6 mo) improvement on symptoms[9,22-24]. Walton *et al*[22] reported a single case with sustained clinical improvement of 8 mo after a single BT injection. Khoshoo *et al*[25] reported BT as a safe and less invasive alternative for symptomatic relief of symptoms in 3 children with achalasia. They also observed weight gain prior to surgery and noted that it could also be a choice in patients with incomplete response following balloon dilatation or myotomy[25]. Hurwitz *et al*[24] found that among children receiving BT as initial treatment for achalasia, 83% responded to therapy with a mean duration of effect of 4.2 mo and more than half of responders required additional procedure 7 mo after receiving BT. Another study demonstrated an inverse relationship between pre-BT LES resting pressure and duration of response[23]. All authors agree that BT should be reserved for children with achalasia who cannot undergo pneumatic dilatation or surgery or to alleviate residual symptoms after these interventions.

BT has been also reported as useful in the management of esophageal spastic disorders in adults[26], to our knowledge no reports are available for this indication in children. The only fatality related to the use of botulinum toxin for gastrointestinal motility disorders has been reported in an adult patient with esophageal spasms who developed a fatal mediastinitis[27].

GASTRIC DISORDERS

Gastroparesis

Gastroparesis is defined as the presence of upper gastrointestinal symptoms with evidence of delayed gastric emptying by a standardized gastric transit study in the absence of mechanical obstruction. Symptoms classically include nausea, vomiting, early satiety, bloating, postprandial fullness, abdominal pain, and weight loss. The etiology of gastroparesis in the pediatric population is limited to a few studies. An observational descriptive analysis of a large pediatric population with gastroparesis reported that approximately 70% of the cases were idiopathic[28]. Another series found gastroparesis to be associated with post-viral gastroenteritis (18%), medications (18%), post-surgical (12.5%), mitochondrial disease (8%) and diabetes mellitus (2%-4%)[29]. Gastroparesis has been treated with medications and in some cases

with surgical interventions aiming to facilitate the transfer of bolus from stomach to small bowel. The endoscopic application of BT injections in gastroparesis has been well studied in adult patients. Multiple large uncontrolled studies have demonstrated symptom improvement with the use of BT[30-32]. However, two small randomized control studies showed no significant difference between BT and placebo on symptomatic as well as gastric emptying improvement[33,34], but some concerns have been raised about the power of such studies. In pediatrics, Rodriguez *et al*[35] assessed the long-term clinical outcomes after intra-pyloric BT injection in children with gastroparesis. After the first injection, 33% of patients reported no response and 67% described improvement in their symptoms. The mean duration of improvement was 3 mo and no significant side effects were reported[35]. From their analysis they also described that older age and vomiting were predictive of response to the initial injection, and male sex predicted response to repeated injections. There are currently no guidelines that indicate the timing of BT injections in pediatric patients with gastroparesis, but the consensus is that its use should be limited to patients that fail medical therapy with prokinetics and before more invasive interventions are considered (gastrojejunostomy, gastric electric stimulator). Although have not observed complications with its use in gastroparesis we have noticed short-lived vomiting in some patients followed by complete resolution of symptoms.

DEFECATION DISORDERS

Chronic constipation is one of the most common complaints at the pediatric offices. Although constipation may have several etiologies, in most children no underlying etiology can be found. Symptoms refractory to aggressive therapy with stool softeners and laxatives should prompt further work up to rule out etiologies like Hirschsprung's disease and internal anal sphincter (IAS) achalasia.

Hirschsprung's disease

Hirschsprung's disease (HD) is characterized by obstructive defecation due to distal colonic aganglionosis caused by a defect in cranio-caudal migration of neuroblasts leading to lack of relaxation resulting in functional obstruction. The diagnosis is confirmed by rectal biopsy demonstrating absence of ganglion cells in the submucosa and myenteric plexus. The treatment of HD consists in surgical removal of the aganglionic segment. Despite many improvements in diagnostic and surgical techniques, many patients continue to exhibit symptoms after surgical correction. The treatment of obstructive defecation initially consists of rectal dilatations to avoid stricturing of the surgical anastomosis. Some advocate performing a myectomy for those who fail medical therapy and dilatations, but results are variable with some reporting good outcomes[36] and others reporting only a moderate success[37] with complications like fecal incontinence. Due to the inconsistent efficacy and concerns of permanent incontinence, other non-invasive and self-limited alternatives have been contemplated, including use of topical nitric oxide[38] and BT. Langer *et al*[39] reported significant clinical improvement in 3/4 children as well as reduction of IAS resting pressure at 4-8 wk post-BT. Minkes *et al*[40] also reported clinical improvement in 14/18 children and described an association between clinical improvement and a post-BT decrease in IAS resting pressure. Another study showed an improvement in short and long-term obstructive symptoms, frequency of enterocolitis episodes and short-term decrease in hospitalization rates in 30 children with HD and prolonged use of BT[41]; 7 patients developed transient fecal incontinence; and, 1 patient reported anal pain after the BT injection. Elevated IAS resting pressure was associated with higher clinical success. A recent report by Han-Geurts *et al*[42] reported similar findings, with clinical improvement in 25/33 (76%) and decrease in hospitalizations due to enterocolitis. Importantly, they reported 2 children developing transient pelvic muscle paresis with walking impairment. General consensus is to use BT for those patients with obstructive defecation and elevated anal canal resting pressure. In our experience BT is more effective when IAS resting pressure is over 50 mmHg.

IAS achalasia

The hallmark of IAS achalasia is absent IAS relaxation with balloon rectal distention in the presence of ganglion cells on rectal biopsy. Some have called it ultra-short segment Hirschsprung's disease. The treatment of IAS achalasia has been aimed at relieving obstructive defecation with dilations or myectomy. IAS myectomy has been reported to be effective in relieving obstructive symptoms and helping achieve normal bowel control in children with IAS achalasia[43,44]. However, it is associated to fecal incontinence. BT has shown excellent results in relieving functional obstructive symptoms and has become the treatment of choice for IAS achalasia[41,45-47]. In several studies, transient fecal incontinence was the most common minor complication reported that resolved within 4 wk after BT injection[41,45,46]. Foroutan *et al*[48] demonstrated that BT has similar efficacy and less complications when compared to myectomy. Nevertheless, a recent meta-analysis found that regular bowel movements and short and long-term improvements were more frequent after surgery with no difference in the continued use of laxatives or rectal enemas, episodes of constipation and soiling and, overall complication rates between the two procedures[49]. BT should be considered the first option of treatment for IAS achalasia.

Chronic anal fissure

Chronic anal fissure is a common and benign anorectal condition associated to elevated anal canal

resting pressures, although other factors might also play a role. The classic symptom is pain on or after defecation that is often severe and may last from minutes to several hours. Most fissures occur in the posterior midline of the anal canal[50]. By definition, an acute anal fissure typically heals within 6 wk with conservative local management, while a chronic anal fissure fails medical management at times requiring more aggressive interventions[51]. Lateral internal sphincterotomy is a surgical technique commonly used to treat chronic anal fissure. It has been favored by most surgeons because it offers long-lasting relief in sphincter spasm by permanently weakening the IAS. However, it may lead to anal deformity and incontinence in 8%-30% of patients that can be permanent in a subset of patients[50]. BT injection to the IAS has been demonstrated to improve healing in chronic anal fissure in adult studies. In a randomized placebo controlled study BT demonstrated to be superior to placebo in healing of chronic anal fissure at two month follow up (73% *vs* 13%), only a small number of patients required a second injection and no relapses were reported after a 16-mo follow up[52]. Its use has also been shown to be effective when used in combination with topical nitroglycerin[53]. Pediatric studies have shown that BT injection to the external anal sphincter is an effective therapy in children with chronic anal fissures[54,55]. Nonetheless, there is discrepancy in the injection site when compared to adult studies. Prospective and long-term studies are needed to evaluate BT therapy in children with chronic anal fissures.

Abstract

Esophageal adenocarcinoma has the fastest growing incidence rate of any cancer in the United States, and currently carries a very poor prognosis with 5 years relative survival rates of less than 15%. Current curative treatment options are limited to esophagectomy, a procedure that suffers from high complication rates and high mortality rates. Metaplasia of the esophageal epithelium, a condition known as Barrett's esophagus (BE), is widely accepted as the precursor lesion for adenocarcinoma of the esophagus. Recently, radio-frequency ablation has been shown to be an effective method to treat BE, although there is disagreement as to whether radio-frequency ablation should be used to treat all patients with BE or whether treatment should be reserved for those at high risk for progressing to esophageal adenocarcinoma while continuing to endoscopically survey those with low risk. Recent research has been targeted towards identifying those at greater risk for progression to esophageal adenocarcinoma so that radio-frequency ablation therapy can be used in a more targeted manner, decreasing the total health care cost as well as improving patient outcomes. This review discusses the current state of the literature regarding risk factors for progression from BE through dysplasia to esophageal adenocarcinoma, as well as the current need for an integrated scoring tool or risk stratification system capable of differentiating those patients at highest risk of progression in order to target these endoluminal therapies.

Key words: Barrett's esophagus; Esophageal adenocarcinoma; Endoscopy; Risk factors; Radiofrequency ablation; Antireflux surgery

Core tip: The transformation of Barrett's esophagus to dysplasia and finally to esophageal adenocarcinoma is a multifactorial process encompassing effects from multiple known and unknown risk factors. Previously, radiofrequency ablation was reserved for use in high risk patients with high-grade dysplasia, but recent evidence supports the expansion of this technique to be potentially used to treat additional patients at moderate risk of progression, such as those with long segments, long duration of symptoms, and those patients who are unable or unwilling to take proton-pump inhibitors's.

INTRODUCTION

Gastroesophageal reflux disease (GERD) has been estimated to affect nearly 20% of the United States population at any given time[1]. Of this group suffering from GERD, roughly 15% are estimated to have Barrett's esophagus (BE), a condition characterized by columnar-lined epithelium in the esophagus[2]. It is well established that BE is the link between GERD and esophageal adenocarcinoma (EAC), a neoplastic lesion with an extremely poor prognosis with 5-year survival rates of less than 15% and which currently has the fastest rising incidence rate of any cancer with approximately a 10-fold increased incidence rate among men aged 15-74 in the last 40 years[3-6]. Unfortunately, little progress has been made in treating this extremely aggressive cancer, with median survival time increasing only 3.2 mo over the last 30 years[7]. BE has been shown to be a paradigmatic model for progression from metaplastic disease through dysplasia to neoplasia[8]. In this review, we summarize the current literature regarding the etiology and pathophysiology of BE and EAC.

RESEARCH

We performed a literature review in the PubMed/Medline database using MeSH term "Barrett's Esophagus" combined with subheadings "etiology", "physiopathology", "therapy", "diagnosis" and "epidemiology" as well as MeSH term "Esophageal Neoplasms" with selected subheadings "diagnosis", "etiology", "physiopathology", "epidemiology" and "therapy" combined by Boolean operator AND with MeSH term "Adenocarcinoma" with selected subheadings "diagnosis", "epidemiology", "etiology", "pathophysiology" and "therapy". We reviewed abstracts published between 1980 and April of 2013 in English and selected articles relevant to topics discussed herein.

EPIDEMIOLOGY

Columnar lined epithelium has been shown to be present in almost 25% of individuals with GERD symptoms, and columnar lined epithelium with intestinal metaplasia is reported as affecting almost 15% of those with GERD symptoms. The probability of progressing to EAC from BE has been estimated to be approximately 0.5%/year[9,10], with the most convincing evidence provided in a meta-analysis of 47 studies by Yousef *et al*[11] showing a pooled cancer incidence of 6.4/1000 person-years for the 13 studies conducted in the United States and 6.1/1000 person-years for all 47 studies pooled. EAC incidence has increased roughly 10-fold in select demographics over the last 40 years, with only a small fraction being attributed to increasing obesity rates[12]. Recent data suggests this increase is slowing but still substantial, with average annual percentage increase in incidence rising 6.1% in men and 5.9% in women[13]. Other causes for this rapid increase in incidence have yet to be elucidated, but this continues to be a highly active area of research.

ETIOLOGY AND PATHOPHYSIOLOGY

BE is caused by reflux of gastric contents into the esophagus, which causes damage to the stratified squamous epithelium. Not surprisingly, it has also been shown that GERD symptoms increase odds of EAC by 7.7 fold, odds which increase to 43.5 fold when comparing patients with long-standing and severe GERD symptoms[13]. It is currently contested as to whether gastric acid, bile reflux, or the combination is responsible. Several studies have shown increased intraluminal bilirubin content, a proxy for duodenal juice content, in patients with BE, suggesting that bile acid plays an important role in BE development[14]. Likewise, gallbladder function was shown to be impaired in patients with BE and EAC in a real-time ultrasonography experiment following a 10-h fast leading to increased duodenogastric reflux[15]. Cholecystectomy has also been shown to increase risk of EAC, albeit slightly[16,17]. The body's compensatory mechanism can but does not always include metaplasia in the form of simple columnar epithelium, which is thought to be more tolerant to the low pH[18,19]. BE is the most predictive risk factor for the development of EAC, with a relative risk for developing esophageal cancer of 11.3 when compared to the general population[20]. Much research recently has been focused on determining what the risk factors are for developing BE. Age has been shown to be correlated with increased risk of developing BE, with a low of 2 diagnoses per 100000 person-years for those aged 21-30 years and peaking at 31 diagnoses per 100000 person-years in those aged 61-70 years[21]. Males also experience BE incidence rates roughly twice that of females, although the reason for this difference remains to be elucidated[21].

Obesity and its related conditions have been shown to be a risk factor for many diseases, and BE is no exception. A meta-analysis by Cook *et al*[22] suggests that increasing obesity is correlated with an increased risk for BE development but only indirectly due to obesity's effect on GERD development. This view is contested by El-Serag *et al*[23], who suggest that increasing visceral adipose tissue to subcutaneous adipose tissue ratio is correlated with the presence of BE [adjusted OR = 1.47 (95%CI: 0.92 to 4.09)]

as well as Kendall *et al*[24], whose data shows a significant correlation between all measures of obesity tracked (waist circumference, waist-hip ratio, sagittal abdominal diameter, and waist-height ratio) and presence of BE in males even after adjusting for GERD symptoms. It has been proposed that the association between obesity and risk of BE is due to several factors including increased intra-abdominal pressure leading to worsening GERD, as well as increased circulating levels of leptin, adiponectin, and other chemicals secreted by adipose tissue, although this link remains to be confirmed. Recently, low birth weight and preterm birth have been implicated as a risk factor for BE, with several studies reporting those born very small for gestational age, < 3rd percentile in one study and < 2000 g in another, having between a three and eleven-fold increase in odds when compared to those born at a normal weight for gestational age[25,26]. Hiatal hernia has been shown to be another risk factor for BE, with size of hiatal hernia correlating with increasing risk of both BE as well EAC[27,28]. Metabolic syndrome, another obesity related factor, has been shown to increase risk for BE by two-fold relative to those without metabolic syndrome[29].

It is being currently debated as to whether *Helicobacter pylori* (*H. pylori*) infection leads to increased or decreased risk of developing BE, but two meta-analyses, of 49 studies conducted by Fischbach *et al*[30] and 19 studies conducted by Islami *et al*[31], both suggest that, although significant selection and information bias may be present in these studies, *H. pylori* infection appears to be associated with a decreased risk of BE. Aggressive eradication of *H. pylori* infection over the last 30 years may provide an explanation for a small portion of the drastic increase in incidence.

Along with being male and older age[32-34], those with low dietary antioxidant intake have also been shown to not only have an increased risk of developing BE, but also have an increased risk of developing EAC[35,36]. Similarly, length of GERD symptoms is a risk factor for both development of BE as well as EAC[36,37]. The reasons for males experiencing high incidence rates is not well understood, but it appears to be due to other reasons than differential exposure to known risk factors[38,39]. Hormonal factors, studied by comparing patients undergoing hormone therapy, do not appear to account for the discrepancy in EAC incidence rates between males and females[40]. Heme iron intake in the diet has been suggested as a risk factor corresponding to EAC development as well[41]. Dietary iron has been shown to be a growth factor for *H. pylori,* making this association one in need of further investigation.

Many studies recently have elucidated relationships between various risk factors and the development of EAC, a goal that has potential to directly affect patient outcomes and change clinical practice with respect to ablative therapy. Sikkema *et al*[42] conducted a prospective cohort study in which they found statistically significant associations between many risk factors and progression to high grade dysplasia (HGD) and/or EAC including esophagitis and length of BE segment, with a risk ratio of 1.11 per centimeter increase in length, and known duration of BE of greater than or equal to 10 years with a risk ratio of 3.2. Also, previous partial gastrectomy is linked to EAC development[43]. Patients who underwent esophagectomy for EAC were shown in a case-control study to have a 45% prevalence of colonic polyps when compared to control patients who also underwent screening colonoscopies, of whom only 14% were shown to have colon polyps[44]. Whether there is a predictive relationship between presence of colon polyps and risk of EAC is still a contested topic and deserves further attention. Also, early research shows no evidence of viral genomic sequences present in tumors[45]. The single most predictive clinical factor for progression to HGD and/or EAC found to date is the presence of low grade dysplasia (LGD) found during biopsy with a relative risk of 9.7 (95%CI: 4.4-21.5) according to Sikkema et al and 5.5 (95%CI: 1.1-28.6) according to Oberg *et al*[46] compared to those without LGD.

Biomarkers have the potential to drastically improve our ability to risk stratify. p53 as well as KI-67, both proteins involved in cell cycle progression, have been shown to be expressed at higher levels in BE samples that progress to EAC[47-51]. Likewise, it has also been shown that cell-free circulating DNA methylation patterns correlate extremely closely (r = 0.92) with aberrant DNA methylation patterns in matched tumor tissue in patients with EAC and also that 911 loci for DNA methylation could perfectly discriminate between EAC and controls, suggesting that cell-free DNA methylation patterns could be used as a non-invasive method to screen premalignant lesions[52]. Promoter hypermethylation of p16 and APC is also strongly correlated with progression to EAC, with one study reporting hypermethylation of p16 and APC, either separately or together, in over 50% of HGD/EAC samples with hypermethylation of the same promoters totally absent in samples from patients with normal esophagus[53]. In a similar way, Mcm2 expression in BE is directly correlated with degree of dysplasia, with 91% of patients diagnosed with dysplasia or EAC in one prospective cohort showing Mcm-2-positive cytological brushings, while brushings from controls without BE showed no signs of Mcm-2 expression on the luminal surface[54]. COX-2 expression is upregulated in BE patients and degree of overexpression is correlated with risk of malignant transformation, suggesting that COX-2 expression could be used as a potential marker as well[55]. This increase in COX-2 expression has been shown to be strongly induced by deoxycholic acid incubation *in vitro* using OE-19 cells as a Barrett's model, suggesting a potential mechanism for this phenomenon[56]. Several bile acids have also been shown to induce the expression of other proteins important in cancer progression such as CDX2 as well as induce

NF-κB signaling[57]. Other notable biomarkers include increased DNA damage detected by Comet Assay, decreased Beclin-1 expression, increased cyclin A, cyclin B1, and cyclin D1 expression, and abnormal DNA content[49,58-65]. Notably, abnormal DNA content, measured by the number of chromosomes arms with loss, has been shown to be directly correlated with the progression from metaplasia, through low and high grade dysplasia, and finally to neoplasia[66]. Likewise, telomerase reverse transcriptase has been shown to be overexpressed in increasing levels along the metaplasia-dyplasia-neoplasia sequence of BE[67]. Whether these two markers can be used to differentiate between BE patients who will progress and those who will not remains to be studied. The field would benefit from further research into how these biomarkers can be integrated and utilized in a clinical setting as well as which can be used cost effectively to better predict risk of progression to EAC.

Interestingly, high serum leptin levels were associated with increased risk of EA, whereas increased levels of high molecular weight adiponectin conferred a protective effect, with a hazard ratio (HR) of 0.34 (95%CI: 0.14-0.82)[68]. The mechanism for this association might be due to leptin's effect on proliferation of adenocarcinoma cells independent of apoptosis or necrosis, as has been shown in BIC-1 and SEG-1 cells *in vitro*[69]. Type 2 diabetes mellitus has been shown to be more prevalent in those diagnosed with EAC, although the effect was attenuated after controlling for differences in BMI[70].

The consumption of several substances have shown to confer protective effects, with use of a multivitamin pill showing a HR of 0.38 (95%CI: 0.15-0.99) when compared to those not taking a multivitamin[71]. Vitamin D intake, however, was found to increase the risk of EAC, showing an OR of 1.99 (95%CI: 1.03-3.86), although vitamin D intake was not associated with BE or reflux esophagitis[72]. Taking proton-pump inhibitors (PPIs) has been shown to confer a protective affect against progressing from BE to EAC, with a hazard ratio of 0.41 (95%CI: 0.18-0.93) and 0.21 (95%CI: 0.07-0.66) for those using proton pump inhibitors at inclusion of the study or during the follow-up period, respectively; a finding supported by several other studies[73,74]. In addition to the use of proton-pump inhibitors, several studies recently have shown decreased rates of progression to EAC from BE when taking aspirin and/or statins, although the mechanism for this protection remains to be elucidated fully[75]. Sadaria *et al*[76] found that simvastatin attenuated growth and increased apoptosis in human esophageal adenocarcinoma (FLO-1) cells in tissue culture, providing one potential mechanism by which statins reduce risk of progression to EAC. One meta-analysis investigating this protective effect found a number needed to treat of 389 patients with statins to prevent one case of EAC[77]. ACE inhibitors could potentially provide a protective effect, although studies regarding this question were underpowered[78]. Medications that have relaxing effects on the lower-esophageal sphincter, specifically anticholinergics and theophyllines, have been associated with a roughly 1.5-2.5 fold increased risk of EAC, a relationship not seen for other types of cancers of the upper digestive tract[79,80].

As is expected, tobacco smoking has been shown repeatedly to increase the probability of progression to EAC. Interestingly, one study from the NIH Barrett's Esophagus and Esophageal Adenocarcinoma Consortium found an increased risk of progression to EAC with smoking and even showed a dose-response effect when considering pack-years, but there was a weaker association when considering cigarettes/day[81]. This study corroborates several other studies showing deleterious effects of smoking on risk of progression to EAC, estimating the risk at roughly double for those who smoke relative to those who do not smoke[82-85]. There appears to be no association between alcohol intake and risk of EAC according to several recent studies including meta-analysis, although this has been contested according to a matched case-control study out of North China[81,83,86-88].

Currently, no definitive genetic cause of BE or EAC has been identified. Several case reports, however, have found a remarkable history of BE and EAC among members of the same family, providing evidence that a subset of the population may be genetically susceptible to BE and potential progression to EAC[89-92]. Additionally, a single nucleotide polymorphism in the gene coding for epidermal growth factor (EGF) has been shown to be associated with decreased levels of EGF expression and has also been shown to be more prevalent in patients with BE and EAC[93]. Further research in this area could help identify specific genotypes that would allow clinicians additional tools when risk stratifying patients and making decisions regarding the management of patients with BE.

Surgical management of GERD has been shown to decrease odds of progression to EAC compared to no therapy, however a 2007 systematic review found that, in controlled studies, there was no statistically significant difference in EAC incidence rates between patients treated surgically and those treated medically. If data from uncontrolled case-series are included, the difference becomes significant. Interestingly, surgical management increased the probability of regression of BE and/or dysplasia by almost 15%[94]. This study shows puzzling results given the data from previous studies showing that fundoplication can reduce or even eliminate the reflux of bile acids into the esophagus, compared to medical therapy which only treats the reflux of hydrochloric acid[95]. One possible answer to this question could come from recent case-control data showing that, among patients who've undergone antireflux surgery, those with recurrent reflux symptoms are three times more likely to develop EAC than those without, underscoring the importance of addressing continuing reflux symptoms after antireflux surgery[96].

Randomized trials to date have only compared antireflux surgery to medical therapy in patients who were complete responders to medical therapy. This, unfortunately, is not the comparison of interest given the current role for surgery in GERD management. Patients selected for antireflux surgery in practice almost exclusively have failed medical therapy as their indication for surgical management. This suggests that there is some fundamental difference between patients who are responders and those who are not, and limits the usefulness of the comparison in these studies. The question of antireflux surgery *vs* continued medical management remains unanswered conclusively, but continues to be an active area of research and could benefit heavily from a randomized controlled trial comparing antireflux surgery to continued medical management in a population of patients who have continued reflux symptoms despite full dose medical therapy. Current data suggests that there is a role for antireflux surgery in the management of patients with BE, but the question of exactly which patients should be receiving these procedures remains to be answered.

CONCLUSION

As can be seen from the wealth of information outlined above, the risks associated with progression from BE to esophageal adenocarcinoma are multifactorial, with many different risk factors each contributing a relatively small portion to the overall risk of progression. This suggests that a single intervention aimed at reducing exposure to individual risk factors other than refluxed gastric contents is unlikely to have a drastic impact on increasing adenocarcinoma rates or to affect the risk for individual patients with Barrett's. Currently, no biomarkers have shown to be clinically useful in BE, but this continues to be an active area of research. More work is necessary to investigate the many risk factors at play and the populations that they apply to, in order to better understand the contributions to risk for any given clinical situation. Recent advancements in knowledge of risk factors and their contributions to progression have made clinical risk stratification models possible in order to target endoluminal therapies capable of eradicating Barrett's tissue and drastically decreasing risk of progression to adenocarcinoma. Currently, these tools are not widely available. Additional work is required to further develop and validate these tools in order to target patients at the highest risk of progression with either therapeutic intervention or endoscopic surveillance. One risk factor, the presence of LGD, has been very clearly shown to drastically increase the risk of progression to EAC by multiple studies. Given this information along with the known safety and efficacy of radiofrequency ablation and other endoluminal therapies, we believe that there is sufficient data to support the use of RFA in all Barrett's patients with LGD, even in the absence of additional risk factors. Additional stratification tools are required in order to dictate exactly which patients without LGD should receive RFA/endoluminal therapy and which should not, but given the evidence outlined above, patients with very long segment, patients who have had reflux symptoms for time periods of 10 years or greater, or patients who are unable or unwilling to take PPI's or are not antireflux surgery candidates should be considered carefully as potential candidates for endoscopic ablation.

Abstract

Biliary complications are being increasingly encountered in post liver transplant patients because of increased volume of transplants and longer survival of these recipients. Overall management of these complications may be challenging, but with advances in endoscopic techniques, majority of such patients are being dealt with by endoscopists rather than the surgeons. Our review article discusses the recent advances in endoscopic tools and techniques that have proved endoscopic retrograde cholangiography with various interventions, like sphincterotomy, bile duct dilatation, and stent placement, to be the mainstay for management of most of these complications. We also discuss the management dilemmas in patients with surgically altered anatomy, where accessing the bile duct is challenging, and the recent strides towards making this prospect a reality.

Key words: Liver transplant; Biliary; Complications; Strictures; Bile leak; Management; Endoscopy; Endoscopic retrograde cholangiography; Biloma; Stone; Cast

Core tip: Biliary complications are being increasingly encountered in post liver transplant patients because of increased volume of transplants and longer survival of these recipients. Overall management of these complications may be challenging, but with advances in endoscopic techniques, majority of such patients are being dealt with by endoscopists rather than the surgeons. Our review article discusses the recent advances in endoscopic tools and techniques which have proved ERCP with various interventions, like sphincterotomy, bile duct dilatation, and stent placement, to be the mainstay for management of most of these complications. We also deliberate the management dilemmas in patients with surgically altered anatomy, where accessing the bile duct is challenging, and the recent strides towards making this prospect a reality.

INTRODUCTION

Biliary tract complications (BTC) are described as Surgeons' "Achilles Heel" after liver transplantation (LT)[1]. They constitute a major source of morbidity after LT and pose a challenge in both diagnosis and treatment. The incidence of BTC varies from 5% to 32% in various studies and has been decreasing with time; however, newer challenges are emerging with the more widespread use of living donor, donation after circulatory death and split-liver transplants[2,3]. The different complications that can be seen post LT include biliary strictures, leaks, cast formation, papillary stenosis and other less common ones[4,5]. Conventionally, post-LT biliary complications can be referred to as early (within 30 d of LT), delayed (1-3 mo post-LT) and late (beyond 3 mo post-LT). Even though each complication has a predominant manifestation period, for management purposes the clinical presentation and diagnosis are more important. With the advancement of imaging techniques, most of these complications are diagnosed using non-invasive imaging like traditional ultrasound (US), computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound (EUS) with more invasive techniques like percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiography (ERC) used for therapeutic purposes[6,7]. Over the last decade, there has been significant improvement in endoscopic techniques with an increase in the array of endoscopic assist devices, and consequently most of these complications are managed endoscopically, which will be the focus of this review.

TYPES OF SURGICAL RECONSTRUCTION AFTER LIVER TRANSPLANT

The technique of biliary reconstruction utilized during LT greatly influences the biliary tract complications seen in these patients[8-10]. It is necessary to be cognizant with the anatomy of the liver segments and its ducts, to be able to successfully diagnose and manage these complications. The two most common methods of biliary reconstruction include choledocho-choledochostomy (CC) or duct-to-duct anastomosis; and Roux-en-Y hepaticojejunostomy or choledochojejunostomy (RYC). It is imperative for endoscopists to have a thorough understanding of these anastomotic procedures as the former can be approached *via* conventional ERC whereas for the latter a percutaneous route is preferred. There is also an increasing usage of living, related-donor and split-liver transplants, because of limited availability of deceased donor liver transplants. During this procedure anastomosis is fashioned between donor's right hepatic duct to the recipient's common bile duct, which is even more complex than the traditional methods due to variability of the anatomy.

DIAGNOSIS AND EVALUATION OF BTC AFTER LT

Recognizing the risk factors for development of biliary complications is an important aspect of overall management, because if a risk factor is identified and appropriate remediation steps taken, the natural course of these complications may be altered. The common list factors are listed in Table 1 and discussed in detail at appropriate places in the article. Post-LT, patients with BTC can have varied presentations, which may range from asymptomatic transaminasemia to frank jaundice with abdominal pain and cholangitis. It is imperative to differentiate obstructive cholestasis from a non-obstructive cause like rejection - acute or chronic, drug induced cholestasis or recurrence of primary disease[11]. This is usually achieved with the help of imaging, which includes trans-abdominal ultrasound with Doppler, CT, MRCP, EUS, and HIDA scan (hepatobiliary iminodiacetic acid scan).

US with doppler can diagnose hepatic artery thrombosis in LT patients with a sensitivity of 91% and specificity of 99%[12]. Hepatic artery thrombosis is a risk factor for biliary leaks due to ischemic injury and hence, if detected on Doppler, warrants a confirmatory hepatic angiogram[2]. US can also be used to diagnose biliary strictures with a specificity of 98%; however, normal US findings do not exclude it and require further investigation with MRCP[13,14]. At present, MRCP is the initial imaging of choice to evaluate an LT patient for a biliary tract complications[15]. It provides detailed evaluation of both extra- and intra-hepatic biliary tree and can potentially avoid use of direct cholangiography[14]. It has several advantages over traditional and direct cholangiography, as it is non-invasive, there is no need of sedation, has minimal side effects and can demonstrate ducts both below and above a stricture. Several studies have been conducted to evaluate its role in LT patients with suspected biliary obstruction and in a meta-analysis, which included almost 400 LT-patients, MRCP was found to have a sensitivity of 96%, specificity of 94% with a positive likelihood ratio of 17 and a negative likelihood ratio of 0.04 for diagnosis of biliary obstruction[16-19]. However, it has limited role if LT was performed along with bilio-enteric anastomosis and for diagnosis of malignant strictures[16,20]. CT scan has limited role in evaluation of biliary tract complications in LT patients and maybe used to diagnose abscesses or fluid collections associated with biliary leaks.

TYPES OF BTC AFTER LT AND THEIR MANAGEMENT

Biliary strictures

Biliary strictures are the commonest complications after liver transplantation, with an incidence of 13% following deceased donor liver transplant (DDLT)

Table 1 List of risk factors responsible development of various biliary complications

Risk factor	Mechanism	Resultant biliary complication
HAT or stenosis	Being the main vascular supply to the bile duct, any compromise to integrity of HA or its branches induces acute and chronic ischemia of the biliary system	Anastomotic disruption Bile leak NAS AS Biliary cast syndrome
Type of transplant	Live-donor LT has higher overall biliary complications compared to Orthotopic LT	Bile leak HAT Unplanned re-explorations Portal vein thrombosis
Type of donor	DCD LT has higher biliary complication rate compared to DBD LT. This is because of increased risk of experiencing insufficient organ perfusion. Also increased risk if ABO blood group incompatibility between donor and recipient	Strictures (NAS) Bile duct filling defects (stones/sludge/clots/casts)
Type of anastomosis (biliary reconstruction)	Duct-to-duct CC anastomosis is preferred whenever possible, being simple and prevents enteric reflux into bile ducts, compared to RYC	Comparative biliary complication data is conflicting
Graft related factors	Use of grafts from older donors or grafts with increased steatosis (extended criteria), as well as increased cold (CIT) and warm ischemia times	Strictures (NAS and AS) Bile leak Bile duct filling defects (stones/sludge/clots/casts)
Surgical (or technical) factors-during both donor and recipient surgeries	Excessive dissection of periductal tissue during the procurement of native liver Excessive electrocautery to control bleeding during surgery Tension between the two ends of the biliary anastomosis Suture material used Denervation or injury to sphincter	Bile leak AS Mucocele Sphincter of Oddi Dysfunction
Placement of T-tubes (old strategy)	This increases chances of delayed healing, and may cause bile leaks.	Bile leak Hemobilia Infections (Cholangitis and Peritonitis)
Pre-LT factors	Infections (CMV or intra-abdominal infections) Diagnosis for LT: PSC or AIH	Infections (Cholangitis and Peritonitis) Strictures (NAS and AS) Bile duct filling defects (stones/sludge/clots/casts)
Post-LT factors	Immunosuppression: Emerging evidence that Sirolimus based regimen have higher risk of biliary strictures Infection, Acute cellular rejection, Obstruction, *etc.* Post-operative small bile leak is risk factor for future strictures Early HCV recurrence post-LT also increases inflammation and hence risk of strictures	Strictures (NAS and AS) Biliary cast syndrome

HAT: Hepatic Artery Thrombosis; NAS: Non-anastomotic stricture; AS: Anastomotic stricture; DCD: Donor after cardiac death; DBD: Donor after brain death; CC: Choledocho-choledochostomy; RYC: Roux-en-Y choledochojejunostomy.

but much higher (19%-32%) among living donor liver transplants (LDLT)[8]. They are encountered irrespective of type of anastomosis, although may be more common with Roux-en-Y hepaticojejunostomy or choledochojejunostomy reconstructions than duct-to-duct anastomoses[21]. They can be classified according to time of stricture development from LT as early (within 1 mo post-LT) *vs* late (more than 1 mo post-LT) or classified according to anatomical site into two categories-anastomotic strictures (AS) and non-anastomotic strictures (NAS) or ischemic strictures.

AS are usually single, localized to the site of anastomosis, short in length and occur within a year after LT[6,8] (Figure 1). Recent literature suggests their incidence to be < 10%, and they are formed as a result of ischemia, fibrosis or bile leak during or after the surgery. They are a reflection of intra-operative technical problems or small bile leaks or transient ischemia, resulting in peri-anastomotic fibro-inflammatory response leading to stenosis. Since bile leak is an important risk factor for development of AS, they need to be recognized early and managed appropriately. They can also form due to the sub-optimal surgical techniques like inappropriate suture material and excessive use of cautery for control of bleeding, in which case they are formed relatively early in the post-operative period[8]. Furthermore, there is emerging evidence that type of immunosuppression being used may have a role in development of AS, and need for early ERC for management of AS[22]. Most patients with very early stricture post-OLT may not have true AS, but a stenosis due to post-operative edema and inflammation, which responds very well to single dilatation and/or stenting session. True AS usually occurs between 3-12 mo after LT.

NAS, on the other hand, tend to be multiple, longer in length and are either intrahepatic or in the donor duct proximal to anastomosis, and defined as being present more than 0.5 cm away from anastomotic site. They tend to occur earlier than AS with mean time of presentation 3-6 mo post-LT and have an incidence of 5%-15%[23,24]. Although most NAS are multifactorial,

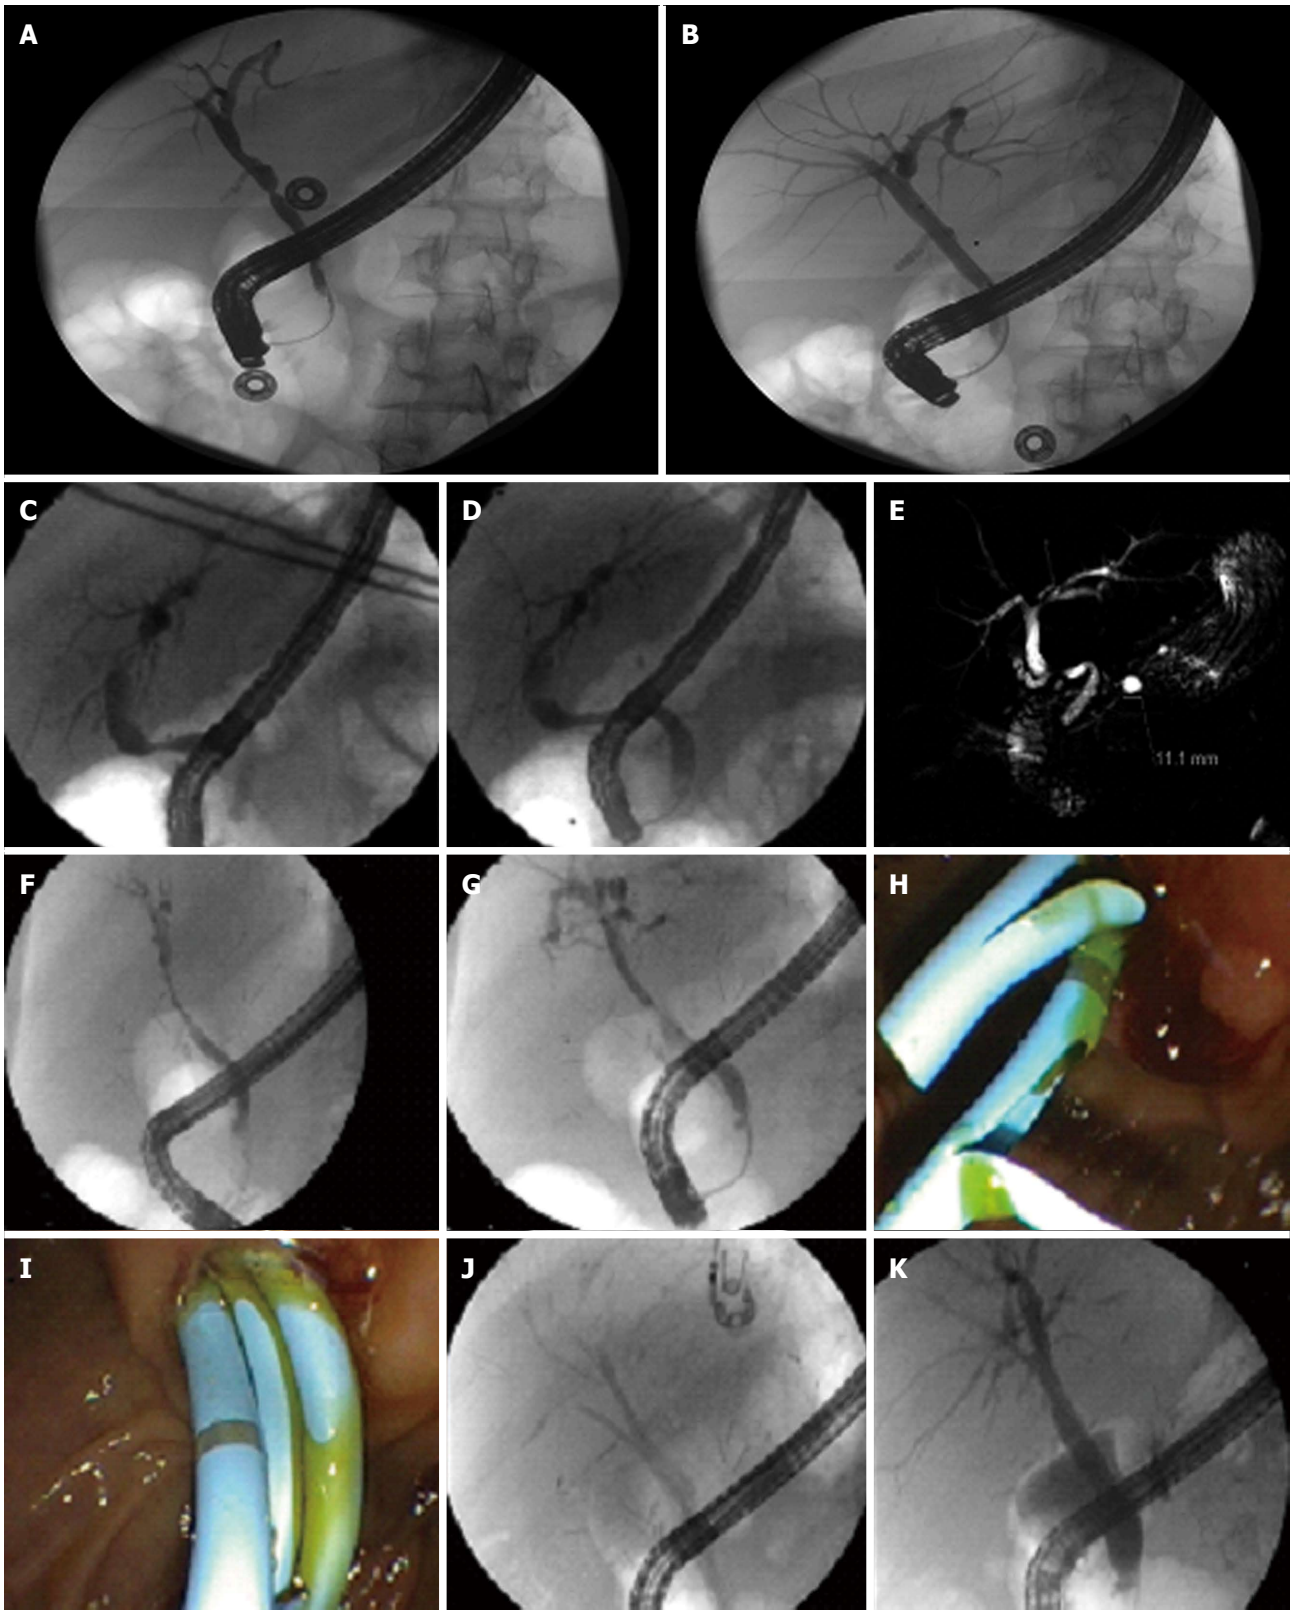

Figure 1 Different management strategies for biliary strictures. A: Post-LT anastomotic biliary stricture (as seen on ERC); B: managed with balloon dilatation only; C: Post-LT anastomotic biliary stricture (as seen on ERC); D: Managed with balloon dilatation; E: MRCP image of the same stricture; F: Long segment biliary stricture due to global hypotension post-LT; G: Dilatation performed with biliary balloon; H: Followed by placement of two plastic stents; I: Due to inadequate effect with two stents, sequential therapy strategy adopted with placement of three stents; J: Fluoroscopic image of three stents in right posterior and anterior hepatic and left hepatic ducts; K: Final cholangiogram suggesting a much improved bile duct diameter. ERC: Endoscopic retrograde cholangiography; LT: Liver transplantation.

they can further be divided into 3 sub-types based on their etiology: (1) macroangiopathic - secondary to hepatic artery thrombosis (HAT) leading to biliary destruction; (2) microangiopathic - secondary to

prolonged use of vasopressors in the donor, donation after cardiac death (DCD), prolonged warm and cold ischemic events; and (3) immunogenic - in patients with primary sclerosing cholangitis, ABO incompatibility, chronic rejection, CC chemokine receptor 5delta32 polymorphism or autoimmune hepatitis, which may act as an independent risk factor[8,23,25]. NAS can also be referred to as type Ⅰ (extra-hepatic), or type Ⅱ (intra-hepatic) and a combination of two[26]. Furthermore, Buis *et al*[27] proposed another classification of the anatomic regions of the biliary tree affected by non-anastomotic biliary strictures: hilar bifurcation (zone A), ducts between the first- and second-order branches (zone B), between second- and third-order branches (zone C) and in the periphery of the liver (zone D). Vascular NAS develops because the blood supply to donor bile duct comes from recipient hepatic artery, which is susceptible to ischemic injury post-transplant, while its native alternative supplies from smaller collaterals and branches of other arteries are transected during organ retrieval. The immunogenic NAS tend to occur later than vascular NAS. Because of their established relationship with ischemia, vascular patency of hepatic artery must be ascertained in these patients with a Doppler ultrasound. Patients who develop manifestations of NAS within the first year of transplant or have recurrent cholangitis, have the most unfavorable prognosis[28].

Management: Historically, post-LT biliary strictures were managed surgically *via* Roux-en-Y hepaticojejunostomy. However, over the past decade there has been tremendous improvement in endoscopic techniques, making endotherapy the treatment of choice for management of these strictures[29-31]. PTC and surgery are less often utilized, and usually reserved for cases where ERC cannot be used or has failed. Although not evidence-based, ursodeoxycholic acid is sometimes used to increase bile flow, and lower the chances of stone formation.

ERC is generally used to perform endoscopic biliary sphincterotomy (EBS) followed by balloon dilation and placement of biliary stent(s) to treat biliary strictures (Figure 1). Balloon dilation, if performed alone, has a high recurrence rate of 62% which decreases to 31% when performed with stent placement[32,33]. However, a recent prospective study by Kulaksiz *et al*[34] showed that dilation alone was as effective as dilation plus stent placement and in fact, stent placement was associated with a higher complication rate. However, more data is needed to clarify this discrepancy.

The most commonly used approach for treatment of AS consists of placement of large-bore 10-French plastic stents after balloon dilation and exchanging them every 3 mo (Figure 1). The median duration of plastic stent patency is around 3 mo (range 2-4 mo), as they are prone to debris deposition in their lumen resulting in obstruction, and risk of cholangitis. This approach has a success rate of 75% to 91% according to different studies for DDLT[32,35-38] but decreases to 37%-71% in patients with LDLT[39,40] because of the more complex duct-to-duct anastomosis. Factors limiting efficacy include peripheral location and presence of smaller and multiple biliary anastomotic strictures. It is also advised that balloon dilation should not be performed for very early strictures and for strictures in the setting of an anastomotic leak to prevent disintegration of biliary anastomosis. Severe complications of this technique are rare, although, a large study showed a complication rate of 6.6% per procedure which increases to 21% per patient as they get more than one procedure[41]. Some of the complications include pancreatitis, cholangitis, stent migration and hemorrhage. There was no death attributable to the procedure itself. An alternative approach to manage biliary strictures is to place maximum number of stents possible, which can then be exchanged at frequent intervals (Figure 1). This method is more aggressive but has shown to achieve a high long-term stricture resolution rate of 90%-94% with less frequent episodes of cholangitis[42,43]. This is a particular advantage of endoscopic therapy, as multiple stents cannot be placed using percutaneous catheter.

Metallic stents are generally useful only for malignant biliary obstruction as they provide effective palliation with a larger diameter (viz. 30-Fr) and longer patency[44]. They are either balloon-mouthed or self-expanding metallic stents (SEMS), but the fact that metal stents cannot be removed makes them less favorable in the setting of benign biliary diseases. Furthermore, possibility of reactive hyperplasia resulting in sludge/stone formation proximal to the stent poses a technical challenge, especially when SEMS cannot be removed. However, covered-SEMS (CSEMS = metallic skeleton with biocompatible and resistant synthetic covering viz. silicon, polyether polyurethane, polyurethane and expanded polytetrafluoroethylene) can be easily removed as the outer coating of the stents prevents tissue ingrowth, seen in about 20% patients. The major limitation with fully covered SEMS, however, is the relatively higher migration rate (6%-10%), which is now counterbalanced by development of partially-covered SEMS (PCSEMS), which provide advantages of covered stent but lower migration rates. Different types of metal stents are currently available, differing in their composition, like stainless steel or nitinol (which is a biocompatible metal alloy of titanium and nickel). Currently available SEMS are either fully covered (Viabil, Wallflex and Niti-S ComVi, *etc.*), or partially covered (Wallstent, Wallflex, *etc.*). Vandenbroucke *et al*[45] showed that Wallstents used in benign strictures after LT can be removed in 66% of patients and offer an option in patients with persistent proximal or anastomotic strictures who have multiple co-morbidities to undergo hepaticojejunostomy or re-transplantation. Similarly, Tee *et al*[46] showed benefit of such SEMSs in patients with refractory post-LT anastomotic biliary strictures. A recent meta-analysis by Kao *et al*[47] inferred that although SEMS appears to be promising

Figure 2 Diffuse non-anastomotic intra-hepatic biliary structuring seen in a donation after cardiac death liver transplant patient, not amenable to endoscopic therapy.

strategy in management of anastomotic biliary strictures in post-LT patients, but current evidence is not enough to suggest clear advantage of SEMS over multiple plastic stents.

NAS are generally more difficult to treat and even though there have been several advancements in endoscopy, overall endoscopic management of NAS remains sub-optimal and endoscopic therapy only acts as a bridging therapy to liver transplantation. This is due to the fact that balloon dilation of all NAS is not feasible (Figure 2) and stent occlusion is rather rapid because of the smaller caliber of the intrahepatic ducts where these strictures are commonly observed. Basic management principles including sphincterotomy and stent placement with scheduled exchange are similar to AS, but endoscopic therapy of NAS typically utilizes smaller diameter balloon dilation (of 4- to 6-mm compared with 6 to 8 mm for AS). Also, just like AS, strategies like use of multiple stents, and stents of progressively increasing diameter have been employed in management of NAS successfully. However, despite all these maneuvers, there is evidence that NAS requires longer time to respond to endoscopic therapy (dilatation + stenting) compared to AS (185 *vs* 67 d)[48]. Use of conventional stents like Amsterdam stent is less satisfactory since these stents are rigid and do not have side holes for draining bile. However, long and large-caliber (up to 20 cm with 10 Fr), flexible and fenestrated stents (Johlin pancreatic wedge stents) can be used. The flexibility helps them to adapt to the tortuous contours of the intrahepatic ducts and multiple side holes allow adequate bile drainage. Endoscopic therapy for NAS, for reasons explained above, has an overall low success rate of 25%-33% in LDLT and 60% in DDLT[40]. In cases of NAS associated with early HAT, aggressive management with either revascularization or early re-transplantation is the key to management, prior to development of intrahepatic complications like biloma and abscess formation.

Endoscopic therapy has generally been reserved for duct-to-duct anastomosis; however, with introduction of single (SBE) and double balloon enteroscopy (DBE), deep ERC can be performed even in patients with Roux-en-Y hepaticojejunostomy[49,50]. A large, multicentric study by Shah *et al*[51] showed that in patients with surgically altered biliary anatomy, SBE, DBE or rotational over-tube enteroscopy can be used to perform ERC successfully in 88% of patients in whom papilla is reachable. Once the duct is accessed, all interventions can be performed like stricture dilatation or stent placement. Another recent advancement has been the use of steerable ERC cannulas like Swing-Tip cannula, which is potentially helpful equipment in management of hilar strictures by using multiple guide wires, and repeated dilation of strictures with placement of stents. These cannulas also help to achieve faster cannulation of the bile duct[52].

Direct cholangioscopy using SpyScope technology has also been utilized to visualize biliary anatomy, and diagnose and manage biliary strictures. It has been studied to be safe and technically superior to conventional cholangiogram in different reports[53-56]. Siddique *et al*[57] demonstrated that direct choledochoscopy also helps in providing targeted treatment to patients. Exciting advancements in this field are happening, although not rapidly enough to make cholangioscopy a consistent tool in management algorithm of post-LT strictures. Balderramo *et al*[58] observed two distinct visual patterns of post-LT AS on direct cholangioscopy, described either as erythema or as edema, sloughing and ulceration, to help predict outcomes after endoscopic therapy. AS patients with only edema responded better with endoscopic therapy, while patients with sloughing and ulceration needed longer duration of stenting[58]. Different types of cholangioscopes (Polyscope) and techniques like use of methylene blue are combined with cholangioscopy to diagnose and delineate features of biliary strictures in patients post-LT[59,60].

Apart from endoscopic therapy, percutaneous transhepatic cholangiography (PTC) can also be used for treatment of AS. However, it is usually reserved for patients with bilio-enteric anastomosis or patients who have failed endoscopic treatment or are at higher risk of complications like bile leaks, infections and hemorrhage[11,61]. Surgery and re-transplantation are reserved for strictures refractory to endoscopic therapy, when all endoscopic and non-surgical options have been exhausted.

Biliary leaks and bilomas

Biliary leaks can be seen in 10%-25% of patients after LT. Although, their incidence has decreased in post-MELD era, it is seen more common after LDLT[62-64]. Biliary leaks mostly occur at 3 sites-anastomotic site, exit site of T-tube and at the site of cystic duct remnant[65]. The bile leaks at anastomotic site are reflection of dehiscence due to technical errors, tension or ischemia and devascularization of the tissue surrounding the biliary tree, in which case hepatic artery thrombosis is a common culprit and must be investigated with

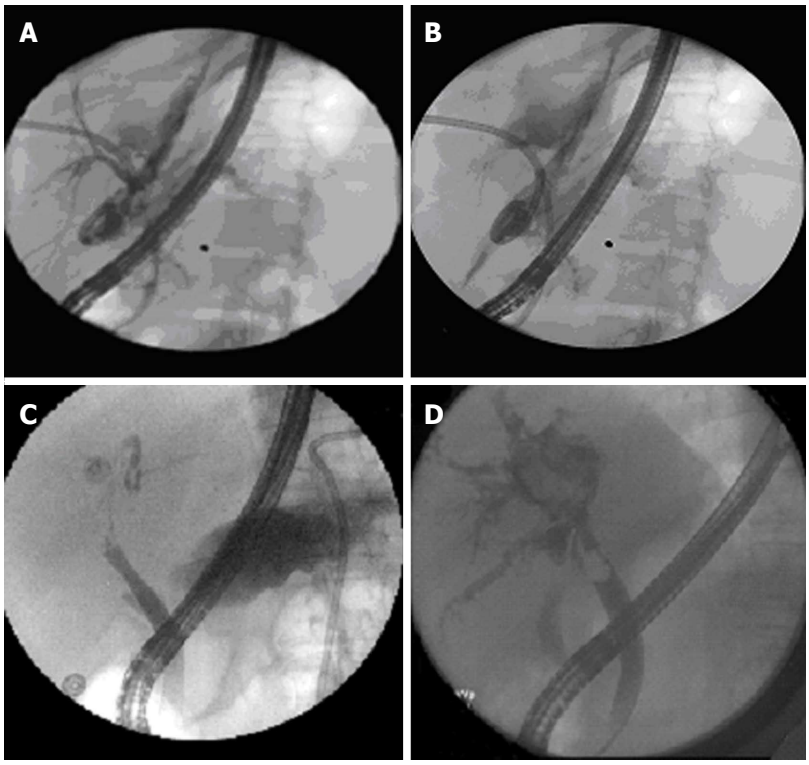

Figure 3 Management strategies for bile leak and biloma. A: Bile leak from split surface of the liver in a patient with split-liver transplant; B: Managed successfully with endoscopic plastic stent placement; C: In a separate patient, bile leak successfully managed by placement of a fully covered metal stent; D: In yet another patient, intrahepatic biloma, which becomes apparent on occlusion cholangiogram.

ultrasound Doppler. Less common sites of bile leak include ischemic injury to extra-hepatic bile duct (at non-anastomotic site), gallbladder fossa, aberrant bile duct (Luschka's duct) and cut surface of liver in LDLT or split livers (Figure 3). If bile extravasation occurs within the liver parenchyma or abdominal cavity, it may form collections called as biloma. Biliary leaks are generally divided according to time of occurrence into[66]: (1) early-occur within a month of the transplant and are usually associated with anastomotic leaks, ischemic injury and leakage around T-tube insertion site[2]; (2) late-occur more than a month after LT and noticed usually at the time of T-tube removal[67,68]. These are less common. Use of steroids or immunosuppressant medications post-LT is also alleged to hamper the healing process after T-tube removal.

Biliary leaks may present with abdominal pain or distension or patient might be asymptomatic, in which case, it is detected accidentally on abdominal imaging. One of the early indicators is the persistence of bile in the operative drain output. This can be confirmed with the help of a T-tube cholangiogram (in patients with a T-tube), or imaging like radionuclide scan (HIDA) or MRCP that can reliably detect a biloma and may localize the level of the leak[69].

Management: Most patients with biliary leaks can be managed endoscopically. ERC is most often used to perform biliary sphincterotomy and placement of biliary stent that can be kept in place for up to 2-3 mo (Figure 3). Although symptom resolution is fast after stent placement, the actual healing of leak may take up to 6-10 wk. Several studies suggest a success rate of 80%-90% using this strategy[8,70,71]. In case of an associated stricture, stent placement across the leak and stricture are prudent. In case of T-tube associated bile leaks confirmed on T-tube cholangiogram, leaving the drain open might suffice, without need for any further interventions. Naso-biliary drainage can also be performed in place of biliary stenting and Saab *et al*[72] in fact suggested that it might be the preferred strategy for management of biliary leaks. Although naso-biliary tubes can be useful for cholangiographic follow-up without further endoscopies and confirmation of leak sealing, however are very poorly tolerated. A small study showed that small leaks can be managed with sphincterotomy alone[73], however this is not the usual practice. In certain circumstances, along with bridging provided with the stent, drainage of the fluid collection might be needed, especially in large biloma with no communication with bile duct. This can be performed *via* EUS guided trans-gastric drainage or the traditional IR-guided drainage. Usually small bilomas resolve spontaneously, if there is adequate communication with duct, and some may require placement of a biliary stent. Despite these endoscopic advancements and options, there may be an occasional case where biliary leak cannot be treated endoscopically and thus requires surgery. These special cases include large anastomotic leaks, cases with Roux-en-Y anastomosis, early biliary leaks (< 1-2 wk after LT), bile duct necrosis or failure of primary therapy[3,69].

Sphincter of Oddi Dysfunction or papillary stenosis

Sphincter of Oddi Dysfunction (SOD) has an incidence of 2%-3.5% after LT. It is an incompletely understood and poorly defined syndrome of questionable significance[74]. It is thought to occur secondary to

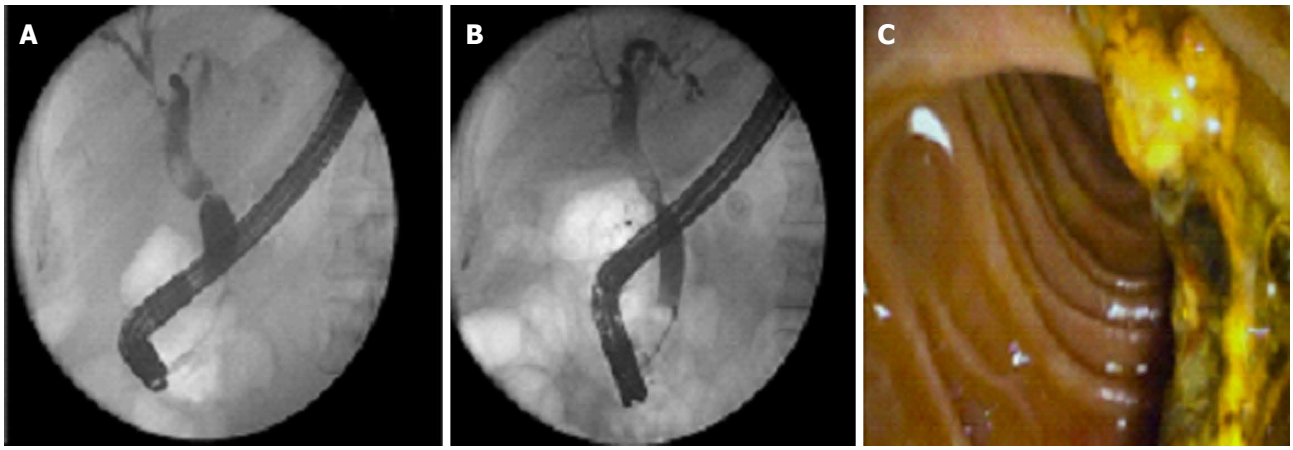

Figure 4 Management of common bile duct filling defects. A: Common bile duct (CBD) filling defect seen proximal to mid-CBD stricture in a post-liver transplantation patient; B: Successful removal of stone after dilatation the stricture; C: Endoscopic image of successfully extracted stone and sludge in this case.

denervation of Sphincter of Oddi during LT leading to a hypertonic sphincter. It can be divided into 2 types based on the mechanism of its pathogenesis: (1) SOD with stenosis - which occurs due to scarring and inflammation. The contributing processes can be CBD manipulation during LT, stone passage through papilla, or infection. Sphincter of Oddi has high basal pressure in this type; and (2) SOD with dyskinesia - which occurs due to functional disturbance of the sphincter resulting in intermittent biliary blockage. The sphincter in these cases has low basal pressure and absent phasic activity[74], and additional neurological or hormonal disturbances may be associated with development of functional disturbance[75].

Both types of SOD can lead to pain, recurrent pancreatitis and cholestasis without any apparent etiology, and hence need a high clinical suspicion for diagnosis. Biliary manometry can be utilized to confirm the diagnosis. Selective patients may be managed endoscopically, and ERC with sphincterotomy is usually reserved for patients with dilated bile duct with cholestasis liver chemistries, without any other obvious cause. It is aimed at cutting the sphincter muscles, resulting in reduction of the intra-luminal biliary and pancreatic hypertension, and symptomatic relief. However, the procedure has high risk of post-procedure pancreatitis and usually pancreatic duct stent is placed prophylactically[76]. In case of failure of endoscopic therapy, choledochojejunostomy is the last resort.

Biliary stones, sludge, casts, and blood clots

Biliary stones, sludge, casts, and blood clots are collectively referred to as "Common Bile Duct (CBD) Filling Defects" and can be seen in 3.3%-12.3% of patients after LT[77,78] (Figure 4). Stricture, infection and ischemia can result in biliary stones and sludge; and sloughed biliary epithelium, chronic rejection, infection, and bile stasis, have been associated with formation of biliary casts. They have been postulated to be related to strictures, bacterial infection, mucosal damage and ischemia[78-80]. These patients might present with abdominal pain, cholestatic liver enzyme pattern or may have recurrent episodes of cholangitis and pancreatitis[11]. However, many patients with choledocholithiasis may be completely asymptomatic, which is often attributed to the fact that transplanted graft is denervated, and may also be afebrile because of steroids and immunosuppressant medications they are on post-LT. Occasionally, CBD filling defects may form due to stagnation of bile proximal to a stricture, in which case management becomes challenging (Figure 4). Because of ischemic etiology to biliary cast syndrome, HAT exclusion with appropriate imaging becomes prudent.

Management: ERC with sphincterotomy has a success rate of 90%-100% in clearing biliary stones and sludge; however removal of biliary casts can be challenging and may require multiple procedures including sphincterotomy, balloon or basket extraction, stent placement and lithotripsy, or may need PTC eventually[77,79]. For removal of biliary casts, endoscopy has shown to successful in 25%-60% of patients across different studies[79,81]. In fact, in cases with severe biliary necrosis and casts, repeated interventions with baskets and dilatations are necessary, and placement of stents is not generally recommended in the early course, for risk of occlusion by biliary debris[82]. On the contrary, biliary duct stones are usually easily removed using ERC with biliary sphincterotomy and balloon sweeps (Figure 4). Occasionally, proximal stones may pose a challenge, and in those cases direct cholangioscopy can be performed to remove biliary stones. Also if filling defect lies proximal to a post-LT stricture, then stricture management becomes first step towards the goal of clearing the duct (Figure 4). Lithotripsy and Holmium Laser can be combined with this procedure for stone dis-impaction. Direct cholangioscopy can be performed using ultra-slim, pediatric endoscopes which can be directly advanced into the bile duct to examine duct anatomy and removal of biliary stones and casts[69]. Again, deep enteroscopy can be utilized to perform

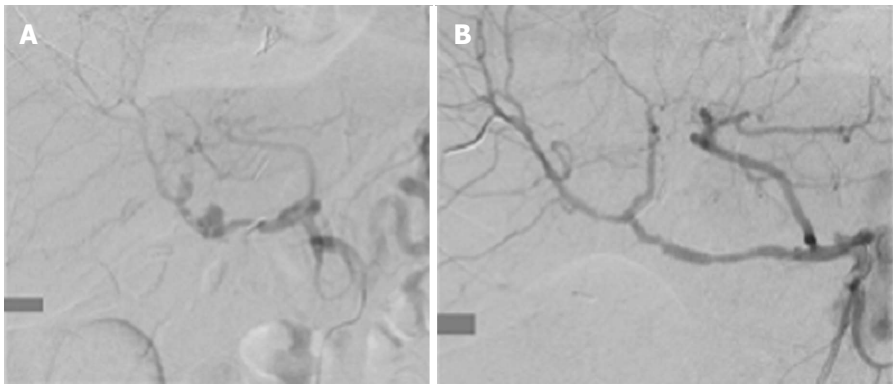

Figure 5 Rare cause of Hemobilia. A: Hepatic artery pseudoaneurysm fistulizing to the common bile duct, resulting in hemobilia; B: Managed with intravascular stent placement by interventional radiology.

ERC in patients with Roux-en-Y anastomosis to remove biliary stones or casts[83].

Mucocele

Mucocele of cystic duct results from collection of mucus from the cells lining the cystic duct remnant, and is an extremely rare entity in post-LT patients. Key to diagnosis is cognizance of this diagnostic possibility in a patient with post-LT obstructive jaundice or cholangitis with no apparent cause, and confirmation with MRCP, which would show an extrinsic mass (fluid collection) compressing the bile or hepatic ducts[84]. Patients usually require surgical or radiological drainage. To prevent this complication, usual operative practice involves either excising the cystic duct, or incorporating the distal end of the transected cystic duct into the suture line of the biliary anastomosis to ensure drainage[85].

Hemobilia

While hemobilia may not be a direct consequence or complication of liver transplant itself, it can happen after liver biopsy or PTC performed in post-LT period for management of various issues. Patients present with abdominal pain, jaundice and gastrointestinal bleeding, and upper endoscopy using regular forward-viewing gastroscope (or side viewing duodenoscope) typically reveals blood extruding from the ampulla. Management goals are hemostasis, as well as confirming clearance of bile duct of any clots, which would otherwise be a source of potential obstruction and cholangitis. Hemostasis may be achieved with a multi-prong strategy of coagulopathy correction, endoscopic therapy with use of epinephrine and electro-cautery if bleeding site is accessible, otherwise localization of bleeding with hepatic artery angiogram followed by embolization of feeding vessel radiologically[86]. Once hemostasis is achieved, clot retrieval and clearance of duct can be achieved with ERC if there is evidence of biliary obstruction. Figure 5 (used with permission from Farshad Aduli, MD) represents a case seen by authors, of post-LT hepatic artery pseudo-aneurysm fistulizing to the common bile duct resulting in hemobilia, which was managed by intravascular stent placement by interventional radiology.

SPECIAL ISSUES AFTER LT

Management of biliary complications in patients with Roux-en-Y Hepaticojejunostomy and Roux-en-Y gastric bypass

With the increase in number of liver transplants being performed and limited number of DDLT, there is increase in use of LDLT and split liver transplant strategies. This has resulted in more complex anatomy post-LT. Roux-en-Y Hepaticojejunostomy and Roux-en-Y gastric bypass are the 2 main altered surgical anatomies that are often encountered in post-LT patients. Roux-en-Y gastric bypass creates a common limb of 150 cm and a bilio-pancreatic limb of 150 cm, which makes conventional endoscopy and ERC challenging. Traditional PTC has been utilized for management of post-LT biliary complications in such patients with altered anatomy. However, as mentioned earlier, development of DBE, SBE and spiral enteroscopy has increased the endoscopic options that permit ERC in these patients[51,87,88]. Details of the success of this technique have been discussed earlier. However, it may not be possible to utilize this strategy in all patients, due to unfavorable surgical anatomy, adhesions, limited maneuverability of the scope around biliary anastomosis, and limited number of small-caliber ERC instruments that can be used through these devices. Also, these procedures require high skill and expertise and the learning curve is steep and hence available only at specialized centers. Another specialized technique that is being tried is formation of gastrostomy, either surgically or percutaneously using EUS, and then performing ERC through the gastrostomy port[89]. A single study using this approach achieved biliary intervention successfully in all patients as compared to 58% success rate with deep enteroscopy, and should be evaluated further[90]. Lastly, an alternative approach that may be potentially used in patients with altered anatomy is the use of direct

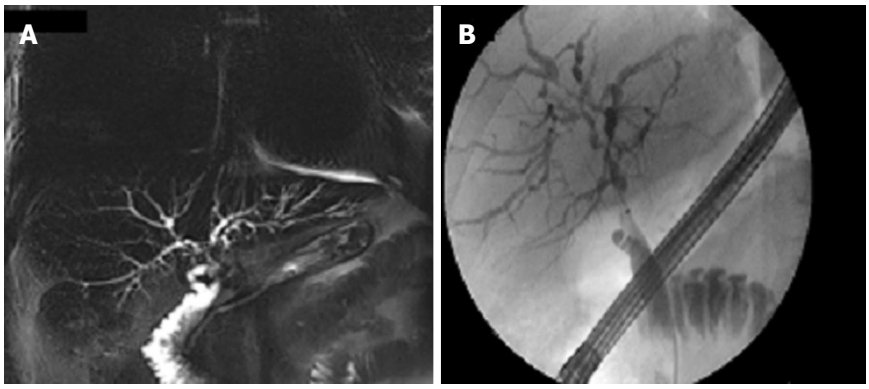

Figure 6 Don't forget the native disease. Recurrence of native disease can mimic biliary complications, hence appropriately investigated with magnetic resonance cholangiopancreatography (A) and/or endoscopic retrograde cholangiography (B). This patient was transplanted for primary sclerosing cholangitis, and had disease recurrence involving the intra-hepatics few years later.

cholangioscopy after percutaneous tract has been created. Direct visualization of bile ducts is possible using this method and can be used for removal of bile duct stones, dilation of stricture and placement of stents.

Biliary complications in recipients of LDLT and DCD transplants

Biliary complications after LT from living donors (LDLT) or grafts from donors after cardiac death (DCD) are more frequent than encountered with conventional donors after brain death (DBD). Complications that occur at a higher rate after LDLT included biliary leak (31.8% *vs* 10.2%), unplanned re-exploration (26.2% *vs* 17.1%), HAT (6.5% *vs* 2.3%) and portal vein thrombosis (2.9% *vs* 0.0%)[91]. However, there is suggestion that these complications may decrease as experience of LDLT center grows. The main reason for higher biliary complications is relatively smaller duct size, making the anastomosis technically difficult, and hence a higher chance of ischemic injury, especially in right-lobe LDLT[92]. Endoscopic management in LDLT recipients may be challenging given the complex nature of their duct-to-duct reconstruction, especially those involving smaller caliber ducts (< 4 mm), than when a hepatico-jejunostomy is used with these duct sizes. If attempted, smaller diameter stents (7.0-8.5 Fr) need to be used in these scenarios, and ERC performed more regularly because rates of re-stenosis are high with shorter duration of stenting. On the contrary, DCD is commonly associated with significant risk for both early and late biliary complications, including strictures, and many patients develop more than one biliary complication[93]. The major difference between pathogenesis of post-LT NAS in DCD is that the contributing mechanism is ischemic injury, which occurs before organ retrieval, rather than ischemia post-anastomosis in conventional DBD NAS[93]. There is also emerging evidence that the type of preservative solution (HTK solution) may also affect future incidence of biliary complications in DCD patients[94]. The endoscopic management principles remain the same, although intra-hepatic and small duct strictures may be more common making them less amenable to endoscopic management. There is evidence that although unilateral and easily approachable strictures may be managed endoscopically (with > 85% long-term survival), most DCD patients have diffuse intrahepatic structuring disease, due to global organ ischemia, which negatively impacts their long-term survival[95].

Sedation for ERC in post-LT patients

The sedation regimen for ERC in non-transplant setting may vary based on country, type of practice, endoscopist preference, age and co-morbidities of patient, and availability of anesthesia support. Conscious sedation (using opioids and/or benzodiazepines) is being increasingly less preferred for ERC, because it is long and uncomfortable procedure, and adequate patient relaxation and sedation is vital for the success of this critical procedure. Data suggests that propofol is superior to benzodiazepines for sedation during an ERC procedure, even in high-risk octogenarians[96]. Further studies proved that the combined use of propofol and midazolam or fentanyl for sedation has some benefits and no safety concerns, compared to using either drug alone[97]. There are adequate safety results for the administration of propofol by nonanesthesiologists[98]. For these reasons, at our center, like most of the other hospitals in the United States, ERC's are usually performed under anesthetist administered general anesthesia or monitored anesthesia care using propofol. Safety of opioids/benzodiazepines as well as propofol based regimens have been adequately demonstrated for GI endoscopic procedures, in several studies[99,100]. However, there is no such data available in post-LT patients, and is an area for further research. Nevertheless, in our experience of performing ERC's on post-LT patients over the last 6 years, we have not encountered any sedation related complication, and we attribute that to proper patient selection and careful optimization of patient co-morbidities before embarking on this critical procedure. Based on our experience, we endorse anesthetist administered anesthesia as a

routine sedation strategy for all post-transplant patients requiring ERC, taking into consideration the overall high-risk nature and length of this procedure, frequent need for multiple therapeutic interventions and patient co-morbidities.

CONCLUSION

Biliary complications are being increasingly encountered in post liver transplant patients because of increased volume of transplants being done and longer survival of these recipients. Overall management of these complications may be challenging, but with advances in endoscopic techniques, majority of such patients are being dealt with by endoscopists rather than the surgeons. ERC with various interventions, like sphincterotomy, bile duct dilatation, and stent placement, remains the mainstay for management of bile leaks, strictures and bile duct filling defects. Recurrence of native disease is the greatest mimicker of post-LT biliary complications, and hence must be investigated thoroughly with advanced imaging or endoscopic means (Figure 6). With increasing number of patients with altered anatomy, whether due to obesity epidemic or use of non-traditional anastomoses in liver transplant strategies like living-donor or split livers, ERC in these patients has been a perplexing issue and many require interventional radiology or surgical procedures. However, with ongoing attempts at developing improved tools and techniques to access the bile duct in patients with surgically altered anatomy, endoscopy will likely become unopposed frontier in this subgroup of patients as well.

Abstract

Advances in stents design have led to a substantial increase in the use of stents for a variety of digestive diseases. Initially developed as a non-surgical treatment for palliation of esophageal cancer, the stents now have an emerging role in the management of malignant and benign conditions as well as in all segments of the gastrointestinal tract. In this review, relevant literature search and expert opinions have been used to evaluate the key-role of stenting in gastrointestinal benign and malignant diseases.

Key words: Endoscopic stenting; Stricture; Leak; Complication; Cancer

Core tip: Endoscopic stenting plays an indispensable role in the treatment of benign and malignant digestive strictures and leaks. In this review, we summarize data from randomized clinical trials or prospective studies together with meta-analytical data, when applicable; to present the most updated recommendations in stenting of gastrointestinal diseases.

INTRODUCTION

Stenting has become an optimal option for the treat-

ment of a variety of gastrointestinal malignant and benign diseases, which plays a vital role in alleviating obstructive symptoms such as dysphagia, pain, and improving patients' quality of life.

Over the past 30 years, dramatic changes have occurred in the composition and design of stents and their application to digestive disorders.

For example, stent composition began with plastic, evolved into self-expandable metal stents (SEMSs) and may soon evolve into biodegradable stents. At the same time, indications for stenting that began with esophageal cancer now include benign and malignant disorders involving a variety of sites in the gastrointestinal tract.

This paper will outline the indications and outcomes of stenting, the techniques of placement, composition and design of stents and prospects for new and improved stents.

TYPES OF STENTS AND PRINCIPLES FOR STENTING

A stent is a cylindrical medical device used to widen a narrow or stenosed lumen in order to maintain the patency of the lumen. The first stents were made of hard plastic and were used for obstructive esophageal cancers. Whereas early stents were mostly composed of plastic, the majority of contemporary stents are metal stents that are composed of either nitinol or stainless steel.

Nitinol mesh has improved the quality of the stents, replacing the other materials. This nickel-titanium shape-memory alloy is soft and flexible, with smoother wire ends, reducing the risk in and overgrowth.

Metal stents are available as uncovered, partially covered (PC), or fully covered (FC). An uncovered SEMS consists of a mesh that is bare and expands into the stenosis. A FCSEMS consists of a mesh stent that is covered by a membrane throughout its length. A PCSEMS consists of a stent with a membrane covering and uncovered proximal and distal ends of the stent.

Recently, FC self expanding plastic stent (SEPS) and biodegradable stent was developed. SEPS is made of woven plastic strands, while biodegradable stent is made from commercially available polydioxanone absorbable surgical suture material. Polydioxanone is a semicrystalline, biodegradable polymer. It degrades by hydrolysis of its molecule ester bonds, which is accelerated by low pH. The amorphous regions of the matrix deteriorate first and the crystalline portion deteriorates later.

Most of the metal stents on the market are mounted on a delivery system that consists of two coaxial tubes, but there is also a type of metal stent mounted on a delivery system with a user-friendly braided-suture release mechanism and it is deployed by pulling a ring attached to the suture string, thereby unraveling the string and slowly releasing the stent (Ultraflex esophageal or colonic stents, Boston Scientific/Microvasive, Natick, Massachusetts).

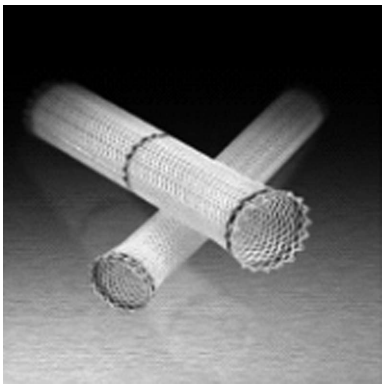

Figure 1 Boston scientific polyflex stent.

There are 2 types of delivery systems: through the scope (TTS), able to pass through the operative channel of the endoscope, and over the wire (OTW) that does not pass through the operative channel of the endoscope. The main differences between the delivery systems are the design of the handles, the lengths and the diameter, which determines the means of deployment.

Although the majority of deployment systems release the stent initially at the distal end of the catheter, there are some types of gastrointestinal stents available in both a proximal and distal release system (*i.e.*, Ultraflex esophageal stent NG/Boston Scientific and the esophageal Nit-S®/TaeWoong). In contrast to most SEMSs, which are sold in a constrained packing, the SEPS requires mounting onto the delivery catheter just before use. One important aspect of deployment is the variable degree of foreshortening that occurs with a majority of SEMSs and SEPS during the transition from the compressed to fully expanded state. The endoscopist must anticipate and allow for this foreshortening to ensure appropriate placement.

Before stenting firstly the lesion should be endoscopically or radiologically evaluated, the proximal and distal aspects of the lesion identified and a guide-wire advanced through the lesion, and the stent positioned across and then deployed under fluoroscopic and/or endoscopic guidance by release of the constraining mechanism.

Esophageal stents: Table 1

The SEPS Polyflex® (Boston Scientific) is a stent of polyester braid completely covered in silicone membrane. The stent need to be loaded prior to insertion into a large diameter delivery device (36-42 Fr) and is available in different sizes (diameters of 16, 18, and 21 mm and lengths of 9, 12 or 15 cm). Are available with proximal flare diameters of 20, 23 and 25 mm, the proximal end is flared for preventing distal migration with radio-opaque markers at the ends and in the middle for a more precise placement (Figure 1).

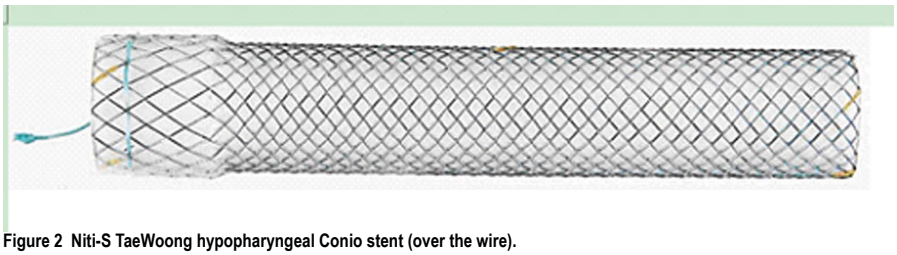

Figure 2 Niti-S TaeWoong hypopharyngeal Conio stent (over the wire).

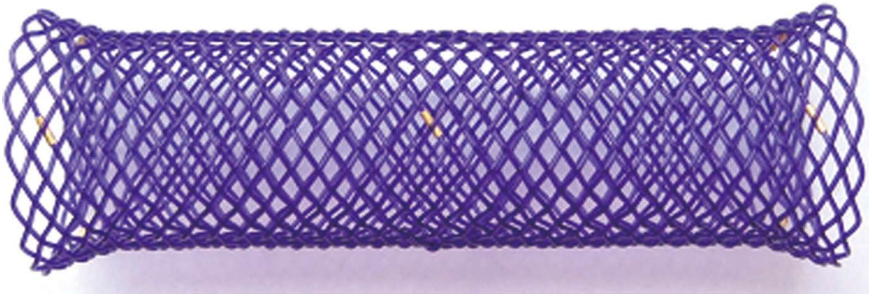

Figure 3 The Ella BD stent.

The most common used esophageal FC-SEMSs are: the Wallflex® (Boston Scientific), Niti-S® (TaeWoong), Evolution® (Cook Medical), Alimaxx-E® (Alveolus, Charlotte, NC, United States), SX-ELLA® stent Esophageal HV (Ella-CS, Hradec Kralove, Czech Republic) and the Hanaro® (M.I. Tech stent) and most of these stents are also available PC.

All these stents are made in nitinol and released OTW, the Alimaxx, Wallflex, Hanaro, SX-ELLA® and Evolution have a distal release, while Niti-S has both distal and proximal release.

The Alimaxx, Niti-S, Hanaro and Evolution are covered in silicone, while the Wallflex stent has the covering made of Permalume®, a particular type of silicone that diminish the food impaction. Actually the only FCSEMS with a possibility of a delivery-system TTS is the Niti-S.

The Wallflex, Alimaxx, Niti-S and Hanaro presents the same OTW release mechanism (the delivery system consists of a coaxial tubing assembly that constrains the stent on the delivery catheter shaft until the stent is released), an innovation, allowing a best control of the release, was recently projected by Cook Medical for the Evolution. The delivery system is composed by a "plastic handgun". With one hand and a squeeze of the trigger, the handle gives a precise control over stent deployment and recapturability. To shift between stent release and recapture, it needs switch the "directional button". There is furthermore a "point-of-no-return" reference mark that alerts when stent recapture is no longer possible.

The Ultraflex (Boston Scientific/Microvasive, Natick, Massachusetts) esophageal stent is another type of prosthesis that has a flared proximal end (23 or 28 mm), available uncovered and PC (the PCSEMS version have 1.5 cm of bare nitinol configured into wire loops at each end, thus sharp elements are absent) and is marketed with both a proximal and distal release design. This stent is highly flexible and is mounted on a delivery system with a user-friendly braided-suture release mechanism, deployed by pulling a ring attached to the suture string, thereby unraveling the string and slowly releasing the stent.

The Taewoong Medical produce specifically designed Niti-S stents. The Niti-S Conio Stent (Taewoong Medical, Seoul, South Korea) is a stent for hypopharyngeal stenosis. The stent have a body with a diameter of 12, 14 or 16 mm, and only the proximal crown has a diameter greater than the body of only 2 mm (14, 16 and 18 mm), to prevent distal migration and reduce the feeling foreign body (Figure 2). The Niti-S Beta stent (Taewoong Medical, Seoul, South Korea) is a newly design OTW stent with distal release with two rings in the body, for the anti-migration mechanism, produced for the treatment of complications of bariatric surgery. The biodegradable implant (ELLA BD stent) (Ella®-CS, Hradec Kralove, Czech Republic) is composed of polydioxanone which is a semi-crystalline polymer biodegradable (Figure 3).

The OTW delivery system has a diameter of 9 mm, the diameter of the stent is 25 mm, while the length varies between 6 and 13.5 cm. After the release in the esophageal lumen, the complete expansion of the stent occurs in 24-48 h. The degradation of the implant begins after 4 wk and the ninth week the radial force (RF) has been reduced by half, therefore the stent does not have to be removed.

The best way to release an esophageal stent is the combined endoscopic and fluoroscopic approach, expecially in presence of a leak, despite some expert endoscopist, only in selected cases, place the stent only with endoscopic control.

Table 1 Characteristics of the most commonly used esophageal stents

Producer	Model	Material	Diameter mm (body/flare)	Length (cm)	Type and characteristics
Merit Endotek	Alimaxx-E®	Nitinol	18/22	7-10-12	Fully-covered with anti-migration system
Merit Endotek	EndoMAXX®	Nitinol	19/24-23/28	7-10-12-15	Fully-covered with anti-migration system
Boston Scientific	Ultraflex®	Nitinol	18/23-23/28	10-12-15	Uncovered and partially-covered Possibility of distal or proximal release
Boston Scientific	Flamingo Wallstent®	Stainless steel	20/30	12-14	Partially-covered
Boston Scientific	Wallflex®	Nitinol	18/23-23/28	10-12-15	Partially and fully-covered
Boston Sientific	Polyflex®	Polyester	16/20-18/23	9-12-15	Plastic stent
Cook Endoscopy	Evolution®	Nitinol	20/25	8-10-12.5-15	Partially and fully-covered
Ella-CS	SX-ELLA® HV	Nitinol	20/25	8.5-11-13.5-15	Fully-covered with collar anti-migration system
Ella-CS	SX-ELLA® Flexella	Nitinol	20/25	8.5-11-13.5-15	Fully-covered Possibility of distal or proximal release Possibility of anti-reflux valve
Ella-CS	FerX-ELLA® Boubella	Stainless steel	20/25	9-10.5-12-13.5-15-16.5-19.5-21	Fully-covered Possibility of anti-reflux valve
Ella-CS	SX-ELLA® Danis	Nitinol	25/30	13.5	Fully-covered (with balloon/specific for variceal bleeding)
Ella-CS	SX-ELLA® Danis Seal	Nitinol	25/30	13.5	Fully-covered (specific for leaks)
Ella-CS	Ella BD stent®	Biodegradable polymer	18/23-20/25-23/28-25/31	6-8-10-13.5	-
Endochoice	Bonastent® ER	Nitinol	18/24	6-8-10-12-14-16	Fully-covered Possibility of anti-reflux valve
M.I. Tech	Hanarostent®	Nitinol	18/24-20/26-22/28	8-9-10-11-12-14-15-16-17	Partially and fully-covered Possibility of double covered configuration, anti-reflux valve and asymmetrical configuration
M.I. Tech	Hanarostent® ECBB	Nitinol	36-30-20-26	18-21-24	Fully-covered (Bariatric surgery)
Micro-Tech	MT® Esophageal stent	Nitinol	(Diameter central/extremities) 18/24-20/26-22/28	8-10-12	Uncovered, partially and fully covered Possibility of anti-reflux valve and radioactive system
Micro-Tech	MT® Cardia stent	Nitinol	16/22-18/24-20/26-22/28-24/30	9-10-11-12-13	Partially and fully-covered
Micro-Tech	MT® Retrievable stent	Nitinol	14/20-16/22-18/24-20/26-22/28-24/30	7-8-9-10-11-12	Fully-covered
TaeWoong Medical	Beta-Stent Niti-S®	Nitinol	18/24-20/26-22/28	10-12-14-15-16-18-20	Fully-covered (Fistula after bariatric surgery)
TaeWoong Medical	Mega-Stent Niti-S®	Nitinol	18/24-20/26-22/28	10-12-14-15-16-18-20	Fully-covered (Stricures or fistula after sleeve gastrectomy)
TaeWoong Medical	Niti-S Conio®	Nitinol	10/12-12/14-14/16	6-8-10-12-14-15	Fully-covered (Hypopharyngeal strictures)
TaeWoong Medical	Niti-S Cervical®	Nitinol	16/18-18/20	6-8-10-12-14-15	Fully-covered (Upper esophageal strictures) Possibility of distal or proximal release
TaeWoong Medical	Niti-S®	Nitinol	16/24-18/26-20/28	6-8-10-12-14-15	Partially and fully-covered Possibility of distal or proximal release for over-the-wire stent Possibility of TTS 10.5 Fr delivery system
TaeWoong Medical	Niti-S® double layer	Nitinol	16/24-18/26-20/28	6-8-10-12-14-15	Fully-covered with additional uncovered nitinol mesh Possibility of distal or proximal release Possibility of anti-reflux valve

Gastro-duodenal stents: Table 2

Different types of enteral stents are actually in use, all with a delivery system TTS (10 Fr) which needs a working scope channel of 3.8 mm.

All the commercialized stent are made in Nitinol, except for the Enteral Wallstent, known as a stainless steel stent, made with a mix of materials called Elgiloy® (Eligoy Inc., Elgin, IL, United States) (cobalt, chromium, nickel, iron, molybdenum, manganese). The Enteral Wallstent is characterized of an excellent RF but with the tendency of straightening, increasing the risk of stent impaction in the angulated sites.

An important role in the gastro-duodenal obstruction is played by two relevant features of the stents: the RF and the axial force (AF).

RF is the expanding force. AF is a force that maintains the stent straight after its placement. Combination of the two forces is more effective than only RF or AF, respectively. The AF straightens the stent, and plays a fundamental role in covered stents. The nature of the nitinol confers to these stents an optimal AF and RF.

Almost all of the TTS SEMS allow re-sheathing of the stent and TTS delivery systems also necessitate a kinking-resistant guide-wire. Delivery systems are

Table 2 Characteristics of the most commonly used duodenal stents

Producer	Model	Material	Diameter (mm) (body/flare)	Length (cm)	Type and characteristics
Boston Scientific	Wallstent®	Elgiloy	20/22	6-9	Uncovered

available in different lengths (135, 180 and 230 cm). An important characteristic of duodenal stents is the diameter. For obtaining an adequate food transit has to be used stents with a diameter > 20 mm. Some stents have distal flared extremity to improve the anchorage and can be covered and uncovered. The choice of a covered *vs* an uncovered stent depends by the endoscopist, evaluating fatures and site of the lesion. Uncovered SEMS are generally used, in this site, because of the low risk of migration. The flexibility of the uncovered stents allows following duodenal angulations, despite could exercitate high pressure on the angulated strictures. The mesh pressure on the mucosa induces epithelial regeneration, that leads to ingrowth, can contribute to stent occlusion. Then, the placement of a covered-SEMS is preferable in non-surgical patients, or patients with a high risk of mortality and morbidity, with a life expectance > 2-3 mo. Covered stent are generally indicated in the treatment of the tissue ingrowth inside an uncovered stent.

Materials used for covered stent are polyurethane, silicone, and expanded polytetrafluoroethylene. Covered SEMS are conceived to prevent tumor ingrowth and for closing fistula, if present; the only disadvantage of these stent is the tendency to migrate.

Two stents are currently marketed for the closure of fistulas post-sleeve gastrectomy, both over-the-wire (OTW): the Beta-stent® (Niti-S - TaeWoong), with lengths of 15, 18 and 23 cm and a diameter of 24 and 28 mm, and the Hanaro® stent (M.I. Tech) with lengths of 18, 21 and 24 cm and a width of 30 mm diameter. Both the two stents must be placed under fluoroscopic vision, after placing a stiff guide-wire in the duodenum, and present the proximal tourniquet on the crown for removal.

Duodenal stricture evaluation with X-ray enema before the endoscopy is generally not required. The passage of orally administered water soluble contrast through the duodenal stricture is generally delayed because of the gastrectasia, presence of residual food and delayed stomach emptying.

Furthermore, assessment of concomitant proximal jejunal strictures is not satisfactory due to the small amount of contrast that can pass the duodenal stricture. For these reasons stricture assessment during duodenal stenting procedure is preferred. Computed tomography is helpful to exclude the presence of peritoneal carcinosis.

To avoid aspiration, insertion of a naso-gastric tube 24 h before the procedure to empty the stomach, and the prone position during the procedure, are recommended.

Commercially available TTS SEMS require an operative endoscope (3.8 mm diameter working channel). Operative duodenoscopes offer a better visualization of the duodenal stricture lumen, the elevator helps the orientation of the catheter, grips of the guidewire, and the delivery system. Duodenoscopes are also useful for the treatment of a concomitant biliary stricture.

Duodenal stenting placement is performed under fluoroscopic guidance because both endoscopic and radiological controls are preferable. Stricture study is performed by contrast injection above the stenosis to assess diameter and length of the stricture; when the duodenal stricture is passed with an ERCP catheter, with or without a wire, contrast is injected downstream for evaluating the patency of the GI lumen, distally to the stenosis. Another accessory, that could be useful in the angulated stricture, is the sphincterotome. Balloon dilation before stent placement is not necessary (it increases the risk of perforation), and a stiff or super-stiff guide-wire is generally preferred. When the guide-wire is correctly in place distal to the stricture the stent catheter is advanced OTW. It is important the choice of a stent few centimeters longer than the stricture to be sure of a correct stenting of the stricture. If possible, the stricture can be measured by a centimeter guide-wire. The presence of a possible angulation of the bowel, immediately after the stricture, has to be considered. In this case the length of the stent should be chosen to avoid stent impaction on the gut wall. In presence of short stenosis of the upper duodenal genu, it is a 6 cm length stents, with the proximal extremity deployed through the pylorus, has to be chosen, avoiding covering the papilla for a possible further ERCP.

Table 3 Characteristics of the most commonly used colo-rectal stents

Producer	Model	Material	Delivery system and diameter	Diameters (mm) (body/flares-flanges)	Length (cm)	Type and characteristics
Boston Scientific	WallFlex®	Nitinol	TTS, 10 Fr	25 (body)-30 (proximal flange) 22 (body)-27 (proximal flange)	6, 9, 12	Uncovered
Boston Scientific	Ultraflex precision®	Nitinol	OTW, 16 Fr	25 (body)-30 (proximal flange)	5.7, 8.7, 11.7	Uncovered
Boston Scientific	Wallstent®	Stainless steel	TTS, 10 Fr	20 (22/minimal to no flare)	6, 9, 12	Uncovered
Cook Endoscopy	Evolution®	Nitinol	TTS, 10 Fr	25 (body) 30 (both ends flanged)	6, 8, 10	Uncovered
EndoChoice	BONASTENT®	Nitinol	TTS, 10 Fr and 12 Fr	22, 24, 26 (minimal flare)	6, 8, 10	Uncovered and partially covered
Ella-CS	SX-ELLA® Enterella	Nitinol	TTS, 10 Fr	22, 25 (no flare)	7.5, 8, 9, 11, 13.5	Uncovered and fully covered
Ella-CS	SX-ELLA® Enterella	Nitinol	OTW, 15 Fr and 18Fr	22, 25, 30 (no flare)	8.2, 9, 11.3, 13.5	Uncovered and fully covered
Endochoice	Bonastent® C	Nitinol	TTS, 10 Fr	22, 24, 26	6-8-10	Uncovered and fully covered
Leufen Medizintechnik	Aixstent®	Nitinol	OTW, 24 Fr	30 (body)-36 (both ends flared)	8, 10	Uncovered and partially covered

M.I.Tech	Hanarostent®	Nitinol	OTW, 24 Fr	20, 22, 24 (body)-26, 28, 30 (both ends flared) (flanged and symmetric and asymmetric)	6-16	Uncovered and fully covered
M.I.Tech	Choostent®	Nitinol	OTW, 24 Fr	22, 24 (body)-30, 32 (both ends flanged) (symmetric and asymmetric)	6-16	Fully covered
S&G Biotech	EGIS® colorectal	Nitinol	TTS, 10 Fr and 12 Fr	18, 20, 22, 24, 26, 28, 30 (no flare)	6, 8, 10, 12	Uncovered and partially covered
Taewoong Medical	Niti-S® D-Type	Nitinol	TTS, 10.5 Fr	18, 20, 22, 24 (no flare)	6, 8, 10, 12, 14, 15	Uncovered
Taewoong Medical	Niti-S® D-Type	Nitinol	OTW, 16 Fr and 18 Fr	18, 20, 22, 24, 26, 28, 30 (no flare)	6, 8, 10, 12	Uncovered
Taewoong Medical	Niti-S® S-Type	Nitinol	TTS, 10.5 Fr	18, 20 (body)-24, 28 (both ends flanged)	6, 8, 10, 12	Fully covered
Taewoong Medical	Niti-S® S -Type	Nitinol	OTW, 16 Fr, 20 Fr and 22 Fr	18, 20, 22, 24, 26, 28 (body) 24, 26, 28, 30, 32, 34 (both ends flanged)	6, 8, 10, 12, 14, 15	Fully covered
Taewoong Medical	ComVi Niti-S®	Nitinol	TTS, 10.5 Fr	18, 20, 22 (no flare)	6, 8, 10	Partially covered
Taewoong Medical	ComVi Niti-S®	Nitinol	OTW, 14 Fr, 16 Fr and 18 Fr	18, 20, 22, 24, 26, 28, 30 (no flare)	6, 8, 10	Partially covered

TTS: Through the scope; OTW: Over the wire.

The majority of the delivery stent systems allow re-sheathing of a partially deployed stent, permitting further adjustments, before the release, if the position is not correct. If the stent is accidentally released beneath the stricture, it should be immediately replaced with a tooth-rat forceps. If the placed stent is shorter than the stricture, a second stent can be released, with the proximal part inside the first.

The correct position of the stent has to be radiologically documented immediately after the deployment, injecting contrast inside the stent. Completely stent expansion is generally obtained at 48 h.

Colo-rectal stents: Table 3

Over the years have been progressively introduced various types of stent. Material was initially steel (Z-stent® Cook Medical) or Elgiloy (Wallstent®, Boston Scientific) and subsequently the nitinol. The stents actually available are all in nitinol and can differentiate between them for the shape, the size, the type of mesh, the presence or absence of coverage, the catheter carrier (TTS or OTW) and the release system. The stent OTW, typically have a 16 Fr catheter and can be used, in consideration of the length and rigidity of the catheter carrier, only for strictures of the rectum

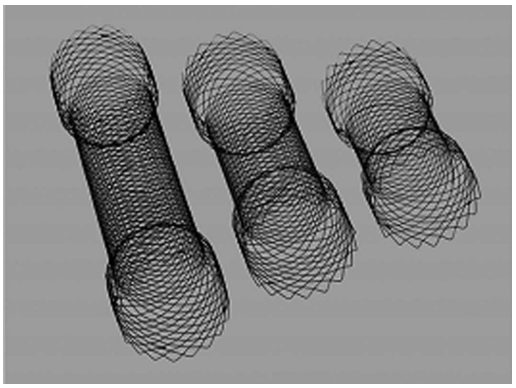

Figure 4 Colonic Evolution® stents.

or sigmoid typically within 30 cm from the anus. For stenosis located further upstream in the bowel, for anatomical reasons, it needs to use TTS stents. The Wallflex® (Boston Scentific) and Niti-S® (TaeWoong) are the most used stents to date and on which there are more data in the literature. The Evolution® stent (Cook) (Figure 4) instead is the most recently introduced on the market and which presents a delivery system that allows a best control of the various phases of the stent placement.

In the study of an occluded patient the diagnostic steps should go include the execution of a contrast medium CT scan that can be extremely useful both to evaluate the seat, the extension and nature of the stenosis, both to obtain a more comprehensive assessment of the situation abdominal (cecal diameter, exclusion of a bowel perforation or evaluation of liver metastases or peritoneal carcinomatosis). In general the onset of symptoms, their severity, and the distension of the cecum are the elements allowing the assessment in how many hours must be executed an attempt of endoscopic stent decompression. In most situations the endoscopic intervention can be performed within 6-8 h from the evaluation, for which reason even if the patient were to arrive later in the evening in the emergency room the stent placement could be deferred to the next morning. Logistically, it is necessary to have an X-ray room, a doctor and one or two experienced nurses or two doctors and a nurse, endoscopic instruments of different sizes to meet all anatomical situations and accessories needed for stent placement (guidewires, catheters, sphincterotome).

Stent TTS have a delivery catheter with a diameter of 10 Fr for which they pass in the channels of 3.8 mm diameter endoscope (standard colonscope, operative gastroscope and duodenoscope). Before placement of the stent is recommended the execution of a rectal enemas toileting which serve to clean the intestinal tract below the stenosis, thus facilitating the endoscopic exploration and identification of the stenosis. The procedure is almost always very well tolerated with minimal sedation with low doses of benzodiazepines. The anesthesia care should be required only for patients very sufferers or those with medical critical conditions.

For the possibility of ab-ingestis polmonitis, it is suggested to leave the stomach in a naso-gastric tube. It is also prudent to work with a very low level of endoscopic insufflation to avoid excessive distension of the colon upstream of the stenosis that could jeopardize the success of the maneuver.

It is preferable the patient lie supine to facilitate the radiological anatomy and identification of markers for the positioning of the stent. After reaching the stenosis, the next step is to cross the stricture with a guide-wire and an ERCP catheter. If the stenosis is very tight, long or very difficult to pass, it is suggested the use of a hydrophilic guide-wire, maybe with curved tip to avoid the risk of making false roads with a rigid (stiff) wire. In some occasional situations, in which the position of the stenosis is very lateralized respect to the endoscopic view for which the catheter fails to be directed in the stenosis, could be use a sphincterotome or, finally, the duodenoscope, having a different viewing angle, which allows to direct the tip of the catheter to the site of stenosis and facilitate the progression of the guide. Once passed the stenosis under radiological assistance, the wire must be withdrawn, injecting contrast medium to identify the correct position of the catheter, check the anatomy of the stricture and colon upstream. After that, a stiff guide-wire will be advanced across the catheter, far beyond the stenosis. This is useful to obtain a sufficient amount of guide-wire beyond the stenosis for all the maneuvers of the wire handling to give tension and straighten to the stent facilitating the advancement on the stricture. Dilation of the stricture before the release of the stent should be avoided because is a risk factor for intestinal perforation.

The choice of the stent will have to keep in mind the location and lenght of the stenosis. It is suggested to use stent with a length of at least 3-4 cm greater than that of the stenosis to allow a good adaptation of the stent also in very angled position where a stent too short might tend to straighten the curve inside and get in tension on the contralateral bowel wall, increasing the risk of dislocation and perforation. Once advanced the stent in the stenosis, the release should be supervised radiological and endoscopic (in the case of stents OTW is suggested to advance a small-caliber endoscope in parallel to the catheter carrying the stent). It is advisable to release the stent in a slow and gradual to always have full control of the maneuver. In the case of TTS stent is important that the endoscopist tends to progressively retract the catheter outside of the stent. Once completed the release, a last check radiological and endoscopic will be necessary to assess the proper expansion of the stent within the stenosis and evaluate the passage of air and fecal material through the stent.

ESOPHAGEAL DISEASES

The SEMSs have acquired a well-defined role in the

Table 4 Classification of dysphagia

Grade of dysphagia	Symptoms
0	No dysphagia
1	Occasional dysphagia for solid foods
2	Dysphagia for solid foods
3	Dysphagia for semi-solid food
4	Dysphagia for liquids

palliation of dysphagia in patients affected by esophageal malignant strictures, with a technical success greater than 95% with regard to their positioning and the ability to quickly resolve the dysphagia in almost all of the patients, reducing the rate of complications during the positioning phase thanks to the small diameter of the delivery catheter, and this, together with the use of an pediatric endoscope, makes unnecessary the preliminary expansion[1,2].

There are several types of esophageal SEMSs actually available for the treatment of malignant and benign esophageal stenosis[3].

The esophageal SEMSs are currently available uncovered, PC (only in the extremes do not have coverage) that FC[4].

The latter have attracted the interest of clinical researchers to evaluate their role in benign stenosis, esophageal mainly because complete coverage would allow their extraction after a certain time. In addition to the FCSEMS is necessary to consider the other two implants which are used in benign esophageal disease, the SEPS (Polyflex®, Boston-Scientific, Natick, MA, United States) and the biodegradable stent (Ella®-CS, Hradec Kralove, Czech Republic).

Benign esophageal diseases

Esophageal strictures: Before starting the endoscopic treatment is necessary to establish the real not malignancy of the stenosis, performing multiple biopsies and, when necessary, using endoscopic ultrasound (EUS) or other radiologic techniques. Essential is the classification of the dysphagia, so as to record the variation in the course of treatment (Table 4)[5].

The benign strictures are relatively frequent finding in clinical practice. In the past peptic strictures were prevalent, but are currently most commonly encountered those caused by caustic and radiotherapy. Esophageal strictures have been recently described in endoscopic mucosal resection, when circumferential and after endoscopic submucosal dissection[6].

Generally most of stenosis responds to a few[7] sessions of endoscopic dilatation, but from 25% up to 30 % requires a larger number of dilatation[8]. There are, however, "complex" strictures that do not respond to dilatation therapy, even if repeated over time (Table 5).

The anastomotic strictures, post-caustic ingestion stenosis and stenosis resulting from radiotherapic treatments, have a low rate of response to endoscopic

Table 5 Characteristic of "complex esophageal stenosis"

Length > 2 cm
Angulated
Irregular edges
Very low diameter

therapy: more than 40% tend to recur[9,10]. The most difficult to treat are the hypopharyngeal strictures, generally refractory.

It was moreover proposed the definition of "refractory stenosis" as: (1) absence of inflammation or motility disorders in presence of stricture; (2) impossibility of maintaining ⩾ 14 mm diameter after 5 sessions of dilation performed with a interval of 2 wk (refractory stenosis); and (3) impossibility of maintaining ⩾ 14 mm diameter for 4 wk after reaching a 14 mm diameter (recurrent stenosis)[11].

In addition to the expansion, have also been proposed other treatments, such as injection, at the level of the four quadrants of triamcinolon and, where appropriate, in particular in the anastomotic stenosis, the incisions of the fibrotic ring with a diathermic needle[12,13]. When these measures fail and dysphagia persists it is mandatory to evaluate the possibility to place a stent that, in addition to determining a laceration of the scarred submucosal layer and muscle of the esophageal wall, it maintains a constant pressure for the entire duration of its stay in the esophagus.

Anastomotic leaks

Total gastrectomy and esophagectomy are generally associated with high rate of morbidity and mortality even in specialized centres. The National Esophagogastric Cancer Audit of England and Wales published a rates of 8.3% of anastomotic leak after esophagectomy and 5.9% after total gastrectomy[14].

Although the improvements in the anastomotic techniques, anastomotic intrathoracic leak is generally associated with bacterial contamination, abscesses, and successive fistulas into pleural cavities. The continuous leakage of gastric juices and saliva into the pleural and mediastinal cavities can be life-threatening, with 30%-40% of post-surgical deaths[15].

Different treatments are described for the management of the esophago-gastric and the esophago-jejunal anastomotic leak. Some authors suggested the surgical treatment, but others prefrer a conservative approach with perianastomotic drainage, parenteral support and nasogastric decompression, and *iv* antibiotic therapy. All of these patients should be treated in appropriate critical care units[16].

The fibrin glue associated to metallic clips has been successfully used in small esophageal leaks[17,18]. An endoscopic stenting remains an attractive option, and SEPS and PC or FC-SEMS ensure good results, although the loading kit device and the delivery of the plastic stent can be difficult in non-expert hands. The leak

closure rates ranges from 60% to 100% with an healing rates > 90%[19,20]. Leak closure should be confirmed by contrast medium injected during the endoscopic procedure. Stents removal is planned at different times, depending by the size of the leak, but the stents are generally removed from 14 to 28 d from the placement with a previous clinical evaluation of healing of the absence or sepsis, radiologically documented.

The majority of the published studies suggest the stent placement immediately after the diagnosis of the leak for minimizing the contamination of the mediastinal cavity[21]. In some cases, the delayed placement can result in the healing of the anastomotic leak. Patients in which a covered stent is placed present an earlier oral intake (11 d *vs* 23 d), short ICU stay (25 d *vs* 47 d), and a less hospital stay (35 d *vs* 57 d). The in hospital mortality ranges from 0% to 20%, in different published series, lower if compared to the groups treated conservatively[22].

Acute and spontaneous esophageal perforations

Esophageal perforation is a life-threatening condition generally requiring surgical intervention. The management of the esopgaheal acute perforation (iatrogenic or spontaneous) is be divided into two groups: conservative and operative. Because of the rarity, the literature on this issue is based mainly on small series and case reports. Surgical repair seems to be the treatment of choice when an early diagnosis is made. The reported mortality in literature ranges from 0% (when the treatment starts within 24 h) to 30% if the treatment is delayed[23].

The conservative treatment is based on broad-spectrum *iv* antibiotic, parenteral nutrition and percutaneous drainage of the collections, when present. Ivey *et al*[24] showed as conservative therapy is appropriate only in presence of a perforation > 5 d; absence of sepsis; wide cavity at radiological imaging draining back into the esophageal lumen and absence of contamination of the pleural space[24]. A recent review advices that conservative treatment is feasible, with a survival rates of 60%-70% if the perforation are promptly diagnosed, but the need of the surgery is mandatory in case of failure[25].

Griffin *et al*[23] showed as in the management of spontaneous esophageal perforation (Boherhaave Syndrom's) they did not use stents. They suppose that the stent may prevent adequate drainage of sepsis, but can be subject to dislocation in absence of a stricture. Moreover, Authors recommend a non-operative management only in selected cases, especially when unfit for surgery[23].

Only three case reports are present in literature about the treatment of spontaneous esophageal perforations with the placement of the SEPS. In the first case the SEPS was placed at 24 h, in another case after 3 wk, in association of chest drainage, broad-spectrum *iv* antibiotic therapy and fibrin-glue injection, and, in the last case, the stent was placed 10 d later. All of the patients survived, and the immediate radiological study after stent placement did not show contrast medium outside from the esophageal lumen[26,27]. Oral intake was started in all of the three patients within 7 d, and were discharged between 7 and 21 d after stent placement.

The stent removal was scheduled between 5 and 10 wk. In two of the three treated patients, the stent was found into the gastric cavity.

Type of esophageal stents and outcomes

Self-expandable plastic stent: The SEPSs (Polyflex®) are usually placed with fluoroscopic assistance, but, in selected cases, deployment only under endoscopic view has been reported. A stent longer from 2 to 4 cm than the stenosis should be used for allowing a 1 to 2 cm extension above the edges of the lesion. Based on the RF of the SEPS, the completely expansion of the stent is obtained from hours to days[28,29].

The delivery device of the SEPS is larger and more rigid, if compared to other delivery system, with a non flexible tip. The assembly of the delivery device can sometimes be difficult in less well trained centres with low volume of cases, than these characteristics increase the challenging of the SEPS placement. The retraction rate of the SEPS is about 18% of the stent length before the release. The delivery system not allows the recapture. Because of the rigidity of the delivery system, it is suggested the neck hyperextension using a super-stiff wire. This may increase the risk of perforation, especially in presence of angulated strictures. This has been demonstrated in a prospective randomized trial (RCT) comparing 3 types of stents (Ultraflex, Niti-S and Polyflex); although dysphagia relief was achieved with all three types of stents, technical problems during stent release are encountered generally during SEPS placement than the other two SEMSs[30].

The SEPS presents some advantages if compared with PC-SEMS, as an easier removal and a less migration[31]. The soft material confers to the stent a well-balanced RF, adapting it to the wall of the esophagus, with a more probability of leak closure. The fully silicone covering does not allow granulation tissue ingrowth with minor overgrowth. It results in a possible successive easier repositioning and removal. The SEPS is available in different diameters and lengths, the exact diameter of stent has to be chosen on the basis of the size and site of the stricture (associated or not with a leak). There is no published evidence that the placement of large-diameter SEPS reduce the migration rate[32].

The SEPS presents other several drawbacks such as: the release takes place very fast, leading to the onset of severe sternal pain which can sometimes persist even 1 wk and the diameter of the introducer system that is excessive, especially in the presence of a "complex

stenosis".

The first study of the placement of SEPS in 15 patients reported a technical success, clinical success and a migration rates of 100%, 80% and 6.6% respectively[33].

Dua *et al*[34] in prospective study including 40 patients reported a clinical success of 40% and a migration rate of 22%, with a death due to a bleeding caused by erosion of the esophageal wall by SEPS[34].

A recent systematic review of the literature that has considered 10 studies with a total of 130 patients evidenced a technical and clinical success of 98% and 52%, respectively. The rate of migration (< 4 wk) was 24%, while complications were observed in 9% of patients with one death (0.8%)[35]. There is no consensus on the time to remove SEPS, but generally it is advisable the retrieval the stent after 6 wk, to prevent the onset of serious complications.

Partially-covered self-expandable metal stent

These stent should be not used in benign pathology because of the proliferation of granulation tissue through the proximal and distal uncovered mesh makes their removal difficult. One study that included 29 patients with benign esophageal strictures, reported the appearance of new stenosis the ends of the prosthesis in 41% of cases, migration in 31%, retrosternal pain and reflux in 21%, trachea-esophageal fistula in 6%[36]. Sometimes, in special cases where it cannot be used a stent completely covered for the high risk of migration, you can insert a PC-SEMS PC. To render its extraction after 6 wk, you can resort to the method indicated by Hirdes *et al*[37] aimed at eliminating the granulomatous tissue ingrowth present at the ends of the prosthesis: in it is placed a SEMS completely covered with similar diameter and length and leaving it up to a maximum of 2 wk. In this way the pressure of the stent will determine the necrosis of granulation tissue between the meshes, thus making possible the extraction of both stents[37].

FC self expandable metal stent

The complete coverage of the stent facilitates the extraction after a predetermined period of time, but could increase the risk of migration. This problem can be reduced if the endoscopist is able to perform an appropriate stent choice, in length and size. The capability of auto-conforming and the diameter should be considered in each individual case. A larger diameter will oppose effectively the migration and in presence of the fistula, and the perfect adhesion of the proximal crown to the wall to effective impermeability to liquids.

Eloubeidi *et al*[38] in 7 patients with benign strictures placed the Alimaxx-E (Alveolus, Charlotte, NC, United States) FCSEMS. The resolution of dysphagia was observed in 29%, while the migration occurred in 36% of the cases, half of the patients developed an ulcer distally to the FCSEMS and the 23% proximally, however these lesions were solved after the removal of the stent[38]. Additional studies have reported a migration rate to 37% up to 50%, a resolution of dysphagia to 21% up to 100 % of cases and the extraction of the stent was possible in all of the cases[39,40].

A meta-analysis that compared SEPS and FCSEMS in esophageal refractory strictures, included 8 studies with a total of 199 patients, found an improvement of dysphagia in the 55.3% patients treated with SEPS and in the 21.8% of the patients treated with FCSEMS, however these data must be accepted with extreme caution because in 6 of the 8 studies was used the SEPS[41].

The FCSEMSs are effective also in the treatment of benign fistulas, perforations and anastomotic leakage.

Van Heel *et al*[42] treated 33 patients with esophageal perforation (19 iatrogenic type, 10 Boerhaave's syndrome and 4 other pathologies), the closure of the perforation was obtained in 32 (97%) patients, recurrence occurred in 37% of cases, which required further stenting (3 patients were treated surgically), and the stents were removed within 6 wk of the placement without major complications[42].

A systematic review, that included 25 studies with a total of 267 patients, showed that the closure of the perforation was successful in 85% of patients, surgery was necessary in 13% and that patients treated with SEPS required a greater number of endoscopic reinterventions compared to patients treated with covered metal stents (26% *vs* 13%, $P < 0.001$)[43].

A particular problem is posed by the hypopharyngeal stenosis resulting from surgery and radiotherapy for cancer ear nose and throat[44,45]. Fibrosis caused by radiotherapy are interested in full thickness bowel and the remodeling of the stenosis is virtually impossible. Expansions of periodic increase fibrosis and therefore the risk of perforation. Generally, the appearance of a fistula requires, when possible, the surgery, with a considerable rate of mortality and morbidity. In these patients has proved useful the use of Niti-S Conio Stent (Taewoong Medical, Seoul, South Korea). The preliminary results are encouraging, but it is necessary to include a larger number of patients to assess the efficacy[46].

Biodegradable stent

The biodegradable implant (Hella® stent - Ella®-CS, Hradec Kralove, Czech Republic) was introduced in the clinical setting in 2008.

One study that included 21 patients with refractory strictures reported a significant improvement in dysphagia at a mean 53 wk of follow-up, 45% of the had not dysphagia at the end of the study, the migration rate was 9.5%, 3 patients complained of retrosternal pain after the release of the stent and one patient presented a slight bleeding after the procedure[47].

Van Boeckel *et al*[48] compared the outcomes

of SEPS (20 patients) and biodegradable stent (18 patients) in refractory strictures. In the group treated with SEPS, 6 (30%) patients were completely free of dysphagia with a median follow-up of 385 d while 10 (50%) had a recurrence of dysphagia, 1 severe bleeding and 1 perforation occurred. In the group treated with biodegradable stent, 6 (33%) patients were free of dysphagia with a median follow-up of 166 d, recurrence was observed in 12 (67%) patients and 2 severe bleeding and 2 cases of severe retrosternal pain occurred. The rate of endoscopic re-intervention was lower in the SEPS compared to the biodegradable stent grosup (15 *vs* 21)[48].

Malignant esophageal disease

Esophageal stents in malignant diseases are mainly placed in presence of unresectable carcinoma of the esophagus, with a short life expectancy, and suffer from marked esophageal stenosis or fistula[49]. Other malignant conditions in which patients are eligible for stent placement are extrinsic esophageal compression or fistula formation as a result of pulmonary cancer, mediastinal cancer or metastatic disease. The main advantages of stent therapy are successful insertion of the device in almost all cases with rapid (24-48 h) improvement of dysphagia. Disadvantages of the stent therapy are the re-occurrence of dysphagia in up to one-third of patients, and other stent related complications, including hemorrhage, pain and fistula[50]. Although most stents are placed in the distal or mid esophagus, insertion in the cervical esophagus is most rarely and it is considered equally effective with dedicated stent[51].

Both SEMS and SEPS are most used in esophageal malignant diseases. Actually to prevent tumor ingrowth PC or FC SEMS were used[51]. Although a FC-SEMS prevents tissue ingrowth over the full length of the stent, it presents a considerable migration risk[52].

Palliative treatment for malignant esophageal strictures

In the last 12 years, only five RCTs comparing different types of stent in patients with malignant esophageal strictures were published[53-56].

The first study randomized 100 patients to treatment with one of three SEMS: the PC-Ultraflex® stent (Boston Scientific, United States), the PC-Flamingo Wallstent® (Boston Scientific) and the FC-SEMS Gianturco Z-stent® (Wilson-Cook, Denmark). The three stents were equally effective in improving dysphagia scores without a significant difference in major complication rate.

The second trial randomized 53 patients with a distal esophageal tumor to a PC-Flamingo Wallstent® (Boston Scientific) or the more flexible PC-Ultraflex® stent (Boston Scientific). Clinical outcome was satisfactory in both groups without significant differences in improvement of dysphagia scores and complication rates.

A third study randomized 101 patients to a Polyflex® (Boston Scientific) or Ultraflex® stent (Boston Scientific), showing similar effectiveness in palliation of dysphagia. However, complications, especially late migration, occurred significantly more often after placement of a Polyflex® stent.

The fourth randomized study with 125 patients evaluated the Ultraflex® stent (Boston Scientific), the FC-double-layered Niti-S stent® (Taewong Medical, South Korea), and the Polyflex stent® (Boston Scientific). The Ultraflex® and Niti-S® stent were equally effective with equal overall complication rates, but recurrent dysphagia generally occurs more frequently with the Ultraflex® stent (52% *vs* 31%), mainly caused by a higher rate of food obstruction. The Polyflex® SEPS was associated with high failure of stent placement (17%) and increased migration risk. Because of a wider diameter of the Polyflex® delivery system, insertion is technically more difficult and dilation had to be performed more frequently. Furthermore, SEPS conform less easily to a stricture, making them more susceptible to slipping.

Observational series had initially demonstrated effectiveness of SEPS in malignant esophageal obstruction; however, the randomized studies revealed an unacceptable high complication rate[57,58].

A recently trial included 80 patients with dysphagia caused by malignant stenosis. Patients were randomized into two groups: PC-Evolution® stent (Cook Medical, Ireland) and Ultraflex® stent (Boston Scientific). The Evolution® stent was related with a significantly lower rate of stent dysfunction (8% *vs* 40%) and major complications (8% *vs* 25%). These data could not be confirmed in another single arm study, which included 44 patients with malignant dysphagia. In this study, the Evolution stent dysfunction rate was much higher (25%), mainly caused by tumor in- or overgrowth[59].

Stent innovations include anti-reflux and anti-migration features. The anti-reflux features were particularly developed for stents bridging the lower esophageal sphincter. This was generally done by attaching a valve to the distal end of the stent, inhibiting backflow from gastric contents into the esophagus. Theoretically, this should prevent reflux symptoms, esophagitis, and possibly aspiration. Although some studies have indicated that anti-reflux stents reduced gastro-esophageal reflux, a recent meta-analysis did not identify a significant difference in adverse events, symptoms and quality of life reflux-related[60]. Therefore, the use of anti-reflux stents has largely been abandoned. Antimigration features include uncovering of distinct areas of the metal mesh and a wider diameter of the stent flares, as well as addition of struts or rings to the outer side of the stent serving as anchoring devices. Both the Alimaxx-E® (Alveolus, United States) equipped with outer antimigration struts and the SX-ELLA® Esophageal HV stent (Ella-CS, Hradec Kralove, Czech Republic), with an anti-migration ring fall in the latter category. Several studies, however, have shown that, in spite of these design modifications, these stents frequently dislocate[61,62]. In addition, the SX-Ella stent

seems to be associated with a major number of adverse events, such as hemorrhage, fistula formation, and severe pain, which likely relate to excessive pressure of the anti-migration ring.

The Niti-S stent has a dog-bone shape to prevent migration. Two design of the stent are present in commerce: a fully-covered self expandable metal stent and a double-layered covering with an FC inner layer made of polyurethane and an outer uncovered nitinol mesh to facilitate the attachment of the SEMS to the wall. Several studies have reported good clinical efficacy and acceptable migration rates (up to 12%) with both types Niti-S® stents[63,64]. In one study, the double-layered version was associated with a significantly lower combined recurrent dysphagia and complication rate than the single layer version (12% *vs* 58%). However, the high complication rate of the single-layered Niti-S® stent used in that study was not confirmed in a recent large single arm study[65]. The FC-Wallflex® stent (Boston Scientific) is characterized by two migration-resistant features: distinct shouldering at both sides and internal covering. This stent has so far only been evaluated in one study for the treatment of neoplastic stenosis. Although the migration risk was low (9%), major complications were commonly seen (30%), which might be associated to the relatively high Wallflex® RF[66].

In summary, the available studies suggest that no major differences in efficacy and safety exist between different stents. However, there is still insufficient evidence to recommend one type of SEMS in the treatment of malignant dysphagia. Specific features reduce migration rates of FC-SEMS; however, they can also induce traumatic injury and lead to major adverse events.

Palliative treatment of malignant fistula

Fistulas usually result from infiltration of esophageal cancer to the respiratory tract or pleural cavity. Additionally, lung and mediastinal cancers can penetrate to the esophagus, also creating fistulas. Multiple series have reported on the use of covered SEMS to seal off fistulas, with closure rates ranging between 73% and 100%[67-69]. At the same time, it is also crucial that pleural and mediastinal fluid collections are drained aggressively. Both PC and FC-SEMS can be used as long as the covering completely seals the fistula. Unfortunately, randomized studies to recommend a specific type of SEMS are lacking. The largest non-comparative series to date reports on 61 patients with esophago-respiratory fistulas treated with covered SEMS. Ten patients also required a trachea-bronchial stent to seal the fistula. Complete fistula healing was reached in the 80% of the cases (49 subjects); the re-intervention was effective in the majority of 17 patients in whom the fistula had re-opened. Based on these data, and in the absence of effective alternative treatments, SEMS is considered the treatment of choice in malignant fistulas[70].

Bridge to surgery and SEMS

Nowadays, neoadjuvant chemoradiotherapy improves long-term survival after esophageal surgery[71]. Stent insertion before neoadjuvant therapy is an interesting new concept in the management of resectable esophageal malignancy. It could be useful as a bridge to surgery during the neoadjuvant chemotherapy, improving nutritional status by ensuring oral solid intake without the need for nasoenteral or percutaneous feeding tubes. Because esophagectomy is scheduled shortly after termination of neoadjuvant therapy, late stent-related complications can be averted. This approach has been evaluated in several studies, using different types of stents and various neoadjuvant regimes[72-74]. Stents were either extracted prior to esophagectomy or removed during surgery. They appear effective in improving dysphagia and maintaining nutrition. However, complications, although rare, may occur. These include esophageal perforation requiring urgent surgery, and stent migration. The latter has in case series been reported to result in small bowel perforation or obstruction. Furthermore, in one study, the number of patients proceeding to curative resection was surprisingly low due to progression or discovery of metastatic disease[75]. These findings indicate that adjunctive studies will clarify the use of the stents meanwhile the patient underwent neoadjuvant chemotherapy before implementing such use in regular practice. These studies should also clarify concerns about the possible spreading of viable tumor cells in the circulation after stent placement.

COMPLICATIONS OF ESOPHAGEAL STENTING

Recurrent dysphagia

Recurrent dysphagia remains a problem after stent insertion and occurs in almost one-third of patients. Endoscopic reintervention is successful in most cases[76]. In cases of tumor over- or ingrowth, insertion of a second stent is effective to restore luminal patency. This can also be considered in cases of stent migration. Conio *et al*[77] in 2010 described the possibility to treat the dysphagia because of the over- or ingrowth by placement of a SEPS. They evaluated 13 patients, previously treated with metal stent developing dysphagia because of tissue in/overgrowth, underwent self-expandable plastic stent (SEPS). Before SEPS placement, the dysphagia score ranged from 3 and 4. After 1 wk from the stent placement the dysphagia score was 0% in 100% of the cases. All of the patients were free of dysphagia till their death. Mean survival after self-expandable plastic stent placement was of 4 mo[77].

However, either endoscopic repositioning or exchanging for a new stent is preferable. Obstruction due to impacted food can easily be managed by endoscopic

stent clearance.

Another rare late complication is spontaneous stent fracture with collapse. The stent-in-stent technique seems safe and effective in these situations and can also be used to facilitate removal of the fractured SEMS[78].

Leak

Esophago-respiratory fistulas are mostly seen several months after stent placement. Due to the RF and resulting pressure necrosis, which is most extreme at the level of the flares, it is usually seen next to the proximal or distal margin of the stent. In these cases, placement of an additional covered-SEMS is an effective method.

Retro-sternal pain

Another complication is the development of retrosternal pain after stent insertion. Didden *et al*[79] found a 60% rate of moderate to severe pain in a prospective assessment of 50 patients after esophageal SEMS insertion for malignant stenosis.

Pain lasted for an average of 10 d and 91% of patients required analgesics, with good effect in all patients without the need for stent removal in any of them.

GASTRIC AND DUODENAL DISEASES

Benign diseases

Complications of bariatric surgery: The sleeve gastrectomy (SG), described for the first time by Gagner *et al*[80] in 2003 is currently a well standardized therapeutic option for the surgical treatment of different degrees of obesity[81,82]. The described complications of the SG include bleeding of the suture line and the stenosis, while the dehiscence of the suture line is the most serious event associated with a high morbidity rate and for whose management have been proposed different therapeutic approaches[83,84].

The re-intervention is often required even if burdened by a high rate of morbidity and mortality.

In recent years some endoscopic methods such as the use of covered-SEMS, have been mostly used for the treatment of anastomotic leakage with the aim of obtaining a non-minimally invasive surgical repair of the fistula[85,86].

The dehiscence of the suture line of the SG could be present in 0.5%-7% of the cases, even if could be underestimated; a detailed review of the American Society for Bariatric and Metabolic Surgery shows an overall rate of complications after SG variable between 0% and 24% with a percentage of dehiscence of 16%-20% of the cases[87]. The esophago-gastric junction and the proximal portion of the stomach near the corner of His are the points where most of you will be dehiscence[88,89].

The use of FC-SEMS in the treatment of dehiscence of the suture line of the SG was proposed by several authors in recent years[90].

The stent constitute a physical barrier between the fistula and the content intraluminal favoring the healing and the closure of the wall defect at the same time allowing the nutrition *per os*. The results of this method are reported in the literature as never variables, even if it is mostly case reports or small case series, so at present there are no extensive data statistically reliable.

Two stents are currently marketed for the closure of fistulas post-SG: the Beta-stent® (Niti-S - TaeWoong), and the Hanaro® stent (M.I. Tech). There are no data about, it is recommended the extraction of the stent between 6 and 8 wk. Currently there are no data comparing the two stents. The migration of the stent is the most common complication, reported in 30% of cases in some papers[87,91] and up to 42%-50% of cases in others[90,92]. The two ends of the stents slightly flared and high profile allow a good anchor. The body of the stents is longer than any of the esophageal stent allowing the opening of the proximal bell at the level of distal esophagus and the distal to the level of the duodenal bulb, by eliminating the pressure gradient, favoring the closure of the wall defect. The large diameter ensures excellent fit of the prosthesis to the wall of the gastric tube.

Malignant gastric outlet obstruction

Gastric outlet obstruction (GOO) is generally secondary to bilio-pancreatic and others. More rarely is due to gastric neoplasia[93]. Gastrojejunostomy (GJ) was the only therapeutic chance till the advent of the SEMS and is characterized by and higher mortality and morbidity, delayed symptoms resolution and longer hospitalization stay when compared to endoscopic stent placement[94,95].

In the last 20 years we observed an emerging role of self-expandable metal stent for palliation of GOO, substituting the GJ. A meta-analysis evaluating nine studies and 307 endoscopic and surgical intervention for palliation of malignant GOO evidenced better clinical success, minor morbidity and mortality, lower time-related procedure and hospital stay for endoscopic stent placement[96]. The rate of endoscopic clinical success was 84%-93%, with a technical success of 93%-97%[97,98].

The correct evaluation of the patients undergoing endoscopic stenting or surgical GJ plays a key role in the management of the malignant GOO. The GJ, in the opinion of some authors, is suggested in patients with a life expectancy more than 6 mo[99] despite a prospective randomized trial suggests GJ when the life expectancy is > 2 mo, and endoscopic SEMS when < 2 mo[100].

During the choice of the stent the endoscopist has to consider the site and the morphology of the stricture. The mean time for endoscopic duodenal SEMS placement is 17.5 min and the use of duodenoscope could

be useful because offer a better view of the duodenal stenosis, moreover, the scope elevator allows also the orientation of the device used, maintaining correctly in place the wire during devices exchange. The use of the duodenoscope is also suggested from some authors in presence of a challenging situation: a concomitant biliary obstruction[101,102].

The concomitant bilio-duodenal strictures are classified in three types: type Ⅰ: involving duodenal bulb/upper duodenal genu in absence of involvement of papillary area; type Ⅱ: involving the medium and distal portion of the duodenum and the papillary area; and type Ⅲ: involving the distal portion of the descending duodenum in absence of involvement of the papillary area[103].

In the type Ⅱ, when a duodenal SEMS is placed, a particular condition is created, the "jailed papilla". ERCP with biliary drainage through the metal mesh of the duodenal SEMS is possible fenestrating the SEMS with argon plasma coagulation (APC)[104]. In case of ERCP failure, percutaneous trans-hepatic biliary drainage is needed.

Actually the reported clinical success rate of duodenal stenting for GOO is 84%-93%, with a technical success of 93%-97%[98,99,101].

Tissue over- and ingrowth, food impaction and stent dislocation are the possible adverse events after SEMS placement, requiring endoscopic intervention in 20%-25% of the patients. Stent migration is more frequent for the covered than the uncovered SEMS[102].

Other complications of enteral SEMS are, bowel perforation and bleeding (< 1%), sometimes due to the uncovered ends of the SEMS[105,106]. The mesh pressure on the epithelium induces tissue regeneration, resulting in the ingrowth of the tissue, conditioning stent failure[107,108]. Then, the placement of a covered-SEMS is preferable in non-surgical patients, or patients with an high risk of mortality and morbidity, with a life expectance > 2-3 mo. Covered stent are usually placed inside of an uncovered stent, in presence of tissue ingrowth or for tumor recurrence and if a leak is present[109,110]. The disadvantage of the covered SEMS is the tendency to migration, even more rare for uncovered SEMS. The migration of a stent might be due to an inadequate stent diameter or after chemotherapy, if a reduction of the neoplastic mass is obtained[111].

COLON AND RECTUM DISEASES

Benign disease

Colo-rectal benign strictures are likely to endoscopic treatment: anastomotic strictures, post-ischemic, Crohn's disease strictures and post-actinic stenosis[112]. Among these, the most frequent is the anastomotic stenosis. It appears on 22%-30% of patients undergoing colorectal surgery and is the most benign colonic pathology treated endoscopically, especially with pneumatic (balloon) or mechanical (Savary) dilation.

Stenting in non neoplastic colorectal stricture is proving to be a viable therapeutic alternative with the intent to bring down the number of endoscopic sessions required to achieve the resolution of the stenosis itself. The data published so far on the use of stents in this setting are still limited and often conflicting.

In the benign stenosis the stents are used with the aim of solving the occlusion or sub-occlusion bowel, which is sometimes an emergency surgical. On the use of stents in benign colorectal diseases are still a few data and with time follow-up is limited, lacking in the literature randomized studies. The results on the efficacy and safety of stents in benign colorectal obstruction is controversial because of the high numbers of adverse events, especially considering the high migration rate[113].

Published studies have demonstrated that colonic stenting in the benign disease has a technical success variable from 85% to 100% with a complication rate of around 30%. The most serious complications observed, although rare, are leaks, bleeding and perforation but the most frequent adverse event is SEMS dislocation[114].

Furthermore, from the "case series" published on colo-rectal inflammatory diseases treatable with SEMS, diverticular stricture are those associated with the higher rate of complications. In fact, as noted by the study of Keränen *et al*[115] the endoscopic stenting in diverticular stenosis is burdened by a considerable risk of adverse events (as leaks, abscesses and perforations) with the need for surgical management in 70% of patients treated with stent[115]. Therefore, the use of stents in diverticular stricture is actually not recommended. The most frequent stricture treated by insertion of stent is than the anastomotic one.

Self-expandable plastic stent

Published data on the use of self-expandable plastic stent in non-neoplastic colonical and rectal diseases consists of case reports and series only[114,116].

Dai *et al*[114] described a series of 14 patients with benign colon and rectal diseases in which SEPS was implanted, anastomotic leak healing in 67% of the patients (4/6) and colonical disobstruction was obtained in the 50% of the patients (7/14). In 2 of 7 patients (28.5%) re-intervention was performed because stricture recurrence at 37 mo[114].

FC self-expandable metal stent

Actually, the biggest series on the use of the FC-SEMS was published in 2013 by the French Society of Digestive Endoscopy (SFED). The study includes 43 patients with bowel obstruction because of anastomotic, post-ischemic or post-radiotherapy stenosis. Stent placement was successful in the 100% of the patients. Clinical success was 81%. Stent migration was in 63% of the cases. The median left in place of the stent was of 21 d. Statistical analysis evidenced that FC-SEMS with a diameter less than 20 mm have a major risk of migration. Recurrence of occlusion was observed in

53% of the cases (23 patients). No predictive factors for occlusive or sub-occlusive symptoms recurrence were individuated at multivariate analysis[117].

Biodegradable stents

Although the use of this stent is limited to benign esophageal strictures, its application on colonic benign stenosis are reported.

Recently was reported its successful use for the treatment of a sigmoid stricture due to Crohn disease[118], however the majority of the published studies on the use this stent in colo-rectal benign strictures is referred to anastomosis.

Pérez Roldán *et al*[119] treated with the biodegradable stent 7 patients with postsurgical colorectal stricture and 3 with rectocutaneous fistula. In 9 patients the biodegradable stents were correctly placed; one early migration was observed. In one patients stent placement was not possible because of the distance to the anal orifice (30 cm) and the deformed anatomy site. Leak healing was obtained in 100% of the cases, despite recurrence was observed in one. Symptoms relief was observed in the 83.3% (6/7) of the occluded or sub-occluded patients; in the other case, the stent migrated 72 h after the placement[119].

Repici *et al*[120] studied 11 patients with anastomotic strictures within 20 cm from the anus, refractory to 3 sessions of endoscopic dilation. They obtained 100% of technical success. In the first 14 d after endoscopic stent placement Authors observed 4 dislocations, with subsequent stricture recurrence. Of the 7 cases with completely meshes biodegradation, 5 had no more symptoms and benign stenosis resolution. In 2 patients surgery was needed. The described clinical success was of 45%[120].

Malignant disease

The endoscopic colo-rectal stenting is indicated for bowel obstruction caused by neoplastic stenosis of the colon-rectum determining a bowel obstruction.

Endoscopic stent placement is also indicated for decompression before of elective surgery (bridge to surgery) in patients affected by colo-rectal neoplasia to avoid emergent surgery and as palliation in presence of patients unfit for surgery candidates because of advanced disease or their poor clinical conditions.

The very low stenosis, which are less than 5 cm from the anus are a contraindication to the stenting. In the case of very low stenosis the use of the stent is invariably associated with the appearance of tenesmus, anal pain and incontinence, making intolerable the presence of the stent in the distal rectum.

More than 20% of patients with acute colo-rectal neoplastic occlusion present metastases and 2/3 of them are unfit for surgery[121,122].

Then, the SEMS placement, especially in patients not suitable for surgery, allows a re-canalization of the bowel patency, avoiding surgery.

In patients with advanced colo-rectal neoplasia causing bowel obstruction surgical intervention with stoma creation is generally performed, with negative implications for patient quality of life[123]. The endoscopic stenting by use of SEMS is nowadays accepted in the palliative therapy of the colo-rectal cancer, becoming a valid alternative to surgical stoma.

Different studies evaluated the role of the SEMS in the palliation of colo-rectal cancer. Three randomized studies are present in literature comparing endoscopic stenting with surgery in patients unfit for surgery affected by colo-rectal neoplasia, causing bowel obstruction.

In these 3 RCTs studies the technical and clinical success was of 92% and 92% respectively, with a morbidity rate of 30% (11/37) in the patients underwent endoscopic stenting and 17% (6/36) in the patients underwent surgery, and a mortality of 8% (3/37) only in the stent group[124-126]. Two of the three Authors of the RCTs suggest superior efficacy and safety of the SEMS group if compared to surgery for palliation of colorectal cancer obstruction, differently to the reported data by the Dutch Stent-in I multicenter RCT. However, in palliated patients with a longer lifespan, SEMS placement in comparison to a colostomy, presents an improvement of the life quality, and with a reduction in cost and length of hospital stay[127,128]. Stents used were the WallFlex (Boston Scientific). The study was closed before the total patients enrollment for the high recorded numbers of perforations related to the SEMS placement, with 3 consequently deaths in 10 patients of the group undergone stenting. Authors had not a clear reason for justifying the high rate of perforations. They supposed a doubtful safety of the WallFlex.

Moreover, no supporting results have been showed by other studies in which WallFlex SEMS was tested as palliative treatment in referral centres. This studies show as the experience of the endoscopist could be an explanation for the high rate of adverse events reported by the Dutch group[129-131].

Bridge to surgery has to be seriously considered in presence of patients with acute obstruction and fit for surgery. SEMS placement provides to bowel patency restoration allowing colonical preparation for surgery and an eventual pre or intra-operative endoscopy for the research of synchronous neoplastic and non-neoplastic diseases. The curative intent for these patients is a single-step intervention with primary anastomosis, especially when a laparoscopic approach is possible.

However, the role of SEMS as bridge to surgery, has been widely debated, because several RCTs studies have shown conflicting and mixed results.

In the 6 RCTs in which endoscopic stenting was evaluated as bridge to surgery (171 patients) compared to emergency surgical resection (169 patients), the technical and clinical success of stenting was 79% and 77% respectively, with a morbidity rate of 33% in the

SEMS group and 53% surgical one with a comparable mortality rate (7% *vs* 8%)[132-137].

Notably evident is the difference in results between RCTs studies carried out in single centers *vs* those carried out in multicenters, particularly with respect to the stent placement outcomes and for the elevated number of stent-related perforations.

An elevated number of stent-related perforations were reported only in the studies specifically designed as multicenter trials and these studies were stopped prematurely.

In these trials, Pirlet *et al*[133] reported 3 stent-related perforations in 35 patients randomized to the stenting strategy and van Hooft *et al*[134] reported 6 stent-related perforations in 47 patients in the stenting group. The elevated number of perforations in these studies remains unexplained.

The worst results in SEMS placement outcomes come from RCTs which are specifically designed as multicenter trials involving low-volume centers. In the of Pirlet *et al*[133], of the nine participating centers, two of them enrolled 3 patients and one only 1 patient; in the study of van Hooft *et al*[134] 21 on 25 endoscopic centers were not referral.

The problem is that in planning RCTs regarding colonic stent placement, the need for involving multiple centers caused the inclusion of endoscopists with limited specific experience and low performance in placing stents. Therefore, this reality could result in confounding data on the real efficacy of the stenting strategy.

Huang *et al*[138] published a recent systematic review and meta-analysis evaluating safety and efficacy of colo-rectal stent placement as bridge to surgery compared to emergency surgery and considered for inclusion the 6 RCTs studies in english language and also another study in chinese language[138].

The technical success of colo-rectal stenting was of 76.9%, in absence of significant statistically difference in the postoperative mortality (10.7% *vs* 12.4%). The study evidenced lower morbidity (33.1% *vs* 53.9%, $P = 0.03$), higher rate of successful primary anastomosis (67.2% *vs* 55.1%, $P < 0.01$) and lower rate of definitive stoma (9% *vs* 27.4%, $P < 0.01$) for the group undergone stent placement[139].

None oncologic adverse events were recorded in the bridge to surgery group, but a major rate of lymphatic invasion was found[140-142]. No significant difference in survival were founded over 5 years (60% *vs* 58%)[143].

Colon stenting procedure does carry some risks, and complications are usually divided into early (within 30 d), including perforation, misplacement, and bleeding, and late, which include migration, reocclusion, tenesmus and delayed perforation.

The most common adverse event described in literature after stent placement as the migration (11%) SEMS obstruction caused by in and overgrowth tissue (12%) and bowel perforation (4.5%), as showed from a systematic review involving 88 published studies[144].

Stent obstruction is generally due to fecal impaction after tissue in or overgrowth, determining the long-term outcomes of the metal stent. The rate of SEMS obstruction by tissue in or overgrowth increases with the time because of the natural tendency of the neoplastic tissue to advance; then, SEMS occlusion is more frequent in patients in which the SEMS is placed for palliation. Literature data evidenced a 16% of SEMS occlusion when the treatment is made with palliative intent[145].

The endoscopic SEMS placement inside a stent is actually the best treatment to solve the stent obstruction due to the tissue in or overgrowth[146].

The migration of a SEMS could be asymptomatic or may cause occlusive or sub-occlusuve symptoms. More rarely is the bleeding. Tenesmus may be present when the SEMS reaches the rectum. Removal of a migrated stents from the rectal ampulla is not a challenging situation and can be also performed manually. Risk factors related to migration are the covering of the stent and the diameter < 24 mm. Some Authors stated that chemotherapy could be also related to the migration because of tumor reduction[147-149].

When the patient becoming symptomatic, the migration of the stent could be treated with the placement of a second one.

Bowel perforation is typically regarded as the only serious complication and is generally procedure or stent related. Most of the perforation occurred within 7 d after stent placement and may be caused by the SEMS delivery insertion into the stricture before the stent deployment, pneumatic dilatation of the stenosis or incorrect advancing of the wire. More rarely the perforation is due to the decubitus of the flared ends of the SEMS on the colonic wall. Over inflation with air can cause a perforation in a yet dilated colon far away from the site of obstruction, usually in the cecum[150-152].

Datye *et al*[152] reviewed the factors involved into the bowel perforation after stent placement, collecting the data from 82 published articles with 2287 patients. They showed a mortality rate related to perforation of 16.2% for patients who had stent-related perforation. The majority of adverse events (> 80%) were recorded within 1 mo from SEMS deployment, and 50% within 24 h from the procedure. Concomitant chemotherapy, steroids, and radiotherapy were significantly associated with perforation[153].

Bevacizumab therapy is considered now a considerable risk factor for post-stenting bowel perforation. The antiangiogenic effect could impair the colonic wall promoting the perforation at the site of maximal stent exercised pressure. Moreover, this perforation risk might be not dependent from the SEMS placement because is nowadays well known that spontaneous bowel perforation can occur during the addition of bevacizumab to chemotherapy.

Abstract

Over the past 30 years, the field of endoscopy has witnessed several advances. With the advent of endoscopic mucosal resection, removal of large mucosal lesions have become possible. Thereafter, endoscopic submucosal resection was refined, permitting en bloc removal of large superficial neoplasms. Such techniques have facilitated the development of antireflux mucosectomy, a promising novel treatment for gastroesophageal reflux. The introduction and use of over the scope clips has allowed for endoscopic closure of defects in the gastrointestinal tract, which were traditionally treated with surgical intervention. With the development of per-oral endoscopic myotomy (POEM), the treatment of achalasia and spastic disorders of the esophagus have been revolutionized. From the submucosal tunnelling technique developed for POEM, Per oral endoscopic tumor resection of subepithelial tumors was made possible. Simultaneously, advances in biotechnology have expanded esophageal stenting capabilities with the introduction of fully covered metal and plastic stents, as well as biodegradable stents. Once deemed a primarily diagnostic tool, endoscopy has quickly transcended to a minimally invasive intervention and therapeutic tool. These techniques are reviewed with regards to their application to benign disease of the esophagus.

Key words: Per-oral endoscopic myotomy; Per-oral endoscopic tumor resection; Antireflux mucosectomy; Submucosal tumors; Subepithelial tumors; Over the scope clips; Stents; Gastroesophageal reflux disease

Core tip: Antireflux mucosectomy is an endoscopic antireflux procedure showing promising results in patients with refractory gastroesophageal reflux. Over the scope clips and esophageal stents permit safe endoscopic closure of esophagogastric defects, decreasing the requirement for surgical intervention. Per-oral endoscopic myotomy allows the precise performance of endoscopic myotomy for the treatment of spastic esophageal motility disorders with the efficacy of a surgical myotomy without the associated surgical morbidity. Per-oral endoscopic tumor resection enables en bloc endoscopic removal of subepithelial tumors (SETs) and is both a diagnostic and therapeutic intervention for esophageal SETs. These techniques will expand the boundaries of therapeutic endoscopy, decrease the need for surgical intervention, and improve patient outcomes.

endoscopy in the esophageal benign diseases. *World J Gastrointest Endosc* 2015; 7(5): 481-495 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/481.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.481

ENDOSCOPIC ANTI-REFLUX PROCEDURES AND ANTI-REFLUX MUCOSECTOMY

Background

Gastroesophageal reflux disease (GERD) is one of the most common gastrointestinal problems with an estimated increasing prevalence of over 25% in North America[1,2]. Consequently, it is a source of significant morbidity as well as considerable healthcare costs. In the United states alone, an estimated 9.3 billion dollars was incurred in direct healthcare cost as a result of GERD[3].

The standard surgical treatment for GERD is the Nissen fundoplication, where the fundus is wrapped around the lower esophagus to reinforce the lower esophageal sphincter (LES). This produces excellent short-term results and is generally safe with a post-operative complication rate of approximately 2%[4]. A recent multicenter randomized trial showed that there was no significant difference in symptom remissions at five years follow-up between oral esomeprazole therapy and laparoscopic Nissen fundoplication[5,6]. Studies with longer follow-up, have reported relapse rates of up to 50% at 12 years post-laparoscopic Nissen fundoplication[7,8]. Furthermore, reoperations in these patients has increased morbidity and relapse is still a possibility[9,10].

Recently, there has been great interest in pursuing endoscopic alternatives to laparoscopic antireflux surgery. There are three categories of such procedures; endoscopic devices for gastric plication, injection/implantable substances at the gastroesophageal junction (GEJ) and ablative therapies.

Endoscopic suturing devices allow plication 1-2 cm below the GEJ with the goal of reinforcing the LES, mimicking laparoscopic anti-reflux surgery. Depending on the device used, total procedure times vary from 30-60 min. However, due to safety, cost, and questionable long-term efficacy, many of these devices are no longer available. One currently available device is EsophyX® (EndoGastric Solutions, Washington, United States) which is marketed to deliver transoral incisionless fundoplication. Due to the fact that long-term efficacy data are not available, significant cost of the device, and the need to confirm safety and define optimal technique, it has not become widely used[11].

Injectable treatments where liquid chemical polymers are directly injected into the LES result in bulking and reinforcement of the natural barrier to reflux. These treatments demonstrated promising early results, but have been removed from the market due to safety concerns related to transmural injection resulting in mediastinits, pericarditis, and death[12-14].

Ablative therapy consists of thermal energy delivered to the GEJ, which results in tissue remodeling that provides reinforcement to the LES. Stretta® (Mederi Therapeutics Inc., Connecticut, United States) is a currently available device which delivers low radiofrequency energy. The Stretta device has been available in the United States since 2000 and has good safety data, contrary to many of the previously mentioned therapies. In short and mid-term follow-up, there is evidence of significant improvement in subjective and objective indicators of GERD. Long-term efficacy has not been consistently demonstrated with some series showing 60% of patients proceed to antireflux surgery, while other series have shown a more durable response[15-19].

Many of the studies on endoscopic antireflux procedures are limited to small single-center case series demonstrating good short-term improvement in symptoms. However, consistent long-term durable efficacy has not been shown, with the few randomized control studies failing to show improvement over sham control arms. Due to the lack of convincing evidence for adequate long-term symptom control, associated high-cost and some safety concerns endoscopic antireflux procedures have failed to become widely used.

With the introduction of strip biopsy by Tada *et al*[20] in 1984, endoscopic resection with local injection of hypertonic saline injection (ERHSE) by Hirao *et al*[21] 1988, cap EMR by Inoue *et al*[22] in 1990 and subsequent development of ESD in Japan, resection of superficial gastrointestinal neoplasia was revolutionized[20-24]. The safety and efficacy of EMR/ESD have been well reported and are now widely applied by endoscopists around the world[23-25]. A known complication of esophageal EMR/ESD, particularly when more than two-thirds circumferential, is stricture development[26-28]. The exact mechanism of stricture formation is unknown. However, from experimental models it has been shown to involve acute inflammation, angiogenesis, fibrous hyperplasia with replacement of the submucosa with dense collagen fibers, and ultimately, atrophy of the muscularis propria[29,30]. In 2003, Inoue *et al*[22] reported a case of circumferential EMR for short-segment Barretts with high-grade dysplasia that was found on endoscopy performed for objectively confirmed (24-h esophageal pH testing) reflux symptoms. A circumferential EMR was performed extending to include a 2 cm wide portion of the gastric cardia. It was hypothesized that this would improve the reflux symptoms by causing fibrosis at the gastric cardia resulting in reinforcement of the LES. As expected, excellent symptomatic and objective (normalization of 24-h esophageal pH testing) improvement resulted and the patient has remained off of PPI for over 10 years[31]. Then in 2014, Inoue *et al*[32] published a series of 10 patients that received the antireflux mucosectomy (ARMs) procedure for

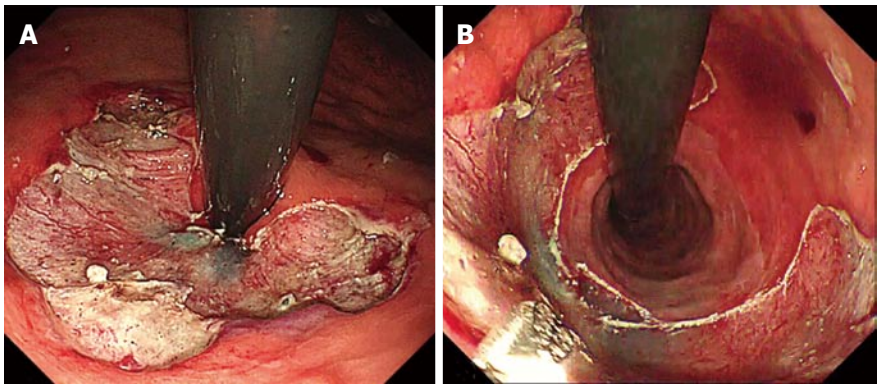

Figure 1 Completed antireflux mucosectomy. A: View on expiration; B: View on inspiration.

refractory GERD showing excellent results both subjectively and objectively.

Indications

Patients with GERD that are considered for ARMs are those without a large sliding hiatus hernia that have been objectively confirmed to be PPI refractory on 24-h esophageal pH testing. The presence of Barrett's esophagus does not preclude the performance of ARMs.

Technique

The ARMs procedure can be performed with ESD or EMR and is generally as follows: Step 1: Marking of area for mucosectomy. Mucosal reduction is planned along lesser curve of the gastric cardia in crescentic fashion (Figure 1A). When retroflexed in the stomach, the length of preserved mucosa on the side of the greater curve is estimated at twice the diameter of the endoscope (approximately 2 cm); Step 2: Submucosal injection. Both EMR and ESD can be used depending on the experience of the operator and the presence of mucosal lesions. Submucosal injection is made along the markings to ensure adequate lift to prevent deep injury or perforation; and Step 3: Mucosectomy. The mucosectomy is performed *via* EMR or ESD (Figure 1B).

Safety

In the first two cases of ARMs, circumferential mucosectomy was performed which resulted in stricture formation, however these were successfully treated with balloon dilation. Subsequently, all ARMS were performed in a hemi-circumferential or crescentic fashion that produced adequate fibrosis to alleviate GERD without stricture formation[32].

Efficacy

All patients had significant improvement in subjective and objective indicators of GERD. The DeMeester, heartburn and regurgitation scores all showed significant impressive improvement. Twenty-four hours esophageal pH testing showed the mean fraction of time at pH < 4 improved from 29.1% to 3.1%[32].

Conclusion

This series of ARMs showed promising safety and efficacy, however, the sample size was small, owing to the low incidence of GERD in Japan. Larger randomized sham-controlled studies with long-term follow-up are required to confirm these findings. Unique aspects of ARMs as an endoscopic treatment for GERD is that the safety of EMR/ESD has already been established, and endoscopists are already familiar with these techniques. These facts would allow ARMs to potentially be performed by most endoscopist with expertise in esophogastric EMR/ESD. In addition, there is no requirement for new, expensive specialized equipment. Thus, if future studies confirm the early promising results of ARMs, it has the potential to become a widely used endoscopic treatment for GERD, as it would meet the demands of safety, efficacy and cost-effectiveness.

OVER-THE-SCOPE CLIPS

Background

The over the scope clips (OTSCs) were initially introduced for closure of perforations and for mechanical hemostasis of complicated arterial bleeds of the gastrointestinal tract. The OTSC consist of a nitinol alloy with a similar shape to a bear trap. The clip, is preloaded on a clear applicator hood which is mounted onto the scope tip. The deployment system is analogous to that of a variceal banding device with the string running through the working channel of the endoscope and is fastened to a rotatable handle that is attached to the port of the working channel.

Indications

Specifically pertaining to the esophagus, the OTSC has successfully been used for refractory bleeds (non-variceal), closer of iatrogenic perforations, Boerhaave's syndrome, anastomotic leaks, tracheaesophageal fistula and securing fully covered self-expandable metal stents (SEMS)[33-43].

Technique

After mounting of the OTSC, the target area is identi-

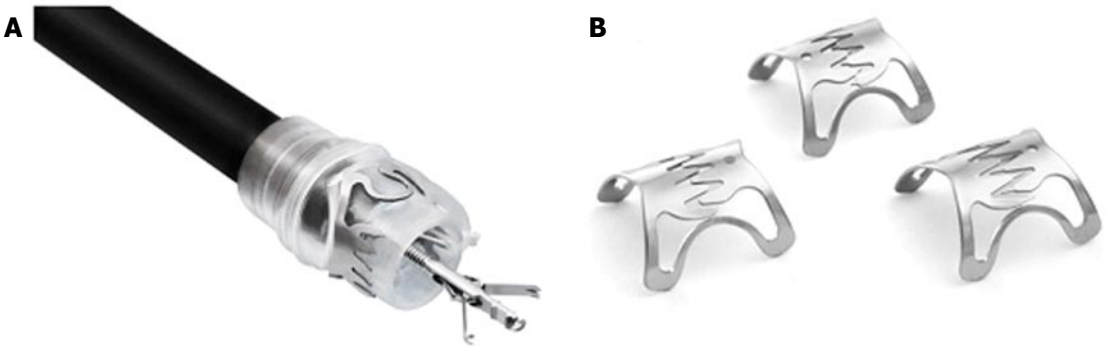

Figure 2 The over the scope clip device. A: Clip mounted onto the distal tip of an endoscope with Twin Grasper projecting from the working channel; B: The different over-the-scope clip tooth configurations available. (With permission from OVESCO Endoscopy, Germany).

fied, suctioned into the hood and the clip is deployed bringing the tissue into apposition. Alternatively, one of the available graspers or anchor can be used, allowing for dimproved apposition of the defect and better visualization of the tissue prior to clip deployment (Figure 2). Once the clip is deployed a permanent closing force of 8-9 Newtons (N) is applied to the tissue without causing necrosis[43]. Depending on the indication, different teeth are available; rounded (type a, Figure 2B left) for atraumatic application, pointed (type t, Figure 2B middle) and long pointed (type gc, Figure 2B right) for more tissue apposition. Some of the challenges with the OTSC device are that it limits sharp angulation which can make maneuverability in the esophagus more challenging and the attached OTSC device slightly impairs the endoscopic view.

Safety

Complications with the OTSC have been uniformly rare in all the published series, the majority reporting no or few complications[33-41,43-52]. However, isolated cases of esophageal perforation, inadvertent tongue piercing and intestinal obstruction (from accidental inclusion of opposing walls into the OTSC) have been reported[44,51,53].

Efficacy

The OTSC device has been shown to be safe and effective for refractory arterial GI bleeding and closure of iatrogenic perforations 20 mm and smaller[47,51]. The successful closure of anastomotic leaks and fistulas in case series has been largely favorable, but efficacy has varied widely between 38%-100% in published series, due to heterogeneity of cases, series size and operators experience[36-38,40-43,45,48-51,54,55]. However, two recent meta-analysis showed success rates of 80%-100% for both perforation and fistula closure, with failure usually associated with chronic fibrotic fistulas[52,56]. Most recently the European Society of Gastrointestinal Endoscopy released its position statement on iatrogenic endoscopic perforations and endorsed the use of the OTSC device for closure of iatrogenic esophageal perforations[57].

Conclusion

Multiple studies have reported that the OTSC device has good clinical efficacy for closure of esophageal, perforations, fistula and anastomotic leaks with few complications. Depending on the expertise available the OTSC device can be considered an early treatment option for esophageal perforation, leaks and fistula.

POEM

Background

Achalasia is an esophageal motor disorder resulting from inhibitory neuron dysfunction causing loss of peristalsis and impaired LES relaxation. This leads to impaired food bolus propulsion and stasis in the esophagus. Patients may experience dysphagia, regurgitation, chest pain, weight loss and heartburn[58-60]. The conventional treatments are laparoscopic Heller myotomy (LHM) and pneumatic dilation (PD). The first account of an endoscopic myotomy dates back to 1980 by Ortega *et al*[61] in Venezuela, where they described two 1cm long myotomies to a depth of 3 mm performed at the LES in 17 patients. In 1997, Pasricha *et al*[62] in the United States, described an experimental technique on a bovine model, where a mucosal incision was made five centimetres above the GEJ and a balloon was placed into the submucosal space to create a tunnel down to the GEJ, where a myotomy of the circular muscle was performed[62]. In 2010, Inoue *et al*[32] in Japan modified the endoscopic myotomy procedure such that it permitted safe and effective human application. Since the introduction of POEM, there has been an dramatic increase in POEM studies and the procedure is now being performed worldwide.

Indications

Currently, there are no universal guidelines for the indication of POEM. It is the opinion of the authors of this review that with the reported efficacy and safety from our center, that POEM can be considered a first line treatment for achalasia. POEM has been safety performed in patients with previous PD, LHM, Botox injection, and even previous POEM. In our center, it

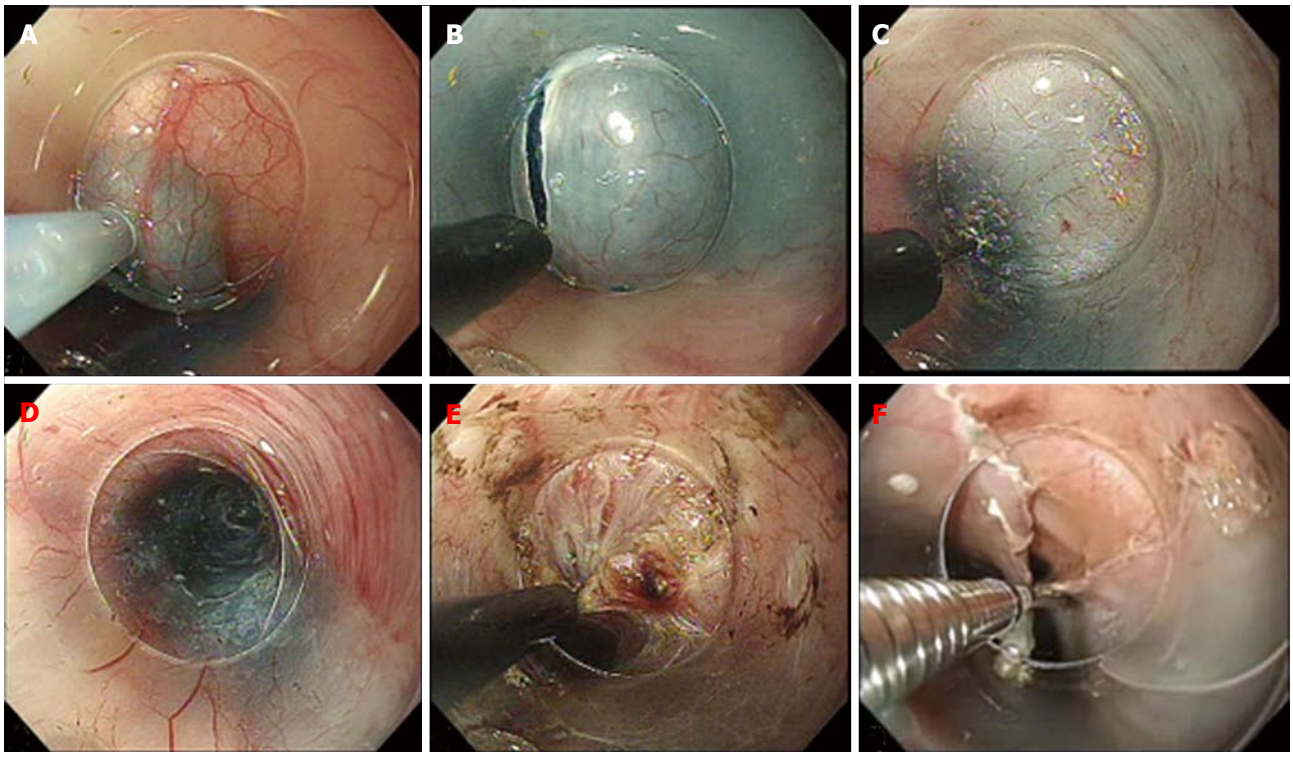

Figure 3 Steps in Per-oral endoscopic myotomy. A: Submucosal injection; B: Mucosal incision; C: Submucosal tunneling; D: Completed tunnel; E: Circular muscle myotomy; F: Closure of mucosal incision.

has also been safely performed in patients with type 1 and type 2 sigmoid achalasia as well as octogenarians. Other motility disorders such as diffuse esophageal spasm (DES), nutcracker esophagus, Jack-hammer esophagus, and hypertensive LES have also been successfully and safely treated with POEM.

Technique

The first successful case of POEM in a human was performed September, 2008 by Haruhiro Inoue. Since then, it has been widely accepted and performed with many slight variations to the original technique. The procedure as performed at our center is as follows (Figure 3): Step 1: Submucosal Injection and Incision. After the area of mucosal incision is chosen (approximately 13 cm above the GEJ for standard myotomy) 10 cc of saline with indigocarmine is injected into the submucosa and a 1.5-2 cm longitudinal incision is made with a triangle-tip knife (KD-640 L; Olympus). To avoid mucosal injury, the submucosal tunnel is dissected as close as possible to the circular muscle; Step 2: Creation of the submucosal tunnel. After enough space is created in the submucosa, mucosal entry is achieved and the tunnel is carefully extended down to the gastric side for approximately 3 cm; Step 3: Endoscopic myotomy. The circular muscle fibers are carefully dissected with the Triangle tip knife. When there is no abnormal contraction of the esophageal body or symptoms of chest pain, the standard myotomy is 8-10 cm; and Step 4: Closure of Mucosal entry. After completion of the myotomy and good hemostasis is confirmed, prophylactic antibiotic is instilled into submucosal tunnel and the mucosal entry site is clipped closed.

The main technical limitation to the performance of POEM is the presence of severe submucosal fibrosis which limits the ability to safety perform the submucosal tunnel and can occur when patients have had severe esophagitis, multiple previous endoscopic treatments, extensive esophageal EMR/ESD in the POEM field or radiation therapy.

Safety

Complications include; capnomediastinum, capnoperitoneum, intraprocedural and delayed bleeding, mucosal laceration/ischemia and GERD. The vast majority of complications reported have been treated conservatively and there have been no mortalities reported or requirement for conversion to open surgical procedure[63-73]. The most robust data comes from the international POEM survey (iPOEMS) database, reporting major complications occurred in 3.2% of 841 cases[74] which were treated conservatively without sequelae. In comparison, the large European trial comparing PD and LHM showed a 4% perforation rate for PD and a 12% rate of mucosal tear for LHM[75].

There is heterogeneity in reporting and classification of complications, partially accounting for the variability in reported complication rates (Table 1). Therefore, a standardized, internationally agreed upon adverse event reporting system for POEM is required. However, it is important to note that all the reported complications

[a]Eckard score was not used, but rather a dysphagia symptoms score which decreased from mean of 10 to 1.3; [b]All patient had previous laparoscopic Heller myotomy; [c]European and North American; [d]Included other spastic esophageal disorders, total 31 achalasia cases; Complications rate reported is for all 40 cases performed. NR: Not reported.

have been treated successfully endoscopically, with needle decompression or conservative management without any significant sequelae.

Efficacy

POEM is now being performed globally with excellent clinical results, with patients showing improvement of mean Eckardt scores from 5.4-8.8 pre-POEM to 0.4-1.7 post-POEM[63-68,76-81]. In addition, many series have reported decreases in LES pressure and barium column height[63-67,76-79,82]. Success rates, defined by a post-POEM Eckardt score $\leqslant$ 3, are summarized in Table 1. Multiple comparative studies have shown that POEM is at least as effective as LHM with shorter hospital stay and decreased post-procedure pain[76-78].

POEM has also been shown to be effective in patients with previous LHM. Zhou *et al*[83] reported a mean improvement in Eckardt score of 9.2 to 1.3, and Onimaru *et al*[81] reported a mean improvement in Eckardt score of 6.5 to 1.1. Patients who have failed Botox injections or PD have also seen comparable improvements post POEM[84].

Expanded Indications for other spastic esophageal motility disorders

Generally, other spastic disorders of the esophagus that have been treated surgically require a longer myotomy necessitating thoracotomy. This is another advantage of POEM, where a long myotomy can be performed without increased invasiveness or complications. From the iPOEMS database, the POEM procedure was performed in 25 DES patients, 106 Nutcracker patients, and 58 Hypertensive LES (HTLES) patients. Compared to achalasia, POEM was equally effective in Nutcracker esophagus and HTLES, but less effective for DES[74]. In the recent series by Sharata *et al*[73] that included 12 Nutcracker esophagus, 5 DES, and 8 HTLES patients, complete dysphagia relief was achieved in 70.8% of non-achalasia cases, while chest pain was relieved in 91.5%[73]. There are also two case reports demonstrating successful application of POEM for Jackhammer esophagus[86,87].

Areas of controversy

In our center, the majority of POEM cases were performed at 2 o'clock (anterior-lesser curve) or 5 o'clock (posterior-lesser curve) positions. In some cases, previous procedures such as LHM, POEM, or ESD (for esophageal lesion) had been performed, precluding safe submucosal tunnelling in the normal location and alternate positions were used. At present there are no studies to guide which site of standard myotomy is most optimal. This will hopefully be addressed with a large multicenter, randomized trial in the near future.

A selective circular muscle myotomy is normally performed in our center. Nevertheless, some centers prefer a full thickness myotomy. Li *et al*[88] compared full thickness myotomy with selective circular muscle myotomy and found no difference in either efficacy or adverse events. However, shorter operative times are observed with full thickness myotomy[88]. Until there is more evidence, we suggest an isolated circular myotomy to prevent potential damage to adjacent structures and.

Conclusion

Over 2000 POEM procedures have been performed worldwide. Most of the of the studies show excellent efficacy with low rate of major complications, all of which have been managed without sequelae. There is also growing evidence for the use of POEM for other spastic disorders of esophagus. Over time, POEM may arguably become the standard of care for achalasia and other spastic disorders of the esophagus.

PER-ORAL ENDOSCOPIC TUMOR RESECTION

Background

Subepithelial tumors (SETs) of the upper gastrointestinal tract are generally uncommon with an incidence of about 0.4% of all routine esophagogastric endoscopic examinations[89]. Gastric SETs have a malignancy rate of approximately 50%, in contrast, esophageal SETs are usually benign leiomyomas and only 1%-3% harbor malignancy[89-91]. Generally, SETs are asymptomatic and found incidentally on endoscopic or radiologic examination for unrelated symptoms or screening. However, larger SETs can cause dysphagia, chest pain, regurgitation and bleeding[92,93]. Traditionally, excision of symptomatic SETs has been performed with open surgical, laparoscopic or thoracoscopic techniques. These procedures are invasive, associated with significant health-care cost and morbidity[94-96]. In addition, if the lesion in question is benign it is difficult to justify surgical excision with associated surgical morbidity. With the introduction of POEM, the submucosal tunnelling technique has been subsequently applied for Per-oral endoscopic tumor (POET) resection by Inoue *et al*[97] in 2012. The technique has allowed SETs to be removed from the esophagus and gastric cardia, safety and effectively. Since its first description, multiple series have been published supporting its safety and efficacy.

Indications

Most of the SETs removed *via* POET have been benign. The presumptive diagnoses were made using a combination of endoscopy, endoscopic ultrasound (EUS) and CT scan. Indications for resection were presence of symptoms, enlarging tumor or unclear diagnosis in which resection was diagnostic.

Technique

An essential part of POET (and POEM) is use of low flow carbon dioxide insufflation to prevent complication from barotrauma as noted by Wang *et al*[98], where air insufflation was used in the first half of their series, which resulted in high rates subcutaneous emphysema, pneumothorax and pneumomediastinum. Subsequently, they used carbon dioxide insufflation for the remaining cases and did not have further adverse events related to insufflation[98]. The POET technique can be summarized as follows with the various steps shown in Figure 4: Step 1: Submucosal Injection and Incision. The area of mucosal incision is generally 5 cm proximal to the tumor and is made as described for POEM; Step 2: Creation of the submucosal tunnel. The submucosal tunnel is extended 1-2 cm distal to the tumor to ensure sufficient working space for the dissection of the tumour; Step 3: Tumour Resection. Once the mass is identified and the tunnel is sufficient, resection of the tumor can proceed. Careful dissection of the mass from the muscular layer should be performed to prevent rupture of capsule or perforation of the overlying mucosa. Tumors that extend to the deep muscular layer can be removed with a full thickness resection of the circular and longitudinal muscles. The free tumor can be withdrawn through the mucosal incision using a snare, grasping forceps or suctioning into the transparent hood; and Step 4: Closure of Mucosal entry. The tunnel is re-examined to confirm adequate hemostasis and the mucosal incision is closed with endoscopic clips. There are also reports of using endoscopic staples, OTSCs, as well as covered metal stents to seal the mucosal incision site[99-102].

Patients are managed analogous to post-POEM patients. Patients are kept nil per os for 24 h. Day 1 post-procedure the patient has an endoscopy as well as a contrast study to check for leak. Some centers perform routine post-procedure CT scan to check for insufflation related complications and perforation[103]. The patient's diet is advanced to clear liquids day-1 post-procedure, and advanced to regular diet by day 4 if asymptomatic. Endoscopy and endoscopic ultrasound are generally performed for follow-up on patients that underwent POET resection. If the lesion removed is malignant or with malignant potential, closer follow-up is performed and includes a CT scan to assess for tumor recurrence and the occurrence of distant metastasis[98,104].

Safety

Almost all of the reported complications have been insufflation related (subcutaneous emphysema, pneumoperitoneum and pneumomediastinum). All were managed with decompression or conservatively without sequelae. Analogous to POEM series, there is variability in reporting and classification of complications.

Efficacy

Nearly all series report 100% successful resection (refer to Table 2). With almost all being *en bloc* with intact capsule. A complete resection refers to an en bloc resection of the tumor with intact capsule. This factor is important to prevent seeding especially if the pre-procedure diagnosis is suggestive of a malignant or pre-malignant lesion. The limiting factor for resection of SETs *via* POET is size. The largest SET removed to date was 60 mm × 28 mm × 22 mm[100]. The tumor (known to be a leiomyoma) required fragmentation to be extracted. In addition, the mucosal incision could not be closed and necessitated placement of fully covered SEMS. Anecdotally, it appears that the upper limit for a complete resection is 4-5 cm depending if the shape of the tumor allows for extraction through the mucosal incision site. The efficacy data is summarized in Table 2[97-99,105-111] below.

Conclusion

Subepithelial tumors of the esophagus and cardia are usually incidental findings on endoscopic or radiologic examinations for unrelated symptoms, with

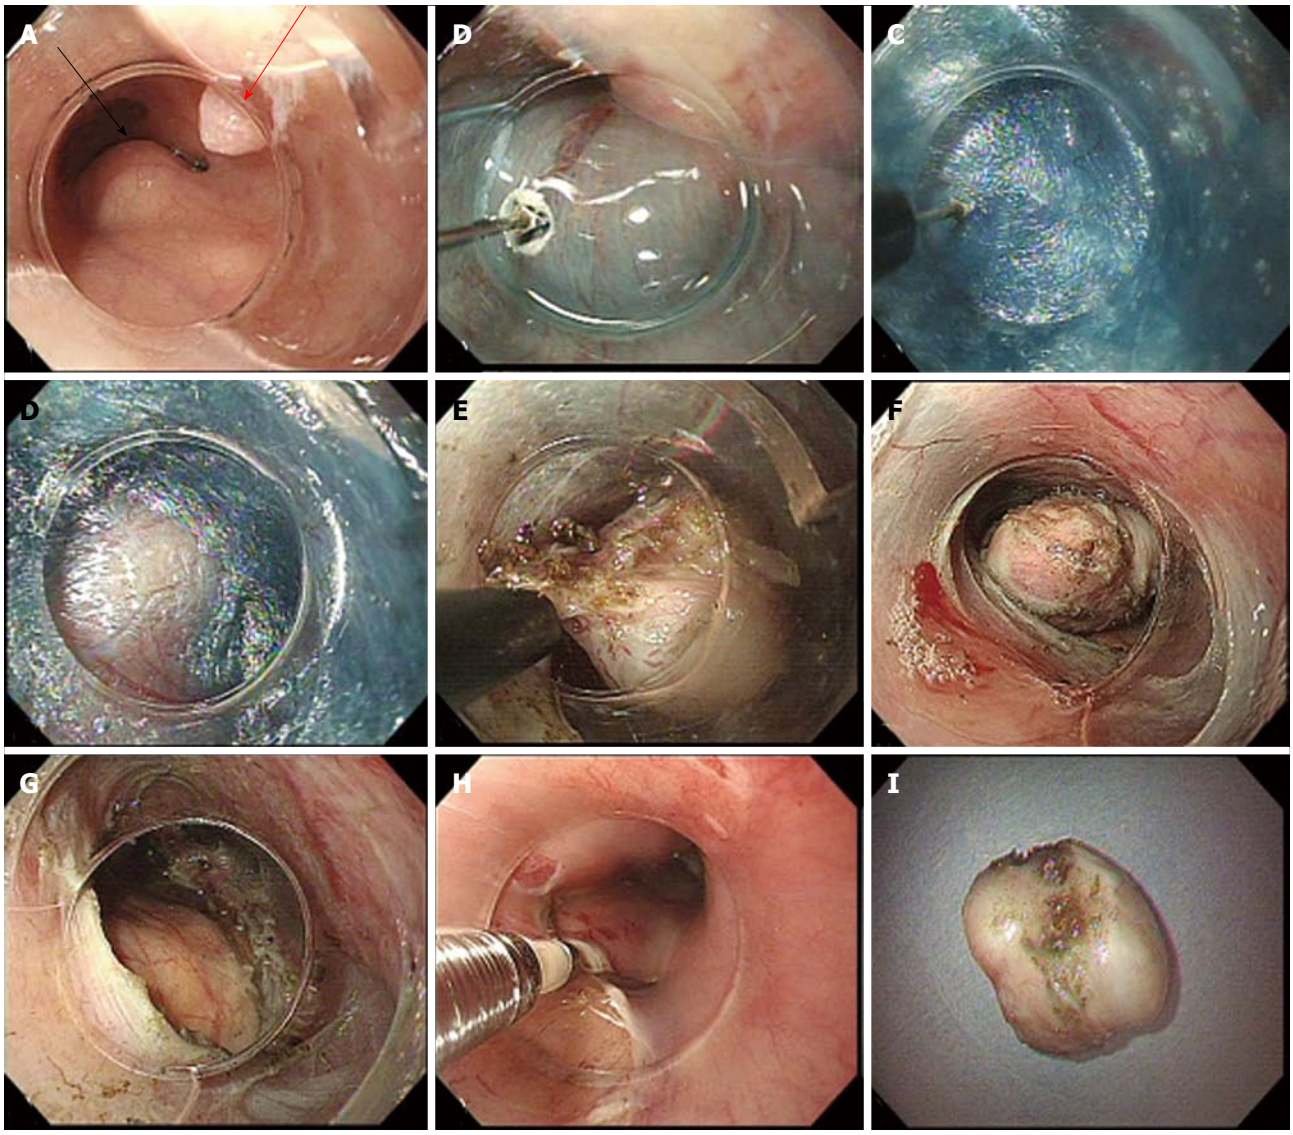

Figure 4 Per-oral endoscopic tumor resection of Leiomyoma. A: Subepithelial tumor (SET) (black arrow) and incidental papilloma (red arrow); B: Mucosal incision with TT knife; C: Creation of submucosal tunnel; D: First encounter with SET in tunnel; E: Dissection of tumor; F: Dissected SET; G: Completed full thickness resection; H: Closure of incision; I: Extracted SET with intact capsule.

the majority being benign. With the moderate yield of EUS, morbidity and costs and surgical resection, a minimally invasive diagnostic and therapeutic procedure is required for the management of SETs. The careful performance of POET is effective and safe, and with continued supportive evidence will likely be performed with increased frequency for resection of most esophageal and gastric cardia SETs, with surgical resection reserved for very large or malignant SETs.

STENTS

Background

When first introduced in 1959, esophageal stents were placed intra-operatively and were indicated only for palliation of dysphagia for non-operable malignant strictures[112]. Endoscopic stents were subsequently introduced in 1977, but were plagued with high complication rates[113]. Since then, SEMS have become widely used for palliation of dysphagia for non-operable malignant esophageal strictures with good safety, efficacy, and cost effectiveness data[114,115]. With the success of SEMS for malignant esophageal disease, there was an effort to expand the use of uncovered/partially covered SEMSS for the use of benign esophageal disease. However, it was found early on that SEMS resulted in increased complications when used for benign disease. Such complications included migration, tissue ingrowth, stent induced stenosis, development of tracheoesogeal fistula, and hemorrhage[116-118].

With the hope to ameliorate the serious issues encountered with SEMS when used for benign disease, manufacturers introduced the fully covered self-expandable metal stents (FCSEMS), fully covered self-expandable plastic stents (SEPS) and biodegradable

stents (BDS).

Indications

For patients with iatrogenic perforations, tracheoesophgeal fistula, and/or surgical interventions complicated by anastomotic leaks, the treatment has traditionally been surgical. However, with the advent of FCSEMS and fully covered SEPS, these have been increasingly used as means to prevent reoperation and to allow healing to take place. Another emerging use is for refractory benign esophageal strictures in which traditional management with dilation has failed.

Equipment

There are currently a variety of stents available depending on the country. Below is a brief summary (Table 3) of the general differences between the FCSEMS, SEPS and BDS with focus on benign esophageal strictures. Examples of each group are shown in Figure 5.

Technique

Once the stricture has been deemed refractory and stenting is considered, or a defect requires closure, then the choice of stent depends on the position and length of stricture/defect and preference of the endoscopist. The length of the stent should be at least about 3-4 cm longer the stricture/defect. The endoscopist should carefully assess the stricture/defect noting the proximal and distal margins, the distance from the upper esophageal sphincter and LESs. The stricture/defect should be greater than 2 cm distal from the upper esophageal sphincter, as if this distance is less it increase the risk of of pain, globus sensation, aspiration pneumonia or development of tracheoesophageal fistula. If the stent is to be deployed across the LES, a stent with an antireflux valve can be considered if available. Once the location of stent placement is chosen, the proximal and distal margins can be marked endoscopically (submucosal injection of radiopaque substance or placement of clips), by specific anatomic landmarks under X-ray or placement of radiopaque markers on the patient. If simultaneous endoscopic visualization is desired, an ultra-slim scope can be used transnasally. Under fluoroscopic control, the stent is deployed keeping adequate margins on both sides. Endoscopic clips, OTSCs or an endoscopic suturing device can used to decrease the risk of stent migration[34,119-122]. After deployment, the stents will radially expand and shorten reaching their final form.

Efficacy

Efficacy is defined as technical and clinical success. Technical success is defined as successful deployment of the stent and clinical success is the achievement of the intended clinical outcome (improvement in dysphagia, closure and healing of defect). FCSEMS and fully covered SEPS show excellent technical and good clinical efficacy for the closure of benign gastrointestinal disruptions with a technical success of 91% and clinical success of 81%[123]. In the cases where only partial closure fully covered achieved, surgical reinvention is still often avoided[123].

Unfortunately, for benign strictures, the clinical efficacy of FCSEMS and fully covered SEPS is less promising than for benign disruptions with a range of clinical success of 40%-50%[124,125]. Biodegradable stents were introduced with the hopes of improving the shortcomings of modest clinical efficacy of FCSEMS and fully covered SEPS. Unfortunately, the clinical efficacy of BDS has not differed significantly compared to its predecessors, with a mean clinical success rate of 47%[126]. However, in the pediatric population, with the use of custom made plastic stents higher efficacy has been demonstrated. Also, with the stents fastened to a nasogastric tube with an external silicon bar at the

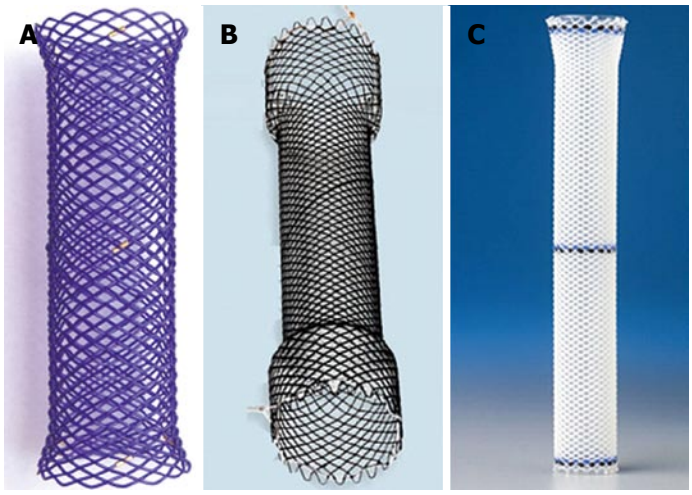

Figure 5 Examples of biodegradable stent, fully covered self-expandable metal stent and self-expandable plastic stent. A: Biodegradable stent (ELLA-CS, Czech Republic) composed of polydioxanone monofilament; B: Fully covered Evolution® stent composed of nitinol silicone coating (Cook, United States); C: Fully covered silicon constructed Polyflex® stent (Boston Scientific, United States).

Table 3 General differences between stents for benign esophageal disease

Stent type	Advantages	Disadvantages
FCSEMS	No requirement for pre-dilation	Expensive
	Recapture is possible	High migration risk
		Increased tissue hyperplasia
SEPS	Cheaper than other covered stents	High migration risk (potentially more than FCSEMS)
	Decreased tissue hyperplasia	Require manual loading
		Require pre-dilation
BDS	No need to remove	Expensive
	Less migration risk	Increased risk of post-procedure pain
		Require manual loading
		Require pre-dilation

FCSEMS: Fully covered self-expandable metal stents; SEPS: Self-expandable plastic stents; BDS: Biodegradable stents.

naris to avoid distal migration, much lower migration rates have been observed[127,128].

Safety

FCSEMS and fully covered SEPS have a modest complication rate, with the most common being stent migration at about 25%-30% with some evidence that the risk of migration is higher with SEPS[129,130]. The risk of migration may also be higher for proximal and anastomotic strictures[131]. Other rare complications of FCSEMS and fully covered SEPS include perforation, tissue hyperplasia, stent induced strictures, hemorrhage, and post-procedure pain. A very rare but dreaded complication is the development of an aortoenteric fistula, which is usually fatal[132-134]. BDS have a lower risk of migration of about 20% and fewer complications overall, but may have increased post-procedure pain[126,135,136].

Conclusion

There is mounting evidence for the efficacy of FCSEMS and fully covered SEPS for closure benign gastrointestinal disruptions with a moderate risk of stent migration. For refractory strictures, the efficacy is less promising likely owing to varying techniques, heterogeneity of patients and the severity of stricture pathology being treated. Depending on the individual case and the experience of the endoscopist, FCSEMS, fully covered SEPS, and BDS are potential options for select patients with refractory strictures. The particular choice of stent depends on the endoscopists preference and experience, perceived risk or migration, tissue hyperplasia and other complications. Hopefully with improvement in stent design, refinement in technique and patient selection, there will be improved clinical efficacy and safety for stents used for benign esophageal strictures.

SUMMARY

Endoscopy has drastically advanced from being primarily a diagnostic tool to becoming the favored modality for treatment of benign disease of the esophagus. Promising efficacy and safety data of POEM and POET is accumulating, and with careful application, these procedures may soon be heralded as the standard of care for various diseases. Despite being a novel procedure, there is extensive experience with the technique used in ARMs in the setting of EMR/ESD. With the early promising results of ARMs, it has the potential to become a prominent treatment of GERD if efficacy confirmed by larger randomized control trials. OTSC usage is becoming widespread and has a remarkably low complication rate with good efficacy in facilitating

the closure of esophageal perforations, fistula, and leaks. At present, the evidence for treatment of benign esophageal disruptions is promising and FCSEMS and SEPS should be considered in their treatment. However, for benign esophageal strictures the evidence for the use of FCSEMS, fully covered SEPS and BDS has been conflicting, but with further improvement in stent design and refinement of technique, there is potential for improved clinical efficacy.

With the ongoing introduction of novel procedures and equipment, it is critical that patient safety remain the top priority. International collaboration in the form of large multi-centered trials provide the opportunity to optimally study safety and clinical efficacy of newly introduced equipment and techniques.

Abstract

Peroral endoscopic myotomy (POEM) incorporates concepts of natural orifice translumenal endoscopic surgery and achieves endoscopic myotomy by utilizing a submucosal tunnel as an operating space. Although intended for the palliation of symptoms of achalasia, there is mounting data to suggest it is also efficacious in the management of spastic esophageal disorders. The technique requires an understanding of the pathophysiology of esophageal motility disorders as well as knowledge of surgical anatomy of the foregut. POEM achieves short term response in 82% to 100% of patients with minimal risk of adverse events. In addition, it appears to be effective and safe even at the extremes of age and regardless of prior therapy undertaken. Although infrequent, the ability of the endoscopist to manage an intraprocedural adverse event is critical as failure to do so could result in significant morbidity. The major late adverse event is gastroesophageal reflux which appears to occur in 20% to 46% of patients. Research is being conducted to clarify the optimal technique for POEM and a personalized approach by measuring intraprocedural esophagogastric junction distensibility appears promising. In addition to esophageal disorders, POEM is being studied in the management of gastroparesis (gastric pyloromyotomy) with initial reports demonstrating technical feasibility. Although POEM represents a paradigm shift the management of esophageal motility disorders, the results of prospective randomized controlled trials with long-term follow up are eagerly awaited.

Key words: Peroral endoscopic myotomy; Achalasia; Myotomy; Dysphagia

Core tip: Peroral endoscopic myotomy (POEM) is a minimally invasive, scarless approach to Heller myotomy for the palliation of symptoms of achalasia and spastic esophageal disorders. Current data demonstrates short-term success with minimal adverse events. POEM is no longer considered experimental with approximately 5000 procedures performed worldwide. In the future, a personalized approach to POEM will be undertaken with tailoring of the length of gastric myotomy based on intraprocedural physiological measurements. This will allow sufficient reduction in pressure at the lower esophageal sphincter for adequate relief of symptoms but also minimize gastroesophageal reflux.

INTRODUCTION

Peroral endoscopic myotomy (POEM) is a minimally invasive endoscopic procedure intended for long-term recovery from symptoms of esophageal achalasia. Achalasia is a benign motility disorder of the esophagus which is characterized by incomplete relaxation of the lower esophageal sphincter (LES) and aperistalsis of the esophageal body. As the etiology of achalasia is not known, all treatment options are directed at decreasing the resting pressure at the LES.

The first reported endoscopic myotomy in humans was published in 1980[1]. In this report, the myotomy was carried out in an uncontrolled manner by incising the mucosa through to deeper layers of the lower esophageal sphincter with a needle knife. The method achieved technical success in all 17 patients although there was concern as the wound was directly exposed to esophageal and gastric contents and if too deep, there would be a direct perforation to the mediastinum and/or peritoneum. There were three minor bleeding episodes which were controlled endoscopically. The clinical, manometric and radiological postoperative results were promising. However, the direct incision method was not considered a reliable and safe approach and was therefore not adopted by the medical community.

Developments in natural orifice translumenal endoscopic surgery (NOTES)[2] have resulted in a submucosal endolumenal approach for the treatment of achalasia using POEM. Sumiyama *et al*[3] was the first to describe the idea of submucosal tunneling. However, Pasricha *et al*[4] initially described the concept of POEM in 2007 in an experimental preclinical model. This report demonstrated the safety and efficacy of performing a myotomy under endoscopic visualization in 4 pigs after the formation of a submucosal tunnel. Inoue *et al*[5] championed translating this innovative technique into clinical care in 2010 with the first human study reporting favorable results in 17 achalasia patients.

Multiple studies from Asia, Europe and the United States reveal that POEM is a safe and effective therapy for achalasia when performed by expert endoscopists. In addition, the recent white paper summary from the American Society of Gastrointestinal Endoscopy provided substantial data to support the notion that POEM is a promising therapeutic modality[6]. This review illustrates the patient selection and preparation, operative technique, clinical outcomes and future directions for POEM.

PATIENT SELECTION AND INDICATIONS

All patients with symptomatic, manometrically proven, primary idiopathic achalasia are eligible candidates to undergo POEM. Among initial published clinical studies, exclusion criteria included previous esophageal or gastric surgery (including Heller myotomy), sigmoid type esophagus, age under 18 years or inability to undergo general anesthesia. Other less common scenarios that rendered patients unsuitable for POEM included severe erosive esophagitis, significant coagulation disorders, liver cirrhosis with portal hypertension or prior therapy that may compromise the integrity of the esophageal mucosa or could have led to submucosal fibrosis (radiation, endoscopic mucosal resection, radiofrequency ablation, *etc.*). Previous therapy, such as uncomplicated pneumatic balloon dilation and botulinum toxin injection are not contraindications to POEM, although, in these cases inflammatory fibrosis is often encountered during submucosal dissection.

There are now multiple series reporting the technical success, efficacy and safety of POEM in patients who have undergone a prior Heller myotomy[7-9]. Successful POEM in the setting of a Roux-en-Y gastric bypass has also been reported[10] where the extensive adhesions and altered anatomy could have proven challenging for the surgical approach. POEM has also been studied in patients with with sigmoid-type achalasia with similar outcomes as those with a non-sigmoid type esophagus[11]. Age is no longer a contraindication to POEM with successful procedures being performed in those even at the extremes of age. In particular, several series have reported its successful use in the pediatric population[12,13].

Though POEM is classically done for the palliation of symptoms of achalasia, it is being increasingly used for the treatment of other foregut disorders. There are growing reports supporting its use in spastic esophageal disorders such as diffuse esophageal spasm (DES) and Jackhammer esophagus[14-19]. It is potentially more efficacious than even surgical myotomy as it allows myotomy not only of the LES, but also of the esophageal body, where hypertensive contractions occur[15,20,21]. Additionally, POEM has even been reported in the stomach (endoscopic pyloromyotomy) as a treatment strategy for selected patients with gastroparesis[22,23].

EVALUATION AND PREPARATION

It is obligatory that patients have a diagnosis of achalasia or spastic esophageal disorder firmly established based on clinical history, esophageal manometry, contrast esophagram and esophagogastroduodenoscopy (EGD). A standardized validated symptom assessment form is completed by all patients, with the majority of centers using the Eckardt score[24]. The Chicago classification of esophageal motility disorders mandates high resolution

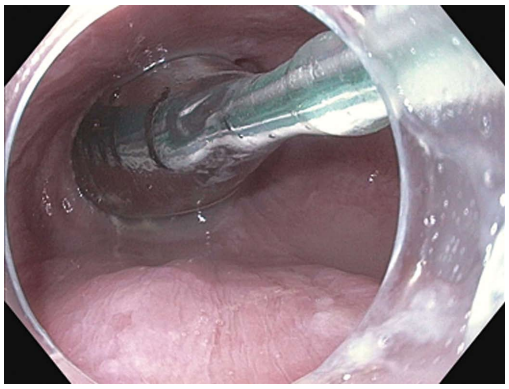

Figure 1 Endosocopic image of the endoluminal functional lumen imaging probe assessing the esophagogastric junction *via* impedence planimetry.

esophageal manometry (HREM) to identify the precise achalasia or spastic esophageal disorder subtype, although the clinical significance of this classification has been recently debated[25]. Computed tomography (CT) is not mandatory, however, some experts find it useful as it provides information on the anatomic features of adjacent structures as well as identifying congenital anomalies or ectopic varices. In addition, CT scan can be an adjunct to contrast esophagram in establishing the presence of a sigmoid-type esophagus.

Our institutional protocol is to perform an EGD on all patients 2 wk prior to their procedure. All patients are placed on a clear liquid diet 2 d prior to this endoscopy and an endoscopic assessment is made of the quantity of residual esophageal contents. If there is persistent solid residue, then even more stringent dietary restriction is advised prior to POEM. This will allow for a clear endoscopic view and may avoid aspiration during induction of anesthesia. Additionally, this evaluation allows for exclusion of underlying malignancy, erosive esophagitis, Barrett's esophagus and Candidal esophagitis. On occasion, a HREM catheter is inserted as passage without endoscopic guidance can be challenging in patients with a tight LES and/or sigmoid esophagus.

In case of use of anticoagulant or antiplatelet therapy, it is generally recommended that these medications be stopped with the exception of acetylsalicylic acid when prescribed as secondary prophylaxis. All patients have a blood type and screen performed on the day of the procedure.

POEM PROCEDURE

Our institutional protocol has been to perform POEM in the endoscopy suite. This is in contrast to most other centers where POEM is performed in the operating room[11,26]. We have performed over 50 cases in the endoscopy unit without a major intraprocedural adverse event. The procedure is performed with the patient in the supine position under general anesthesia with endotracheal intubation and complete paralysis. Our protocol is to use a specialized endotracheal tube that has a taper-shaped cuff with an evacuation port and suction lumen (TaperGuard Evac, Covidien, Mansfield, MA, United States). We have noted that approximately 100mls of fluid is aspirated through this specialized endotracheal tube during each procedure with no episodes of aspiration or pneumonia in our cohort[27].

Carbon dioxide (CO_2) insufflation is mandatory for safe POEM and to reduce the risk of mediastinal emphysema, tension pneumoperitoneum, pneumothorax and air embolization. An arterial line may be inserted such that an arterial blood gas can be performed and CO_2 levels monitored as needed. An indwelling urinary catheter is inserted and a forced air warming blanket is used to cover from the waist down.

The patient's abdomen remains in unrestricted view to allow for an immediate diagnosis of severe pneumoperitoneum. The abdomen is palpated periodically and if tidal volumes begin to diminish or the abdomen is markedly distended, decompression is accomplished using a Veress needle.

A thorough cleansing of the esophageal lumen is performed prior to commencement of the intervention. In certain cases, a therapeutic gastroscope with a 3.8mm working channel (GIF-Q260J; Olympus, Center Valley, PA, United States) equipped with a water jet is necessary. If adherent residue is present on the esophageal mucosa, a soft cleaning cap (Barrx RFA Cleaning Cap - Medium: CP-002A, BARRX Medical Inc., Sunnyvale, CA) can be used to safely scrape off the residue. Broad-spectrum intravenous antibiotics are administered.

Measurements of esophagogastric junction distensibility can be performed using the endoluminal functional lumen-imaging probe (EndoFLIP; Crospon, Galway, Ireland) (Figure 1). This provides a baseline by which the operator can assess the adequacy of the myotomy and may play a role in predicting which patients will likely be non-responders[28-30]. Subsequently, the esophagus is lavaged with 240 mL of sterile saline solution mixed with 180 mg of gentamicin.

A high-definition gastroscope fitted with a transparent cap is used. It is recommend to secure the cap on the endoscope tip with tape as anecdotal reports exist of dislodgement of the cap within the submucosal tunnel. A gastroscope that has a dedicated water jet channel such as the GIF-HQ190/GIF-H180J (Olympus, Center Valley, PA, United States) or EG2990i/EG2990k (Pentax Medical Corp., Montvale, New Jersey, United States) is recommended. For all our procedures, a bottle filled with saline and a second bottle of saline mixed with indigo carmine are attached to the water jet channel *via* a stopcock. Individual foot pedals activate each bottle[31] (Figure 2).

Four step approach to poem

The procedure can be split into four consecutive steps: the mucosal incision, formation of the submucosal tunnel, myotomy and closure of the mucosal incision[32].

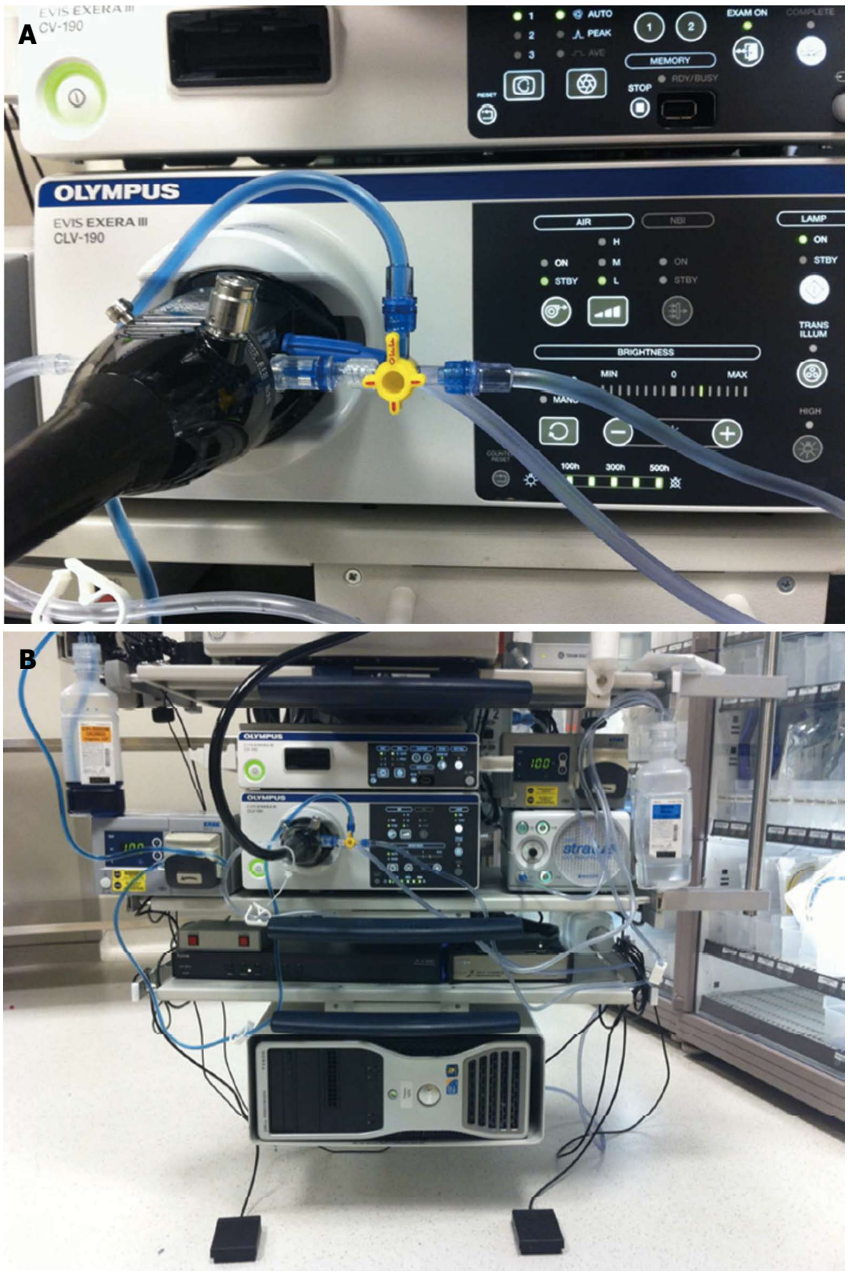

Figure 2 Endoscope setup for jet injection of dyed saline. A: One bottle of saline and a second bottle of saline mixed with indigo carmine are directly connected to the water jet channel *via* a stopcock; B: Separate foot pedals control injection of either pure saline for optimizing visual field or dyed saline for submucosal tunneling.

Step 1: Mucosal incision: The level of the esophagogastric junction (EGJ) is identified and determines the level submucosal tunneling is commenced. In most centers, an anterior (2 o'clock position) is used for the submucosal tunnel and myotomy. However, in some centers a posterior orientation (5 o'clock position) is favored. An anterior myotomy may decrease the damage to the angle of His, a barrier to post-operative GERD. If there is doubt as to the identification of the anterior and posterior walls, water can be injected into the esophageal lumen and will pool on the posterior aspect when the patient is positioned supine.

A submucosal cushion is then made 3 cm proximal to the proposed commencement of myotomy using 0.01% epinephrine, 0.25% indigo carmine and 0.9% saline solution. A 1.5 cm vertical mucosal incision is made using a hybridKnife (HK) (ERBE, Tubingen, Germany) or triangular tip (TT) knife (KD 640 L, Olympus, Center Valley, PA, United States) using a dry cut mode at 50 W on effect 3 (ERBE, Tubingen, Germany) (Figure 3). The gastroscope is then inserted into the submucosal space after dissection of the submucosal fibers at the level of the mucosal incision.

The length of the submucosal tunnel (and hence myotomy) must be determined prior to commencement of the mucosal incision. In patients with achalasia subtype Ⅰ and Ⅱ, a 6-10 cm esophageal myotomy is performed. In patients with spastic esophageal disorders, the length of myotomy is determined based on the proximal extent of the hypertensive contractions on HREM and/or the level of visible spastic contractions seen endoscopically.

Step 2: Creation of submucosal tunnel: The submucosal tunnel is created distally using a technique similar to endoscopic submucosal dissection. Using

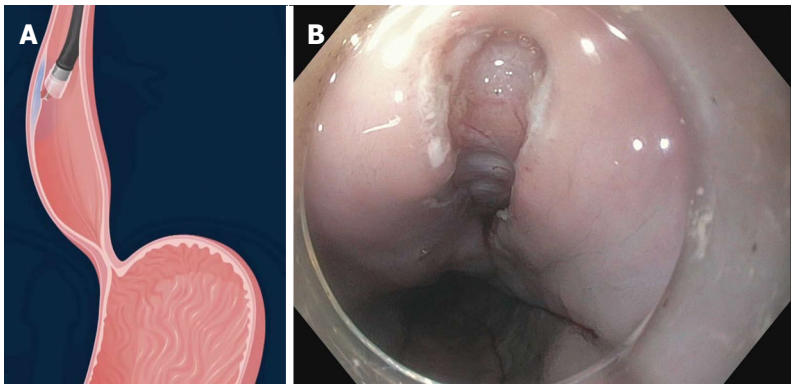

Figure 3 Longitudinal mucosal incision 1.5 to 2 cm on the anterior esophageal wall.

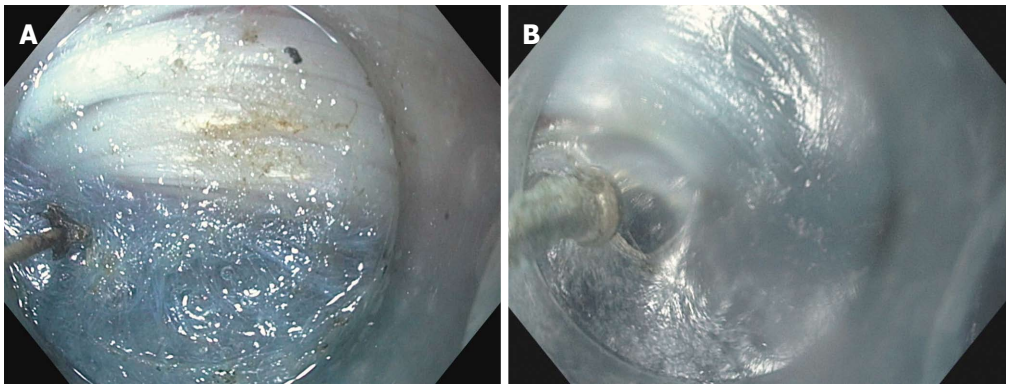

Figure 4 Creation of the submucosal tunnel. A: Dissection of the submucosal fibers using spray coagulation with the triangular tip knife (KD 640L, Olympus, Center Valley, PA, United States); B: Dissection of the submucosal fibers using the hybridKnife (ERBE, Tubingen, Germany) which allows for both submucosal dissection and fluid injection into the submucosal space.

a TT knife or HK, the submucosa is dissected with a no-touch technique using spray coagulation mode at 50 W on effect 2 (ERBE, Tubingen, Germany) (Figure 4). The dissection plane is located nearly on the surface of the muscularis propria. Recurrent jet injection of indigo carmine mixed with saline is done to increase the delineation between the submucosal fibers and muscularis propria whenever the planes become ambiguous (Figure 5). Care must be taken to avoid injury to the mucosal layer during creation of the submucosal tunnel as the mucosal layer is the only barrier between the esophageal lumen and mediastinum after myotomy. Large vessels in the submucosa are coagulated using the Coagrasper (Olympus, Center Valley, PA, United States) in soft coagulation mode at 80 W on effect 5 (ERBE, Tubingen, Germany).

An alternative technique for centers that do not have a water jet for injection is to use the HK (ERBE, Tubingen, Germany). This device obviates the need for multiple accessory exchanges between needle injector and knife as needless submucosal injection using a high-pressure water jet and electrosurgical dissection can both be performed. A randomized controlled trial demonstrated that the HK resulted in statistically significant quicker operating times as compared to using the TT knife. This was primarily the result of a statistically significant lower average number of accessory exchanges during the procedure (2 *vs* 19.2, $P < 0.0001$)[33]. However, the above-described water jet injection method obviates the need for these frequent exchanges as well.

Another technique uses a balloon, such as a standard biliary stone extraction balloon, to dissect the submucosal fibers without the use of electrosurgery. Operators who use this technique claim that it allows for a more rapid creation of the tunnel without substantial bleeding as the vessels are momentarily displaced rather than ruptured using this technique. Proponents of this technique also state that this method is particularly useful at the LES when the space between the muscle and mucosal layer is limited.

The submucosal tunnel is extended 3cm beyond the EGJ (Figure 6). This is essential as an adequate gastric myotomy is considered critical to eradicate the sling and clasp fibers which are considered essential to maintain LES continence[34,35]. The techniques to assess the location of the EGJ include: insertion depth, narrowing of the submucosal space and resistance of passage of the endoscope through the EGJ followed by prompt expansion of the space at the gastric cardia, change in vasculature, visualization of aberrant longitudinal muscle fibers at the EGJ and injection of epinephrine or indocyanine green (ICG)[36,37]. Many of these methods are subjective. Our preference is to use one of two objective techniques: double endoscope

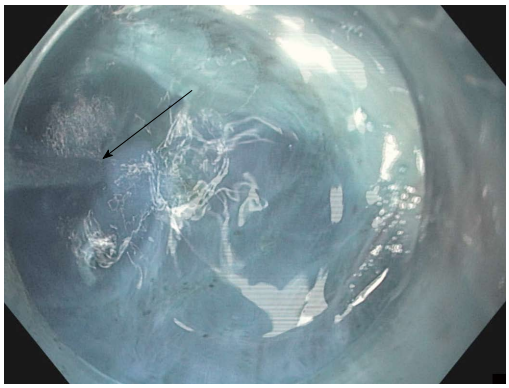

Figure 5 Repeated jet injection (arrow) of dyed saline is performed during submucosal tunneling to improve the demarcation between the submucosal layer and muscularis propria whenever the submucosal dissection plane becomes unclear.

transillumination technique or intraprocedural fluoroscopy[38,39].

Double endoscope transillumination for extent confirmation technique

After the submucosal tunnel is created, the gastroscope is withdrawn and an ultraslim, 5.9-mm endoscope is inserted through the mouth into the stomach and then retroflexed. The cap fitted gastroscope is reinserted alongside the ultraslim gastroscope into the submucosal tunnel. The brightness of the light of the ultraslim gastroscope is reduced while transillumination is switched on for the standard gastroscope within the submucosal tunnel. The transilluminated light is seen by the ultraslim gastroscope and hence allows exact appreciation of the extent of the tunnel into the proximal stomach (Figure 7).

Intraprocedural fluoroscopy

After the formation of a submucosal tunnel, a radiopaque marker (endoscopic clip placed at EGJ on the opposite side to the submucosal tunnel or fluoroscopically guided placement of a 19-gauge needle on the skin) is used to mark the EGJ. The endoscope is then re-inserted to the terminal aspect of the submucosal tunnel. Using a C-arm, a fluoroscopic image is obtained in the anterior-posterior axis. The distance between the jaws of the endoscopic clip or needle, and the endoscope tip is calculated using the known diameter of the endoscope as a scale (Figure 8). This allows for an objective measurement of the length of the submucosal tunnel below the EGJ.

Step 3: Myotomy: Selective myotomy of the inner circular muscle is performed 1cm below the end of the mucosal incision. The HK or TT knife is used to grasp and lift circular muscle fibers followed by cutting with spray coagulation current at 50 W on effect 2 (ERBE, Tubingen, Germany). Selective myotomy of the inner circular muscle, preserving the outer longitudinal esophageal muscular layer is usually preferred during POEM (Figure 9). The selective circular muscle myotomy is intended to prevent the endoscope entering the pleural space and decrease morbidity. However, it can be difficult to accomplish because the longitudinal muscle fibers of the esophagus are very thin, and therefore inadvertent splitting of these fibers often occur during POEM. Either trauma from maneuvering the endoscope in the tunnel, electrocautery damage, or CO_2 insufflation alone can result in splitting of the longitudinal muscle layer and adventitia and hence direct exposure to the mediastinum or peritoneum[32] (Figure 10). Moreover, the ability to differentiate between circular and longitudinal muscular layers becomes particularly challenging at the level of the EGJ and stomach. Therefore, some experts are of the opinion that a full-thickness myotomy at this level is mandated for adequate and long-term reduction of pressure at the LES.

Li *et al*[40] compared the outcomes between 131 patients that underwent selective inner circular muscle myotomy and 103 who underwent full-thickness myotomy. The average procedure times were briefer in the full-thickness myotomy cohort (42 min *vs* 49 min, $P = 0.02$). No difference was found in the frequency of adverse events between the cohorts. During follow-up, clinical success (Eckardt score $\leqslant 3$) persisted for 115/121 (95.0%) of patients in selective inner circular myotomy cohort and 95/99 (96.0%) of patients in full-thickness myotomy cohort ($P = 0.75$). There were no significant differences in absolute (pre and post) or mean reduction in LES pressures between groups (both $P > 0.05$). There was no statistically significant difference in the rate of clinical reflux events (21.2% *vs* 16.5%, $P = 0.38$). The authors concluded that there was no meaningful difference between the two methods in terms of symptom relief and manometric outcomes.

It is believed that selective inner circular myotomy adds an element of extra safety to POEM and hence may lead to easier dissemination, especially when performed by endoscopists with lesser experience. Although the myotomy is not the most challenging part of the procedure, it must be performed carefully such that there is adequate separation of muscle fibers and inadvertent damage to vessels is avoided. Once the myotomy is completed, smooth passage of the endoscope through the area of the LES into the stomach should provide confirmation of complete myotomy.

Step 4: Closure of the mucosal incision: Prior to closure of the mucosal incision, a careful inspection of the submucosal tunnel is performed and any oozing is controlled. Then the esophageal mucosa is interrogated and any laceration or mucosotomy is addressed. Lower esophageal sphincter relaxation is evaluated by retroflexed visualization of the gastric cardia. Repeat EndoFLIP measurements can now be performed to determine post myotomy distensibility.

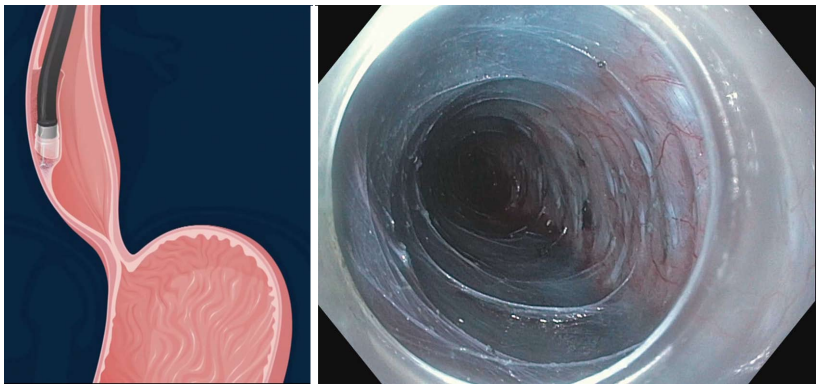

Figure 6 Submucosal tunnel after the submucosal fibers have been dissected away. The myotomy can now be commenced.

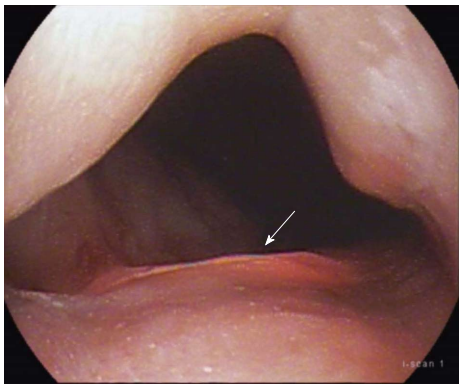

Figure 7 Transillumination can be seen 2 cm below the gastroesophageal junction indicating that the submucosal tunnel can be extended a further 1 cm prior to commencing the myotomy.

The mucosal entry can be closed with endoscopic clips[37,41] or the use of a flexible endoscopic suturing device (OverStitch; Apollo Endosurgery, Austin, TX, United States)[42] (Figure 11). When endoscopic clips are used, the initial clip is deployed at the most distal part of the mucosal incision to facilitate approximation of the incisional borders. Placement of subsequent clips is performed in a proximal direction until complete closure. Salvage closure techniques have been reported when standard methods fail. These include over-the-scope clip and a covered esophageal stent[43-45].

POSTOPERATIVE CARE

Patients are admitted overnight for observation and kept nil per oral. Intravenous prophylactic antiemetics and broad-spectrum antibiotics are prescribed. A contrast esophagram is obtained the following morning and a soft diet is commenced after exclusion of an esophageal leak. Routine thoracic CT scan is not warranted because of the high rate of minor and clinically irrelevant findings[46]. Patients are routinely prescribed broad-spectrum antibiotics for 5 to 7 d. Patients remain on soft diet for 2 wk after which a normal diet can be commenced. In order to avoid any potential damage to the esophageal mucosa, we prescribe twice daily proton pump inhibitor for 2 wk. Follow-up clinic visit to assess for delayed complications and assessment of clinical response (Eckardt score) occur at 3 mo post procedure. Additionally, repeat HREM and esophageal acid exposure testing are ordered routinely.

EFFICACY OF POEM

The published literature to date illustrates that POEM is highly effective in the short-term management of achalasia. In the almost all series, clinical success was defined as postprocedure Eckardt score $\leqslant$ 3. It should be noted that a patient could suffer dysphagia at each meal despite an Eckardt score of 3. Other metrics used are decrease in LES pressure, improvement in esophageal emptying and quality of life. It must be noted that most data are derived from studies that are uncontrolled and open label. Additionally, the follow-up interval is often short and frequently not standardized. Only one prospective multicenter study exists which reports outcomes to 12 mo[41]. The recent white paper summarized data from 14 studies with outcomes based on 804 patients[6]. Clinical success was reported in 82% to 100% of patients with significant reductions in Eckardt score and LES pressure. Several studies have described efficacy based on timed barium esophagram (an objective measurement of esophageal emptying)[42,47,48]. Recent reports have also documented a significant improvement in several measures of quality of life after POEM[42,49].

EndoFLIP has been increasingly reported as a method of assessing the adequacy of myotomy during the POEM procedure. This method involves using a balloon catheter outfitted with a series of electrodes that is placed across the EGJ and allows measurement of luminal diameter, cross-sectional area and balloon pressure *via* impedence planimetry (Figure 12). An index of EGJ distensibility can be determined and this has been shown to correlate better with postoperative symptoms than manometric pressure measurements[50]. Patients within a "sweet spot" of postoperative EGJ distensibility (4.5-8.5 mm^2/mmHg) are almost twice as likely to have optimal symptom outcomes as those outside this window[28].

The literature to date supports the notion that POEM is feasible, safe and efficacious in patients that have undergone prior botulinum toxin injections or pneumatic balloon dilation and is comparable to

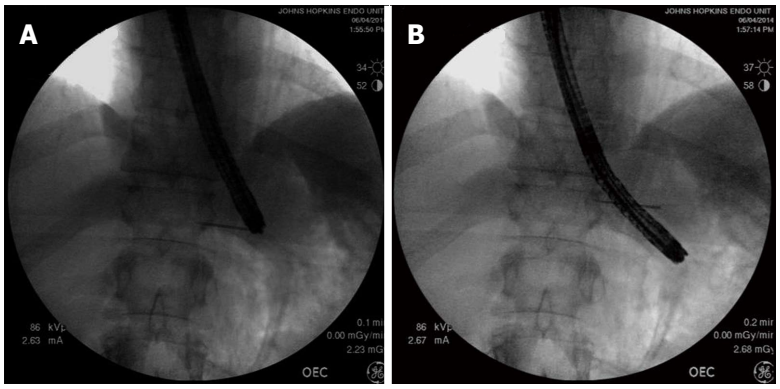

Figure 8 Using fluoroscopy to assess the adequacy of gastric myotomy during peroral endoscopic myotomy. A: The needle is fluoroscopically lined up with the tip of the endoscope and leveled with the EGJ; B: The endoscope has a diameter of 1 cm, and therefore, the endoscope tip is measured to be 3 cm below the needle marking the EGJ. EGJ: Esophagogastric junction.

Figure 9 Selective myotomy of the circular muscle fibers. The longitudinal muscle fibers have been preserved.

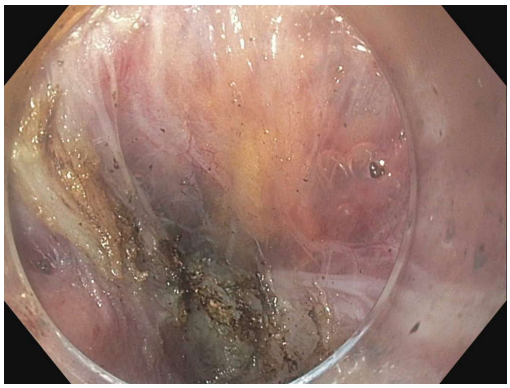

Figure 10 Splitting of the longitudinal muscle fibers despite attempted selective cardiomyotomy. Peritoneal fat can be seen through the translucent adventitia.

patients who are treatment naive[51-53]. In the IPOEMS survey, 40% of patients had undergone POEM after prior endoscopic therapy[36]. The consensus from POEM operators is that botulinum toxin injections injections induce submucosal fibrosis and results in a more challenging dissection (which can be overcome by operator experience) with undiminished efficacy[36]. POEM after prior pneumatic balloon dilation did not render the procedure more technically challenging or increase the rate of complications and the efficacy was undiminished[36].

Relapse or persistence of symptoms after a Heller myotomy happens in 10% to 20% of patients at 2-year follow-up[54]. There are 3 studies that specifically examined the utility of POEM in patients that have undergone a prior Heller myotomy. A prospective study of 12 patients by Zhou *et al*[8] with relapse or persistence of symptoms after Heller myotomy underwent technically successful POEM after a mean of 12 years from the time of the primary Heller myotomy. No major adverse events related to POEM were encountered. Treatment success was achieved in 11/12 (91.7%) patients (mean Eckardt score pretreatment *vs* posttreatment: 9.2 *vs* 1.3; $P < 0.001$) at a mean follow-up of 10.4 mo. Onimaru *et al*[7] reported their series of 11 patients who had relapse or persistent achalasia and had undergone Heller myotomy as initial therapy. Ten patients underwent salvage POEM which was performed successfully without adverse events. One patient responded to pneumatic dilation. At 3 mo follow-up, a significant reduction in Eckardt symptom scores (6.5 *vs* 1.1, $P < 0.001$) and LES resting pressures (22.1 *vs* 10.9 mmHg, $P < 0.01$) were noted. Finally, Vigneswaran *et al*[9] reported 5 patients who had symptom recurrence after Heller myotomy and subsequently underwent POEM. The average procedure time was 149 min. In all patients, there was a significant reduction in average postprocedure Eckardt score (6.8 *vs* 0.6, $P < 0.001$). Therefore, its appears that POEM may be a worthwhile treatment option for patients with relapse or persistent symptoms after Heller myotomy.

While POEM is usually performed for the management of achalasia, preliminary data suggest it is a

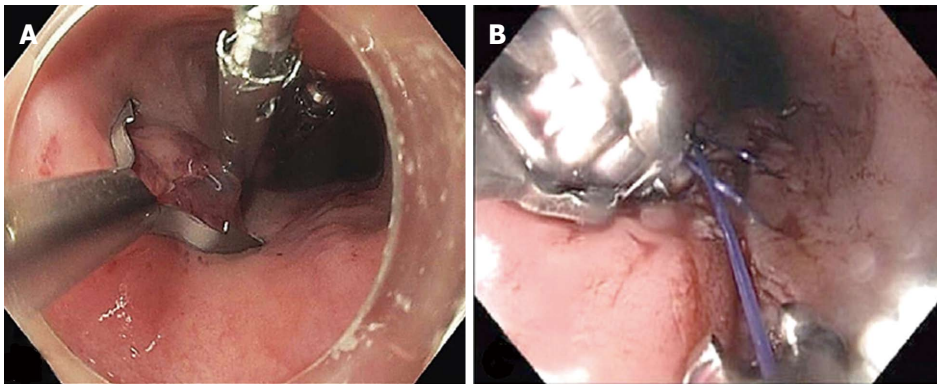

Figure 11 Closure of the mucosal entry after completion of the myotomy. A: A posterior mucosal incision was closed with three endoscopic clips; B: A posterior mucosal incision was closed with a running suture pattern using transoral flexible endoscopic suturing (OverStitch; Apollo Endosurgery, Austin, TX, United States).

viable option for the management of spastic esophageal disorders since it permits myotomy of the proximal esophagus (where hypertensive contractions occur). It is has been suggested that in those patients, a greater improvement in dysphagia is noted compared to chest pain in patients undergoing POEM[21,55]. Based on expert opinion, it is recommended that a longer esophageal myotomy be performed for spastic esophageal disorders and the level of commencement should be based on the findings of HREM and endoscopy[15].

ADVERSE EVENTS

POEM is a safe endoscopic technique associated with a low rate of perioperative and postoperative adverse events when performed by experienced operators.

Intraprocedural adverse events

Subcutaneous emphysema and pneumoperitoneum are often encountered during the procedure and are no longer considered adverse events. Pneumothorax is infrequently encountered and does not usually require treatment as CO_2 is rapidly absorbed. If there is respiratory compromise then a chest tube should be inserted and the procedure continued. In cases of tension pneumoperitoneum a Veress needle can be inserted through the abdominal wall. Excessive hypercarbia resulting from extended CO_2 administration may require the endoscopist to momentarily remove the endoscope from the patient for 5 to 10 min.

The most feared complication is an inadvertent mucosotomy which results in a perforation. As the submucosa and muscle have been dissected, even a small mucosotomy is potentially dangerous. Most mucostomies happen at the level of the LES and cardia as this is the site of narrowing in the submucosal tunnel. If a mucosotomy is identified it should be closed with endoscopic clips. Larger mucosotomies have been closed with a flexible endoscopic suturing device (OverStitch; Apollo Endosurgery, Austin, TX, United States)[56,57]. Other salvage techniques used have included fibrin glue[58] and over-the-scope clips[43]. If the mucosotomy is detected during submucosal tunneling then it should be addressed immediately as delayed closure may result in significant increase is the size of the mucostomy (Figure 13).

Bleeding during submucosal tunneling is not uncommon although the need for specialized interventions is rare (Figure 14). Careful step-wise dissection will allow vessels to be visualized and prophylactically treated using coagulation with the electrocautery knife itself (forced coagulation 25 W effect 2) or hemostatic forceps (Coagrasper; Olympus, Center Valley, PA, United States) for treatment of bigger vessels that are usually encountered in the gastric cardia. If bleeding appears to originate from a vessel along the mucosal surface, hemostasis can be achieved with gentle pressure using the tip of the endoscope for several minutes.

Late advers events

Delayed bleeding has been reported in 0.7% of patients in a large series of 428 patients[59]. Hematemesis with or without chest pain requires an emergent endoscopy and removal of the clips or sutures from the mucosal entry so that the submucosal tunnel and muscle can be assessed. In the aforementioned series, the bleeding point was identified in 2/3 cases and in the third patient there was no focus found and the patient was effectively treated with a Sengstaken-Blackmore tube. It is important to note that hematoma in the tunnel can result in pressure necrosis of the mucosal flap with potentially disastrous consequences. The safety of the Sengstaken-Blackmore tube in this setting is also debated as it can potentially result in pressure necrosis of the already devascularized mucosa.

The most common adverse event with POEM is gastroesophageal reflux (GER). When objective data are reviewed, such as erosive esophagitis on EGD and/or an abnormal acid exposure on a pH study, the prevalence of GER appears to be between 20% to 46%[6]. This is similar to the rates seen with Heller myotomy with partial fundoplication[60,61]. There is no consensus on how to manage patients with objective GER. One center reported the use of transoral endoscopic fundoplication in an patient with GER symptoms refractory to proton pump inhibitor[62].

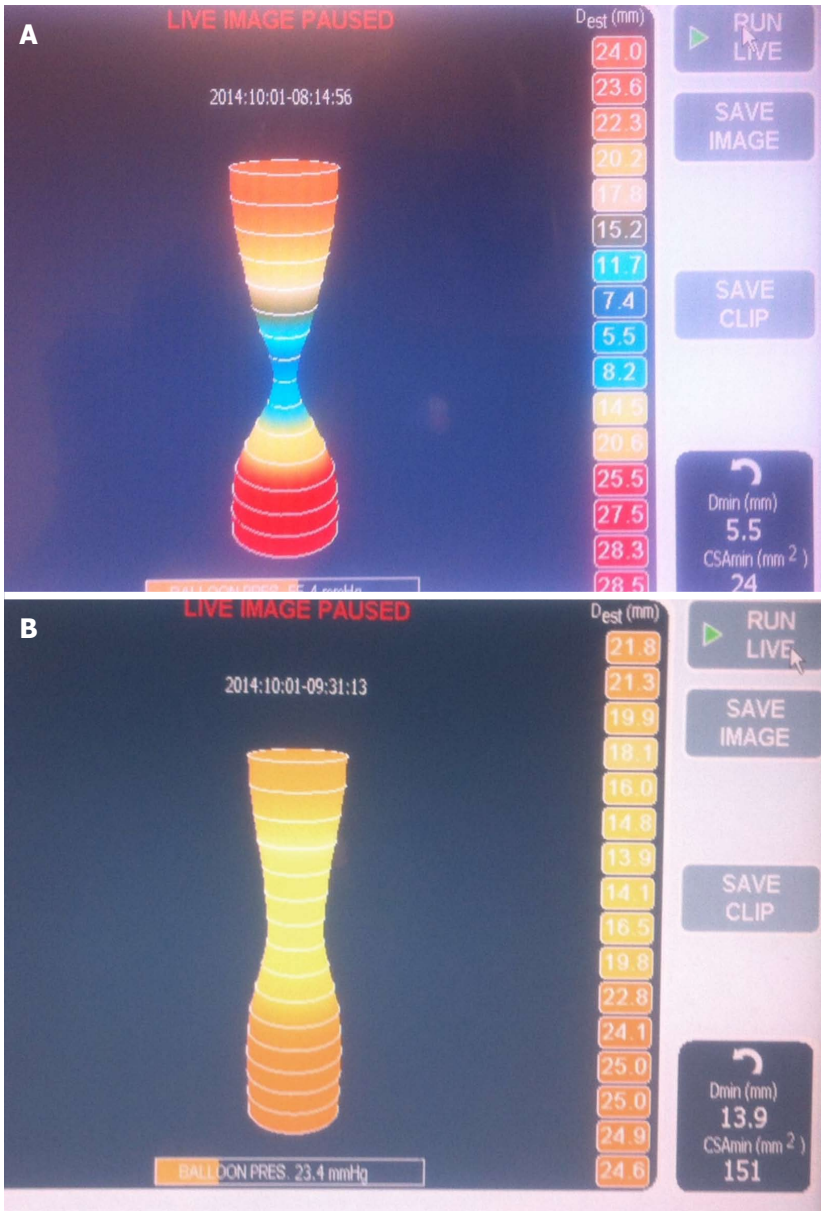

Figure 12 Endoluminal functional lumen-imaging probe (EndoFLIP; Crospon, Galway, Ireland). A: EndoFLIP measurements performed prior to commencement of POEM. A tight hourglass shape at the EGJ can be seen; B: On completion of the myotomy the waist is widened with a corresponding increase in the distensibility index. POEM: Peroral endoscopic myotomy; EGJ: Esophagogastric junction.

POEM IN THE MANAGEMENT ALGORITHM FOR ACHALASIA

For decades, pneumatic balloon dilation and Heller myotomy were the primary methods for the palliation of symptoms of achalasia. POEM appears to have potential advantages over these techniques. POEM appears to be associated with decreased need for retreatment and a lower rate of perforation than pneumatic balloon dilation although no comparative studies exist. There are several uncontrolled studies comparing POEM to Heller myotomy which reveal that they have similar short term efficacy and safety[47,63-65]. Aside from POEM, insertion of self-expandable metallic stents across the EGJ have been studied as an alternative management strategy. Although early reports show promise in terms of symptom palliation, stent migration and intolerance appear to be an issue[66-68].

At this stage, there are no gastrointestinal or surgical society guidelines that have incorporated POEM into their treatment algorithm for achalasia. The American College of Gastroenterology clinical guideline on the management of achalasia cautioned against the use of POEM until the results from further clinical studies are available[69]. Similarly, Vela *et al*[70] in his expert review, comments that POEM should only be performed in the context of clinical trials and that more data is needed before it can be incorporated into the treatment algorithm for achalasia patients. As POEM disseminates worldwide, it is inevitable that it will establish its place in management algorithms of the future.

GASTRIC PERORAL ENDOSCOPIC MYOTOMY (ENDOSCOPIC PYLOROMYOTOMY)

We have published the first human endoscopic pyloromyotomy for medication refractory gastropa-

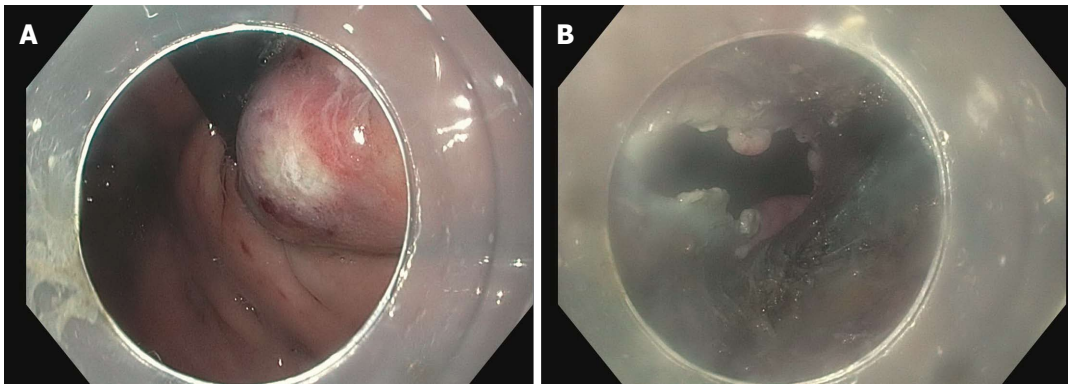

Figure 13 Inadvertent mucosotomy at the gastric cardia. A: Coagulation injury seen on the gastric mucosa at the level of the cardia during the process of submucosal tunneling; B: The procedure continued, however, on completion of the myotomy a frank 12 mm mucosotomy was now present.

Figure 14 Bleeding encountered during gastric myotomy. This was treated with the use of coagulation graspers.

resis[22]. One year later Shlomovitz *et al*[23] reported gastric peroral endoscopic myotomy in 7 patients with gastroparesis. Six of the 7 patients experienced significant improvement in symptoms with normalization of gastric emptying seen in 4 out of 5 patients. This procedure appears viable and can be executed using similar techniques to that of esophageal POEM. It should be noted that only a subset of patients with refractory gastroparesis are likely to benefit from this approach.

COMMENCING A POEM PROGRAM

It is general consensus that institutions commencing a POEM program do it with institutional review board approval[36]. POEM is a technique that requires a unique set of skills combining good endoscopic manipulation and recognition of anatomical structures. In particular, knowledge of the EGJ anatomy and pathophysiology of achalasia is necessary. Of significant importance, is the maintenance of a consistent team throughout the learning curve. This includes nursing as well as anesthetic staff. Additionally, knowledge of the use of accessories necessary to deal with complications is mandatory. Expert operators propose that an efficient training method involves careful observation of POEM by an expert, experience using live animal models and then performing the procedure in humans with a proctor present.

The learning curve for POEM has not been clearly defined. Kurian *et al*[71] used the duration of the procedure per centimeter of myotomy and the incidence of inadvertent mucosotomies and calculated that the learning curve appeared to plateau at approximately 20 procedures. Teitelbaum *et al*[72] found that reduction in time for the mucosal entry and myotomy as well as reduction in the incidence of inadvertent mucosotomies occurred at a "learning rate" of 7 procedures. Expert operators comment that the creation of the submucosal tunnel, particularly at the LES, is likely the most difficult aspect of POEM.

FUTURE DIRECTIONS

Given that achalasia is a chronic disease, long-term outcomes for POEM are essential. Furthermore, POEM needs to be compared to Heller myotomy and pneumatic balloon dilation in multicenter prospective randomized controlled trials.

Progress is being made to simplify POEM in order to increase its efficiency and safety. We published our experience of a novel technique of "auto-tunneling" during POEM in 5 pigs[73]. After creation of the submucosal bleb at the site of the mucosal entry, a proprietary submucosal lifting gel (Cook Medical, Winston-Salem, NC, United States) was injected and resulted in a complete submucosal tunnel to the level of the EGJ. This and other innovative modifications may alleviate current technical challenges.

The most contentious issue surrounding POEM remains the frequency and clinical importance of gastroesophageal reflux. Rigorous evaluations of patients post POEM using pH measurements are required in patients from the East and West. Individualizing the length of the gastric myotomy based on the results of EndoFLIP may reduce the incidence of this problem. Additionally, performing a transoral partial fundoplication in all patients or those that have abnormal acid exposure on post procedure testing may improve outcomes.

Further investigation needs to be performed to

study other technical considerations for POEM. Is an anterior or posterior myotomy the preferred approach? Is it cost-effective and safe for POEM to be performed in the endoscopy unit? Is same day discharge suitable if an immediate contrast esophagram demonstrates no extravasation? These, as well as other questions, will need to be answered by high quality controlled trials.

CONCLUSION

POEM likely represents the first sentinel application in NOTES and has the potential to supplant the current treatment methods for achalasia. It fulfils an important clinical need as both pneumatic balloon dilation and Heller myotomy have their short comings. POEM is an elegant minimally invasive treatment with a short-term clinical response of 82% to 100% and with a low risk of adverse events. The results of prospective multicenter randomized controlled trials are awaited.

Abstract

Peroral cholangioscopy (POC) is an important tool for the management of a selected group of biliary diseases. Because of its direct visualization, POC allows targeted diagnostic and therapeutic procedures. POC can be performed using a dedicated cholangioscope that is advanced through the accessory channel of a duodenoscope or *via* the insertion of a small-diameter endoscope directly into the bile duct. POC was first described in the 1970s, but the use of earlier generation devices was substantially limited by the cumbersome equipment setup and high repair costs. For nearly ten years, several technical improvements, including the single-operator system, high-quality images, the development of dedicated accessories and the increased size of the working channel, have led to increased diagnostic accuracy, thus assisting in the differentiation of benign and malignant intraductal lesions, targeting biopsies and the precise delineation of intraductal tumor spread before surgery. Furthermore, lithotripsy of difficult bile duct stones, ablative therapies for biliary malignancies and direct biliary drainage can be performed under POC control. Recent developments of new types of conventional POCs allow feasible, safe and effective procedures at reasonable costs. In the current review, we provide an updated overview of POC, focusing our attention on the main current clinical applications and on areas for future research.

Key words: Peroral cholangioscopy; Biliary tract disease; Direct visualization; Indeterminate biliary strictures; Bile duct stones

Core tip: Peroral cholangioscopy is a rapidly developing endoscopic technique that provides the possibility to directly explore the bile duct, thereby increasing diagnostic accuracy in selected cases. Less expensive and safer than in the past, the field of applications of peroral cholangioscopy, through the development of new dedicated accessories, has been recently expanded and includes several therapeutic options such as the lithotripsy of difficult bile duct stones, ablative therapies for biliary malignancies and direct biliary drainage.

INTRODUCTION

Since the 1970s, the dream of all biliopancreatic endoscopists was the ability to directly explore the bilio-pancreatic tree. The first cholangioscopic mother-baby scope system appeared to realize this ambition; however, the technique was too rudimentary, cumbersome, labor intensive and time-consuming because the scopes were very fragile, and two highly skilled endoscopists were required to perform the procedure. Therefore, the effect on clinical practice was marginal and was strictly confined to the research field[1].

In 2005, the advent of new types of peroral cholangioscopes led to renewed interest in endoscopic visualization of the biliary tree. Several technical improvements were introduced, and the leading one was the single-operator system. Furthermore, the endoscopic image quality was progressively improved, and the size of the working channel increased. All these technical improvements have led to an increased diagnostic accuracy.

The aim of the current review is to provide an updated overview on peroral cholangioscopy, focusing our attention on the main current clinical applications and on areas for future research.

TECHNICAL ASPECTS

Currently, two different systems for the direct visualization of the biliary tree are available. The first one, the so-called indirect peroral cholangioscopy, is based on a catheter with an optical probe inside that is inserted within the duodenoscope. SpyGlass® (Boston Scientific, Natick, MA, United States) is the most frequently used and widely diffused probe; the second system is based on an ultraslim upper endoscope (direct peroral cholangioscopy).

Indirect peroral cholangioscopy

The SpyGlass® system is inserted through the instrument channel of the duodenoscope, and the previous placement of a guidewire into the biliary tree is generally recommended. The insertion of the cholangioscope into the bile duct is one of the most challenging aspects of the technique because it can damage the cholangioscope. Once inside, the SpyScope has two dials that allow for four-way tip deflection. The SpyScope has a 10 French outer diameter, is 230 cm in length, and houses four channels: a 1.2-mm instrument channel, two 0.6-mm independent air and irrigation channels, and the 0.9-mm channel used for the fiberoptic probe. This latter channel is a 6000 pixel,

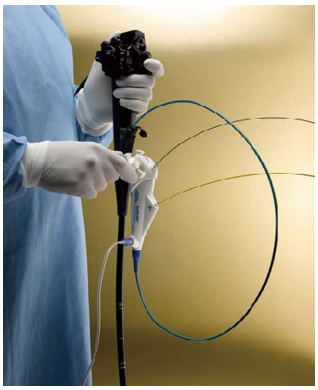

Figure 1 SpyGlass® (Boston Scientific, Natick, MA, United States).

reusable probe with a camera in its distal portion that conducts light and acquires and transmits images. The quality of the endoscopic images can be adjusted by moving the probe forward and backward throughout the procedure. The working channel allows the passage of biopsy forceps (SpyBite®) and dedicated accessories, such as the Holmium laser, for the intraductal fragmentation of non-removable stones (Figure 1).

Similar to the SpyGlass scope is the Polyscope® (Polyscope system; Polydiagnost, Pfaffenhofen, Germany), which consists of a detachable flexible endoscope system available in 8 Fr (185 cm length) with separate optical, working/irrigation (1.2 mm), illumination, and steering channels (Figure 2). There are few differences between the two systems, as summarized in Table 1, but potentially the most important one lies in the image quality because the optical fiber has 10000 pixels of definition; however, the angle of view (70°) is the same as in the SpyGlass scope.

Direct peroral cholangioscopy

Ultraslim endoscopes present larger outer diameters, generally 5-6 mm; therefore, they can be used only after a large endoscopic sphincterotomy and/or sphincteroplasty. The use of this system is definitely more challenging because of the significant difficulties that can be encountered in the initial insertion into the biliary tree as a result of the looping and in remaining anchored inside the duct. Therefore, a 0.025-0.035 inch diameter super-stiff guidewire previously placed within the intrahepatic duct is mandatory to introduce the scope into the acute angle of the biliary system from the second part of the duodenum. Once the duodenoscope is removed, the ultraslim endoscope is then advanced over the guidewire. Large loop development is common, particularly within the gastric fundus and the deep portion of the second part of the duodenal lumen. Hence, several accessories may be useful to successfully advance the ultraslim scope into the biliary tree. Recently, two techniques for an ultraslim endoscopic peroral cholangioscopy (POC) have been reported. The implementation of an intraductal 5 French balloon catheter that is inserted

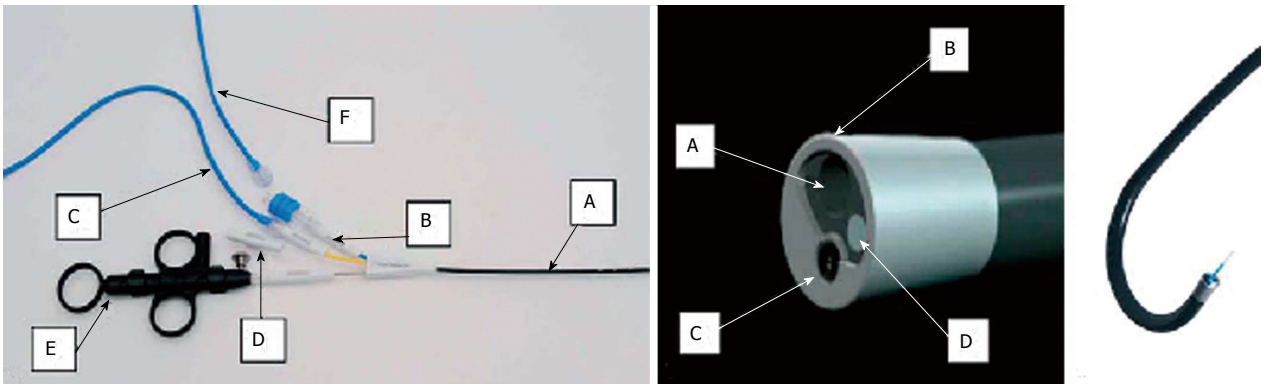

Figure 2 Polyscope system (Polydiagnost, Pfaffenhofen, Germany).

Table 1 Comparison of different equipment for indirect peroral cholangioscopy

Characteristics	Spyglass	Polyscope
Optics resolution	6000 Pixel	10000 Pixel
Working channel	1.2 mm	1.2 mm
Viewing angle	70°	70°
Outer diameter	10 Fr	8 Fr
Re-useable	Yes	Yes
Optical channel hermetically close	No	Yes (The optical fiber doesn't need to be sterilized; this prolongs its life cycle)
Steerability	4 way	1 way (With locking of the bending and rotating of the tip)
Compatibility with existing endoscopy tower	No (You have to buy a complete endoscopy tower system)	Yes (You can use, through adapters an existing endoscopy tower in the Hospital)

and fixed within a branch of the intrahepatic duct or proximally to a stricture has been proposed[2]. This technique facilitates the advancement of the ultraslim scope and the cannulation of the bile duct; however, it presents several drawbacks: the balloon must be withdrawn from the working channel of the scope for interventional procedures, and this maneuver can provide technical difficulties in maintaining the desired position; in addition, the balloon placement within the intraductal branches is not always easily reached. The implementation of the balloon doubles the success rate of direct peroral cholangioscopy from 45.5% with only the guide-wire in place to greater than 95% using a 5 F balloon catheter.

Notably, an anchoring balloon produced by Cook Medical (Winston-Salem, NC, United States) was removed from the market after a fatal complication because of an air embolus[3]. This development represents the most worrisome complication that can develop during a cholangioscopy; therefore, the use of CO_2 rather than room air is mandatory.

An overtube balloon-assisted cholangioscopy has also been proposed with successful results[4-9]. This device is generally adapted from the overtube of either a single or double-balloon enteroscope; however, these overtubes are too large in diameter for an ultraslim scope, making the manipulation cumbersome[4,10].

An overtube allows the right position to be obtained by securing the endoscope and preventing loop formation during advancement; it also provides an easier access to the papilla. Several techniques have been described to achieve easier cannulation of CBD, including the inflation of the overtube balloon in the distal gastric antrum rather than in the duodenal bulb, which may or may not make a J-turn maneuver right in front of the papilla[11].

CLINICAL APPLICATIONS

Twenty-five years ago, endoscopic retrograde cholangiopancreatography (ERCP) was the gold standard for the diagnosis of biliary diseases. Currently, that role has been almost completely replaced by other imaging modalities, including endoscopic ultrasound, magnetic resonance (MRI) and computed tomography (CT). However, the accuracy of these methodologies does not always allow for a definitive diagnosis. Therefore, the necessity of direct viewing and tissue sampling has always been claimed as a demanding goal in selected cases. Both direct and indirect cholangioscopy offer great advantages in terms of diagnostic and therapeutic options, as reported in the details in Table 2. Nevertheless, the main field of application of cholangioscopy is the work-up of indeterminate biliary strictures and, less frequently, the treatment of difficult bile duct stones.

Indeterminate biliary strictures

Direct visualization of biliary strictures is one of the most interesting applications of cholangioscopy, and it allows the physician to improve the diagnosis to plan the most suitable treatment. Indeterminate biliary strictures, in which a diagnosis has not been reached after standard procedures have been performed (*i.e.*, CT, RMN, or ERCP with brushing), is the initial and natural field of application of cholangioscopy.

Table 2 Diagnostic and therapeutic applications for cholangioscopy

Diagnostic applications		Therapeutic applications	
Common	Uncommon	Common	Uncommon
Indeterminate biliary strictures	Biliary cyst evaluation	Lithotripsy for choledocholithiasis	Biliary guidewire placement
Verification of bile duct stone clearance	Bile duct ischemia evaluation (post-liver-transplant)		Transpapillary gallbladder drainage
Staging of cholangiocarcinoma	Ductal involvement in ampullary adenoma		Foreign body removal (*e.g.*, stent)
	Hemobilia		

Currently, the visual criteria for malignancy are not fully standardized, and clinical experience interpreting cholangioscopic visual findings is still limited[12].

Criteria highly suggestive for malignancy include dilated and tortuous "tumor vessels" (also known as "capillary signs"), intraductal nodular or papillary masses, and oozing and irregular vascular patterns with an irregular surface. A benign condition should be considered when a smooth or fine granular surface structure without neovascularization or intraductal mass is observed[13,14]. The diagnostic accuracy of the "tumor vessel" sign for malignancy has been evaluated in 63 patients with indeterminate strictures, reporting a sensitivity of 61% and a specificity of 100% with excellent interobserver agreement (100%)[15].

A definitive diagnosis requires histological assessment. Several prospective trials have shown enthusiastic diagnostic accuracy results achieved with cholangioscopic-direct tissue sampling. Draganov *et al*[16] compared three sampling techniques during the ERCP: standard cytology brushing *vs* standard forceps biopsies *vs* SpyBite miniforceps biopsies. The authors enrolled 26 patients with biliary strictures, and the sample quality was adequate in 25 of 26 of the cytology brushings (96%), in 26 of 26 of the standard forceps biopsies (100%) and in 25 of 26 of the SpyBite miniforceps biopsies (96%). Three high-quality prospective trials showed a diagnostic accuracy of SpyBite forceps biopsy for indeterminate biliary lesions ranging from 72% to 85%, with a sensitivity of 49% to 82%, a specificity of 82% to 100%, a positive predictive value of 100% and a negative predictive value of 69% to 100% (Table 3)[12,16,17].

Although the high values of both the positive predictive value and specificity did not differ from those observed with traditional sampling techniques (*i.e.*, brushing and standard forceps biopsies), the interesting finding was the high sensitivity and negative predictive value, likely because of the possibility of directly targeting the altered mucosa. Although the SpyBite miniforceps biopsy showed expected disappointing

Table 3 Results of cholangioscopic-guided biopsies in indeterminate lesions

Ref.	Sensitivity	Specificity	Negative predictive value	Accuracy
Ramchandani *et al*[17]	82%	82%	100%	82%
Chen *et al*[18]	49%	98%	72%	75%
Draganov *et al*[16]	76.5%	100%	69.2%	84.6%

results for extrinsic lesions, with a sensitivity of only 8%, the sensitivity of the SpyGlass visual impression alone was less severely compromised (62%)[12].

Concerning extrinsic compression, the specificity is unavoidably reduced when direct visualization is solely used because it can be secondary to benign conditions, and in the case of several benign intraductal diseases, such as primary sclerosing cholangitis (PSC), it can present irregular biliary mucosa without harboring malignancy[18].

Nevertheless, it should be noted that in a prospective trial enrolling 53 patients with PSC and dominant stenosis, cholangioscopy, which was performed using a 9 Fr cholangioscope, was found to be significantly superior to ERCP for detecting malignancy in terms of its sensitivity (92% *vs* 66%), specificity (93% *vs* 51%), PPV (79% *vs* 29%) and NPV (97% *vs* 84%), respectively[19]. In patients with PSC, the main limitation is that the small diameter of their ducts frequently does not allow endoscope passage[19,20].

Image-enhanced cholangioscopy techniques have been proposed to improve diagnostic accuracy, particularly through new techniques that are currently being investigated, including chromocholangioscopy and narrow band imaging. Only limited experiences with chromocholangioscopy have been reported[21,22]. Hoffman *et al*[22] prospectively enrolled 55 patients who underwent chromoendoscopic cholangioscopy for biliary strictures or filling defects as a result of various etiologies (orthotopic liver transplantation, PSC, idiopathic). After the initial inspection of the bile duct, 15 mL of methylene blue (0.1%) was administered *via* the working channel of a Pentax "baby" cholangioscope, and the lesions were judged according to the macroscopic type and staining features. The authors identified characteristic surface and staining patterns in chronic inflammation, dysplasia and ischemic-type biliary lesions; in particular, they found that homogeneous staining predicted the presence of normal mucosa, the absence of staining predicted circumscribed lesions, and the diffused staining of such lesions represented neoplastic changes or inflammation. Unfortunately, these findings have not been confirmed by other studies, and their clinical usefulness remains limited.

Narrow band imaging (NBI) was developed by the Olympus medical system and is based on narrowing the bandwidth of spectral transmittance, resulting in optical color separation. In particular, the shorter band

(415 nm) is thought to provide information regarding the capillary and pit patterns of the superficial mucosa, whereas the longer band (540 nm) provides more information regarding thicker capillaries in slightly deeper tissues. NBI is available on a few models of cholangioscopes. The literature concerning NBI application in cholangioscopy is limited to case reports and small case series[23-25].

Based on these preliminary experiences, it appears that the addition of NBI to the usual inspection with conventional white light cholangioscopies increases the ability to identify unknown strictures and might be helpful in differentiating benign from malignant strictures. Azeem *et al*[26] recently published the results of a prospective study conducted on a total of 30 patients with PSC using NBI and high-resolution peroral video cholangioscopy with NBI-directed biopsies of suspicious lesions. The goal was the early detection of cholangiocarcinoma and high-grade dysplasia and the identification of candidates for liver transplantation. Even if there was a 48% increase in suspicious lesions biopsied with NBI compared to white-light imaging, the NBI-directed biopsies did not improve the dysplasia detection rate. Additional experience is required to assess the exact role of NBI in detecting dysplasia.

Theoretically, systems with a higher image quality definition should allow a better identification of such alterations; however, comparative studies focusing on this issue have not been conducted. In 2012, we published a case-series describing the clinical usefulness of peroral cholangioscopy that implements a new type of cholangioscope, the Polyscope®, which enhances image quality as a result of the 10000 pixel definition[27]. Peroral cholangioscopy was performed in 12 patients with different indications: 4 patients with strictures that developed after orthotopic liver transplantation and were suspected of being ischemic biliary lesions; three patients in which the indication was indeterminate biliary strictures, three patients in which retained bile duct stones were suspected, and finally two cases in which a cholangioscopy was performed for evaluating the intraductal spread of adenomatous tissue after ampullectomy. All the peroral cholangioscopies were successful, no procedure-related morbidity was reported and a correct diagnosis was reached in all the patients.

Missed stones and difficult bile duct stone treatment

The diagnosis of biliary stones is easily obtained using imaging techniques that are routinely available. However, these techniques are often insufficient because small stones can be missed and larger stones can block a duct, thus preventing the passage of contrast and avoiding detection during an ERCP. Indeed, it has been shown that previous ERCPs failed to correctly identify choledocholithiasis in 8%-16% of cases that were referred for a SpyGlass choledochoscopy[17,28]. In a study conducted in patients with primary sclerosing cholangitis, stones were not detectable in a cholangiography in approximately 30% of cases (7 out of 23 patients)[20]. In a multicenter study, stones were missed in 29% of cases that underwent an ERCP for different indications[12].

The most interesting feature of cholangioscopy is the possibility of fragmenting difficult-to-remove stones for which conventional techniques have failed. The "difficult stones" may result from several factors related to size, shape, texture or position. In these cases, intraductal electro-hydraulic (EHL) or laser lithotripsy (LL) under direct vision may be performed. Probes that pass through the accessory channels of cholangioscopies for EHL or LL are commercially available. These probes must be positioned close to the stones to increase effectiveness and reduce possible complications, thereby avoiding potentially dangerous shock waves delivered to the bile duct wall. Several studies have reported high success rates in clearing the bile ducts of stones after a cholangioscopic EHL or LL, ranging from 80% to 100%; these results are frequently achieved in only one session[12,29]. In the case of intrahepatic stones, the thinner LL probe is generally preferred to the EHL probe, whereas the EHL is the most widely used technique, particularly with the SpyGlass system, because of the dedicated irrigation channel providing the flowing water that is required to perform the EHL.

Uncommon applications of cholangioscopy

Several infrequent applications of cholangioscopy have been described, such as the study of cystic lesions of the biliary tree[30], the evaluation of ductal involvement in ampullary neoplasms[27], the diagnosis and treatment of cases of hemobilia as a result of rare causes[31,32], the identification of biliary varices in patients suffering from portal hypertension[33] and the use of different ablative therapies for intraductal tumor lesions, such as Nd-YAG laser photo-ablation, argon plasma coagulation or brachiotherapy for mucin-producing bile duct tumors[24]. Anecdotal cases of the cholangioscopy-assisted removal of stents that migrated proximally, targeted placements of guide-wires, transpapillary gallbladder drainage in cholecystitis and foreign body extractions have also been reported.

One interesting field of application of cholangioscopy is the evaluation of the biliary tract lesions in liver transplant patients or the treatment of liver complications after surgical resection or anti-tumoral therapies (*i.e.*, transarterial chemoembolization, TACE). In a study of 20 liver transplant patients, direct cholangioscopy helped identify the biliary stricture etiologies, such as ischemia, scar tissue, intraductal clots and retained suture material, that were otherwise missed by the ERCP[34].

The usefulness of cholangioscopy in the management of complications after the anti-tumoral treatment of hepatocarcinoma has also been reported by our group. In 2011, we described a choledochoscope-assisted percutaneous fibrin glue sealing of a bile leak

complicating a TACE of a nodule of hepatocellular carcinoma after conventional ERCP treatments had failed[35]. An inverse rendezvous procedure was successfully performed, allowing the insertion of the percutaneous wire-guided choledochoscope (Polyscope system) into the biloma and the injection of fibrin glue around the distal opening of the bile leak, allowing the direct closure of a fistula.

SAFETY

Peroral cholangioscopy is generally considered a safe procedure; however, cases of cholangitis, pancreatitis, bleeding and infection have been reported[15,36,37]. In particular, the most commonly reported complication is cholangitis, which is reported in up to 14% of cases[36]; hence, prophylactic antibiotics are mandatory. Chen *et al*[12] conducted a large, prospective, international, multicenter study using the SpyGlass system and reported an overall complication rate of 7.5% (17/226); the most frequent adverse event was early onset cholangitis. All the episodes were resolved without sequelae. Aspiration pneumonia is theoretically possible because of the large amount of normal saline generally used. Air embolism is a rare but fatal complication associated with direct peroral cholangioscopy[3]; therefore, CO_2 insufflation is strongly recommended rather than room air.

FUTURE APPLICATIONS

Cholangiocarcinoma has one of the worst prognoses of virtually all tumors, with a 5-year survival rate lower than 5%[38]. The early diagnosis of biliary preneoplastic lesions could reasonably identify patients who are at an increased risk of developing cholangiocarcinoma. Biliary duct pathology may be evaluated by intraductal endoscopy, but feasibility studies are required to test the diagnostic accuracy of cholangioscopy in the identification of preneoplastic lesions of the extrahepatic biliary tree. The improvement of image quality and the development of dedicated accessories will further promote the diffusion of peroral cholangioscopy.

Endoscopic drainage can be performed by direct cholangioscopy using a 5-Fr catheter or stent inserted in the 2.0-mm working channel, particularly in patients who require "ultra" selective guidewire access, such as for the orifice of the cystic duct or major intrahepatic branches[39]. Additionally, proximally migrated biliary stents, which cannot be removed *via* conventional ERCP, can be removed using 5-F baskets or other accessories under direct visual cholangioscopic control[40].

Cholangioscopy have been reported for the evaluation of recurrent pancreatitis because of T-tube remnants in the cystic duct stump that were previously not detected *via* ERCP, CT or MRI[41]. Although there are no published data on the therapeutic applications of cholangioscopy for the resection of a biliary lesion, a biliary polypoid lesion could be removed using a 5-F snare.

CONCLUSION

The introduction of peroral cholangioscopy has constituted a turning point for biliary endoscopy. In particular, the single-operator systems are able to address a new, enthusiastic approach to biliary tract diseases, with great advantages in everyday practice. The greatest interest has centered on the evaluation of indeterminate stenosis, in which a diagnosis has not been reached after standard procedures; this is the main field of application of POC. The development of standardized criteria for the differential diagnosis between benign and malignant strictures is the main goal for the future. Prospective multicenter studies are required to define criteria with high intra- and inter-observer agreements and adequate diagnostic accuracy. Peroral cholangioscopy currently remains a challenging and expensive technique in expert hands. However, the renewed interest of researchers, clinicians and the medical device industries, and the substantial technological improvements in image quality and dedicated accessories, might contribute in the near future to the dissemination of this technique.

Abstract

With over a third of Americans being considered obese, bariatric procedures have now become the most performed operation be general surgeons in the United States. The most common operations are the Laparoscopic Roux-en-Y Gastric Bypass, the Laparoscopic Sleeve Gastrectomy, and the Laparoscopic Adjustable Gastric Band. With over 340000 bariatric procedures preformed worldwide in 2011, the absolute number of complications related to these operations is also increasing. Complications, although few, can be life threatening. One of the most dreaded acute complication is the anastomotic/staple line leak. If left undiagnosed or untreated they can lead to sepsis, multi organ failure, and death. Smaller or contained leaks can develop into fistulas. Although most patients with an acute anastomotic leak return to the operating room, there has been a trend to manage the stable patient with an endoscopic stent. They offer an advantage by creating a barrier between enteric content and the leak, and will allow the patients to resume enteral feeding much earlier. Fistulas are a complex and chronic complication with high morbidity and mortality. Postoperative bleeding although rare may also be treated locally with endoscopy. Stenosis is a more frequent late complication and is best-managed with endoscopic therapy. Stents may not heal every fistula or stenosis, however they may prevent certain patients the need for additional revisional surgery.

Key words: Bariatric surgery; Bariatric complications; Endoscopic treatment; Sleeve gastrectomy; Roux-en-Y gastric bypass; Anastomotic leak; Self-expanding metal stent

Core tip: The majority of general surgeons and all bariatric surgeons will be faced with complications related to bariatric surgery. Understanding the new anatomy and most frequent complications is paramount to treating these patients appropriately. The use of endoscopic self-expanding stents alone or in combination with an operation can stabilize and occasionally completely heal anastomotic leaks and fistulas. Endoscopy can also be useful in the diagnosis and treatment of bleeding, stenosis, and ulcerations. This review will summarize the current literature on endoscopy for bariatric complications.

INTRODUCTION

Obesity is a complex and chronic disease that is attributed to a combination of genetics and environmental factors. In the United States in 2011-2012, 69% of adults aged over 20 were considered overweight, 35.1% were obese, and 6.8% were morbidly obese. Similar trend are also seen in children (2-19 years) with obesity rate of 16.9% during the same period[1]. It is the second leading cause of preventable death in the United States, second only by smoking. The gap between these two has be diminishing and obesity is thought to overtake smoking in the near future[2]. Although lifestyle modifications have good short term results (1 year)[3], longer follow up has demonstrated a significant advantage to patients who have undergone a bariatric procedure[4]. The number of bariatric procedure performed worldwide in 2011 is estimated at 340768. The most commonly performed operations are the [Roux-en-Y gastric bypass RYGB (46.6%)], sleeve gastrectomy [SG (27.8%)], bilio-pancreatic diversion with duodenal-Switch [BPD/DS (2.2%)], and the Adjustable Gastric Band [AGB (17.8%)][5]. Over 90% these procedure are performed laparoscopically. The mean percentage of excess weight loss is 61.6%, 57%, 70.1%, and 47.5% respectively[6,7]. With an increase in the number of procedure being performed worldwide, as will the complications. These can be divided into intraoperative, perioperative, and late. The two latter can be further subdivided into local and systemic (Table 1). The sleeve gastrectomy is noteworthy as is does not create any mesenteric defects, thus the potential for internal hernia is eliminated.

Perioperative complications, although rare, are life threatening and must be diagnosed and treated promptly. Many of the clinical signs and symptoms are vague and subtle and can easily be overlooked. Late complications, although less life threatening, can be a diagnostic dilemma. Endoscopy is an excellent first line tool and may be simultaneously diagnostic and therapeutic. We will explore the pathophysiology, incidence and management of anastomotic/staple line leak, fistulas, stenosis, ulcers, and bleeding.

Table 1 Postoperative complications

	Local	Systemic
Intraoperative	Iatrogenic splenectomy (0.41%)	
Perioperative	Anastomotic leak (1.1%) GI hemorrhage (2.5%) Trocar injury (0.1%)	Deep vein thrombosis (1%) Pulmonary embolism (0.5%) Bowel obstruction (1.7%) Wound infection (3%) Pneumonia (0.2%) Cardiac event Mortality (0.2%-1%)

ANASTOMOTIC AND STAPLE LINE LEAKS

Leaks occur when there is discontinuity of tissue apposition at the site where the tissue has been stapled and divided. It is generally felt that leaks within 48 h are caused by a technical failure. This can be a result of stapler misfire, wrong staple size for the tissue, or tissue trauma. Leaks occurring after several days are more likely due to tissue ischemia cause by tension on the anastomosis, distal bowel obstruction, or hematoma. In both situations, the intraluminal pressure exceeds the strength of the staple line[8]. Risk factors for leaks are increased age, male gender, sleep apnea (SA), and reversional surgery[9]. The incidence of leaks after RYGB has been as high as 8.3%, however most recent data would suggest the incidence to be closer to 1.1%[8,10,11]. The most common sites for anastomotic leak in the Roux-en-Y gastric bypass is the gastrojejunal anastomosis (GJA) 42.2%-67.8%, gastric pouch 10.2%, excluded stomach 3.4%, jejunojenual anastomosis 5.5%-7.8%, or in a combination or these sites in 14%[11,12]. As for sleeve gastrectomies, the most common location of staple line leak is the proximal third of the stomach occurring at the level of the cardiac notch in approximately 75%-87.5%[13,14]. Overall leak rate-related mortality is low (0.6%) in RYGB, however leak associated mortality is significantly higher (14.7%-17%)[9,15]. The results are similar in the sleeve gastrectomy population with an incidence of 1%-2.7%[14,16-18], overall leak-related mortality 0.14%, and leak associated mortality 9%[14].

Anastomotic leaks can be classified as acute < 7 d, early 1-6 wk, late 6-12 wk, chronic > 12 wk[17]. Regardless of the time at which the anastomotic leak occurs, a thorough clinical assessment must me performed. Diagnosis of these leaks can be quite difficult with the most commonly found abnormality being sustained tachycardia > 120 bpm[19,20]. Other symptoms that have been reported are abdominal pain, use of more analgesics than expected, no ambulation within 2 h of surgery, and shortness of breath[11]. Laboratory abnormalities may show leukocytosis or an elevated C-reactive protein, although these are not always present. The use of an upper gastrointestinal series with water-soluble contrast or computed

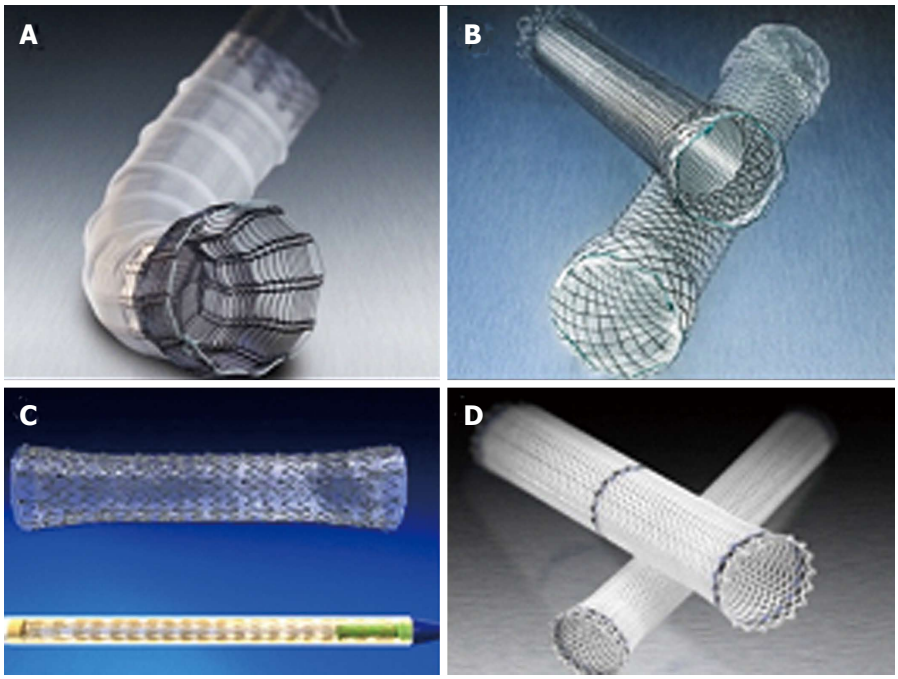

Figure 1 Self-expanding metal stents. A: Partially covered self-expanding metal stent; B: Partially and fully covered self-expanding metal stents; C: Fully covered self-expanding metal stent; D: Self-expanding plastic stent. Images courtesy of BostonScientific.com and Endotek.merit.com.

tomography may confirm the diagnosis, however these tests should not delay a return to the operating room. Most surgeons (86%) would take the patient to the OR with an unconfined and persistently symptomatic patient[17]. The majority (39%-81%) of patients with acute or early anastomotic leaks will ultimately return the the OR[11,12,19,20]. In the subgroup of patients who have minimal symptoms, are hemodynamically stable, and have a contained leak, conservative management may be warranted. Traditionally this management was NPO status, broad-spectrum antibiotics, percutaneous drains, and parenteral nutrition[11].

Endoscopic stents were initially designed as a tool of palliation for obstructing esophageal, gastric, and colorectal cancer. Some of the first published data for using stents across an anastomotic leak was in the thoracic population after esophageal resections. Leak rates as well as mortality after re-operation in this population was much higher therefore prompting a more conservative solution[21]. Most endoscopic stents used today are covered self-expanding metal stents (SEMS), partially covered self-expanding metal stents, and covered self-expanding plastic stents (SEPS) (Figure 1). These stents will provide a barrier between endoluminal bacteria and the acidic enteric content and the anastomotic disruption. Having an intraluminal device that will keep the anastomosis patent may also prevent wound contraction and the subsequent development of stenosis. The presence of these stents also confers the advantage of early enteral feeding. Healing success is defined as radiological confirmation of no leak after removal of stent. Stents are successful in 80%-94% of acute anastomotic leaks with stents left in place ranging from a mean of 41 d to 3.2 mo. Most patient may resume an oral liquid diet within 1-3 d. The most common side effects of the stent are early satiety, nausea, epigastric pain, and hypersialosis[22-24]. In a recent international expert panel consensus including 24 centres and over 12000 cases of laparoscopic sleeve gastrectomy (LSG), 93% of responders found the use of a stent for and acute proximal leak is a valid treatment option[17]. The most frequent complication of stent placement is stent migration seen in 16.9%-59%[25]. Most migrations are only a few centimetres, however this is enough to uncover the leak. The stents may also migrate distally with most passing per rectum. Only a few require an elective operation for stent retrieval. An urgent OR for erosion through the gastrointestinal wall and laceration of a blood vessel has also been described. Partially covered SEMS, larger diameter (18-22 mm), and longer length (15 cm) seem to have the least potential to migrate. The procedure of stent placement is most commonly performed in the operating room under general anesthesia with edotracheal intubation. The endoscope is use to identify the location of the leak and mark the location with radio-opaque clips. A guide-wire is also placed through the Roux limb. Under fluoroscopy, the stent deployment system is positioned across the leak and released. The length of the procedure can range from 23-47 min[24,26,27]. Endoscopic extraction is easiest with fully covered SEMS or SEPS. They can be grasped with large toothed graspers and extracted with firm steady pressure. Partially covered SEMS may have tissue ingrowth at either end. Two common techniques from removal are argon plasma coagulation and insertion of SEPS within the SEMS to induce tissue necrosis and easy extraction at a later date.

BLEEDING

Early bleeding after surgery can be intraluminal or extraluminal. The most frequent site of bleeding is the site of the anastomosis of staple lines. A risk factor for early bleeding is the presence of diabetes mellitus. The minority of bleeds will require an intervention more involved than a simple blood transfusion, and even fewer will require reoperation (21%)[28]. Bleeding is most often diagnosed with a postoperative decrease in hemoglobin. Uncommon clinical findings are hemoptysis, bright red blood pre rectum, or melena. A patient with hemodynamic instability, a distended or tender abdomen, or falling hemoglobin should be managed with an expeditious return to the operating room.

The gastroscope may be used may be used cautiously in the early post op with minimal air insufflation to avoid undue tension on the fresh anastomosis. The use of endoclips (Figure 2) alone or in combination with epinephrine is preferred to electrocautery[29].

FISTULAS

Anastomotic disruption with a more indolent and contained leak may ultimately form a fistula. A theory for the formation of a gastrogastric fistula is an incomplete transection of the gastric pouch and gastric remnant. The most common locations of an enteric fistula after bariatric surgery are gastrogastric, gastrocutaneous, duodenocutaneous, gastroperitoneal, and more rarely gastro-bronchial[8,26,30]. The incidence of gastric fistulas after bariatric surgery has not been well described, it may be in the order of 14.2% after an anastomotic leak[19]. The presence of a fistula will increase mortality with an order of magnitude of 8%-37.5%. It will also increased morbidity associated with a prolonged hospital stay, frequent hospital/clinic visits, and home care[31]. Success after stenting has been much less favourable than in the acute leaks. The success ranges from 19%-81%[19,26,32]. During an international expert panel for LSG, 89% of centres agree that stenting has a limited utility for chronic leaks (> 12 wk)[17]. Bège *et al*[25] have described a series of interventions starting with endoscopic drainage and debridement (± Amikacin 500 mg into the cavity), placement of a nasocystic tube, and placement of a plastic double-pigtail stent. A stent was inserted if the opening was more than 1 cm in diameter. The stent was secured proximally with endo-clips. If there was no resolution after 6 wk, therapeutic endoscopy was performed with placement of clips and/or injection of synthetic glue (N-butyl-2-cyanoacrylate) within the fistula cavity. Success after the first intervention was 64% of patients with late leaks/fistulas. Eisendrath *et al*[26] had a 61.9% success after stent alone, and an increased success rate of 80.9% the use after biologic glue, fistula plug, or clips.

ULCERS

Marginal ulceration may be seen in 0.49%-20% after RYGB[33-35]. The most common symptoms include epigastric pain, nausea, vomiting, food intolerance and bleeding. It is one of the most common finding on endoscopy in patients presenting with abdominal pain (52%)[36]. Risk factors include smoking (OR = 30.6), NSAIDs (OR = 11.5), diabetes (OR = 5.6), ischemia, increased stomach acid, bile acid reflux, *Helicobacter pylori* (*H. pylori*), steroids, alcohol, and foreign body[35,37-40]. Management is largely directed to the suspected etiology. Cessation of smoking, NSAIDs, and good blood glucose control is paramount. Proton pump inhibitors taken twice daily and tapered for 3-6 mo have had good results. If sampling of gastric fluid reveals normal or alkaline pH, sucralfate four times daily may have better results[41]. Biopsy proven *H. pylori* should be treated and visible suture should be removed. Non-healing ulcers should raise the possibility of a gastrogastric fistula.

STENOSIS/STRICTURE

This late complication can present with early satiety, nausea, vomiting, dysphagia, obstruction, retrosternal or abdominal pain[35]. These most commonly occur at the GJA and have an incidence of approximately 3%-12%[42-45]. Less frequently, stenosis can be seen at the enteroenteric anastomosis, the passage of the Roux limb through the mesocolon (Retrocolic approach only), and the Petersens defect. They most commonly present after 4-8 wk post op[46,47]. GJA with a linear stapler has a lower stricture rate of 2% compared to the 21 mm circular EEA stapler with a rate of 14%[19]. Risk factors include small (< 25 mm) circular stapler and marginal ulcers. The majority (90%) of patients will be amenable to endoscopic dilatation[47-49]. Dilatation may be attempted cautiously in as early as 4 wk post operatively. Frequently two, three or more dilatation may be required. With conscious sedation, the endoscope is passed to the level of the GJA. The diameter of the stricture is frequently be smaller than 3 mm and precludes passage of the endoscope. Caution must be applied when passing a guide wire

and the balloon dilator through the stenosis blindly. If any resistance is encountered, it should raise the possibility of passage into the blind limb. The balloon dilator is passed through the structured segment until its midpoint is at the maximal level of the stenosis. The smallest balloon is used initially and the size is progressively increased with every successful dilatation. This is felt to reduce the risk of perforation reported to be 3%-5%[46]. Dilatations of up to 15 mm, even in the first procedure, have been shown to be safe. The use of stents for treating strictures that have failed dilatation has not been fruitful. Puig *et al*[32] have had minimal success with only 2 of 16 patients not requiring and operative revision.

CONCLUSION

As the number obese patients increases, as will the number bariatric procedures. We will be left with a large number of patients with complications requiring adequate diagnosis and treatment. The surgeon is expected to promptly identify and appropriately manage early and late complications. Only surgeons who have performed the operations truly understand the new anatomy. Diagnostic and therapeutic endoscopy should be considered a first line tool in stable patients with perioperative complications such as anastomotic/staple line leaks, and bleeding. The placement of self-expanding metal or plastic stents in a patient with an anastomotic leak has shown favourable results. Late complication often present with vague complaints such as nausea, vomiting, or abdominal pain. Endoscopy is an excellent instrument for early diagnosis and treatment. SEMS, SEPS alone or in combination with metal clips, biologic glues, and biologic fistula plugs for treatment of fistulas should be considered first line therapy despite modest results. This strategy should greatly decrease the morbidity and mortality by reducing the rate of a revision surgery.

Abstract

The prognosis of early gastric cancer (EGC) is good if there is no concomitant lymph node metastasis. Therefore, the early detection of EGC is important to improve the prognosis of patients with gastric cancer. In Japan, 40% to 50% of all gastric cancers are EGC, and endoscopic submucosal dissection (ESD) is widely accepted as a local treatment for these lesions, particularly for large lesions that at one time were an indication for gastrectomy because of the difficulty of *en-bloc* resection. Consequently, this procedure can preserve the entire stomach and the patient's postoperative quality of life. ESD has become a general technique with improved procedures and devices, and has become the preferred treatment for EGC rather than gastrectomy. Therefore, ESD may demonstrate many advantages in patients who have several comorbidities, particularly elderly population, patients taking antithrombotic agents, or patients with chronic kidney disease, or liver cirrhosis. However, it is not yet clear whether patients with both EGC and comorbidities are feasible candidates for ESD and whether they would consequently be able to achieve a survival benefit after ESD. In this review, we discuss the clinical problems of ESD in patients with EGC and those comorbid conditions.

Endoscopic submucosal dissection in early gastric cancer in elderly patients and comorbid conditions. *World J Gastrointest Endosc* 2015; 7(5): 524-531 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/524.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.524

INTRODUCTION

Gastric cancer is the fourth most common cancer and the second most common cause of cancer-related death in both sexes worldwide[1,2]. The incidence of gastric cancer has declined in younger populations along with decreasing infection rates of *Helicobacter pylori (H. pylori).* The infection rate of *H. pylori,* however, remains high in elderly Asian populations. In 2002, nearly 1 million new cases of gastric cancer were diagnosed, and more than half of these cases were from East Asia, including 41% from China and 11% from Japan[3]. Therefore, gastric cancer remains one of the most common cancers in Asian countries[4]. Patients with advanced gastric cancer have a poor prognosis; however, the prognosis of early gastric cancer (EGC) is good[5,6], and the 5-year gastric cancer-specific survival rate was reportedly 99% in cases that lacked concomitant lymph node metastasis[7]. EGCs account for 40% to 50% of all gastric cancers in Japan. Endoscopic resection (ER) is an alternative to surgery for treatment of mucosal neoplasms[8]. The criteria for ER for EGC was classified into the following three groups proposed by Gotoda *et al*[9] based on the characteristics of the initially detected tumor: "guideline group", "expanded guideline group" and "non-curative group". The guideline group was defined as mucosal differentiated cancer with the largest diameter measuring ≤ 20 mm. In Japan, ER is definitely indicated for this group. The expanded guideline group was defined as the following: (1) mucosal differentiated cancer measuring > 20 mm in diameter; (2) mucosal differentiated cancer with ulceration and measuring ≤ 30 mm in the largest diameter; and (3) differentiated cancer measuring ≤ 30 mm in the largest diameter with a submucosal invasion depth of < 500 μm. If the lesions did not meet these criteria, they were classified as the non-curative group. ER includes endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD)[10]. EMR has been a standard technique for early gastric cancer with no risk of lymph node metastasis. EMR is, however, reportedly difficult to achieve *en-bloc* complete resection for the removal of lesions with the extended indication[11]. ESD is widely accepted as a treatment for EGC, particularly for larger lesions that at one time were an indication for gastrectomy because of the difficulty of *en-bloc* resection. Consequently, this procedure can preserve the entire stomach and improve the patient's postoperative quality of life. Moreover, ESD has become a standard technique with improved procedures and devices. Now, EMR has been replaced by ESD.

Because most patients with EGC are elderly, these patients commonly have several comorbidities that involve medical treatment, such as antithrombogenic agents to combat thrombosis, chronic kidney disease, or liver cirrhosis. In this review, we discuss the clinical problems associated with ESD in patients with EGC and comorbid conditions.

ELDERLY PATIENTS

Most patients with gastric cancer are diagnosed between their late 60s and 80s[12]. Therefore, most patients with EGC are elderly and therefore have an increased risk for procedure-related complications or events. EGCs generally grow slowly, and thus, we must determine a therapeutic strategy that considers the presence of comorbid diseases.

Most of elderly individuals have multiple chronic medical conditions[13]. Therefore, any indication for elderly patients with EGC must account for both life expectancy and concomitant conditions or diseases. However, there is little evidence that endoscopic resection is well tolerated in the elderly EGC patients who are most likely to benefit from resection.

Kakushima *et al*[14] previously reported the safety and efficacy of ESD for EGC in elderly patients aged 75 years or older (average age, 79 years old). Indeed, 57% of these patients also presented with comorbid diseases, but the *en-bloc* plus R0 resection rate and the complication rate in elderly patients were not significantly different from those of younger patients. Kakushima *et al*[14] concluded that ESD for gastric neoplasms is safe and effective in both elderly patients and younger patients. We also retrospectively validated whether gastric ESD was feasible even for elderly patients. In a study of 459 patients aged 75 years or older among 1188 EGC patients, perforation occurred in 20 patients (4.4%), and bleeding occurred in 12 patients (2.6%)[15]. The incidences of those complications were similar to those in the younger patients. Advanced age (*i.e.,* older than 75 years), however, is associated with an increased risk for postoperative pneumonia. Toyokawa *et al*[16] reported that the rate of late bleeding rate was significantly higher in elderly patients aged 75 years or compared with

Zhang *et al*[56]	≥ 75	171, 187	98, 94.1		(15.2%)[2]	NE

[1]Bleeding was defined in cases that required endoscopic management with methods such as clip placement and/or monopolar electrocoagulation to stop the bleeding, including early and late bleeding. One patient required surgery to treat the bleeding; [2]Immediate bleeding. NE: Not evaluated.

younger patients (9.6% *vs* 5.3%, $P = 0.0473$). After a multivariate analysis, the size of the resected specimen was the only significant risk factor for delayed bleeding. Recently, Park *et al*[17] reported that with expanded criteria as proposed by Gotoda *et al*[18], overall survival did not differ between elderly patients with EGC who underwent ESD and those who underwent surgery, although the risk of metachronous lesions was higher in patients who underwent ESD[17]. A propensity-matched analysis indicated that all of the adverse events observed in the ESD group were successfully treated and did not result in mortality. In contrast, two patients in the surgery group died of operation surgery-related complications, although no significant difference was observed between the two groups. Based on these data, we believe that gastric ESD in elderly patients is feasible and that EGC is manageable with this treatment (Table 1).

PATIENTS TREATED WITH ANTITHROMBOTIC AGENTS

In the last few decades, the number of patients treated with oral antithrombotic agents, including antiplatelet agents and anticoagulants, has increased worldwide in an effort to prevent or reduce thromboembolic events[19]. Recently, many novel oral anticoagulant drugs have been presented as alternatives to vitamin K antagonists and are either currently available or in the early or advanced stages of clinical development[20].

In patients who undergo minor surgical procedures, the discontinuation of antithrombotic therapy may not be required. However, patients who undergo major surgical procedures are required to discontinue the use of these drugs to minimize their risk for perioperative bleeding, as the continuation of antithrombotic agents in the perioperative period may lead to an increased risk of bleeding. In endoscopic procedures, antithrombotic agents may be discontinued when a patient is judged to have a low risk of thrombosis. The appropriate cessation of antithrombotic therapy has recently been reported to not increase the rate of delayed bleeding[21,22]. However, when gastric ESD is scheduled in a patient treated with oral anticoagulants (*e.g.*, warfarin) and judged by the prescribing doctor to have a high risk of thromboembolism, he or she will also undergo heparin replacement (HR). Similarly, when gastric ESD is scheduled in a patient treated with antiplatelet agents (*e.g.*, aspirin, ticlopidine, clopidogrel and cilostazol) and judged to have a high risk of thromboembolism, he or she will be placed on a continuous aspirin or cilostazol regime according to recently published guidelines from the Japan Gastroenterological Endoscopy Society[23]. In patients at high risk of thrombosis, the risks of both bleeding and thrombosis are unclear in patients who undergo endoscopic invasive procedures, such as gastric ESD.

Regarding antiplatelet agents, the continuous use of aspirin during the perioperative period of ESD has been reported to be acceptable, although the rate of delayed bleeding is slightly higher[24,25]. In an analysis of the combination of antiplatelet agents and anticoagulants, Koh *et al*[26] reported that antithrombotic therapy increased the risk of delayed bleeding. Takeuchi *et al*[27] also reported that the rate of postoperative bleeding in patients taking antithrombotic agents was 23.3%, which is significantly higher than the 2.0% observed in patients not treated with antithrombotic agents. Despite the discontinuation of antithrombotic agents, the authors found that combination therapy of low-dose aspirin (LDA) plus warfarin was a significant predictor of post-ESD bleeding (OR = 14.83, $P < 0.001$).

We believe that not only is LDA plus warfarin combination therapy a risk factor for late bleeding but also that HR is a risk factor for this condition. HR therapy is used as a bridge therapy along with invasive treatments to prevent antithrombotic events. We previously showed that the rate of delayed bleeding was high during gastric ESD (38%)[22] or colon polypectomy (20.0%)[28] under HR therapy.

However, few studies on the relationship between thrombotic events and endoscopic procedures have been conducted. The incidence rates of thrombotic events related to gastric ESD have been reported to range from 0 to 4.2%[21,22,24,27] (Table 2). We encountered one patient (4.2%) with delayed bleeding in the HR group who experienced a thrombotic event[22]. The patient's activated partial thromboplastin time was sufficiently prolonged under HR after successful endoscopic hemostasis for late bleeding. Although the patient discontinued the use of all antiplatelet agents, a cerebral infarction developed on post-operative day 13. Therefore, thrombosis during bleeding should be carefully considered, despite the presence of a sufficient anticoagulant effect during the perioperative period (Table 2).

[1]Forty-four low-risk patients stopped treatment with antithrombotic agents for 1 wk before and after endoscopic submucosal dissection (ESD). Three high-risk patients underwent intravenous heparin replacement during the cessation period; [2]A total of 274 patients were treated with antiplatelet medication, 102 of whom discontinued the use of these drugs for 7 d or more before ESD, whereas the remaining patients continued use; [3]One (1%) of the 102 patients who discontinued the use of antiplatelet medication developed an acute cerebral infarction; [4]Antithrombotic drug therapy was principally interrupted preoperatively and restarted when hemostasis was confirmed by second-look endoscopy. The rate of early postoperative bleeding during the first 5 postoperative days was 4%, and the rate of subsequent bleeding was 5.7%; [5]All patients commenced treatment with proton pump inhibitors immediately following surgery. Antiplatelet agents were discontinued for 7 d preoperatively until postoperative day 1, and anticoagulants were discontinued for 5 d preoperatively until postoperative day 1. A total of 46 patients received low-dose aspirin (LDA) only, 23 received LDA + thienopyridine, and 21 received LDA + warfarin. Anticoagulants were discontinued from preoperative day 4 to postoperative day 2. Heparin was substituted for anticoagulants after the latter were discontinued; [6]All patients underwent intravenous heparin replacement during the cessation period because of an increased risk of thromboembolism. HR: Heparin replacement; NA: Not applicable; NE: Not evaluated.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is associated with significant morbidity and mortality and is now recognized as a worldwide problem because the number of patients with CKD is sharply increasing[29]. In Japan, clinical practice guidelines have reported that the frequencies of stage 1, 2, 3, and 4/5 CKD in adults were 0.6%, 1.7%, 10.4% and 0.2%, respectively, in 2009. The total number of patients in stages 3 to 5 was estimated to be approximately 10.97 million[30]. Renal function linearly deteriorates with age. Therefore, the number of patients with CKD is higher in elderly populations, and consequently, the number of patients with gastric cancer and CKD is also believed to be increasing. Patients with CKD are more likely to experience multiple complications during the surgical procedure, such as procedure-related bleeding due to uremic platelet dysfunction and tissue vulnerability, compared with patients without CKD[31,32]. The safety and feasibility of gastric ESD for patients with CKD, however, are unclear.

Mannen *et al*[33] reported no significant risk factors for complications from gastric ESD among 17 patients with CKD. Goto *et al*[34] reported complications from gastric ESD in 7 patients with CKD who underwent hemodialysis (HD), one patient experienced delayed bleeding that required a blood transfusion, followed by shunt occlusion. Although all of the lesions were resected *en-bloc* with R0 resection, the authors concluded that ESD in patients with CKD should be carefully considered for substantial risks because late-onset complications may turn out to be severe. Kwon *et al*[35] also conducted a single-center retrospective study in which 17 patients with CKD were compared with 894 control patients who received gastric ESD. They reported no significant differences in *en-bloc* resection and perforation rates between patients with CKD and patients without CKD, but a tendency to hemorrhage was observed in patients with CKD. Numata *et al*[36] reported that the rate of post-ESD bleeding was 33% in 15 lesions in 12 patients with HD among the 63 patients with CKD, whereas the rate of post-ESD bleeding was only 9% in patients without HD. In addition, 2 deaths related to the ESD procedure were reported, but no deaths due to EGC occurred. Both of these patients were receiving HD, and the deaths occurred subsequent to the bleeding. The authors concluded that the cause of the bleeding was associated with other comorbidities, such as the use of anticoagulants during HD[36]. To focus on the eGFR, we also evaluated 144 patients with CKD in a multicenter survey that included municipal hospitals, where many patients with CKD were among those who underwent ESD[37]. In our study, we included patients with gastric cancer under the expanded criteria[7], and found that 20 patients did not achieve curative resection (13.9%), whereas additional surgeries were performed in 14 patients (9.7%). No ESD-related deaths were reported in these 144 patients. With respect to short-term outcomes, late bleeding was observed in 1.1% of patients in stage 3 (1/92), 13.0% in stage 4(3/23), and 13.8% in stage 5 (4/29). All incidences of bleeding were controlled by endoscopic hemostasis, but 5 patients required a blood transfusion (3.5%). In a univariate Poisson regression analysis including CKD stage, HD, diabetes mellitus, use of antithrombogenic

ND: Not described; NE: Not evaluated.

agents and HR, the critical factors related to bleeding were CKD stage and HD. In multivariate Poisson regression analyses, the risk ratio of bleeding was 11.4 in patients with stage 4 CKD and 11.0 in patients with stage 5 CKD. Thus, we concluded that CKD calculated from the eGFR would be an independent risk factor regardless of whether a patient undergoes HD[37].

Gastric ESD in patients with CKD is technically feasible, even in patients undergoing HD. However, bleeding in patients with CKD may lead to death due to other comorbidities, such as conditions that require the use of anticoagulants. Therefore, particular attention should be paid to late bleeding in patients with CKD, particularly patients with advanced CKD (Table 3).

LIVER CIRRHOSIS

Liver cirrhosis (LC) is a common disease, especially in Japan and other East Asian countries, due to the high prevalences of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections[4]. *H. pylori* and HBV/HCV, respectively, are the leading causes of bacterial and viral diseases in humans worldwide, particularly in East Asian. Consequently, it is not rare for patients to be affected by these two diseases. Patients with LC have a poor prognosis because of liver failure or the development of hepatocellular carcinoma (HCC)[38], esophagogastric varices[39], compromised host[40], or glucose intolerance[41]. In contrast, the prognosis of patients with EGC is good[7]. Therefore, it is difficult to determine whether patients with cirrhosis and EGC are suitable for ESD because this procedure may not increase the survival benefit for patients with LC. Until now, several studies have focused on the clinical outcomes of radical gastrectomy in patients with gastric cancer and comorbid LC[42-47]. These studies indicate that 10%-20% of patients with LC develop postoperative intractable ascites, and that the perioperative mortality rate is approximately 10%. However, few investigators have reported whether gastric ESD can be performed safely in patients with poor liver function or gastric varices. During gastric ESD, the rate of bleeding rate may increase because LC is frequently accompanied by complex alterations in the hemostatic system[48,49], and patients with LC have fewer platelets and a prolonged prothrombin time. More specifically, it is technically difficult to perform ESD when a varix is located near a gastric lesion. Kim *et al*[50], however, reported a successful ESD adjacent to a fundal varix after treatment with endoscopic variceal obturation using N-byutyl-2-cyanoacrylate (Histacryl®).

Ogura *et al*[51] performed a case series study on short-term ESD outcomes for 18 patients with LC. The authors reported that *en-bloc* resection was achieved in 88.9% of patients with EGC and cirrhosis but that the rate of late bleeding rate appeared to be higher (20%). Kwon *et al*[35] reported that the procedure time and short-term outcomes in patients with cirrhosis, such as the rates for *en-bloc* and complete resections, did not differ from those of the control group, even though the results of endoscopic mucosal resection were included. Immediate bleeding tended to occur more frequently in patients with both LC and CKD than in controls (47.5% *vs* 33.9%, $P = 0.077$). However, no significant difference was observed in the incidence of perforation[35]. We also evaluated outcomes of gastric ESD among 69 patients with LC. Based on a propensity-matched analysis, 53 (77%) of these patients had Child Pugh Grade A (CP-A) and 16 (28%) had Child Pugh Grade B/C (CP-B/C) compared with patients without LC[52]. In that study, short-term outcomes did not differ between the patients with LC and controls or between the patients with CP-A and those with CP-B/C. This study, however, revealed that the CP grade and HCC history were significantly independent risk factors for poor prognoses according to a Cox proportional hazards model. Patients with cirrhosis and CP-A demonstrated an overall survival that was nearly equivalent to that of patients without cirrhosis; however, patients with cirrhosis and CP-B/C or with histories of HCC had significantly worse long-term outcomes (the overall 3- and 5-year survival rates after ESD were 58% and 26%, respectively). Therefore, the long-term outcomes of patients with cirrhosis were likely influenced by liver

function or cirrhosis-related conditions rather than by gastric cancer. We concluded that patients with cirrhosis and CP-A appear to be good candidates for ESD but that patients with CP-B/C or with histories of HCC benefit less from ESD (Table 4).

CONCLUSION

This review demonstrated that gastric ESD could be performed safely, even in medically complex patients, such as elderly patients, those who are being treated with antithrombotic agents, and those with CKD or LC regarding the risk of complication, particularly bleeding. Although the short-term outcomes were not inferior, ESD was less beneficial to the survival of patients with a poor prognosis.

Abstract

Beta-adrenergic receptor antagonists (β-blockers) have been well established for use in portal hypertension for more than three decades. Different Non-selective β-blockers like propranolol, nadolol, timolol, atenolol, metoprolol and carvedilol have been in clinical practice in patients with cirrhosis. Carvedilol has proven 2-4 times more potent than propranolol as a beta-receptor blocker in trials conducted testing its efficacy for heart failure. Whether the same effect extends to its potency in the reduction of portal venous pressures is a topic of on-going debate. The aim of this review is to compare the hemodynamic and clinical effects of carvedilol with propranolol, and attempt assess whether carvedilol can be used instead of propranolol in patients with cirrhosis. Carvedilol is a promising agent among the beta blockers of recent time that has shown significant effects in portal hypertension hemodynamics. It has also demonstrated an effective profile in its clinical application specifically for the prevention of variceal bleeding. Carvedilol has more potent desired physiological effects when compared to Propranolol. However, it is uncertain at the present juncture whether the improvement in hemodynamics also translates into a decreased rate of disease progression and complications when compared to propranolol. Currently Carvedilol shows promise as a therapy for portal hypertension but more clinical trials need to be carried out before we can consider it as a superior option and a replacement for propranolol.

Key words: Portal hypertension; Chronic liver disease; Non-selective beta-blockers; Propranolol; Carvedilol

Core tip: Carvedilol is a promising agent among the beta blockers of recent time that has shown significant effects in portal hypertension hemodynamics. For primary prophylaxis of variceal bleeding, the effects of carvedilol were compared to band ligation in a few trials and showed some promise, but there has been no comparison with propranolol. Patients not responding to propranolol have shown clinical response to carvedilol, opening a new window of clinical application. For secondary prophylaxis of variceal bleeding, carvedilol has been shown to be effective. However no head-to-head trials comparing propranolol and carvedilol for variceal re-bleeding were found in literature.

INTRODUCTION

Liver cirrhosis remains the 12th leading cause of death worldwide according to estimates by the Global Burden of Disease Study[1]. Portal hypertension is an inevitable consequence of cirrhosis and underlies most of its complications like: variceal bleeding, ascites and hepatic encephalopathy[2]. Portal hypertension is characterised by a pathologic increase in the portal pressure gradient (the pressure difference between the portal vein and the hepatic veins) y greater than 5 mmHg. This causes the creation of porto-systemic collaterals leading to shunting of portal blood to the systemic circulation, bypassing the liver parenchyma. It has been shown that therapeutic reduction in portal pressure has been shown to improve clinical outcomes and reduces the incidence of recurrent haemorrhage, ascites, encephalopathy, and death[3-5].

Beta-adrenergic receptor antagonists (β-blockers) have been well established for use in portal hypertension for more than three decades. Non-selective β-blockers (NSBB) have been widely utilized since 1980, when the first article on their role in portal hypertension was published by Lebrec *et al*[6]. Portal hypertension results from fibrosis or regenerative nodules in the liver parenchyma increasing resistance to flow and causing mechanical obstruction; contraction of sinusoidal and perisinusoidal contractile cells (stellate cells and vascular smooth muscle cells) with intrahepatic imbalance between vasoconstrictors (such as endothelin 1 and angiotensin) and vasodilators; and splanchnic vasodilatation in secondary to a relatively ischemic liver or extrahepatic excess of NO, with sGC-PKG signalling and smooth muscle cell relaxation[7] (Figure 1).

NSBB have a dual mode of action decrease portal pressure, *i.e.*, reduction of cardiac output and splanchnic blood flow by β-1 receptor blockade, and β-2 receptor blockade, resulting in splanchnic vasoconstriction caused by unopposed effect of alpha 1 receptors[7]. NSBBs have been proven to decrease incidence of bleeding (primary prophylaxis) and re-bleeding (secondary prophylaxis) from esophageal varices[8-11]. It has been demonstrated that they also prevent bleeding from portal hypertensive gastropathy and development of spontaneous bacterial peritonitis[4,12,13]. Due to their widely diverse effects in patients with cirrhosis and widespread use, they have been dubbed as "aspirin" in clinical hepatology[14].

Different NSBBs like propranolol, nadolol, timolol, atenolol, metoprolol and carvedilol have been in clinical practice in patients with cirrhosis. Propranolol was the first, most widely studied NSBB and mainstream for treatment of portal hypertension. Carvedilol is a nonselective beta-blocker with intrinsic anti-alpha1-adrenergic activity. It has been a relatively newer addition to the NSBBs, in the arena of portal hypertension and has demonstrated promising results in terms of clinical outcomes.

Carvedilol has proven 2-4 times more potent than propranolol as a beta-receptor blocker in trials conducted testing its efficacy for heart failure[15]. Whether the same effect extends to its potency in the reduction of portal venous pressures is a topic of ongoing debate.

The aim of this article is to compare the hemodynamic and clinical effects of carvedilol with propranolol, and attempt assess whether carvedilol can be used instead of propranolol in patients with cirrhosis.

HEMODYNAMIC EFFECTS

To achieve successful protection against gastrointestinal bleeding, the portal pressure [usually measured as the hepatic venous pressure gradient (HVPG)] has to be decreased to ⩽ 12 mmHg or by 20% of baseline values[16]. Long-term follow-up of cirrhotic on beta blockers has shown that decrease of HVPG of above mentioned values results in lesser risk of developing variceal bleeding, ascites, spontaneous bacterial peritonitis (SBP), hepatorenal syndrome and hepatic encephalopathy[4].

Comparison of carvedilol to propranolol for portal hypertension was made in a recent systematic review with meta-analysis which included five head-to-head randomised trials[17-22]. This analysis favored carvedilol against propranolol, in terms of: (1) acute effects on reduction in HVPG [mean weighted difference in % of reduction in hepatic vein pressure gradient; -7.70 (95%CI: -12.40--3.00)]; (2) long term effects [mean weighted difference in % of reduction in hepatic vein pressure gradient was -6.81 (95%CI: -11.35--2.26)]; and (3) overall effects [(mean weighted difference in % of reduction in hepatic vein pressure gradient -7.24 (95%CI: -10.50--3.97)].

Additionally the same metaanalysis showed that Carvedilol had a lower relative risk of failure to achieve hemodynamic response than propranolol. The number of patients who achieved a reduction in HVPG to ⩾ 20% or to ⩽ 12 mmHg was reported in 4 of the 5 studies and was also markedly higher with carvedilol *vs* propranolol (57/94 *vs* 33/87). However, this favourable difference for carvedilol did not reach statistical significance.

Carvedilol caused more reduction in arterial blood pressure resulting in orthostatic hypotension as compared to propranolol. Propranolol caused a - 6.66 mmHg (95%CI: -10.17--3.15) mean reduction in arterial pressure whereas carvedilol caused a mean reduction of -10.40 (95%CI: -13.9--6.9). The reduction in mean arterial pressure was found to be significant

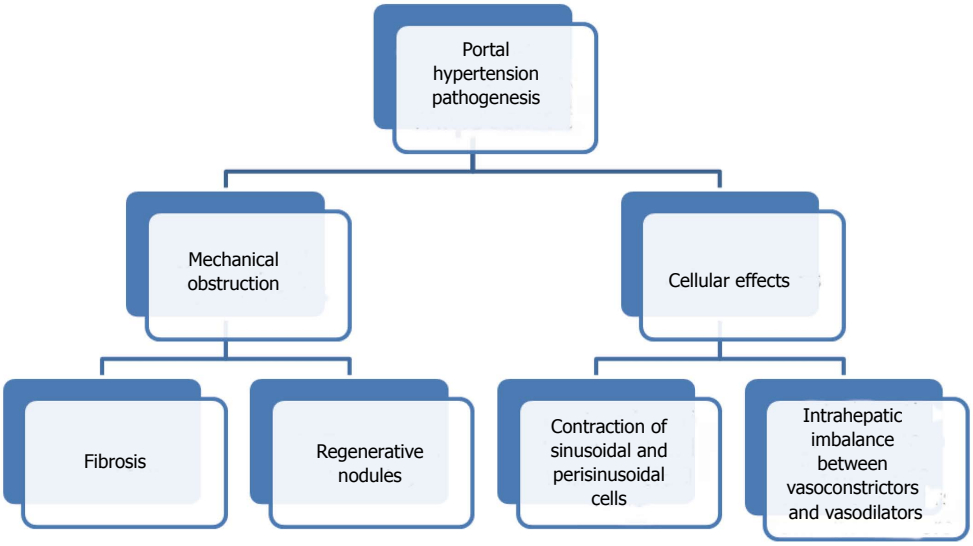

Figure 1 Pathogenesis of portal hypertension.

with both drugs, but the degree of reduction was in the order of one-third more with carvedilol compared to propranolol[17] (Figure 2).

Therefore carvedilol has been shown to be superior to propranolol in causing of acute, long-term and overall reduction of the hepatic venous pressure gradient, *i.e.*, portal venous pressure. The proportion of patients who demonstrated an adequate response is also higher for carvedilol.

Although the translation of these effects in terms of clinical benefit of reduced gastrointestinal bleeding events is significant, these changes in hemodynamic parameters come at the cost of orthostatic hypotension and fluid retention including ascites, with the use of carvedilol. However carvedilol can be a safe alternative in patients who are not hypotensive. In addition carvedilol has achieved significant hemodynamic response in more than half of the patients who were resistant to propranolol[23].

CLINICAL EFFECTS

Variceal bleeding

Pre-primary prophylaxis: Prevention of development of varices in patients with portal hypertension is known as pre-primary prophylaxis. Experimental models of portal hypertension have shown that B-Blockers delay the development of collaterals[24,25]. Escorsell *et al*[26] demonstrated that administration of β-blockers (timolol) to patients without varices caused a greater reduction in portal pressure than the reduction seen in patients with varices[26]. However this effect of use of timolol did not translate into prevention of variceal formation and variceal hemorrhage in a randomised study by Groszmann *et al*[27] which compared timolol with placebo in patients without varices. The study by Calés *et al*[28] using propranolol, for pre-primary prophylaxis did not show clinical benefit in terms of variceal development. To-date there were no studies using carvedilol for pre-primary prophylaxis.

Due to lack of any demonstrated clinical benefits of β-blockers in patients with portal hypertension without varices and adverse effects of these medications, none of the current guidelines (including Baveno V consensus[2], AASLD[29], and EASL/AASLD consensus[30]) recommend their use for pre-primary prophylaxis.

Primary prophylaxis: NSBB are recommended for use in primary prevention of variceal bleeding, as they have been associated with decrease in incidence of first bleeding episode and mortality benefits[2].

A meta-analysis of published randomised controlled trials on primary prophylaxis including 1859 patients, revealed pooled risk difference of 11% in incidence of variceal bleeding with use of propranolol against controls[31]. In another meta-analysis, D'Amico *et al*[32] demonstrated that in patients with varices of any size, β-blockers reduced the risk of a first bleeding episode from 25% to 15% within 2 years. The absolute risk difference was 9% (15% *vs* 24%) as compared to placebo. Moreover, the absolute risk reduction in mortality was found to be 4% (from 27% to 23%)[32].

Another meta-analyses has reported the usage of Beta blockers as primary prophylaxis to be associated with a 40% reduction in bleeding risk and a trend towards improved survival[33]. In a double-blind randomised trial, the Boston-New Haven-Barcelona Portal Hypertension Study Group compared propranolol with placebo for primary prophylaxis. There was significant difference in incidence of bleeding between the study groups favouring propranolol (incidence of bleeding 4% *vs* 22%; $P \leqslant 0.01$) during a mean follow-up of 16 mo. However there was no difference in mortality rates between the two groups[34].

Propranolol has been compared to esophageal band ligation (EBL) in terms of bleeding prevention

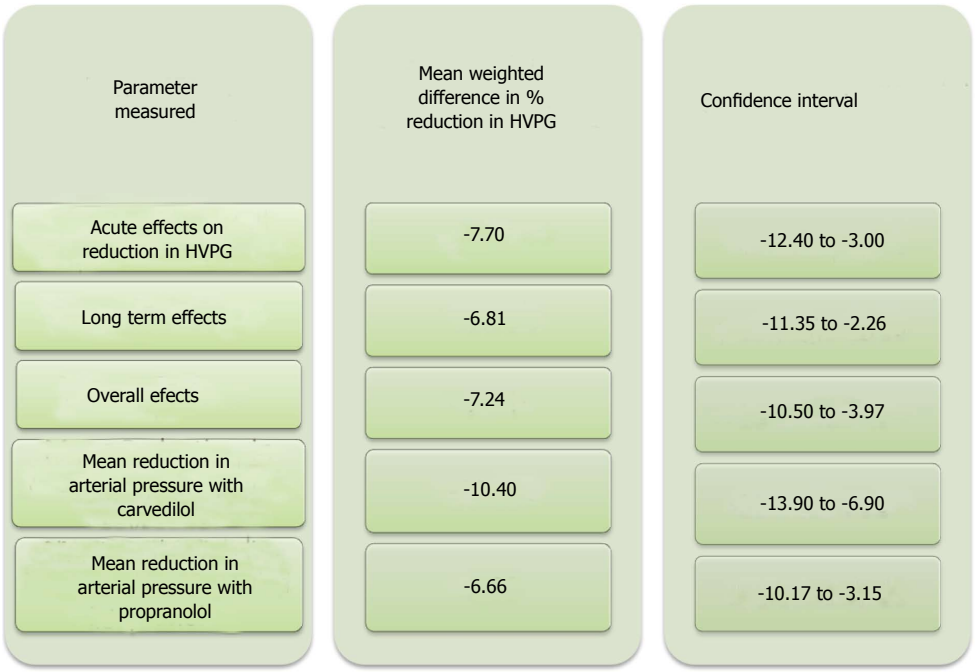

Figure 2 Hemodynamic effect of carvedilol compared to propranolol (Data from ref.[19]). HVPG: Hepatic venous pressure gradient.

and mortality reduction in patients with cirrhosis in several randomised controlled trials. A meta-analysis of sixteen randomised controlled trials found EBL causing significant reduction of the risk of first variceal bleeding compared to propranolol (relative risk difference 9.2%, 95%CI: 5.2%-13.1%, and POR 0.5, 95%CI: 0.37–0.68). However there was no statistically significant difference in Mortality between the two groups (POR 0.94, 95%CI: 0.70-1.28). On average, 3 endoscopic sessions were required to eradicate varices and at least 33 endoscopic procedures were needed to prevent one bleeding episode as compared with NSBBs[35]. However as NSBB are cheap, as haemodynamic monitoring is not required[36].

In a randomized control trial, Carvedilol has been compared with EBL and showed a significantly lower rate of first variceal bleeding (with minor adverse effects) in patients taking carvedilol 12.5 mg daily compared with EBL (10% *vs* 23%, HR = 0.41, 95%CI: 0.19-0.96)[37]. The lowest dose of carvedilol tested in this trial was 12.5 mg, which is known to cause a smaller reduction in HVPG than to actually cause prevention of first bleeding episode. So the results of this study need to be interpreted after considering its limitations[38].

Another randomised controlled trial by Shah *et al*[39] reported that both EBL and carvedilol groups had comparable variceal bleeding rates (8.5% *vs* 6.9%), bleeding related mortality (4.6% *vs* 4.9%) and overall mortality (12.8% *vs* 19.5%) respectively[39]. Although the study was underpowered, the authors suspect that carvedilol is not superior to EBL for primary prophylaxis of varices.

Use of carvedilol has been found to cause reduction of HVPG in patients failing to respond to propranolol, thus leading to lesser bleeding episodes in this group of patients. Bleeding rates followed up for 2 years were 11% with propranolol *vs* 5% with carvedilol and 25% with EBL (P = 0.0429)[23]. We did not find any studies comparing propranolol with carvedilol head-to-head for primary prevention.

Secondary prophylaxis: Secondary prophylaxis is prevention of recurrence after index variceal bleeding episode. The 1-year mortality after an episode of variceal bleeding is 40%[11]. Variceal bleeding recurs in 60% at 1-year with 6-wk mortality of 20% for every re-bleeding episode[2]. NSBBs have been widely used for prevention of re-bleeding and have been shown to decrease the rate of re-bleeding from varices to 42%, as compared to 63% in controls in several meta-analyses[32]. In addition these agents decrease overall mortality from 27% to 20%, and bleeding related mortality[40].

Carvedilol was compared with combination of nadolol and isosorbide-5-mononitrate in a randomized controlled trial in patients who previously had variceal bleeding. This study demonstrated that after a follow-up of 30 mo there was no significant difference in incidence of recurrent upper gastrointestinal bleeding between carvedilol and combination groups (62% *vs* 61%; P = 0.90). There was no significant difference between the Rate of recurrence of variceal bleeding between the carvedilol and combination groups (51% *vs* 43%; P = 0.46)[41]. Interim analysis of a multicentre randomised controlled study comparing carvedilol with endoscopic band ligation for secondary prevention of variceal bleeding, demonstrated no significant

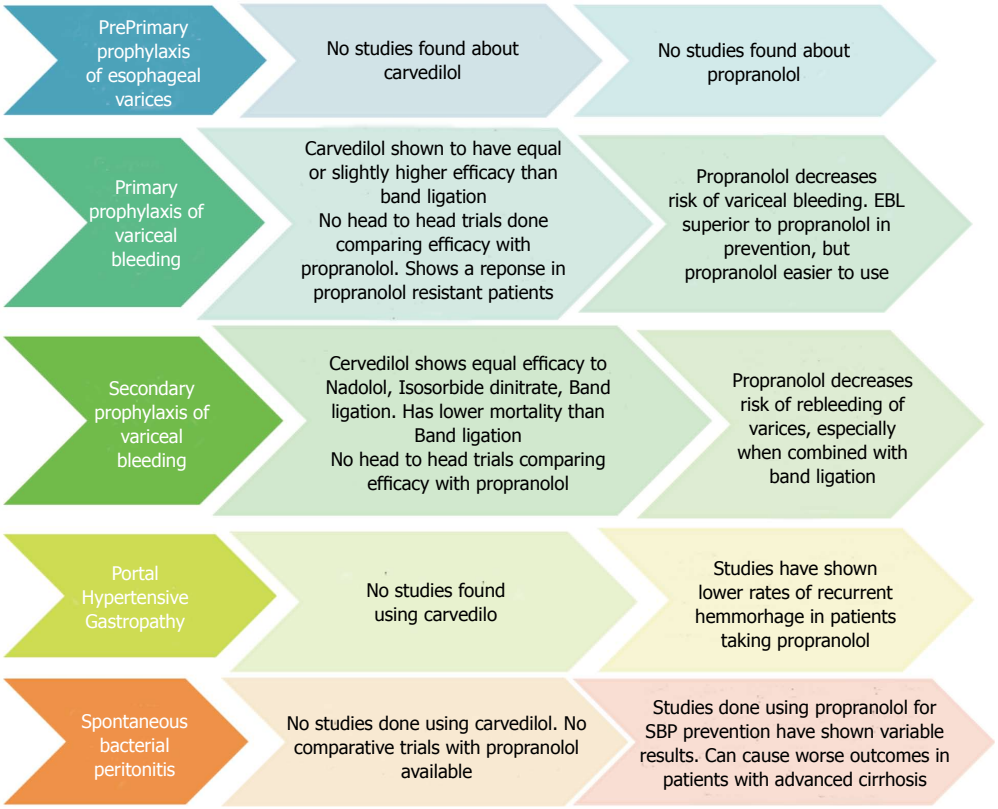

Figure 3 Current evidence about carvedilol and propranolol as prophylactic therapy.

difference between the groups in re-bleeding rates (37.5% *vs* 29%; $P = 0.72$). However the patients in carvedilol group had lower 1-year mortality rates as compared to EBL group (25% *vs* 51.6%; $P = 0.058$)[42].

The pioneer trial by Pagliaro *et al*[8] demonstrated that propranolol was effective in decreasing the incidence of variceal re-bleeding when compared to controls. A comprehensive meta-analysis of 12 randomised controlled trials for secondary prophylaxis of variceal bleeding showed that, use of β-blockers (11 using propranolol) was associated with increase in mean percentage of patients with no re-bleeding (21% mean improvement rate, 95%CI: 10%-32%, $P < 0.001$), the mean percentage of patients with no variceal re-bleeding (20% mean improvement rate, 95%CI: 11%-28%, $P < 0.001$), the mean survival rate (5.4% mean improvement rate, 95%CI: 0%-11%, $P < 0.05$, RR = 1.27), the mean percentage of patients free of bleeding death (7.4%, 95%CI: 2%-13%, $P < 0.01$, RR = 1.50)[40].

Baveno V consensus guidelines recommend a combination of β-blockers and variceal band ligation as the preferred therapy for secondary prophylaxis because it results in lower re-bleeding rates compared to either therapy alone[2]. Ahmad *et al*[43] compared combination of EBL and propranolol against propranolol for secondary prevention and found no statistical difference in re-bleeding (22% *vs* 38%) and mortality rates (23% *vs* 19%) between the groups. However the incidence of re-bleeding was higher in patients on propranolol alone[43].

Propranolol retains its place as the most widely used and studied drug for secondary prophylaxis with clear benefits as compared to placebo and combination with EBL. The evidence for carvedilol in variceal rebleeding recurrence is minimal but promising.

Portal gastropathy

Described as mosaic, snake-skin-like appearance of gastric mucosa with or without red punctuate erythema, portal hypertensive gastropathy (PHG) is estimated to be present in up to 80% of cirrhotic patients[44]. PHG can cause acute bleeding rarely with an incidence of 3% in three years, and in 2.5%-30% patients it may result in chronic insidious bleeding[45,46].

NSBBs have been shown to lower the incidence of bleeding in acute and chronic forms of haemorrhage from PHG. One of the earliest randomised controlled trials using propranolol showed lower haemorrhage rates, increase in haemoglobin level and an apparent improvement in the endoscopic appearance of the lesion when compared to placebo[47]. Pérez-Ayuso *et al*[12], in a randomised trial of used propranolol against no therapy in patients for secondary prophylaxis of bleeding from PHG. The study demonstrated higher number of patients remaining free of bleeding with propranolol in acute (85% *vs* 20%) and chronic setting (69% *vs* 30% at 30 mo). On multivariate analysis, the sole independent predictor of recurrent haemorrhage was the absence of propranolol[12].

Although the use of β-blockers for PHG is widespread, based upon current evidence strong recommendations can't be made for NSBB for this indication. We also did not find any studies using carvedilol to control bleeding from portal gastropathy.

Spontaneous bacterial peritonitis

NSBBs have been shown to have preventive effect on development of spontaneous bacterial peritonitis in a meta-analysis by Senzolo *et al*[13]. This analysis included three randomised controlled trials and two retrospective studies all using propranolol for prophylaxis of variceal bleeding, with respect to the incidence of SBP. Statistically significant difference of 12.1% ($P < 0.001$) was found in favour of propranolol in prevention of SBP.

A recently published thorough retrospective analysis of data from 607 patients with cirrhosis by Mandorfer *et al*[48] demonstrated no difference in incidence of SBP between NSBB users and patients who did not. Occurrence rates of SBP were similar between patients with and without NSBB treatment. However, NSBB use was associated with higher transplant-free survival in patients without SBP and reduced hospitalization rates[48].

In contrast, Mandorfer *et al*[48] demonstrated that in patients who have developed SBP, NSBB were associated with hemodynamic compromise and decreased blood pressures, reduced transplant free survival, increased hospitalization rates, and increased incidence of the hepatorenal syndrome and acute kidney injury. In another study, using a NSBB (propranolol) in patients with refractory ascites was found to reduce 1-year survival against those not using this drug (median survival: 5 mo *vs* 20 mo respectively)[49]. These results advocate against the use of NSBB in patients with advanced cirrhosis with ascites and SBP.

To conclude, the current evidence is variable about the role of NSBB in decreasing the incidence of SBP. However they can increase transplant-free survival in patients without SBP. In cases of advanced cirrhosis with ascites and the patients who have developed SBP, their use proves detrimental causing higher rates of hemodynamic compromise, time of hospitalization and risks of renal dysfunction. All the studies on NSBB use for SBP have used propranolol. We did not find any study about the use of carvedilol in patients with advanced cirrhosis and SBP, nor a head-to-head comparison of propranolol and carvedilol in this regard.

CONCLUSION

After reviewing the existing literature, it seems that Carvedilol has more potent desired physiological effects when compared to Propranolol. However, it is uncertain at the present juncture whether the improvement in hemodynamics also translates into a decreased rate of disease progression and complications when compared to propranolol (Figure 3).

There have been no clinical trials comparing carvedilol and propranolol for pre-primary prophylaxis. For Primary prophylaxis, the effects of Carvedilol have been compared to Endoscopic band ligation in a few trials and show some promise, but there has been no head to head comparison with propranolol. However, patients not responding to propranolol have shown clinical response to Carvedilol, opening a new window of clinical application.

For secondary prophylaxis, carvedilol has been compared to Beta blockers other than propranolol and Endoscopic Band Ligation, and seems to be equally effective. However, the most effective therapy to date remains a combination of Endoscopic Band Ligation, and no head to head trials have been conducted comparing carvedilol with propranolol. Similarly, there have been no trials exploring the role of carvedilol in portal hypertensive gastropathy and spontaneous bacterial peritonitis.

Thus, currently Carvedilol shows promise as a therapy for portal hypertension but more clinical trials need to be carried out before we can consider it as a superior option and a replacement for propranolol.

Abstract

AIM: To compare the characteristics of two single-incision methods, and conventional laparoscopy in cholecystectomy, and demonstrate the safety and feasibility.

METHODS: Three hundred patients with gallstones or gallbladder polyps were admitted to two clinical centers from January 2013 to January 2014 and were randomized into three groups of 100: single-incision three-device group, X-Cone group, and conventional group. The operative time, intraoperative blood loss, complications, postoperative pain, cosmetic score, length of hospitalization, and hospital costs were compared, with a follow-up duration of 1 mo.

RESULTS: A total of 142 males (47%) and 158 females (53%) were enrolled in this study. The population characteristics of these three groups is no significant differences exist in terms of age, sex, body mass index and American Society of Anesthesiology (P > 0.05). In results, there were no significant differences in blood loss, length of hospitalization, postoperative complications.The operative time in X-Cone group was significantly longer than other groups.There were significant differences in postoperative pain scores and cosmetic scores at diffent times after surgery (P < 0.05).

CONCLUSION: This study shows that this two single-incision methods are safe and feasible. Both methods are superior to the conventional procedure in cosmetic and pain scores.

Key words: Cholecystectomy; Laparoscopic surgery; Single-incision laparoscopic cholecystectomy

Core tip: This is an article about single-incision laparoscopic surgery. It compares three methods in laparoscopic cholecystectomy. The study concludes that the three-device and X-Cone methods are safe and feasible for single-incision laparoscopic cholecystectomy. Compared with conventional laparoscopic cholecystectomy, single-incision laparoscopic surgery techniques have advantages in pain and cosmetic factors.

Tripartite comparison of single-incision and conventional laparoscopy in cholecystectomy: A multicenter trial. *World J Gastrointest Endosc* 2015; 7(5): 540-546 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/540.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.540

INTRODUCTION

Single-incision laparoscopic surgery (SILS) is an area of research interest in minimally invasive surgery. Its main advantage is a scar-free abdominal wall after surgery, as well as milder postoperative pain, faster recovery, shorter hospital stay, and better cosmetic outcomes. Since the first report of single-incision resection of gallbladder through the abdominal cavity by Navarra *et al*[1] in 1997, there has been a growing number of clinical reports on this topic[2-10]. At present, a variety of auxiliary means are used, such as the X-Cone method, triport method, Kirschner-aid exposure method, suspension sutures method, and three-device method[11-16]. However, there has been no comparative study of the various methods.

We enrolled 200 cases of laparoscopic cholecystectomy completed using the three-device and X-Cone methods in our two centers, as well as 100 cases of conventional laparoscopic cholecystectomy, to compare their technical characteristics and clinical outcomes, and demonstrate the safety and feasibility of the single-incision methods.

MATERIALS AND METHODS

Patients

Inclusion criteria were: patients with gallstones or gallbladder polyps; age 18-85 years; either sex; and body mass index (BMI) < 35 kg/m^2. Exclusion criteria were: complication by common bile duct or intrahepatic bile duct stones; acute cholecystitis; suspicion of complicated cholecystitis; BMI $\geqslant$ 35 kg/m^2; drug addiction; ASA physical classification > 3; previous upper abdominal surgery; pregnancy; presence of umbilical hernia; or previous umbilical hernia repair.

All 300 patients were admitted to the two clinical centers for laparoscopic cholecystectomy from January 2013 to January 2014. They were randomly assigned to three groups of 100. The case characteristics are shown in Table 1. All surgery was performed by three surgeons, each of whom had conducted > 1000 cholecystectomies, including $\geqslant$ 100 single-incision laparoscopic cholecystectomies.

The primary end points of this study were feasibility and safety of the three-device method and X-Cone method compared with conventional laparoscopic cholecystectomy, as indicated by intraoperative and postoperative adverse events up to 1 mo, operative time, and estimated blood loss. The secondary end points were: (1) pain as determined by a 10-point pain intensity scale performed at days 1 and 2, 1 wk, and 1 mo; (2) cosmesis evaluated *via* a body image questionnaire, photo series questionnaire, and cosmesis scale performed at 1 and 2 wk, and 1 mo; and (3) length of hospital stay and hospital costs.

Surgical methods

Umbilical disinfection was completed 1 d before surgery. Following routine anesthesia with tracheal intubation, second-generation cephalosporin was intraoperatively administered once. After pneumoperitoneum was established in patients undergoing three-device or conventional surgery, the patients were placed with their legs closed in the Trendelenburg position at approximately 30°, left tilted at approximately 20°. The surgeons stood on the left side of the patient, with the monitor on the right side. For patients undergoing X-Cone surgery, the legs were placed apart in the Trendelenburg position at approximately 30°, left tilted approximately 20°. The surgeons stood between the legs with the monitor on the patient's head side.

General anesthesia was induced with propofol (2 mg/kg) and sufentanil (0.5-2 μg/kg). Tracheal intubation facilitated by injection of Atracurium (0.5 mg/kg). Anesthesia during surgery was maintained with isoflurane 1.2% and administration of Atracurium (0.1 mg/kg) and sufentanil (0.1 μg/kg) and every 30 min. The patients were monitored by ECG, pulse oximetry, noninvasive blood pressure. Patients were recovered by administration of neostigmine (40 μg/kg) and atropine (20 μg/kg).

Three-device method: The umbilical incision was approximately 2.0 cm. Three trocars were directly placed into the incision. The locations are shown in Figure 1. The inferior 10-mm trocar was for insertion of the 30° laparoscope, while the two 5-mm trocars above were working ports for the scalpel and forceps,

respectively. There was 1-2 mm of tissue between the three trocars to prevent leakage. The cystic artery was directly cut with the ultrasonic scalpel, and the cystic duct was closed with a 5-mm Hem-o-lok titanium clamp and transected with scissors. If the 5-mm Hem-o-lok was too small for the occlusion, the 5-mm trocar in the right working port was replaced with a 10-mm one for placement of a 10-mm Hem-o-lok. Once there was no abnormality of the abdomen, the gallbladder was removed. All equipment was removed first, and a pair of vessel forceps was inserted into the original 10-mm trocar to enlarge the incision in the abdominal cavity, and grasping forceps and a 10-mm trocar laparoscope were in turn placed to extract the gallbladder as a whole. The umbilicus white line was closed with a 3-0 Polysorb absorbable suture, and the umbilical skin incisions intradermally closed with absorbable sutures.

X-Cone method: A 3.0-cm curved incision was made around the upper or lower edge of the umbilicus. The subcutaneous tissue and anterior sheath were divided and the posterior sheath separated. As the middle space was pulled with hemostatic forceps, the X-Cone device (Karl Storz, Tuttlingen, Germany) was inserted (Figure 2). Pneumoperitoneum up to 12 mmHg was established through the pole of the X-Cone, and a 5-mm 30° laparoscope was inserted. The clamp and scalpel were placed into the other two ports. The surgeon pulled the gallbladder with curved traction forceps in the left hand and resected the gallbladder triangle with the ultrasonic scalpel in the right hand. The cystic artery was directly separated with the scalpel. After separation of the cystic duct, a 5 or 10-mm Hem-o-lok was used to close it and the cystic duct was then cut with scissors. The gallbladder was then removed as a whole from the gallbladder bed. The gallbladder was taken directly from the umbilical port. The umbilicus white line was closed with a 3-0 Polysorb absorbable suture, and the umbilical skin incisions intradermally closed with absorbable sutures.

Conventional method: A curved incision of 1.0 cm was made at the umbilical lower edge, an incision of 1.0-1.2 cm was made below the xiphoid, and a 0.5-cm incision was made 1-2 cm above the right clavicular line at the umbilical level. Two 10-mm trocars and one 5-mm trocar were placed into these incisions. The 10-mm umbilical trocar was for placement of the laparoscope, and the other two were working ports for placement of the ultrasonic scalpel and forceps.

Postoperative care: After completion of surgery in all three groups, the incisions were treated with a 50% dose of 75 mg ropivacaine for local anesthesia. Subsequently, the patients were extubated and closely

[1]Estimated intraoperative blood loss; LC: Laparoscopic cholecystectomy.

observed in the postanesthetic care unit and then transferred to the surgical ward once their Aldrete score was ⩾ 9. Postoperative electrocardiography was performed and oxygen was administered for 6 h, in combination with rehydration and bleeding control, as well as other fluid replacement. Liquid food and ambulation were allowed 6 h after surgery. In the postoperative period, Intravenous rotundine sulfate, at a dose of 1 mg/kg was administered according to patient request every 12 h until discharge home. Surgical dressings were changed on the first day after surgery. The patients were discharged on the second day after surgery. They were also asked to return for check-up at 1, 2 wk and 1 mo after surgery.

Statistical analysis

Data were analyzed using SPSS version 13 (Chicago, IL, United States). Base on Kolmogorov-Smirnov test, operative time, estimated blood loss, postoperative hospital stay, pain scores and cosmetic scores were all summarized using mean ± SD and compared among the 3 groups by using the One-Way ANOVA test (Tukey method). Intraoperative and postoperative adverse events was compared among the three procedures by Fisher exact test. χ^2 tests were performed to explore the effects of sex, and the clinical diagnosis. A value of $P < 0.05$ was considered to indicate significance.

RESULTS

A total of 300 patients were enrolled in this study and assigned to three groups of 100: three-device, X-Cone method, and conventional method. There were no significant differences in age, sex, BMI and ASA among the groups. The operation time, blood loss and complications are listed in Table 2. There were no significant differences in blood loss and postoperative hospital stay. The X-Cone method required longer operation time compared to the conventional (56.3 min *vs* 42.1 min, P = 0.000) and three-device methods (56.3 min *vs* 45.6 min, P = 0.000), while the latter two did not differ significantly in this regard (42.1 min *vs* 45.6 min, P = 0.111). Hospitalization costs were higher in the X-Cone group than the three-device group (P = 0.000) and the conventional group (P = 0.000). The conventional group was the cheapest group in the three groups.

In the X-Cone group, there were three cases of surgical incision contusion, and one case of wound hematoma. In the three-device group, two patients required additional working ports due to severe inflammatory adhesions, and there were four cases of incision contusion. In the conventional method group, all patients were successfully operated, and there were one case of incision contusion and three cases of incision wound infection under the xiphoid. No patient converted to laparotomy, and there was no serious complication such as bile duct injury or bile peritonitis. There was no postoperative bleeding or conversion to laparotomy. Percutaneous incision suture was successful without umbilical hernia.

The pain and cosmetic scores are listed in Table 3. The pain score was evaluated using a visual analog scale of 1-10 on days 1, 2 and 7, as well as 1 mo after surgery. There were differences in the pain scores on day 1 between the single-incision methods and

[1]Pain score 1-10; [2]Cosmetic score 1-10.

the conventional method in favor of the former (P < 0.0001), there was no difference between the two single-incision methods (P = 0.296). The X-Cone group was the most comfortable on day 2, while the three-device group on day 7 after surgery. At 1 mo, single-incision methods were better than the conventional method.

The cosmetic scores were rated on a 1–10 scale with questionnaires, with 10 being satisfied and 0 being unsatisfied. At 1 wk (P = 0.000), 2 wk (P = 0.000) and 1 mo (P = 0.000) after surgery, the single-incision methods were significantly better than the conventional group in terms of cosmetic scores. The X-Cone group and the three-device group had no differences (P > 0.05).

DISCUSSION

SILS techniques have been extensively applied both at home and abroad in recent years[7,11,17-20]. It is performed using a 1-wound laparoscopic surgical procedure or by using speciic ports[21-24].Compared with conventional laparoscopic cholecystectomy, they are associated with fewer injuries and better cosmetic outcomes, as well as many other advantages[25-29]. Some investigators believe that single-incision laparoscopic cholecystectomy will replace conventional laparoscopic cholecystectomy, and become the new gold standard[13,14].

This was an unplanned preliminary analysis of a continuing clinical trial to establish the safety of SILS as an operative approach for treatment of gallbladder disease. This article presents preliminary data of a multicenter, prospective randomized, single-blinded study comparing two single-incision cholecystectomy (three-device and X-Cone methods) with conventional standard multiport laparoscopic cholecystectomy. Primary end points included feasibility and safety, with pain, cosmesis, and costs as secondary end points.

In terms of feasibility and safety, except for the two patients who had additional working ports due to severe inflammatory adhesions in the three-device group, all patients underwent surgery successfully. None of the 200 patients converted to laparotomy or had complications such as bile duct injury, suggesting that single-incision laparoscopic cholecystectomy was feasible and safe. The low conversion rate may differ from that in other studies[18,30], which was probably due to the fact that patients with acute cholecystitis were excluded from our study. There were no significant differences in the complication rates among the three groups. There were four cases of incision contusion in

the three-device group, and three and one cases in the X-Cone and conventional groups, respectively. To avoid conflict of instruments in the abdominal cavity with the single-incision method, repeated external squeezing of the surrounding tissue is often required, which may explain the incision contusion in the three-device and X-Cone groups. In addition, there were different numbers of cases of bile leakage in all groups, which were treated with repeated rinsing with saline until the liquid turned clear. There was no case of biliary peritonitis infection afterwards.

There was no significant difference in blood loss and postoperative hospital stay. The X-Cone method required a longer operation time compared to the conventional (56.3 min *vs* 42.1 min, $P = 0.000$) and three-device methods (56.3 min *vs* 45.6 min, $P = 0.000$). Although all three surgeons had conducted > 100 cases of gallbladder SILS, the X-Cone procedure was associated with inconvenient operation across multiple ports and conflicting handling of instruments such as curved apparatus and solid textures, which might have extended the operation time. In contrast, the three-device method and conventional technique did not differ significantly in this regard (45.6 min *vs* 42.1 min, $P = 0.111$). The space between the instruments in the three-device method comprises soft subcutaneous tissue, which allows for a wider range of motion for the instruments, which is conducive to surgery.

Regarding the pain and cosmetic scores, there were differences between the single-incision methods and the conventional method in the pain score on day 1 after surgery, in favor of the single-incision methods. The main complaint was pain below the xiphoid incision in the conventional group. As the pain scores declined on days 2 and 7, as well as 1 mo after surgery, the differences became insignificant. At 1 and 2 wk and 1 mo after surgery, the single-incision methods were significantly better than the conventional group in terms of cosmetic scores. No difference was noted between the three device and X-Cone methods.

There was no difference in the hospitalization costs between the three-device and conventional methods, but there was when compared with the X-Cone method, suggesting that the latter method had an impact on the overall hospital costs. In three-device techniques, conventional equipment and devices were used, resulting in no cost difference from the conventional method, so the three-device method has a more cost-effective. Hence, the three-device approach is more suitable for community hospitals in China.

The present study had the following limitations. First, patients with acute cholecystitis were excluded, and this explains the low laparotomy conversion and low complication rates. Second, although all three surgeons had conducted > 100 operations for gallbladder SILS, the X-Cone procedure was associated with inconvenient operation across multiple ports and conflicting handling of instruments such as curved apparatus and solid textures, which might have extended the operation time. Both of these limitations are routinely seen when a new technique is evaluated. Also, long-term complications were not addressed by this study. The frequency of events still needs to be evaluated by long-term trials.

In summary, both the three-device and X-Cone methods are safe and feasible for single-incision laparoscopic cholecystectomy. Compared with conventional laparoscopic cholecystectomy, SILS techniques have advantages in pain and cosmetic factors. Due to its use of conventional instruments and cost-effective nature, the three-device method is more suitable for community hospitals in China, while the X-Cone device, which allows the placement of more surgical instruments, is more advantageous in more complicated procedures such as laparoscopic liver resection.

COMMENTS

Background

Single-incision laparoscopic cholecystectomy is a new laparoscopic procedure in laparoscopic surgery. This technique has been denominated by some authors as "scarless". The best advantage is a scar-free abdominal wall after surgery, as well as milder postoperative pain, faster recovery, shorter hospital stay, and better cosmetic outcomes.

Research frontiers

It is a lot of studies about the single-incision laparoscopic surgery (SILS). But there has been no previous reported study of the comparison of these three methods in cholecystectomy.

Innovations and breakthroughs

In this study, the three-device and X-Cone methods are safe and feasible for single-incision laparoscopic cholecystectomy. Compared with conventional laparoscopic cholecystectomy, SILS techniques have advantages in pain and cosmetic factors.

Applications

These two SILS techniques were used more and more in different hospitals. Further study is needed to confirm whether these potential advantages of the SILS techniques can change the clinical course of patients with liver surgery.

Peer-review

This is a very interesting paper about the SILS in cholecystectomy. The most important innovations of this study that was applied in the manuscript is the comparison of three methods in cholecystectomy. In addition, it demonstated that single-incision three-device and X-Cone methods are safe and feasible for laparoscopic cholecystectomy.

Abstract

AIM: To investigate the results of endoscopic treatment of postoperative biliary leakage occurring after urgent cholecystectomy with a long-term follow-up.

METHODS: This is an observational database study conducted in a tertiary care center. All consecutive patients who underwent endoscopic retrograde cholangiography (ERC) for presumed postoperative biliary leakage after urgent cholecystectomy in the period between April 2008 and April 2013 were considered for this study. Patients with bile duct transection and biliary strictures were excluded. Biliary leakage was suspected in the case of bile appearance from either percutaneous drainage of abdominal collection or abdominal drain placed at the time of cholecystectomy. Procedural and main clinical characteristics of all consecutive patients with postoperative biliary leakage after urgent cholecystectomy, such as indication for cholecystectomy, etiology and type of leakage, ERC findings and post-ERC complications, were collected from our electronic database. All patients in whom the leakage was successfully treated endoscopically were followed-up after they were discharged from the hospital and the main clinical characteristics, laboratory data and common bile duct diameter were electronically recorded.

RESULTS: During a five-year period, biliary leakage was recognized in 2.2% of patients who underwent urgent cholecystectomy. The median time from cholecystectomy to ERC was 6 d (interquartile range, 4-11 d). Endoscopic interventions to manage biliary leakage included biliary stent insertion with or without biliary sphincterotomy. In 23 (77%) patients after first endoscopic treatment bile flow through existing surgical drain ceased within 11 d following biliary therapeutic endoscopy (median, 4 d; interquartile range, 2-8 d). In those patients repeat ERC was not performed and

the biliary stent was removed on gastroscopy. In seven (23%) patients repeat ERC was done within one to fourth week after their first ERC, depending on the extent of the biliary leakage. In two of those patients common bile duct stone was recognized and removed. Three of those seven patients had more complicated clinical course and they were referred to surgery and were excluded from long-term follow-up. The median interval from endoscopic placement of biliary stent to demonstration of resolution of bile leakage for ERC treated patients was 32 d (interquartile range, 28-43 d). Among the patients included in the follow-up (median 30.5 mo, range 7-59 mo), four patients (14.8%) died of severe underlying comorbid illnesses.

CONCLUSION: Our results demonstrate the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage after urgent cholecystectomy.

Key words: Urgent cholecystectomy; Acute cholecystitis cholecystectomy complications; Biliary leakage; Endoscopic retrograde cholangiography; Endoscopic treatment

Core tip: Biliary leakage can be a serious complication of urgent cholecystectomy even in the hands of an experienced surgeon. Endoscopic interventions replaced surgery as first-line treatment for most of the biliary ducts injuries and biliary leakage after cholecystectomy. Long-term follow-up results demonstrate the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage after urgent cholecystectomy. Early cessation of bile output from the external abdominal drain strongly indicates healing of the leak and in those patients repeat cholangiography is not necessary, particularly if the presenting symptoms and/or signs of the biliary leakage disappeared.

INTRODUCTION

Biliary leakage can be a serious complication of urgent cholecystectomy even in the hands of an experienced surgeon and can lead to considerable morbidity and prolonged hospitalization. Despite the fact that there are no properly controlled trials which could identify risk factors for bile duct injury, the risk of possible perioperative complications can be estimated based on patient characteristics (commorbidity, age, gender, body weight), intraoperative findings, and the amount of training and experience of the surgeon[1-3]. Large prospective and retrospective studies have defined the risk of biliary leakage arising from either open[4-6] or laparoscopic[6-9] cholecystectomy. The number of occurrences of biliary leaks during open cholecystectomy is not precisely known, but most large series demonstrated rates of 0.5% or less[10,11]. Despite several advantages over the open approach, laparoscopy, particularly in the cases of urgent cholecystectomy, provides a limited view of the biliary tract anatomy and can result in a higher rate of biliary leaking[7]. A two to four-fold increased incidence of biliary leakage following laparoscopic cholecystectomy was demonstrated[6,9,12].

The role of endoscopic retrograde cholangiography (ERC) in the management of biliary leakage is well established. Endoscopic treatment of biliary leakage includes biliary stent insertion with or without biliary sphincterotomy, biliary sphincterotomy alone or nasobiliary tube placement. All those methods have been demonstrated to be effective treatment for biliary leakage without need for further surgery[13-15]. However, the need for an endoscopic sphincterotomy, the choice between nasobiliary tube drainage and endoscopic biliary stenting and the preferable type of stent (short or long stent; larger or smaller diameter) are still the matter of extensive debate. Therefore, optimal endoscopic intervention is still not established and data regarding the long-term follow-up of those patients is missing.

The aim of this study was to determine the results of endoscopic treatment of postoperative biliary leakage occurring after urgent cholecystectomy with a long-term follow-up.

MATERIALS AND METHODS

This is an observational database study conducted in a tertiary care center with primary uptake area covering a population of approximately 300000 people (City of Zagreb, Republic of Croatia). The study was approved by the "Sestre milosrdnice" University Hospital Review Board. All consecutive patients who underwent ERC for presumed postoperative biliary leakage following urgent cholecystectomy between April 2008 and April 2013 were considered for this study. All the patients included in the study signed the informed consent statement. Patients with bile duct transection and biliary strictures were excluded. Biliary leakage was suspected in case of bile appearance from either percutaneous drainage of abdominal collection or abdominal drain placed at the time of cholecystectomy.

Information of all consecutive patients with postoperative biliary leakage, including cholecystectomy details such as indication for cholecystectomy, etiology and type of leakage, ERC findings and post-ERC complications, were reviewed from our electronic database. The grading of overall health and comorbidity

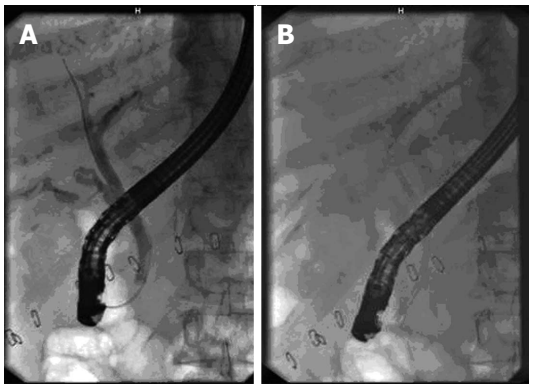

Figure 1 Radiograph at endoscopic retrograde cholangiography. A: Radiograph at endoscopic retrograde cholangiography showing biliary leakage into peritoneum from cystic duct stump; B: Radiograph showing 10 F biliary stent inserted above the level of the leak from cystic duct stump.

was performed according to the American Society of Anesthesiology classification[16]. All ERC successfully treated patients were followed-up after they were discharged from the hospital and the main clinical characteristics and laboratory data, including levels of bilirubin, alanine transaminase (ALT), aspartate aminotransferase, GGT, alkaline phosphatase, CRP and common bile duct diameter measured on transabdominal ultrasound were electronically recorded every month during first 6 mo, then every 6 mo.

ERC was performed with standard equipment (TJF 145, Olympus Optical Co., Japan), and by the well-trained endoscopists, each with at least five-year experience. Selective cannulation of the common bile duct was attempted with a standard wire-guided sphincterotome and 0.035-inch hydrophilic guidewire. If the efforts to enter the common bile duct were unsuccessful, a needle-knife papillotomy was performed. In all patients ERC was performed under intravenous sedation and analgesia (propofol and fentanyl) under direct anesthesiologist control. Pre-procedural antibiotics were administered (ciprofloxacin 400 mg *iv*).

Post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis was identified by characteristic abdominal pain associated with serum amylase levels at least three times the upper limits of normal. Postprocedural bleeding was defined as one or more signs of ongoing bleeding, including fresh hematemesis or melena, hematochezia, aspiration of fresh blood *via* nasogastric tube, vital signs instability, and a reduction of hemoglobin level by more than 2 g/dL over a 24-h period.

In all patients with a cholangiographic evidence of a biliary leakage the placement of a plastic 10 F biliary stent without biliary sphincterotomy was performed. The standard procedure was to place proximal end of a biliary stent above the level of the leak in patients with the cholangiographic evidence of a leakage from the common bile duct or from cystic duct stump or cholecystohepatic duct of Luschka (Figure 1). If biliary leakage from the right hepatic duct or intrahepatic duct was confirmed, and in patients in whom biliary leakage was not located, only short plastic 10F biliary stent was inserted. In patients with a cholangiographic evidence of a biliary leakage and a common bile duct stone(s), biliary sphincterotomy was performed and after the stone was removed (with balloon catheter or Dormia basket), plastic 10F biliary stent was placed.

The clinical healing of the biliary leakage was determined by the complete absence of the symptoms, cessation of the output of the bile from the drain and by the removal of the drain without any further adverse outcomes. The failure of the endoscopic treatment was determined by the need for further intervention to control the leak including surgery and/or percutaneous drainage of the biliary tree.

Statistical analysis

All analysis were performed by an expert biomedical statistician with a statistical package (Statistica 10.0 for Windows, United States). Descriptive statistics were used in this case series to describe characteristics of the patients, procedures and outcomes. Continuous variables are expressed as medians with interquartile ranges for nonparametric values. Median time to biliary leakage closure and median time were estimated using a Kaplan-Meier survival curve. Spearman correlation coefficients were calculated to assess interrelationships of certain quantitative variables. A *P* values below 0.05 were considered statistically significant.

RESULTS

Study population

Among 2472 ERCP procedures that were performed in our center between April 2008 and April 2013, there were 34 patients who underwent ERC because of postoperative biliary leakage occurring after urgent cholecystectomy: 23 patients in whom urgent cholecystectomy was performed at our institution and 11 patients referred from our collaborating institutions (Figure 2). In the same period urgent cholecystectomy was performed in 1058 patients (31 patients with gallstones and hydrops of the gallbladder, 662 patients with acute or subacute calculous cholecystitis, 365 patients with gangrenous cholecystitis and one patient with Mirizzi's syndrome) at our institution. Since endoscopic treatment is a standard practice for management of post-cholecystectomy biliary leakage at our hospital, all the patients with suspected biliary leakage were referred to the endoscopy unit. Therefore, during a 5-year period biliary leakage occurred in 2.2% of all patients who underwent urgent cholecystectomy. In all those patients indications for urgent cholecystectomy were acute or subacute calculous cholecystitis (21 patients) or gangrenous cholecystitis (13 patients).

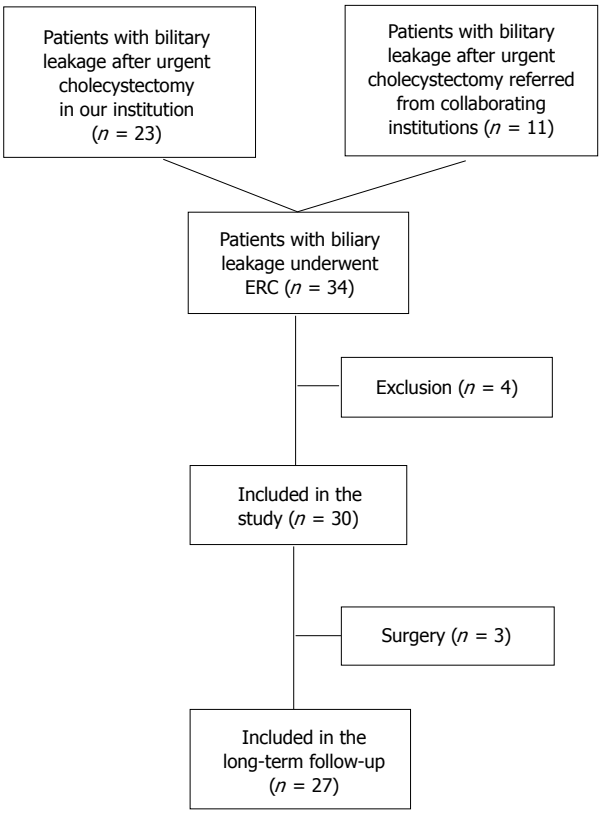

Figure 2 Schematic of subjects included in the study and long-term follow-up. ERC: Endoscopic retrograde cholangiography.

Endoscopic procedures

Initial ERC was successful in 32 out of 34 patients (94%). The reasons for failure of ERC in two patients were intradiverticular location of the papilla seen in one patient and the presence of a Billroth Ⅱ operation in a second patient. Patient with intradiverticular location of the papilla was successfully treated with the rendezvous technique[12] and this patient was included in the study. In two patients in whom ERC was successfully performed, the cholangiography demonstrated a complete transection of the common bile duct (first patients) and significant common bile duct stenosis because of multiple clips across the bile duct (second patient). Surgery was recommended for those patients as well as for the patient with the presence of a Billroth Ⅱ operation. Those three patients were excluded from the study. One patient, at the age of 79, with severe comorbidities, including heart failure with permanent atrial fibrillation, arterial hypertension, diabetes and renal insufficiency, died immediately after ERC (with stent in place) because of acute myocardial infarction and cardiac arrest. This patient was also excluded from the study.

The main clinical characteristics of 30 consecutive patients with postoperative biliary leakage included in the study are summarized in Table 1.

The median time from cholecystectomy to ERC was 6 d (interquartile range, 4-11 d) and 4 (13%) patients underwent ERC more than 2 wk after surgery.

Table 1 Clinical characteristics of 30 consecutive patients with post-cholecystectomy biliary leakage included in the study

Parameter	*n* (%)

ASA: American Society of Anesthesiology.

Most common biliary leakage sites included leak from the cystic duct stump in 13 patients, the right hepatic duct or intrahepatic duct in 12 patients, leak from the common bile duct in three patients and from cholecystohepatic duct of Luschka in one patient (Table 2).

Endoscopic biliary sphincterotomy was performed in 17 patients: 11 patients with cholangiographic evidence of common bile duct stone(s), 3 patients with suspected but not proven common bile duct stone, and three patients in whom cannulation of the common bile duct was difficult (in two of them needle-knife papillotomy was performed). All those patients underwent plastic 10 F biliary stent placement. The proximal end of the biliary stent was placed above the site of the biliary leakage in 16 patients with leakage from the cystic duct stump, cholecystohepatic duct of Luschka and leakage from the common bile duct (based on the endoscopist's discretion, only in one patient biliary stent was placed below the site of the biliary leakage). In patients with biliary leakage from the right hepatic duct or intrahepatic duct and in patients in whom biliary leakage was not located on cholangiography, only short plastic 10 F biliary stent stranding the papilla was inserted.

After first endoscopic treatment bile flow through existing surgical drain ceased in 23 (77%) patients within 11 d following biliary therapeutic endoscopy (median, 4 d; interquartile range, 2-8 d). Those patients become asymptomatic with the normalization in laboratory data, and the biliary stent was removed on gastroscopy.

Mild post-ERC pancreatitis was observed in two patients after needle-knife papillotomy was performed. The occurrence of ERC-related pancreatitis did not affect the ultimate outcome in any of them. Post-ERC bleeding

Table 2 Endoscopic retrograde cholangiography findings in patients with post-cholecystectomy biliary leakage included in the study

ERC: Endoscopic retrograde cholangiography; EBS: Endoscopic biliary sphincterotomy; CBD: Common bile duct.

was observed in only one patient with liver cirrhosis and heart failure in which biliary sphincterotomy was performed (reduction of hemoglobin level by more than 2g/dL over a 24-h period). This patient was successfully treated conservatively and the occurrence of post-ERC bleeding did not affect the ultimate outcome of this patient. Duodenal perforation was not observed (Table 2).

Necessity for repetition of endoscopic procedure

In seven (23%) patients in whom persistent bile flow through existing surgical drain was demonstrated, suggesting the absence of the biliary leakage resolution, repeat ERC was performed within one to 4 wk, depending on the extent of the biliary leakage. In all those patients biliary stent was removed and replaced with a new one (Table 2). In two patients common bile duct stone was recognized and removed with a balloon catheter. After the repeat ERC was performed, four of those seven patients had cessation of bile flow through existing surgical drain within two to nine days (median, 5.5 d). Those four patients become asymptomatic with the normalization in laboratory data, and the biliary stent was removed on gastroscopy. There were no adverse events related to the repeat ERC.

Overall, 27 (90%) patients with biliary leakage after urgent cholecystectomy included in study were successfully treated with ERC, and all those patients were included in the long-term follow-up. ERC was repeated in 14.8% of patients, and 1.1 ERC procedure was needed for every patient with leakage resolution.

Three patients (10%) with biliary leakage after urgent cholecystectomy included in the study had more complicated clinical course. One of them had a continuous biliary leakage demonstrated as the high-output bile flow through existing surgical drain. In this patient second repeat ERC revealed large right hepatic duct biliary leakage. This patient was referred to surgery together with two patients in whom large symptomatic subphrenic abscess was confirmed along with a persistent biliary leakage through the surgical drain. Altogether eight patients had the abdominal fluid collection, and six were treated conservatively.

Table 3 Clinical characteristics of endoscopic retrograde cholangiography successfully treated patients with post-cholecystectomy biliary leakage in the long-term follow-up

Parameter	*n* (%)
Number of patients	27
Abdominal pain	0
Abdominal distension	0
Elevated bilirubin[1]	0
Elevated ALT[2]	13 (48.2)
Dilated common bile duct (> 6 mm)[3]	0
Death	4 (14.8)

[1]Bilirubin > 20 mmol/L; [2]ALT > two times above normal; [3]Measured by transabdominal or endoscopic ultrasound. ALT: Alanine transaminase.

Endoscopic treatment outcomes and long term follow-up

In all patients in whom endoscopic therapy led to the complete resolution of biliary leakage, median interval from the first endoscopic intervention and biliary stent placement to the stent extraction was 32 d (interquartile range, 28-43 d) (Figure 3). Median interval from the therapeutic ERC (first or repeated) to the stent extraction was 32 d, also (interquartile range, 28-42 d). Cessation of the bile flow through existing surgical drain occurred up to eleventh day after therapeutic ERC (first or repeated; median, 4 d, interquartile range, 2-8 d). There was no correlation between the volume of bile leak output on a surgical drain and the probability of bile leakage resolution after ERC ($r = 0.161$, $P = 0.537$).

Among 27 patients initially included in the long-term follow-up (median 30.5 mo, range 7-59 mo), four patients (14.8%) died. All of deceased patients died of severe underlying comorbid illnesses: malignancy (one patient), cerebrovascular accidents (one patient), heart failure (two patients). The main clinical characteristics and laboratory data of patients included in the long-term follow-up are demonstrated in Table 3. All those patients were asymptomatic with normal levels of bilirubin and without any signs of cholangitis and bile duct dilation. In 13 (48.2%) patients increase in ALT

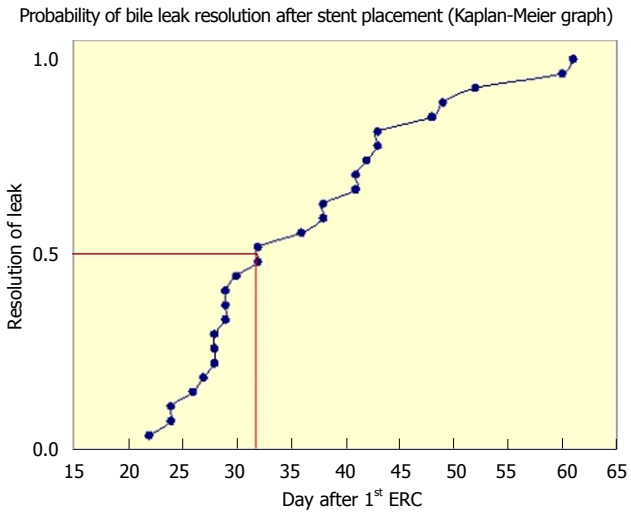

Figure 3 Kaplan-Meier graph demonstrates probability of resolution of bile leak after first endoscopic retrograde cholangiography with biliary stent placement for postcholecystectomy biliary leakage. ERC: Endoscopic retrograde cholangiography.

concentration (up to two times above the normal values) was observed. In all those patients endoscopic ultrasound revealed normal finding of common bile duct.

DISCUSSION

Postoperative biliary leakage is a serious complication that occurs in 0.2%-2.2% of all cholecystectomies[4-7,17], and even more frequently after laparoscopic cholecystectomy for acute cholecystitis[9]. In accordance with the results of our study, during 5-year period biliary leakage occurred in 2.2% of patients who underwent urgent cholecystectomy. This percentage is high with regard to the percentage of biliary leakage among patients who underwent either open or laparoscopic cholecystectomy that had been reported previously. It is possible to assume that mechanisms responsible for those findings in patients after urgent cholecystectomy include the presence of inflammation and edema (the cystic duct is indurated and shortened, lying in close contact with the common bile duct), or bleeding[6,9]. That may lead to the poor identification of anatomical structures including possible aberrant anatomy and dislodgement of suboptimally placed clips or a bile duct injury, where the experience of the surgeon is crucial[1,6,9,13].

Endoscopic interventions replaced surgery as first-line treatment for most of the biliary ducts injuries and biliary leakage following cholecystectomy. All of them are aimed towards decreasing the transpapillary pressure, allowing bile to flow through the path of decreased resistance. As a consequence, biliary leakage closes spontaneously. Recent data strongly suggest that biliary stent placement without biliary sphincterotomy is more efficient and has a lower complication rate than biliary sphincterotomy[18,19]. Since endoscopic treatment is a standard practice for management of postcholecystectomy biliary leakage at our institution, all the patients with suspected biliary leakage were referred to the endoscopy unit. Therefore, only patients with biliary leakage after urgent cholecystectomy were included in our study. To our knowledge this is the first long-term follow-up study investigating the efficiency of the endoscopic therapy in patients with biliary leakage occurring after urgent cholecystectomy. Our results clearly demonstrated the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage. Among our group of patients closure of bile leaks was achieved with endoscopic therapy in great majority of patients (90%).

There are several limitations to this study. First, the number of patients was relatively small, although the study period included five years, but the protocol narrowed the inclusion criteria. Second, our management algorithm did not include some other available imaging methods like magnetic retrograde cholangiography because technical success of the initial ERC was rather high (94%) and this could be regarded as redundant.

There are no uniform recommendations regarding the need for repeat cholangiography at the time when previously positioned biliary stent need to be removed after resolution of biliary leakage. Namely, when endoscopic biliary stents are placed, the precise time when the leak closes cannot be determined. To our results, early cessation of bile output from the external abdominal drain strongly indicates healing of the bile leak. In majority of those patients presenting clinical symptoms and/or signs disappear very fast. Contrary, the persistent bile flow through existing surgical drain, in our study more than 11 d after endoscopic stent placement, indicates the persistent biliary leakage. In those patients, repeat ERC or some other procedure seems to be necessary. Reason for the persistent biliary leakage, as we found in our study, might be the presence of a previously unrecognized common bile duct stones, inadequately drained abdominal collection with inflammation and abscess formation or magnitude of bile duct defect.

Despite the fact that there are no uniform recommendations regarding the need for cholangiography at the time of stent removal, few studies demonstrated that repeat cholangiography is not necessary in patients in whom the presenting symptoms and/or signs of the biliary leakage had been disappeared. In those clinically well patients gastroscopy with biliary stent removal is effective if performed after the median time of 33 d following biliary stent placement[20-22]. In our study we clearly demonstrated that in asymptomatic patients following urgent cholecistectomy in whom early cessation of bile output from the external abdominal drain occurred (median, 4 d, interquartile range, 2-8 d), biliary stent removal on gastroscopy is safe after the median time of 32 d after biliary stent placement

without any need for repeat cholangiography.

During hospitalization, only one 79 years old patient with severe comorbidities, including heart failure with permanent atrial fibrillation, arterial hypertension, diabetes and renal insufficiency, died immediately after ERC (with stent in place) because of acute myocardial infarction and cardiac arrest. Among 27 patients included in the long-term follow-up four of them died. The main contributory factor that considerably affects patient's prognosis seems to be the comorbidity. Namely, among deceased patients all of them died of severe underlying comorbid illnesses, unrelated with cholecystectomy or endoscopic procedure.

In conclusion, despite the fact that the major limitation of our study is relatively small number of patients, long-term follow-up results demonstrate the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage following urgent cholecystectomy. Early cessation of bile output from the external abdominal drain strongly indicates healing of the leak and in those patients repeat cholangiography is not necessary, particularly if the presenting symptoms and/or signs of the biliary leakage disappeared.

COMMENTS

Background

Biliary leakage can be a serious complication of urgent cholecystectomy even in the hands of an experienced surgeon. Endoscopic interventions replaced surgery as first-line treatment for most of the biliary ducts injuries and biliary leakage. Long-term follow-up results in this study demonstrate the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage after urgent cholecystectomy.

Research frontiers

This paper describes a novel approach to endoscopic retrograde cholangiography procedure as a treatment for resolution of biliary leakage following urgent cholecystectomy.

Innovations and breakthroughs

This paper for the first time demonstrates the great efficiency of the endoscopic therapy in the treatment of the patients with biliary leakage after urgent cholecystectomy. Early cessation of bile output from the external abdominal drain strongly indicates healing of the leak and in those patients repeat cholangiography is not necessary.

Applications

Considering the tendency of early cholecystectomy in acute cholecystitis, and an increase in the number of laparoscopic procedures in the future, it is possible to expect a lot of patients with biliary leakage, especially after the urgent cholecystectomy. These results could be also applied to all patients with biliary leakage.

Peer-review

This is an interesting and practical paper about biliary leakage after surgery for acute cholecystitis. The subject is of paramount importance because most of the series mixed leakage after planned and emergency cholecystectomies.

Abstract

AIM: To compare the yield of adenomas between narrow band imaging and white light when using high definition/magnification.

METHODS: This prospective, non-randomized comparative study was performed at the endoscopy unit of veteran affairs medical center in Phoenix, Arizona. Consecutive patients undergoing first average risk colorectal cancer screening colonoscopy were selected. Two experienced gastroenterologists performed all the procedures that were blinded to each other's findings. Demographic details were recorded. Data are presented as mean ± SEM. Proportional data were compared using the χ^2 test and means were compared using the Student's t test. Tandem colonoscopy was performed in a sequential and segmental fashion using one of 3 strategies: white light followed by narrow band imaging [Group A: white light (WL) → narrow band imaging (NBI)]; narrow band imaging followed by white light (Group B: NBI → WL) and, white light followed by white light (Group C: WL → WL). Detection rate of missed polyps and adenomas were evaluated in all three groups.

RESULTS: Three hundred patients were studied (100 in each Group). Although the total time for the colonoscopy was similar in the 3 groups (23.8 ± 0.7, 22.2 ± 0.5 and 24.1 ± 0.7 min for Groups A, B and C, respectively), it reached statistical significance between Groups B and C ($P < 0.05$). The cecal intubation time in Groups B and C was longer than for Group A (6.5 ± 0.4 min and 6.5 ± 0.4 min *vs* 4.9 ± 0.3 min; $P < 0.05$). The withdrawal time for Groups A and C was longer than Group B (18.9 ± 0.7 min and 17.6 ± 0.6

min *vs* 15.7 ± 0.4 min; $P < 0.05$). Overall miss rate for polyps and adenomas detected in three groups during the second look was 18% and 17%, respectively (P = NS). Detection rate for polyps and adenomas after first look with white light was similar irrespective of the light used during the second look (WL → WL: 13.7% for polyps, 12.6% for adenomas; WL → NBI: 14.2% for polyps, 11.3% for adenomas). Miss rate of polyps and adenomas however was significantly higher when NBI was used first (29.3% and 30.3%, respectively; $P < 0.05$). Most missed adenomas were ⩽ 5 mm in size. There was only one advanced neoplasia (defined by size only) missed during the first look.

CONCLUSION: Our data suggest that the tandem nature of the procedure rather than the optical techniques was associated with the detection of additional polyps' and adenomas.

Key words: Colonoscopy; Narrow band imaging; High-definition; Magnification; Screening; Yield

Core tip: The role of narrow band imaging for polyp detection is controversial. We studied 3 groups of 100 patients each, undergoing tandem colonoscopy by (1) white light followed by narrow band imaging; (2) narrow band followed by white light; and (3) white light followed by white light. Detection rate for polyps with white light used first was similar irrespective of the light used afterwards. Miss rate of polyps and adenomas was higher when narrow band imaging was used first (29.3% and 30.3%, respectively; $P < 0.05$). Our study suggests that the tandem nature of colonoscopy rather than the optical techniques, detects missing pathology.

Polyp detection rates using magnification with narrow band imaging and white light. *World J Gastrointest Endosc* 2015; 7(5): 555-562 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/555.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.555

INTRODUCTION

Colonoscopy and polypectomy is aimed at prevention or identification of early colorectal cancer[1-3]. Colonoscopy however is not infallible in the detection of polyps and adenomas with reported miss rates in the order of 14% to 32% using tandem colonoscopy[4-10] and 23.3% for lesions (polyps and cancers) in resected colonic specimens[11]. Advances in the optics of endoscopy such as high definition, magnification and narrow band imaging have been introduced in clinical practice, and amongst others, are aimed at improving the yield of polyp and adenoma detection[12-20]. Our hypothesis was that narrow band imaging (NBI) detects more polyps and adenomas than white light (WL) when used in a tandem fashion during screening colonoscopy.

MATERIALS AND METHODS

As part of a quality improvement assessment of new technology, we sought to assess the yield of polyp and tubular adenoma detection when using wide angle magnification colonoscopy either with narrow band imaging or white light in average risk patients referred for their first colorectal cancer screening colonoscopy. These procedures were performed using the Olympus 180 H series colonoscopies (Olympus America Inc., Center Valley, PA). Cecal intubation was carried out using WL and without magnification. Once the cecum was reached, the electronic magnification featured at 1.5X was turned on. All these procedures were performed by one of two experienced board certified gastroenterologists (who had performed > 2500 and > 5000 colonoscopies each and > 250 colonoscopies using narrow band imaging) using one of the following strategies: (1) Group A: white light followed by narrow band imaging (WL → NBI); (2) Group B: narrow band imaging followed by white light (NBI → WL) and; (3) Group C: white light followed by white light (WL → WL) in a sequential and segmental fashion of tandem endoscopy every 15-20 cm. Measurements included: cecal intubation, withdrawal and total procedure times; grading of bowel preparation; anatomical location, size and histological diagnosis of polyps detected with white light or NBI, when using either of the strategies. Removed polypoid lesions, were classified based on histology as neoplastic (adenomas, hyperplastic and other tumors) and non-neoplastic (normal mucosa, hyperplastic mucosa, prominent lymphoid aggregates).

Patients underwent bowel cleansing with 4 L of polyethylene glycol solution and 4 bisacodyl tablets (20 mg total dose). Patients with suboptimal preparation (as determined by the colonoscopist during the insertion portion of the examination) were not included in the study. All procedures except four were performed using moderate sedation with incremental doses of midazolam and meperidine or fentanyl. Cecal intubation was confirmed by photo documentation of appendiceal orifice and ileocecal valve. Procedure times (cecal intubation, withdrawal and total procedure times) were documented by the Olympus stopwatch built in the processors. The watch was not stopped for rinsing and cleaning or while performing polypectomy. Polyp's size was estimated using an open biopsy forceps or the snare used for polypectomy. All polyps were removed during the withdrawal portion of the procedure even if visualized during the insertion phase. Colon was anatomically divided into proximal (proximal to splenic flexure) and distal (splenic flexure or distal to it) portions. Advanced neoplasia was defined as the presence of a tubular adenoma ⩾ 10 mm, villous component, or the presence of high grade dysplasia or

invasive carcinoma on histology.

The study was approved by the local Institutional Review Board and exemption for informed consent was granted due to non-randomized design and the fact that all patients underwent standard white light colonoscopy. However, informed consent for colonoscopy was obtained from all patients undergoing procedures.

Statistical analysis

SPSS 16.0 was used for statistical analysis. Data are presented as mean ± SEM. Proportional data were compared using the χ^2 test and means were compared using the Student's *t* test.

RESULTS

Three-hundred patients, 100 consecutive in each Group were studied. Table 1 shows the demographics, adequacy of bowel preparation and procedure-related times in each group. Although the total time for the colonoscopy was similar in the 3 groups, it reached statistical significance between Groups B and C ($P < 0.05$). The cecal intubation time in Groups B and C was longer than for Group A. The withdrawal time for Groups A and C was longer than Group B ($P < 0.05$).

In Group A, (WL → NBI) 211 polyps were detected in 78 patients (2.7 polyps/ patient); in Group B (NBI → WL) 147 polyps were detected in 67 patients (2.2 polyps/ patient) whereas in Group C (WL → WL) 219 polyps were detected in 73 patients (3.0 polyps/ patient). Adenomas were detected in 151 patients (50% of all patients) and similar in the 3 groups (47%, 47% and 57% for Groups A, B and C, respectively).

Yield for detection of polyps

As shown in Figure 1, in Group A (WL → NBI), the withdrawal with WL detected 181 polyps (62.4% distal and 37.6% proximal). Of those detected distally, 89.4% were ⩽ 5 mm in size; 7.1%, 6-9 mm in size and, 3.5%, ⩾ 1 cm. Of those detected proximally, 72% were ⩽ 5 mm in size; 17.7%, 6-9 mm and, 10.3%, ⩾ 1 cm in size. Switching to NBI detected 30 additional polyps (14.2% of all polyps detected in Group A) of which 70% were distal and 30% proximal. Ninety-five percent and 89% of the newly detected distal and proximal polyps were ⩽ 5 mm in size, respectively.

In Group B (NBI → WL), the first withdrawal with NBI detected 103 polyps (59.2% distal and 40.8% proximal). Of those detected distally, 91.8% were ⩽ 5 mm; 6.6%, 6-9 mm and, 1.6% was ⩾ 1 cm in size. Of those polyps detected proximally, 83.3% were ⩽ 5 mm; 14.3%, 6-9 mm and, 2.4%, ⩾ 10 mm in size. Switching to WL detected 44 additional polyps (30.8% of all polyps detected in Group B) of which 48% were distal and 52% proximal. Ninety-five percent and 92% of the newly detected distal and proximal polyps were ⩽ 5 mm in size, respectively.

In Group C, (WL → WL) the first withdrawal with white light detected 189 polyps (61.9% distal and 38.1% proximal). Of the polyps detected distally, 76.9% were ⩽ 5 mm in size, 17.1% were 6-9 mm and the remaining 6% were ⩾ 10 mm in size. Of the polyps detected proximally, 65.3% were ⩽ 5 mm in size, 23.6% were 6-9 mm and 11.1% were ⩾ 10 mm. When the second look with white light again was used, 30 additional polyps (13.7% of all polyps in Group C) were detected and of which 56.7% were proximal and 43.3% distal. Eighty-five percent and 76.5% of the polyps newly found in the distal and proximal colon were ⩽ 5 mm in size, respectively.

The newly diagnosed polyps detected with NBI (Group A, 14.2%) and white light (Group C, 13.7%) during the second look were significantly fewer than the ones detected using the WL after NBI (Group B, 30.8%) ($P < 0.05$). Overall, the second look of the tandem segmental colonoscopy detected 18% new polyps (104/577 polyps).

Yield for detection of adenomas

As can be seen in Figure 2, In Group A (WL → NBI), the first withdrawal with WL detected 86 adenomas: 50 (58.1%) proximal (64%: ⩽ 5 mm in size, 20%:

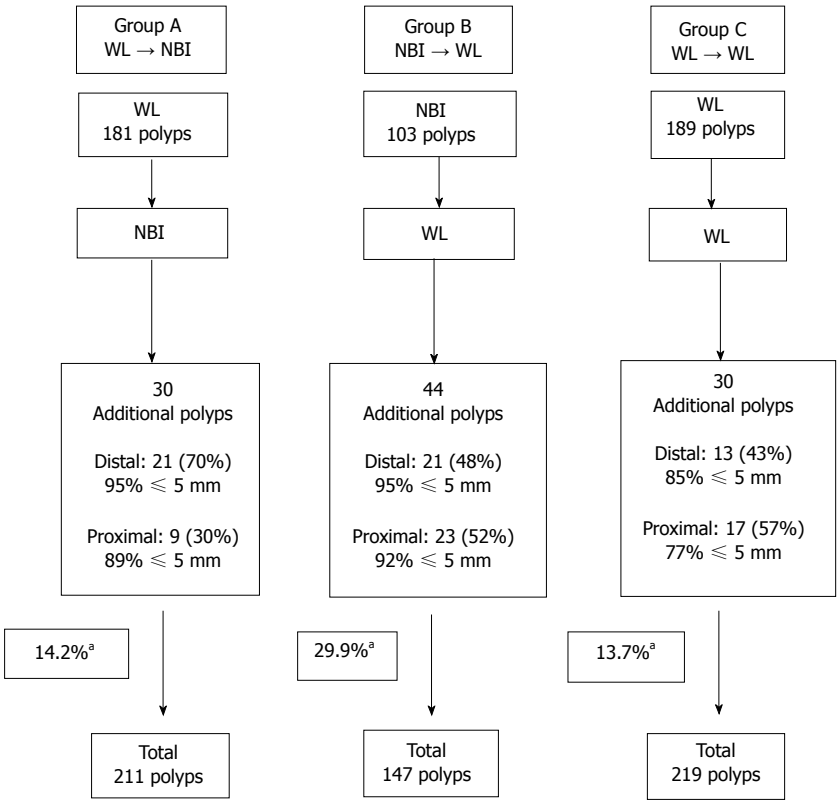

Figure 1 Yield of polyp detection. [a]*P* < 0.05, Group A and Group C *vs* Group B. WL: White light; NBI: Narrow band imaging.

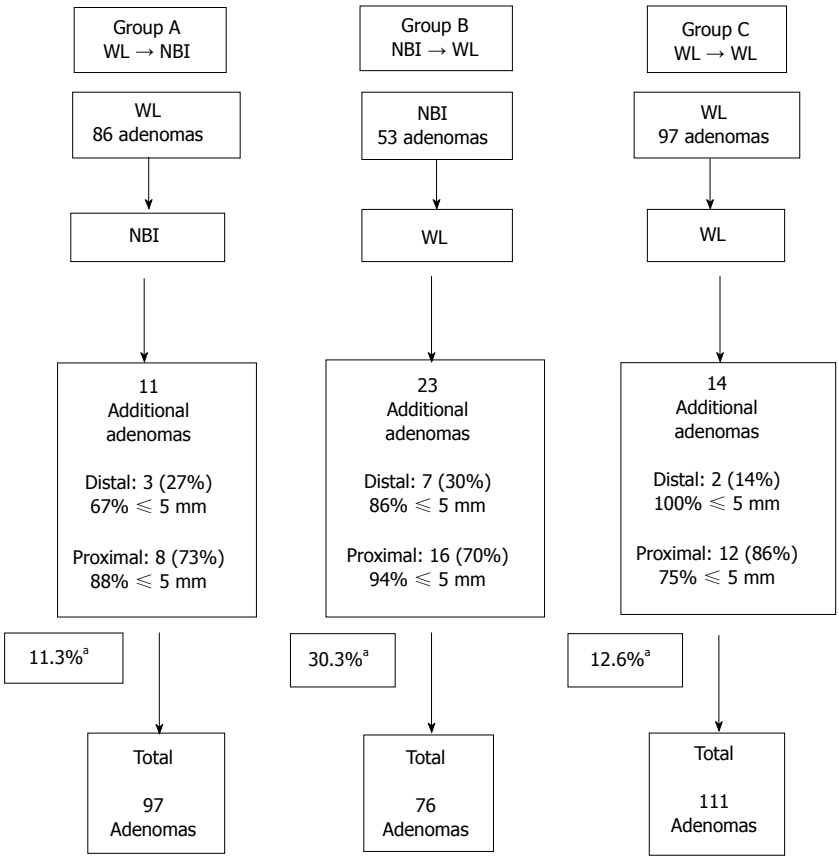

Figure 2 Yield of adenoma detection. [a]*P* < 0.05, Group A and Group C *vs* Group B. WL: White light; NBI: Narrow band imaging.

6-9 mm and, 14%: ⩾ 10 mm in size) and, 36 (41.9%) distal (77.8%: ⩽ 5 mm, 13.9%: 6-9 mm and 8.3%: ⩾ 10 mm). Switching to NBI detected 11 additional adenomas (11.3% of all adenomas detected in Group A): 8 (73%) proximal (88%: ⩽ 5 mm and 12%: 6-9 mm), and 3 (27%) distal (67%: ⩽ 5 mm and 37%: 6-9 mm).

In Group B (NBI → WL), the first withdrawal with

NBI detected 53 adenomas: 34 (64.2%) proximal (79.4%: ⩽ 5 mm, 17.6%: 6-9 mm and 2.9%: ⩾ 10 mm) and 19 (35.8%) distal (89.5%: ⩽ 5 mm, 5.3%: 6-9 mm and 5.3%: ⩾ 10 mm). Switching to WL detected 23 additional adenomas (30.3% of all adenomas detected in Group B): 16 (70%) proximal (94%: ⩽ 5 mm, 6%: ⩾ 10 mm) and 7 (30%) distal (86%: ⩽ 5 mm, 14%: 6-9 mm).

In Group C (WL → WL), there were 97 adenomas detected by white light during the first withdrawal: 61 (62.9%) proximal (70.5%: < 5 mm, 23%: 6-9 mm, 6.5%: > 10 mm) and 36 (37.1%) distal (58.3%: ⩽ 5 mm, 25%: 6-9 mm, 16.7%: ⩾ 10 mm). During the second withdrawal with white light, 14 additional adenomas were detected (12.6% of all adenomas detected in Group C): 12 (85.7%) proximal (75%: ⩽ 5 mm, 25%: 6-9 mm) and 2 (14.3%) distal (100%: ⩽ 5 mm).

The newly diagnosed adenomas detected with NBI (Group A, 11.3%) and WL (Group C, 12.6%) during the second look were significantly fewer than those detected using the WL after NBI (Group B, 30.3%) ($P < 0.05$). The second look of the tandem segmental colonoscopy thus, detected 16.9% new adenomas (48 out of 284 adenomas).

Yield for detection of advanced neoplasia

In Group A (WL → NBI), there were 8 patients (10 polyps) with advanced neoplasia (all defined by size ⩾ 10 mm only). None of these advanced neoplasias were detected during the second look performed by NBI. In Group B (NBI → WL), there were 3 patients (3 polyps) with advanced neoplasia (all defined by size ⩾ 10 mm only), and one of these (10 mm polyp in ascending colon) was detected during the second look using WL. In Group C (WL → WL), there were 9 patients (11 polyps) with advanced neoplasia including 1 villous adenoma in the sigmoid and 1 invasive carcinoma in the rectum (the remaining 9 adenomas were defined as advanced neoplasia by a size ⩾ 10 mm). None of the advanced neoplasias were detected during the second look with WL.

When NBI was used as the second look, it diagnosed 2 patients (1 adenoma each) that otherwise would have been diagnosed as having no adenomas at all and representing 4.3% (2 out of 47) of patients with adenomas. When WL was used as the second look, it identified 8 patients that otherwise would have been missed as having any adenomas (6 of these had single adenomas, and the other 2 had 2 adenomas each) and representing a pick up rate of 17% (8 out of 47 patients with adenomas). For Group C, when a second look with white light was performed, 5 patients (1 adenoma each) were detected that otherwise would have been missed as having any adenomas at all and representing 10.6% (5 out of 57) of patients with adenomas. The differences among the groups were not statistically significant. None of these patients in either group had advanced neoplasia that would have been undetected at all.

Yield for non-neoplastic polypoid lesions

Non-neoplastic polyps represented 17.8% (103/577) of all polyps and were similarly distributed among the 3 groups.

There was one case of post-polypectomy bleeding requiring admission and endoscopic intervention to secure hemostasis with endoscopic clips. There were no sedation-related complications.

DISCUSSION

The impact of new optical technologies such as high-definition, magnification and NBI on polyp detection rate is unknown. Tandem colonoscopy studies have yielded an additional detection rate up to 22% for adenomas and 27% for non-adenomas[9]. Our study showed that the detection rate of missed polyps and adenomas after a first look with white light was similar when using narrow band imaging (14.2% for polyps, 11.3% for adenomas) or white light (13.7% for polyps and 12.6% for adenomas) as the second look modality. We also found that when white light was used after narrow band imaging, the detection rate of missed polyps (29.9%) and adenomas (30.3%) was higher in comparison to where white light was used as first modality. The explanation for this unexpected finding is not completely clear. To further address this issue, we studied 100 additional consecutive patients undergoing screening colonoscopy using the following strategy (NBI → NBI → WL). Out of 198 polyps (92 adenomas) detected, the second look with NBI added 24 new polyps (7 adenomas) and the "third look" with WL added 28 additional polyps (15 adenomas) representing 12.1% polyps and 7.6% adenomas with the second NBI look and, 14.1% polyps and 16.3% adenomas with the "third look" using WL. Thus, the combined miss rate after a first look with NBI (26.2% and 23.3% for polyps and adenomas, respectively) was similar to the one reported in the present study when using the NBI → WL strategy. In our study, the bowel cleanliness was not associated with improved polyp detection. Another shortcoming of NBI appears to be relative poor visualization unless endoscope is held closer (more so than the WL) to the inspected area.

The adenoma miss rate in the tandem colonoscopy studies is inversely related to the size and directly related to the number detected during the first look[9]. In a prospective multicenter study[10] of tandem colonoscopy the miss rates for polyps, adenomas, polyps > 5 mm, adenomas > 5 mm and advanced neoplasia was 28%, 20%, 12%, 9% and 11%, respectively. The sessile or flat shape and left colonic location were associated with higher miss rates. Interestingly, in that study, not all recto-sigmoid polyps (thought to be hyperplastic) were removed. The explanation for rather significant and fairly similar miss rates reported by experienced endoscopists remains

speculative at best. Operator's-related factors that may influence the miss rate include: technique, rate of withdrawal, difference in recognition of pathology (only applicable when two different endoscopists with different levels of expertise are involved) and thus related to inter-observer variability, a more careful look performed by the second endoscopist because of the prior knowledge of the goals/objectives of the study (bias). Other factors may be polyp-related: location (*i.e.*, behind folds) that possibly becomes "more exposed" to the second look and, estimated polyp size; and/or, bowel preparation-related: a cleaner colon resultant from the cleaning performed during the first look. Optical enhancements in endoscopy are expected to reduce the miss rate of both polyps/adenomas; better predict histology and, enhance demarcation of neoplastic tissue and thus improve the rate of complete polypectomy. The development of these technologies in part, is in response to the lack of complete protection against interval cancer development[21], polyp detection and clearance such as adequacy of bowel preparation[22,23], operator's expertise and completeness (cecal intubation) of examination[24-28], adequate withdrawal times[29,30], incomplete polyp resection[31,32] and inherent limitations of the colonoscopy itself[33-35]. NBI was initially reported to increase the yield of detection of polyps and adenomas[12,15,17,19,20]. The studies investigating the role of NBI in the detection of colonic polyps have yielded controversial results. In a study[36], of 40 patients undergoing screening colonoscopy, NBI detected 51 additional polyps (41.5% of total polyps) and 29 adenomas (40.3% of total adenomas). The polyp/adenoma miss rate appeared somewhat higher than what has been reported in the literature (10%-20%), even if a potential gain provided by NBI from 5% to 15% was added. The study included WL → NBI arm but lacked NBI → WL and WL → WL) arms. In another study[15], NBI detected numerically more adenomas (23%) than conventional endoscopy (17%). However, procedures were not performed in a tandem fashion. There also appeared to be a learning effect upon adenoma recognition/detection due to involvement of multiple endoscopists, some with less experience even in conventional endoscopy. In a randomized controlled study[37], again, tandem colonoscopy was not performed, and thus the miss rate with each of the lights remained unknown. Nevertheless, in that study the authors found no difference in the detection rates of overall adenomas or adenomas of any size. To compare, detection rate for adenomas in our group of 300 patients was 50% (range: 47% to 57%) which is similar to the above mentioned study[37]. This may suggest that in the hand of experienced endoscopists with a high detection rate, NBI may not have an added benefit. In another randomized study comparing conventional *vs* pan-colonic narrow band imaging[38], NBI detected significantly more adenomas, especially diminutive (< 5 mm) in the distal colon without compromising the withdrawal time than conventional colonoscopy. The main limitation of the study again was the lack of tandem colonoscopy. Finally, a randomized tandem colonoscopy study[39] comparing NBI → WL *vs* WL → WL showed that there were no significant differences either in the miss or detection rates between two modalities (12.6% miss rate in NBI and 12.1% in WL group). Although, the miss rates in the, WL → WL group was similar to ours, the miss rate in the NBI → WL was lower than that found in our study.

The main limitations of our study are a non-randomized nature and being carried out by two experienced endoscopists at a single center, and thus the results may not be generalized.

In summary, the overall miss rate of adenomas by segmental tandem endoscopy was 17%; being highest (30%) after NBI had been used as the first modality. Most missed adenomas were in the proximal colon and were ⩽ 5 mm in size. When white light was used first, the detection rate of missed adenomas was similar with white light and NBI. In conclusion, our data suggest that the tandem nature of the procedure rather than the optical technique used was the most important factor for detecting missed pathology. We recommend taking extra time to "take a second look" at each segment during colonoscopy to increase the yield for detection of pathology.

COMMENTS

Background

Polyp detection is of paramount importance during colonoscopy. Conventional colonoscopy may miss polyps, some of which could be pre-cancerous. Narrow band imaging (NBI) is one of the several modalities that are being investigated to enhance polyp and adenoma detection rates.

Research frontiers

In narrow band imaging, light of specific blue and green wavelengths is used to enhance the details of certain aspects of the mucosa. NBI has been utilized to classify the colon polyps based on their pit patterns, to differentiate normal from dysplastic tissue in Barrett's esophagus and ulcerative colitis, and in some cases to improve the detection of colonic polyps/lesions.

Innovations and breakthroughs

The impact of new optical techniques such as high-definition, wide angle, magnification and NBI on polyp detection rate is unknown. The authors know, that a second look back-to-back colonoscopy when performed by a second endoscopist (tandem colonoscopy), may yield additional polyps. The study showed, that the additional detection of missed polyps and adenomas after a first look with white light (WL) was similar when either NBI (WL → NBI) or white light (WL → WL) were used as a second look. This suggests that NBI did not increase the rate of detection of polyps/adenomas but that the tandem nature of the procedure did.

Applications

This study suggests that white light may be a relatively better modality in comparison to narrow band imaging when routinely used for purposes of polyp detection during colonoscopy.

Terminology

NBI: Light of specific blue and green wavelengths that can be used in endoscopy to enhance the details of certain aspects of the lining of gastrointestinal tract; Adenoma: A potentially pre-cancerous polyp.

Peer-review

The authors present a well-designed study investigating the use of second look with narrow band *vs* white light endoscopy and the effect on polyp detection rates.

Abstract

Mesenteric panniculitis is a chronic illness that is characterized by fibrosing inflammation of the mesenteries that can lead to intractable abdominal pain. Pain control is a crucial component of the management plan. Most patients will improve with oral corticosteroids treatment, however, some patients will require a trial of other immunosuppressive agents, and a minority of patients will continue to have refractory disease. Endoscopic ultrasound guided celiac plexus block is used frequently to control abdominal pain in patients with pancreatic pathology. To our knowledge there are no case reports describing its use in mesenteric panniculitis patients with refractory abdominal pain.

Key words: Endoscopic-ultrasound; Abdominal pain; Celiac plexus; Mesenteric panniculitis

Core tip: Mesenteric panniculitis is a rare disorder that can present with refractory and disabling abdominal pain, we describe a novel intervention using endoscopic ultrasonography guided celiac plexus block to control the refractory abdominal pain in a patient with mesenteric panniculitis. This approach is based on the anatomical supply of the epigastric area where the pain is originating.

Alhazzani W, Al-Shamsi HO, Greenwald E, Radhi J, Tse F. Chronic abdominal pain secondary to mesenteric panniculitis treated successfully with endoscopic ultrasonography-guided celiac plexus block: A case report. *World J Gastrointest Endosc* 2015; 7(5): 563-566 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/563.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.563

INTRODUCTION

Mesenteric panniculitis is a rare, benign condition

characterized by acute inflammation of the mesenteric adipose tissue that can progress to chronic fibrosis[1]. The disease was first described by Jura[2] in 1924, he used the term retractile mesenteritis to describe this condition. Subsequently, the term mesenteric panniculitis was developed by Aach *et al*[3] to describe the acute inflammatory phase of the disease. Since then, this has been widely used and adopted term to describe this disease. Mesenteric panniculitis is also known as mesenteric lipodystrophy, primary liposclerosis, isolated lipodystrophy, lipogranuloma, and Weber-Christian disease[4]. The etiology of this disorder remains largely unknown; an association with inflammatory disorders, infection, malignancy (particularly lymphoma)[5], trauma, and abdominal surgery has been described[6]. The prevalence of the disease is estimated to be around 0.6%, and it is more common in Caucasians. The clinical course of mesenteric panniculitis is indolent and favorable[7].

The disease usually progresses slowly and may subside spontaneously[7], around 30%-50% of patients are asymptomatic[5]. However, 20% of patients will have more symptomatic debilitating disease[8]. The most common symptom is chronic abdominal pain, some patients may present with acute abdomen[9]. Abdominal pain can be accompanied by other non-specific symptoms including fever, nausea, vomiting, anorexia and non-intentional weight loss[10]. The diagnosis is usually suggested by high resolution computed tomography (CT) scan[11]. Histological confirmation is rarely required[1]. The majority of patients will respond to systemic corticosteroids[8]. However, some patients will require a more intense immunosuppressive therapy like azathioprine or cyclophosphamide. Only a minority of patients will continue to have refractory disease despite immunosuppressive therapy[12]. Other modalities including progesterone, colchicine, tamoxifen, antibiotics and emetine, or radiotherapy have been used in refractory disease with limited success[13,14]. Surgical resection is reserved for the treatment of complication like intestinal obstruction or ischemia[7]. Refractory abdominal pain can be a major source of morbidity in these patients[15].

CASE REPORT

We report here on a 62-year-old caucasian male who presented with right upper quadrant abdominal pain for several months prior to his first presentation to our institution in 2005. The abdominal pain was not associated with changes in bowel habits, nausea, vomiting, or constitutional symptoms. Initial investigations including complete blood count, liver and kidney function tests, and abdominal ultrasonography were normal. The patient underwent cholecystectomy in 2005 for possible biliary cause of pain, but the pain persisted after surgery. Subsequently, imaging study using CT imaging scan demonstrated thickening and irregularity of the mesentery surrounding the pancreatic head. The radiologic findings were in keeping with the diagnosis of mesenteric panniculitis (Figure 1). Extensive investigations ruled out luminal pathology, pancreatic or adrenal diseases, intermittent porphyria, vascular etiology, and other conditions.

Figure 1 Computed tomography of the abdomen. Computed tomography scan of the abdomen showing mesenteric irregularity and thickness.

Given the radiologic findings and the patient symptoms, the patient was started on prednisone 40 mg once daily for two months. This was associated with a significant improvement in the severity of abdominal pain. However, prednisone therapy was complicated by severe systemic side effects, including worsening of pre-existing depressive disorder, hypertension and cataracts. For this reason, the patient was subsequently weaned off corticosteroids. He remained symptom free for 6 mo after discontinuation of steroid therapy, and then had recurrence of abdominal pain. Because of the chronicity and severity of the symptoms, the patient underwent diagnostic laparoscopy primarily to rule out malignant process. The operative findings showed thickening of the mesentery with no discrete visible masses. Samples from the thickened mesentery were obtained. The pathology results confirmed the diagnosis of mesenteric panniculitis (Figure 2). The patient was started on a steroid-sparing agent (azathioprine) for 6-mo with no response. Further attempts using 3 to 6 mo courses of tamoxifen and subsequently thalidomide failed to improve his symptoms. Different non-opiate analgesic agents were unsuccessful in controlling his symptoms, including acetaminophen and non-steroidal anti-inflammatory drugs. Eventually the patient was started on opioids (oxycodone and morphine) and a serotonin-norepinephrine reuptake inhibitor for pain control. A follow-up CT imaging of the abdomen showed similar findings.

After discussion with the patient, the patient was referred for endoscopic ultrasonography (EUS) guided celiac plexus block in an attempt to control relief the intractable abdominal pain and minimize the use of narcotics.

After obtaining consent from the patient, the linear echoendoscope was advanced through the oral cavity

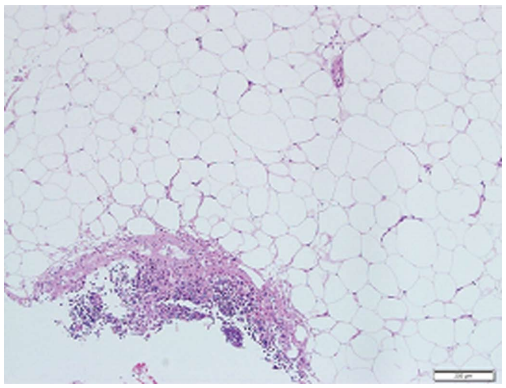

Figure 2 Mesenteric biopsy. Mesenteric biopsy showing fibrotic band of dense collagen infiltrated by mixed inflammatory cells (lymphocytes, plasma cells and neutrophils). There is fat necrosis, no vasculitis or malimgnancy seen. There is no cellular atypia or lipoblast identified in the biopsy.

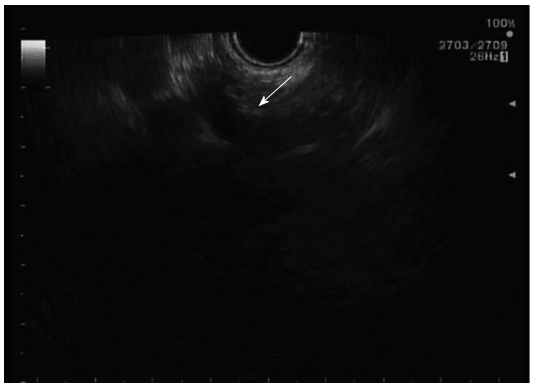

Figure 3 Ultrasonographic image of celiac plexus. This image is showing the celiac artery and celiac plexus (arrow).

into the stomach; the celiac trunk was identified using the ultrasound images (Figure 3). A 19-gauge needle (Echotip; Wilson-Cook) was used to inject 40 mg of Triamcinilone and 10 mL of 0.25% bupivicaine on both sides of the celiac trunk. This protocol is similar to that described by Gress *et al*[16]. Intravenous crystalloids were administered during the procedure to prevent hypotension caused by the procedure. The patient tolerated the procedure well and was discharged home within few hours.

Within the first week after the procedure, the patient noticed a dramatic improvement in his symptoms. Within 2 mo, he was weaned off narcotics with complete resolution of his symptoms. However, symptoms recurred 6 mo after the procedure. Given the initial response to this therapy, the procedure was repeated using identical protocol. Few days after the procedure, the patient developed a back injury that led to a surreptitious diagnosis of a 1 cm schwannoma at T12-L1 spinal levels. Surgical resection of the spinal cord tumor was done soon after celiac block, which confounded the assessment of pain. Three months after the second EUS-guided celiac plexus block, the patient was pain free and off all analgesics.

DISCUSSION

To our knowledge, there are no published reports of applying this unique intervention to control refractory abdominal pain in a patient with mesenteric panniculitis. Mesenteric panniculitis is a rare disorder that is characterized by chronic inflammation leading to fibrosis of the mesentery. Patients' presentation varies from asymptomatic incidental radiologic findings to severe abdominal pain, vomiting, changes in bowel habits, and constitutional symptoms[17,18]. Associated malignancy is not uncommon, with one report showing that 70% of included patients had radiological findings consistent with malignant disorders[19].

Due to the low incidence of this condition, the prognosis of the disease is not well defined. One report with more than 5 years of follow-up showed that mortality rate approaches 45%, majority of fatalities (50%) were related to co-existing malignancy[20]. Several case reports showed that immunosuppressive medications are effective in controlling disease activity[4,21,22]. However, there are no published reports on the utility of celiac plexus block for controlling refractory symptoms.

Celiac plexus is composed of sympathetic efferent fibres, which are derived from the greater, lesser, and least splanchnic (T5-T12) nerves[23]. The visceral afferent fibres supplying the distal esophagus down to the transverse colon pass through the celiac plexus, before ending in the spinal cord. Therefore, pain originating from pancreatic disease may respond to celiac plexus block. In fact, the most studied application of EUS-guided celiac block is in pancreas-related pain[1,24-26]. The application of this procedure in other disorders is very limited. There are few case reports on the use EUS-guided block in the management of pelvic cancer pain[27], acute intermittent porphyria[28], and pain caused by diabetic gastroparesis[29]. No published literature on the utility of this intervention in patients with mesenteric panniculitis related pain.

Theoretically, pain originating from upper abdominal organs could be alleviated by this procedure. However, this was not tested in clinical trials or observational studies. More research in this area is required in order to ascertain or dispute our observation.

COMMENTS

Case characteristics

Recurrent right upper quadrant abdominal pain.

Clinical diagnosis

Mesenteric panniculitis.

Differential diagnosis

Upper endoscopy ruled out an intraluminal pathology, computed tomography (CT) scan finding was not suggestive of neuroendocrine or pancreatic malignancy, diagnostic laparoscopy done to rule out intra-abdominal malignant process.

Laboratory diagnosis

Extensive investigations including complete blood count, Lipase, Liver enzymes, kidney function, porphyria screening, radiological imaging with CT scan, the

diagnosis was confirmed with histology.

Imaging diagnosis

Imaging study using CT scan demonstrated thickening and irregularity of the mesentery surrounding in keeping with the diagnosis of mesenteric panniculitis.

Pathological diagnosis

Mesenteric biopsy showing fibrotic band of dense collagen infiltrated by mixed inflammatory cells (lymphocytes, plasma cells and neutrophils) in keeping with the diagnosis of mesenteric panniculitis.

Treatment

The patient was treated with multiple pharmacological agents including prednisone, azathioprine, tamoxifen and thalidomide that failed control his symptoms. Subsequently, responded to endoscopic ultrasonography (EUS)-guided celiac plexus block.

Abstract

A 32-year-old female presented with 5-year history of iron deficiency anemia, marked pallor and edema of both lower limbs. Laboratory investigations including complete blood count, blood film, iron studies, lipid profile, ascitic fluid analysis, test of stool for occult blood and alpha 1 anti-trypsin. Upper, lower gastrointestinal (GIT) endoscopies, and enteroscopy were performed. Imaging techniques as abdominal ultrasonography and computed tomography were done. Echocardiography, lymph node biopsy and bone marrow examination were normal. The case was diagnosed as Waldmann's disease with protein losing enteropathy and recurrent GIT bleeding. Management started with low fat diet with medium chain triglyceride, octreotide 200 μg twice a day, tranexamic acid and blood transfusion. Then, exploratory laparotomy with pathological examination of resected segment was done when recurrent GIT bleeding occurred and to excluded malignant transformation.

Key words: Waldmann's disease; Lymphangiectasia; Gastrointestinal bleeding; Iron deficiency anemia

Core tip: To our knowledge, this is the first "Egyptian" case of primary intestinal lymphangiectasia. In addition, its presentation is rare with blood loss anemia in contrast to the more common presentation with hypoproteinemia and edema. So, we are reporting a case with a rare clinical presentation of a rare disease. Double balloon enteroscopy was so beneficial in the diagnosis of the case superior to capsule endoscopy

because the advantage of biopsy and histopathologic examination. There is controversy about medical treatment options, surgical treatment may be preferred in localized lesions otherwise, has no role. Prognosis may be favorable.

Anaemia in Waldmann's disease: A rare presentation of a rare disease. *World J Gastrointest Endosc* 2015; 7(5): 567-572 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i5/567.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i5.567

INTRODUCTION

Waldmann's disease; also called primary intestinal lymphangiectasia (PIL) is a rare form of protein losing enteropathy caused by leakage of lymph inside the small intestinal lumen from dilated lacteals. The manifestations begin before the age of 30 years in 90% of cases, often in childhood. Whether bleeding into gastrointestinal tract a feature of PIL or not is still controversial. Here, we present a case of a young women with chronic blood loss anemia (iron deficiency and positive fecal occult blood test) caused by Waldmann's disease.

CASE REPORT

A 32-year-old female with 5 year history of iron deficiency anemia was referred to our Gastroenterology Unit for further evaluation. History was irrelevant apart from easily fatigability and repeated blood transfusions as well as iron therapy. Examination revealed marked pallor and edema of both lower limbs.

Laboratory findings of a 32 years old female with Waldmann's disease are shown in Table 1.

Upper and lower GI endoscopies were done twice within two-month period and did not reveal any gross pathology. So, Fujinon's Double Balloon Endoscopy System (with 2.8 mm forceps channel) was used to examine the small bowel through oral route down to 310 cm from the ligament of Trietz. Multiple lymphangectasias (Figure 1) were seen starting at about 100 cm, extending all through the assessed parts; some of them were actively bleeding. The most affected area (at about 100 cm) was tattooed with India Ink. Histopathological examination of the lesions revealed multiple dilated vascular and lymphatic spaces and few lymphocytes with no evidence of malignancy, picture consistent with capillary telangiectasia.

Abdominal ultrasonography, abdominal computed tomography (CT), echocardiography, inguinal lymph node biopsy, and bone marrow examination were performed to exclude secondary causes of lymphangiectasia. All tests were normal except for mild splenomegaly (due to multiple hemangiomas).

Table 1 Laboratory results for the patient

Test	Result	Normal reference
Complete blood count		
Hemoglobin	5.2 g/dL	12-18 g/dL
HCT	18.30%	37%-51%
MCV	70.2 pg	80-97 flpg
MCHC	28.4 g/dL	31-36 g/dL
Platelets	284	140-440 cell/cm^3
WBCs	3.8	4.1-10.9 cell/cm^3
Lymphocytes	500	600-1400
Blood film		
Hypercellular bone marrow with no blast cells		
Blood chemistry		
s. Albumin	2.1 g/dL	3.5-5 g/ dL
AST	30 IU/L	Up to 40 U/L
ALT	25 IU/L	Up to 45 U/L
s. cholesterol	107 mg/dL	Up to 200 mg/dL
s. triglyceride	54 mg/dL	Up to 160 mg/dL
s. iron	23 ng/dL	28-170 ng/dL
s. ferritin	12 ng/mL	40-430 ng/mL
TIBC	750 ng/dL	261-478 ng/dL
s. TSH	1.2 mIU/L	0.3-3.04 mIU/L
Stool tests		
Occult blood	Positive	
α-1 AT clearance	2 folds above normal range	

HCT: Hematocrit; MCV: Mean corpusclar volume; MCHC: Mean corpuscular hemoglobin concentration; WBCs: White blood cells; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; TIBC: Total iron binding capacity; TSH: Thyroid stimulating hormone; α-1 AT: Alpha 1 antitrypsin.

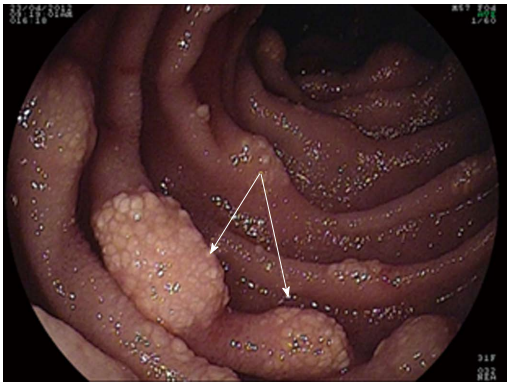

Figure 1 Multiple jejunal lymphangiectasia.

Management started with low fat diet with medium chain triglyceride, octreotide 200 μg/twice a day, tranexamic acid and blood transfusion till an acceptable level of hemoglobin was achieved (about 9 g/dL). She was discharged on diet regimen and regular follow up.

Nine months later during routine follow up, clinical examination showed marked pallor (Hb 6 g/dL) and abdominal ultrasonography revealed moderate ascites and mild right sided pleural effusion. Ascitic fluid was milky and turbid. Chemical analysis of ascitic fluid sample revealed glucose of 108 mg/dL, total protein of 1170 mg/dL, lactate dehydrogenase of 195 U/L, triglycerides of 1232 mg/dL (diagnostic of chylous ascites), WBCs of 250 cell/cm^3 mainly lymphocytes,

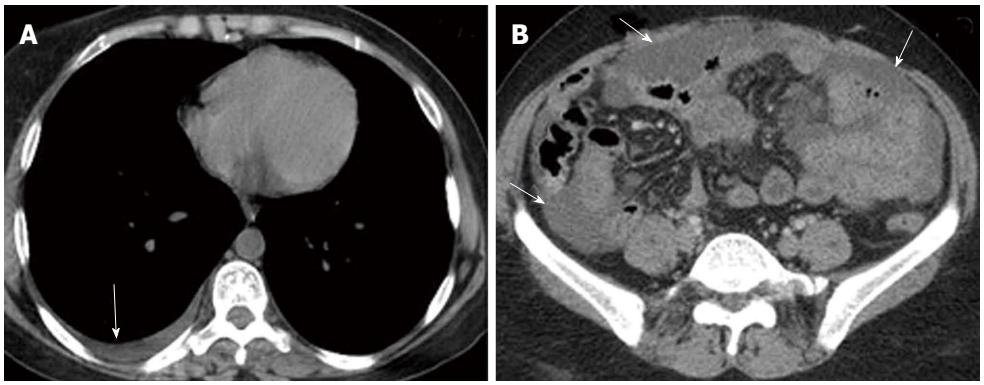

Figure 2 Pre contrast axial computed tomography scan showing (A) mild right-sided pleural effusion and (B) mild ascites.

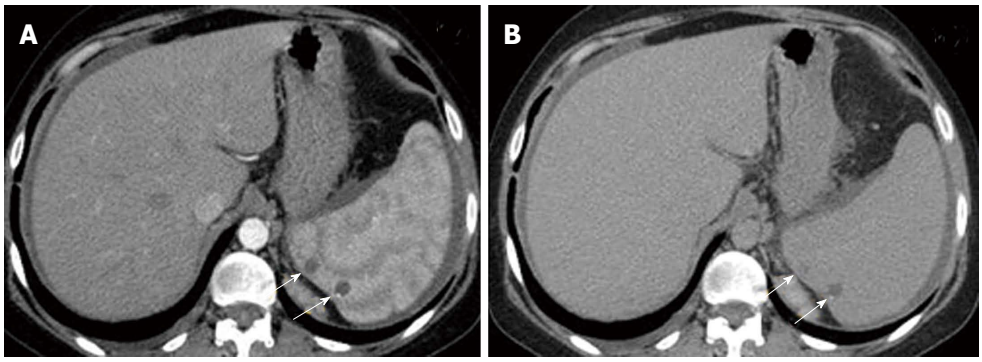

Figure 3 Triphasic post contrast axial computed tomography showing. Multiple splenic hemangiomas in portal (A) and delayed (B) phases respectively showing filling in (arrows).

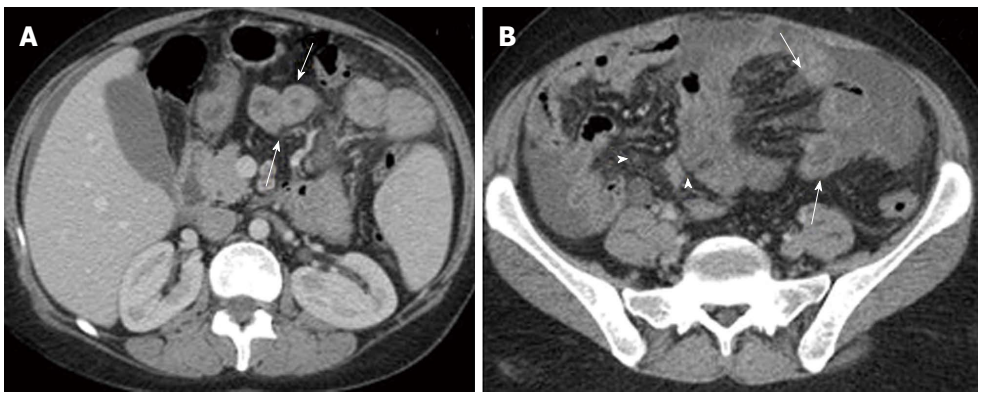

Figure 4 Triphasic post contrast axial computed tomography (portal phase) showing. A: Dilated small intestinal wall (arrows); B: Mesenteric hypodense bands indicating obstructed lymphatics (arrows), and dirty fat appearance due to mesenteric oedema (arrow heads).

and RBCs of 0.01×10^6. Cytological examination of ascitic fluid revealed no atypical or malignant cells. ZN stain and adenosine deaminase were negative. Triphasic CT scan was performed by 8 multi-slice G.E. CT scanner. It revealed right pleural effusion, mild ascites; both had uncomplicated fluid density: 0-20HU (Figure 2) and multiple splenic hemangiomas (Figure 3). Regarding small intestine, CT revealed dilated small intestinal loops with diffuse, nodular wall thickening (reaching up to 9 mm), mesenteric hypodense bands representing dilated lymphatic channels and mesenteric edema (Figure 4). Neither lymphadenopathy nor hepatomegaly was detected.

Surgical opinion was sought and malignant transformation was suspected. So, exploratory laparotomy was done through midline incision. Findings include minimal ascites, multiple cysts related to the small intestinal wall and its mesentry and a discolored segment of the proximal jejunum previously marked with India Ink by enteroscopy (Figure 5) but no masses were found. Resection anastomosis of the discolored segment was done. Histopathological examination revealed large gaping vascular spaces lined by flat endothelial cells and filled by lymph fluid, picture consistent with primary intestinal lymphangectasia (Figure 6).

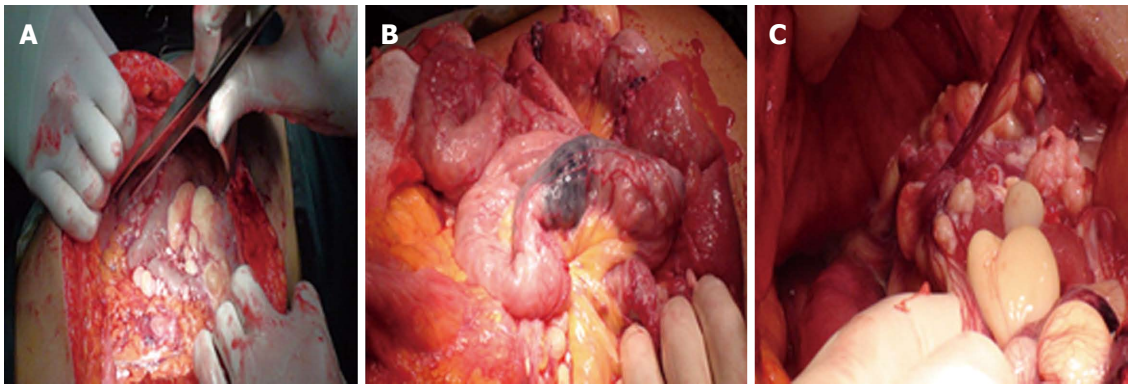

Figure 5 Exploratory laparotomy, multiple cysts was seen related to the small intestinal wall and its mesentry and a discolored segment of the proximal jejunum.

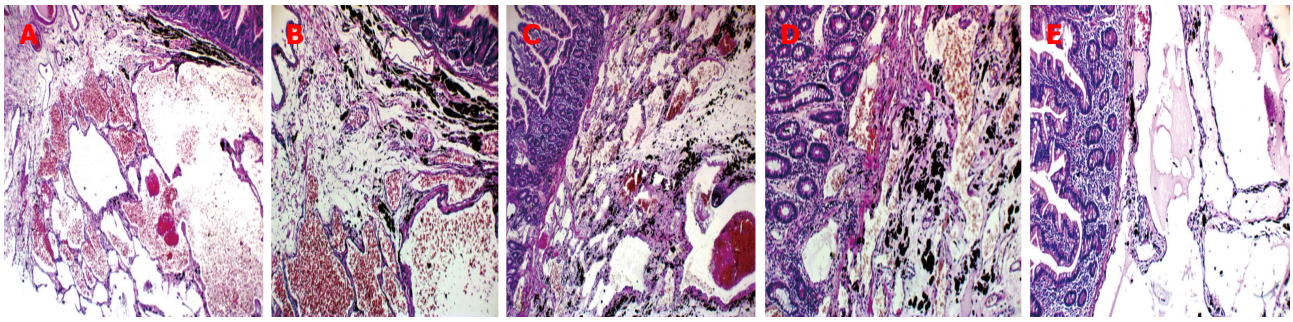

Figure 6 Histopathological examination of the resected part of small intestine. A: The sub-mucosa shows large gaping vascular filled by RBCs (HE × 40); B: The vascular spaces are lined by flat endothelial cells (HE × 100); C: Black staining is due to labeling material (India Ink) (HE × 100); D: The sub-mucosal vascular are see encroaching upon the mucosal lining (HE × 100); E: Some vascular spaces lined by flat endothelial cells and filled by lymph fluid (HE × 100).

Postoperative outcome was favorable and she was discharged home after 5 d.

On the 20th postoperative day, patient achieved marked improvement of her general condition, disappearance of edema lower limb, ascites, and pleural effusion. Laboratory investigations were; s. albumin 4.1 g/dL, HB 10.9 g/dL, platelets count 147 cell/cm^3, WBCs 4900 cell/cm^3 with normal distribution. Six months later, she remained asymptomatic with weight gain of 5 kg and rather stable hemoglobin level.

DISCUSSION

Protein losing enteropathy (PLE) is a rare cause of hypoproteinemia due to gastrointestinal (GI) loss of serum protein. This rare condition has many reported causes (Table 2) including the rare Waldmann's disease (PIL) in which GI protein loss results from leakage of lymph through the ectatic intestinal lacteals[2].

PIL predominantly affects young children although it may also be diagnosed in older age. There is slight male preponderance with 3:2 ratio. On the other hand, race is not a predictor of PIL[3,4].

Patients usually present with bilateral lower limb edema[2-7]. Other manifestations like pain, loose motion, and malnutrition are less common[8]. Rare manifestations include abdominal mass, Mechanical ileus[9-11], chylous reflux[12,13], iron deficiency with anemia[14], necrolytic migratory erythema[15], recurrent hemolytic uremic syndrome[16], and osteomalacia[17]. Recurrent gastrointestinal bleeding was even more rare being reported in only 2 cases[18,19].

Work up of diagnosis consist of laboratory, imaging studies and GIT endoscopy with confirmatory histopathological examination[20].

The most common laboratory finding is hypoproteinemia. Hypo-albuminemia is most prominent and lymphopenia. Cholesterol levels are not usually elevated. PLE can be confirmed by presence of excess fecal α1-antitrypsin[21,22].

Abdominal CT scan may show dilated thickened small intestinal loops, ascites, halo sign and edematous mesentery. It also helps rule out secondary causes[23,24].

Diagnosis can only be confirmed by finding dilated lacteals both on endoscopic and histopathologic examination[25,26]. Video capsule endoscopy imaging provides the same information and allow exploration of the whole small bowel but does not allow biopsies[27].

PIL has to be differentiated from secondary causes of intestinal lymphangiectasia such as Crohn's disease, intestinal tuberculosis, and Whipple's disease as well as from causes of PLE without lymphangiectasia such as Mentrier's disease and systemic lupus erythematosus (SLE)[20].

Medical management relies on diet modification with low fat replaced by medium-chain triglycerides

Table 2 Causes of protein losing enteropathy[1]

Erosive gastrointestinal disease
Inflammatory bowel disease
Gut malignancy
Non steroidal anti-inflammatory drug enteropathy
Erosive gastropathy
Acute graft vs host disease
Pseudomembranous enterocolitis
Ulcerative jejunoenterocolitis
Intestinal lymphoma
Sarcoidosis
Non erosive gastrointestinal disease
Celiac disease
Hypertrophic gastropathies
Eosinophilic gastroenteritis
Connective tissue disorders
Small intestinal bacterial overgrowth
Amyloidosis
Microscopic colitis
Tropical sprue
Whipple's disease
Parasitic diseases
Viral gastroenteritis
Increased interstitial pressure
Intestinal lymphangiectasia
Congestive heart failure
Constrictive pericarditis
Congenital heart diseases
Fontan procedure for single ventricle
Portal hypertensive gastroenteropathy
Hepatic venous outflow obstruction
Enteric lymphatic fistula
Mesenteric venous thrombosis
Sclerosing mesenteritis
Mesenteric tuberculosis or sarcoidosis
Neoplasia involving mesenteric lymph nodes or lymphatics
Chronic pancreatitis with pseudocysts
Congenital malformations of lymphatic
Retoperitoneal fibrosis

thus preventing fat overloading of intestinal lacteal[28,29].

Response to other medications, such as[30-31] octreotide[32-36] and steroids[37] is variable.

Small intestinal resection is indicated in localized forms of the disease[38,39].

Natural history of PIL is greatly variable; depending on involvement of intestine either generalized or localized with blockage of mesenteric lymphatic drainage. Prognosis may be favorable unless it is complicated by intestinal B-lymphoma or effusion in serous sacs[20,40].

COMMENTS

Case characteristics

A 32-year-old female presented with 5-year history of iron deficiency anemia, marked pallor and edema of both lower limbs.

Clinical diagnosis

Examination revealed marked pallor and edema of both lower limbs.

Differential diagnosis

Primary intestinal lymphangiectasia has to be differentiated from secondary causes of intestinal lymphangiectasia such as Crohn's disease, intestinal tuberculosis, and Whipple's disease as well as from causes of protein losing enteropathy without lymphangiectasia such as Mentrier's disease and systemic lupus erythematosus.

Laboratory diagnosis

Patient hemoglobin level and serum albumin were 5.2 g/dL, 2.1 g/dL respectively. α-1 AT clearance was 2 folds above normal range and stool test for occult blood yield positive result.

Imaging diagnosis

Computed tomography of the abdomen revealed dilated small intestinal loops with diffuse, nodular wall thickening, mesenteric hypodense bands representing dilated lymphatic channels and mesenteric edema.

Endoscopy diagnosis

Double balloon enteroscopy was performed, and revealed presence of multiple lymphangectasias, some of them were actively bleeding.

Pathological diagnosis

Histopathological examination of the lesions revealed multiple dilated vascular and lymphatic spaces and few lymphocytes with no evidence of malignancy, picture consistent with capillary telangiectasia.

Treatment

Management started with low fat diet with medium chain triglyceride, octreotide 200 μg/twice a day, tranexamic acid and blood transfusion till an acceptable level of hemoglobin was achieved (about 9 g/dL). But the results was unsatisfactory.

Related reports

Only two cases with primary intestinal lymphangiectasia were presented in literatures by gastrointestinal bleeding.

Term explanation

Chronic blood loss anemia (iron deficiency and positive fecal occult blood test) could be a one of manifestation of primary intestinal lymphangiectasia.

Experiences and lessons

This case report represents a case of primary intestinal lymphangiectasia with rare presentation, recurrent gastrointestinal bleeding and iron deficiency anemia. Also, it yields our experience with different treatment modalities that could be used.

Peer-review

The article highlights the clinical characteristics, diagnostic modalities and treatment options available for primary intestinal lymphangiectasia.

Abstract

We report an unexpected, previously unreported complication of Bravo pH capsule dislodgement. During Bravo pH testing of a 44-year-old man with gastroesophageal reflux disease, we were unable to endoscopically visualize the capsule attached to the esophageal wall after deployment. After multiple attempts to detect the capsule, it was visualized in the left pyriform sinus. As there was significant risk for pulmonary dislodgement, ENT and pulmonary physicians were immediately consulted to review options for safe removal. Ultimately, ENT successfully retrieved the capsule with a foreign body removal forceps. The Bravo pH test is generally a well-tolerated diagnostic tool used to confirm the presence of abnormal esophageal acid reflux. While few complications have been reported, technical difficulties can occur, including poor data reception, misplacement, and early dislodgement. Rarely, more serious complications can occur, ranging from esophageal wall trauma to capsule aspiration. Gastroenterologists performing this procedure should be aware of the low, but non-trivial, risk of complications.

Key words: Gastroesophageal reflux disease; Esophageal pH monitoring; Bravo capsule; Dislodgement; Esophagogastroduodenoscopy

Core tip: We report an unexpected, and so far unreported, complication of a Bravo pH capsule dislodgment. While Bravo probe placement is generally a well-tolerated procedure, dislodgment into the pyriform sinus in this case necessitated immediate action by an interdisciplinary team. Complications of Bravo capsule use range from technical difficulties, such as poor data reception and non-deployment, to more serious events such as esophageal wall trauma and capsule aspiration. Gastroenterologists performing this procedure should be aware of the risk of potential complications.

LETTER TO THE EDITOR

We report an unanticipated, previously undocumented complication of Bravo capsule dislodgement. A forty-five year old patient with gastroesophageal reflux disease (GERD), non-compliant with medical therapy, presented with increasing cough, hoarseness, and other acid reflux symptoms. To verify presence of acid reflux, he underwent upper endoscopy and Bravo pH testing at our hospital. The gastroesophageal junction (Z line) was visualized at a distance of 40.0 cm from dentition. The Bravo device was deployed at 34.0 cm from dentition (6 cm above the Z line). When the capsule was not endoscopically visualized to be adherent to the esophageal wall, the endoscope was advanced beyond 34.0 cm to assess for possible device movement to the distal esophagus or stomach. When the capsule was not visualized at these locations, the endoscope was withdrawn. When the scope was withdrawn from the upper esophageal sphincter, the device was seen in the left pyriform sinus (Figure 1). The nonadherent capsule likely was either pulled up by the endoscope during withdrawal or coughed up by the patient. ENT and pulmonary physicians were immediately consulted for assistance in ensuring safe removal of the capsule from this precarious location, as there was significant risk for pulmonary dislodgement. After the anesthesiologist performed endotracheal intubation, ENT successfully retrieved the capsule with a foreign body removal forceps without further complications.

The Bravo pH test is generally a well-tolerated diagnostic tool that can verify the presence of abnormal esophageal acid reflux and determine if treatment refractory symptoms are due to persistent acid reflux in patients with GERD. As the deployment of the Bravo pH device is typically a innocuous procedure[1], very few complications have been reported. Technical difficulties most commonly include non-deployment, non-attachment, misplacement, premature dislodgement, and insufficient data reception. Infrequently, patients develop significant chest pain after capsule placement[2], necessitating removal. Rarely, more serious complications can occur in less than 2% and include esophageal wall trauma, excessive bleeding, and capsule aspiration[3]. In one reported case, the patient aspirated the capsule into the bronchus immediately after deployment, causing retching, heavy coughing, and desaturation to 74%[4]. After initial pushing into stomach with a transnasal video-endoscope, this capsule was removed with grasping forceps.

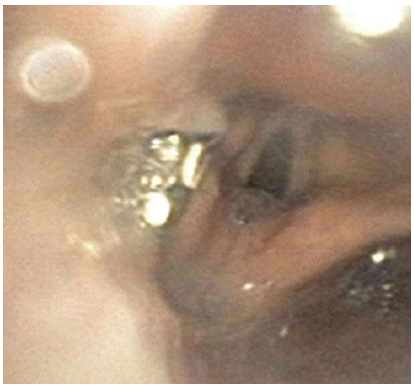

Figure 1 Bravo pH capsule in left pyriform sinus.

Gastroenterologists using the Bravo pH test should be cognizant of the low but non-trivial risk of complications, ranging from technical difficulties to aspiration of a dislodged capsule. Providers can use reports of documented complications to troubleshoot and resolve difficulties that may arise during deployment of Bravo pH capsules.

Abstract

Fecal incontinence has a profound impact in a patient's life, impairing quality of life and carrying a substantial economic burden due to health costs. It is an underdiagnosed condition because many affected patients are reluctant to report it and also clinicians are usually not alert to it. Patient evaluation with a detailed clinical history and examination is very important to indicate the type of injury that is present. Endoanal ultrasonography is currently the gold standard for sphincter evaluation in fecal incontinence and is a simple, well-tolerated and non-expensive technique. Most studies revealed 100% sensitivity in identifying sphincter defect. It is better than endoanal magnetic resonance imaging for internal anal sphincter defects, equivalent for the diagnosis of external anal sphincter defects, but with a lower capacity for assessment of atrophy of this sphincter. The most common cause of fecal incontinence is anal sphincter injury related to obstetric trauma. Only a small percentage of women are diagnosed with sphincter tears immediately after vaginal delivery, but endoanal ultrasonography shows that one third of these women have occult sphincter defects. Furthermore, in patients submitted to primary repair of these tears, ultrasound revealed a high frequency of persistent sphincter defects after surgery. Three-dimensional endoanal ultrasonography is currently largely used and accepted for sphincter evaluation in fecal incontinence, improving diagnostic accuracy and our knowledge of physiologic and pathological sphincters alterations. Conversely, there is currently no evidence to support the use of elastography in fecal incontinence evaluation.

Key words: Endoanal ultrasonography; Fecal incontinence; External anal sphincter; Internal anal sphincter; Obstetric anal sphincter injuries; Three-dimensional endoanal ultrasonography; Elastography

Core tip: Clinicians need to be more alert to fecal incontinence, which is a serious under-reported problem. Endoanal ultrasonography is currently the gold standard for sphincter evaluation in these patients. The most important cause of fecal incontinence is obstetric injury and the most relevant questions and controversies are related to this. The diagnosed of sphincter injury after delivery and after complete primary repair is much lower to that found by ultrasonography, and many

of these women developed fecal incontinence. The clinical evaluation, technical aspects, advantages and limitations and the current role of three dimensional ultrasonography and real-time elastography will also be discussed.

Albuquerque A. Endoanal ultrasonography in fecal incontinence: Current and future perspectives. *World J Gastrointest Endosc* 2015; 7(6): 575-581 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i6/575.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i6.575

FECAL INCONTINENCE: WHAT SHOULD WE KNOW BEFORE PERFORMING ENDOANAL ULTRASONOGRAPHY?

Fecal incontinence (FI) has a profound impact in a patient's personal life, impairing social interaction, professional and sexual activity and carries a substantial economic burden due to health costs.

The prevalence varies from 2.2% to 25 % in the community[1] and up to 50% of the nursing home residents[2]. Although a relevant problem, it is an underdiagnosed condition, since many affected patients are reluctant and embarrassed to report it. In a study by Sultan *et al*[3], none of the women that developed FI after vaginal delivery spontaneously reported their symptoms or sought medical attention. So, it is essential that health professionals, mainly those who look after women ask about symptoms of FI, especially in the postpartum period.

Loss of continence can result from several mechanisms, dysfunction of the anal sphincters, abnormal rectal compliance, decreased rectal sensation, altered stool consistency, or a combination of any of these abnormalities. FI is often multifactorial condition, may be the consequence of local, anatomical or systemic disorders, non-traumatic or traumatic lesions. Not every patient with sphincter injury develops incontinence, and, in addition, patients can have incontinence without sphincter injury. There are several women that only develop FI several years (20 or 30 decades) after delivery.

Patient evaluation should always include a detailed clinical history, inspection of the perianal area and a digital rectal examination. The type of incontinence (urge or passive), obstetric history (vaginal deliveries, use of forceps, perineal laceration), previous anorectal surgery, coexisting comorbidities, anal resting tone and squeeze pressure are fundamental to understand the mechanism behind the impairment and this information should never be neglected. Patients with urge incontinence often have weakness of the external anal sphincter (EAS) and reduced squeeze pressures or reduced rectal capacity with rectal hypersensitivity. Patients with passive FI, often have weakness of the internal anal sphincter (IAS) and lower resting pressure[4]. Taking all this information into consideration before endoanal ultrasonography (EAUS) is performed, can indicate the type of injury found.

There are several clinical scores that can be used to access severity, like the American Medical System, Pescatori score, Vaizey scale, Rockwood score or the Cleveland Clinic (Wexner) Incontinence Score[5]. These scores allow a more objective and reproducible assess of FI severity and a comparison of patients and treatments, namely the outcomes of both conservative and surgical treatments.

EAUS IN FECAL INCONTINENCE

EAUS is currently the gold standard technique for sphincter evaluation in FI[6]. The first studies in EAUS were performed by Law *et al*[7,8], in the early 1990s, comparing EAUS with electromyography, EAUS proved to be better tolerated and a useful technique for assessing defects of the anal sphincters. Most studies revealed 100% sensitivity in identifying sphincter defect. It is important to search for sphincter discontinuity, sphincter thinning and perform perineal body measurement. Discontinuity of the sphincter indicates a tear, and scarring is characterized by loss of the normal texture that usually has low reflectiveness. IAS tears appear normally as hyperechoic breaks and EAS tears appear as relatively hypoechoic areas (Figure 1). IAS thickness measurement in adults is abnormal if less than 2 mm (suggestive of degeneration) and generalized EAS atrophy is difficult to evaluate in EAUS. Perineal body measurement improves visualization of anterior sphincter lesions in females. A perineal body thickness of 10 mm or less is considered abnormal, whereas 10 mm to 12 mm is associated with sphincter defect in one-third of patients and those with 12 mm or more are unlikely to harbour a defect unless they previously have undergone reconstructive perineal surgery[9-11].

During the exam, the number, the circumferential extent (radial angle in degrees or in hours of the clock) and longitudinal extent (proximal, distal or full length) of the defect should be reported.

There are several possible pitfalls during EAUS that can simulate sphincter tears. A correct diagnose is important for FI assessment and for choosing the best therapeutic approach; a proper training in EAUS is fundamental. In many cases, it is not the endoscopic ultrasound practitioner that is performing the EAUS. These are two different techniques and specific training is needed for endoscopic ultrasound practitioners enrolled in EAUS.

Anal sphincteroplasty should be considered in patients with FI who do not respond to conservative therapy and who have an anatomic sphincter defect. Short-term outcomes suggest good-to-excellent results,

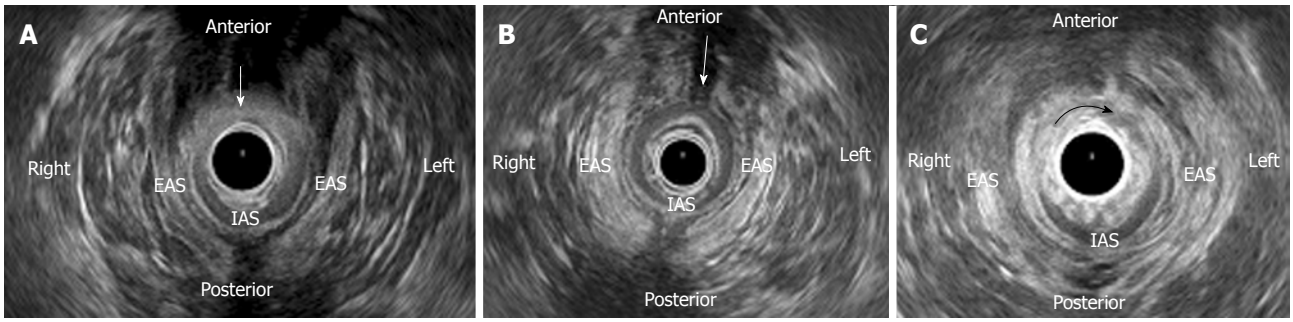

Figure 1 Endoanal ultrasound images of patients with fecal incontinence. A: A combined defect (arrow) of the external anal sphincter (EAS) from 10 to 2 o'clock and of the internal anal sphincter (IAS) from 9 to 3 o'clock positions, in a woman due to an obstetric anal sphincter injury; B: An anterior EAS defect (arrow), in a woman due to an obstetric anal sphincter injury; C: An IAS defect (arrow) from 8 to 4 o'clock position, in a man as a complication of a previous anorectal surgery (due to fistula).

but the benefits tend to deteriorate with long-term follow-up[4].

EAUS and endoanal magnetic resonance imaging (MRI) are comparable for the diagnosis of EAS defects, but IAS defects are less well assessed on MRI[12]. EAUS is simple, well-tolerated and non expensive. Endoanal MRI is expensive, not generally available, unsuitable in claustrophobic patients and those with metal implants. Endoanal MRI is superior to two-dimensional (2D) EAUS for identifying EAS atrophy. EAUS cannot distinguish fatty infiltration from normal muscle tissue and the boundaries of the EAS are harder to determine. Comparison between endoanal MRI and three-dimensional (3D) EAUS capacity for EAS atrophy evaluation revealed conflicting results. Cazemier *et al*[13] showed that both techniques are comparable in detecting EAS atrophy, although there is a substantial difference in grading. West *et al*[14] demonstrated that no 3D EAUS measurements are suitable parameters for assessing EAS atrophy. It is important to recognize atrophy because it is associated with a poor clinical outcome of sphincter repair.

EAUS and anorectal manometry are complementary investigations. EAUS allows anal sphincter morphology assessment and manometry anal sphincter function evaluation. Studies comparing both techniques show good correlation between them in partial or complete defects of the anal sphincter[15].

Most studies show poor agreement between digital anorectal examination and EAUS. In a study by Sultan *et al*[16] the clinical examination was only 50% accurate at predicting anal sphincter defects and Jeppson *et al*[17] show a specificity of 32% for digital anorectal examination in detecting anal sphincter defects seen on EAUS; however, Dobben *et al*[18] reported increased correlation between digital examination and EAUS based on size of the sphincter defect. Notwithstanding, performing digital anorectal examination is important in the evaluation of a patient with FI, helping to differentiate other potential causes such as tumor or fecal impaction.

It is important to ask patients about the presence of FI directly rather than relying on spontaneous reporting[4] and initial patient evaluation should include a detailed clinical history, inspection of the perianal area and a digital rectal examination. Manometry is important for anal sphincters function evaluation, anal sphincter resting and squeeze pressures are the key parameters[4]. EAUS is the gold standard for diagnosing anal sphincters tear and IAS degeneration. If EAS atrophy is suspected, endoanal MRI should be performed. Needle electromyography of the anal sphincter should be considered in patients with clinically suspected neurogenic sphincter weakness, particularly if there are features suggestive of proximal (*i.e.*, sacral root) involvement[4].

OBSTETRIC ANAL SPHINCTER INJURIES: A REAL PROBLEM

The most common cause of FI is anal sphincter injury related to vaginal delivery in female, due to direct anal sphincter laceration or indirect damage to sphincter innervation.

Two EAUS-based scoring systems have been proposed to define the severity of anal sphincter damage, both of them in women with obstetric anal sphincter injuries (OASIS). Starck *et al*[19] introduced a specific score, with 0 indicating no defect and 16 corresponding to a defect > 180° involving the whole length and depth of both sphincters. Norderval *et al*[20] reported a simplified system, including fewer categories and not recording partial defects of the IAS. The maximal score of 7 denotes defects in both the EAS and the IAS exceeding 90° in the axial plane and involving more than half of the length of each sphincter. Both scoring systems have demonstrated a good correlation between the extent of sphincter defects and the degree of FI. Scoring systems may help the clinician in choosing the appropriate treatment for patients with FI, but studies are needed.

Obstetric tears are divided into several subclasses, initially described by Sultan[21], and then adopted by the Royal College of Obstetricians and Gynaecologists (RCOG): injury to the perineal skin grade 1; injury to

the perineum involving the perineal muscles grade 2; involving the anal sphincter < 50% EAS grade 3a; > 50% EAS grade 3b; involvement of the IAS grade 3c; involvement of the anal sphincter as well as the anorectal epithelium grade 4[19]. OASIS encompasses both third- and fourth-degree perineal tears. They are identified in 0.6%-9.0% of vaginal deliveries where mediolateral episiotomy is performed, but the detection in EAUS is much higher[22].

A landmark study by Sultan *et al*[3] in 1993, using EAUS reported occult anal sphincter injury in 35% of women, six weeks after their first vaginal delivery. The incidence of *de novo* defects in multiparous females was 4.2%. The incidence of occult sphincter damage after vaginal delivery was unknown, previously to this study. Only 3% of primiparous women had an injury during delivery that was apparent in clinical examination. Results also suggested that the structural injury to the sphincters was permanent, since they were also present at 6 mo. Notably, only one third of women with sphincter defects in EAUS had FI.

In 2003, Oberwalder *et al*[23] published a meta-analysis of 717 vaginal deliveries (including the study by Sultan[21]) and found an incidence of occult sphincter damage of 26.9% in primiparous women and 8.5% of new defects in multiparous women. In one third of these women, postpartum sphincter damage was symptomatic.

Perhaps women with occult sphincter defect, but without FI can have sufficient residual sphincter function[21] or, since several mechanisms contribute to continence, they may compensate for this injury. The peak of incidence of FI is in the fifth and sixth decades of life in women, so the cumulative effect of deliveries, aging, menopause, progression of neuropathy may contribute for sphincter weakness in the long term and FI developing several years (20 or 30 decades) after delivery.

The clinical relevance of screening for occult anal sphincter laceration is controversial, mainly in asymptomatic defects. In a prospective cohort study by Frudinger *et al*[24], including primiparas with occult anal sphincter lacerations, at 10-year follow-up, only women who were symptomatic in the immediate postpartum period had deterioration over time of FI. Conversely, a randomized control trial by Faltin *et al*[25] showed that EAUS after childbirth improves the diagnosis of anal sphincter tears, and their immediate repair decreases the risk of severe FI. In this study, 752 primiparas with no clinically recognized anal sphincter laceration (occult) were assigned to undergo or not an EAUS immediately after delivery and diagnosed lacerations were repaired. In the EAUS group significantly fewer women reported severe FI at 3 and 12 mo compared to those who did not undergo EAUS. Using these data, it was estimated that 29 women would have to undergo EAUS to prevent one case of severe FI.

The current guidelines of the RCOG from 2007[22] state that "As there are clear difficulties with availability, access to staff trained in EAUS on the labour ward, image quality and patient acceptability, the use of EAUS in detecting anal sphincter injury immediately after delivery should be viewed as a research tool at present". There is no recommendation about screening women later after vaginal delivery for occult sphincter defects. Thus, data are controversial for asymptomatic patients. There are no cost-benefit studies of EAUS in this setting, or whether asymptomatic patients could benefit from it. Currently, the major investment should be in improving the identification of OASIS immediately after delivery. It is unclear, if occult sphincter defects are missed tears or true "occult" defects; probably the vast majority are not diagnosed clinically at time of delivery.

If an OASIS is identified immediately after vaginal delivery, it should be repaired. The RCOG[22] recommend that for repair of the external anal sphincter, either an overlapping or end-to-end (approximation) method can be used; if the IAS is identified, it is advisable to repair separately with interrupted sutures. Repair should be conducted in an operating theatre, under regional or general anaesthesia, by appropriately trained practitioners. Although primary reconstruction of the sphincters, more than 50% of women experience some change in continence (mainly to flatus) and the effect deteriorates with time[26]. Having a persistent sonographic defect after primary repair of OASIS has been shown to be associated with ongoing incontinence symptoms[27,28]. Studies show a high frequency of endosonographic sphincter defects after primary repairs, between 54% and 93% of women[29-32]. In a study using EAUS performed 2-7 d after delivery in women who had undergone a primary repair of an OASIS, 90% had endosonographic sphincter defects. In this study the extent of the endosonographic defects were mainly determined by the surgical experience of the doctor performing the repair, and not by the clinical degree of the tear[19].

The current guidelines of the RCOG[22] also do not make recommendations about using EAUS for confirming a complete primary repair. According to these guidelines "If a woman is experiencing incontinence or pain at follow-up, referral to EAUS and anorectal manometry should be considered". Considering the very high rate of sphincter defects detected by EAUS after primary repair, the high percentage of women that have some continence alteration and the difficulty in assessing the complete reparation of defects immediately after delivery, is EAUS confined to symptomatic women enough? In 2006, Starck *et al*[32] conducted a prospective study that included women who had suffered an OASIS at delivery and underwent EAUS at 1 wk, 3 mo and 1 year after primary suture. There was a positive correlation between the endosonographic sphincter defect score at 1 wk, 3 mo and 1 year and the Wexner incontinence score at 1 and 4 years. Endosonographic sphincter defect score at 1 wk was the variable that was most predictive of the Wexner score at 4 year. There are no systematic reviews or randomised

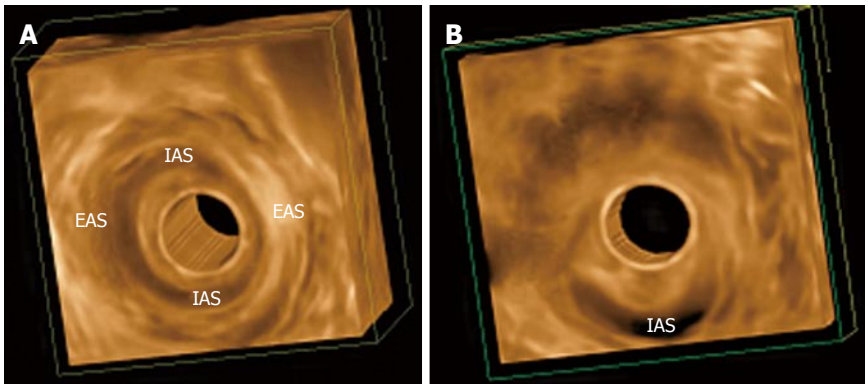

Figure 2 Three-dimensional endoanal ultrasonography images. A: Normal appearance of the external anal sphincter (EAS) and internal anal sphincter (IAS); B: An IAS defect in woman as a complication of a previous anorectal surgery (due to fistula).

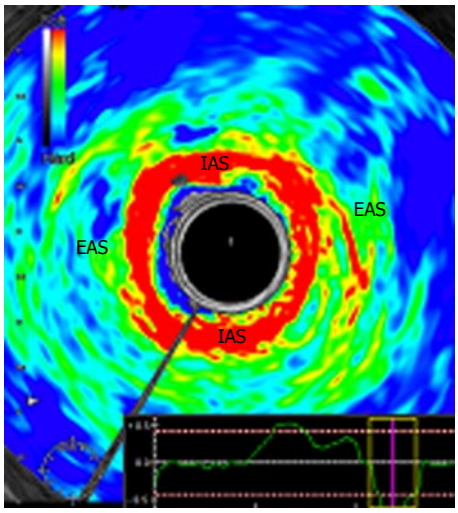

Figure 3 Normal appearance of the internal and external anal sphincters in endoanal ultrasound real-time elastography. The internal anal sphincter appears in red (softer) and external anal sphincter in green/blue (harder). EAS: External anal sphincter; IAS: Internal anal sphincter.

controlled trials to suggest the best method of follow-up after obstetric anal sphincter repair[22].

EAUS can also be important to aid decision for future delivery. According to the RCOG guidelines[22], "all women who have sustained an OASIS in a previous pregnancy and who are symptomatic or have abnormal EAUS and/or manometry should have the option of elective caesarean birth. Between 17% and 24% of these women with previous third-degree tear developed worsening fecal symptoms after a second vaginal delivery".

THREE-DIMENSIONAL EAUS

Three-dimensional EAUS has been used in the evaluation of the anal canal since the late 1990s[33,34]. Before 3D, imaging of the anal canal was mainly limited to the axial plane, impairing accurate longitudinal measurement, which is important for complete surgical repair. Three-dimensional EAUS produces a digital volume that can be seen from any plane, allowing length, thickness, area, and volume measurement (Figure 2).

Christensen *et al*[35] conducted a study to investigate the differences of 3D and 2D EAUS in visualizing damage to the anal sphincter complex. The agreement between the two observers that evaluated the images was better when using 3D (98.2% using 3D and 87.9% using 2D), so 3D improved diagnostic confidence.

The studies involving 3D EAUS also allowed for a better understanding of sex differences in sphincter configuration and between parous and non-parous females, continent and incontinent patients[36]. FI was not associated with loss of sphincter volume, but anterior sphincter length and EAS thickness is smaller[36]. Williams *et al*[37] assessed changes to anal canal morphology after delivery, in the absence of sphincter trauma, and there was a decrease in the length of the anterior portion of the EAS following childbirth.

ULTRASOUND REAL-TIME ELASTOGRAPHY

Real-time elastography (RTE) has been evaluated previously in tumours and inflammatory tissues, and has proven to provide valuable additional information.

In 2010, Allgayer *et al*[38] performed the first study to access RTE in FI, 50 patients were included. The IAS, a smooth muscle, consisted of softer areas (red) than the EAS and, conversely, the EAS, a striated type of muscle, contained harder elements (blue) than the IAS (Figure 3). There was an absence of a correlation of elastogram color distributions of the IAS and EAS with major clinical, functional and gray-scale B-mode parameters, so RTE did not seem to provide additional information in the diagnostic workup of FI. However, there was a non-significant increase in the percentage of blue (hard) areas in the IAS in patients neoadjuvantly irradiated for rectal or cervical cancer compared to non-irradiated patients. To confirm this data, the authors performed a larger study[39], but RTE with quantitation of sphincter elastic properties yielded no further diagnostic and prognostic information compared to

conventional EAUS in irradiated and non-irradiated patients and, therefore, cannot be regarded as a new tool in the assessment of those patients.

Hence, currently there is not evidence to support the use of RTE in FI evaluation.

CONCLUSION

FI is a serious clinical and social problem, frequently under-reported, and clinicians need to be more alert to it in the routine clinical practice. EAUS is a fundamental tool when assessing these patients.

The most important cause of FI is obstetric injury and the more relevant questions and controversies in EAUS are related to this aetiology. The diagnosed of sphincter injury after delivery and after complete primary repair is much lower to that found by EAUS, and many of these women developed FI, later in life.

While three-dimensional EAUS is currently accepted for sphincter evaluation in FI, there is presently no evidence to support the use of elastography.

Abstract

In the last decades many advances have been achieved in endoscopy, in the diagnosis and therapy of cholangiocarcinoma, however blood test, magnetic resonance imaging, computed tomography scan may fail to detect neoplastic disease at early stage, thus the diagnosis of cholangiocarcinoma is achieved usually at unresectable stage. In the last decades the role of endoscopy has moved from a diagnostic role to an invaluable therapeutic tool for patients affected by malignant bile duct obstruction. One of the major issues for cholangiocarcinoma is bile ducts occlusion, leading to jaundice, cholangitis and hepatic failure. Currently, endoscopy has a key role in the work up of cholangiocarcinoma, both in patients amenable to surgical intervention as well as in those unfit for surgery or not amenable to immediate surgical curative resection owing to locally advanced or advanced disease, with palliative intention. Endoscopy allows successful biliary drainage and stenting in more than 90% of patients with malignant bile duct obstruction, and allows rapid reduction of jaundice decreasing the risk of biliary sepsis. When biliary drainage and stenting cannot be achieved with endoscopy alone, endoscopic ultrasound-guided biliary drainage represents an effective alternative method affording successful biliary drainage in more than 80% of cases. The purpose of this review is to focus on the currently available endoscopic management options in patients with cholangiocarcinoma.

Key words: Cholangiocarcinoma; Malignant bile duct obstruction; Interventional endoscopy; Endoscopic therapy; Self-expandable metal stent

Core tip: Cholangiocarcinoma are an heterogeneous group of tumor and represent a challenge in medicine because of the difficulty in establishing the diagnosis and an high recurrence rate after surgery which represents the only curative treatment. Endoscopy has gained a

pivotal role in the management of the disease, before surgery if patient is amenable to surgical intervention or in those unfit for surgery. New stent prototype able to release drugs and/or photodynamic therapy have been commercialized with promising results. When endoscopy fails, endoscopic ultrasound-guided biliary drainage represents an effective alternative method affording biliary drainage.

INTRODUCTION

Cholangiocarcinoma (CC) is an epithelial malignancy with markers of cholangiocyte differentiation arising within the biliary tree. It is characterized by a marked genetic heterogeneity which explains its high therapeutic resistance[1]. CC is rare but related mortality is high because it is most often diagnosed at a locally advanced stage, not amenable to curative surgery.

Although the incidence of CC is rapidly increasing it remains a rare disease. Data about endoscopic therapeutic options are often comprised into large databases of malignant obstructive jaundice mainly due to pancreatic head cancer. This may have influenced the reported outcomes and benefits of endoscopic treatment modalities[2].

Currently, classification of CC is based on anatomical site, defining intrahepatic, perihilar and distal CCs[2]. Intrahepatic CC is defined as a tumor located proximally to the branch of the right and left lobe bile ducts; the extrahepatic and perihilar cholangiocarcinoma is localized to the area between the second branches bile ducts and the insertion of the cystic duct into the common bile duct (Figure 1); whereas distal CC is confined to the area between the origin of the cystic duct and the ampulla of Vater[3].

Several progresses in the management (diagnosis, treatment and palliation) of CC have befallen in the last decades. However, surgical resection or liver transplantation represents the only potential curative alternative for all subtypes of CC[2]. Unfortunately, involvement of the vascular structures and lymphnodes is associated with very low 5-year survival rates even after curative-intent surgery[2] and, overall the clinical results of patients undergoing liver resection are disappointing with a survival rate of 20%-35% within 5-year[4-9]. Palliative therapy, in patients not amenable of surgical intervention includes systemic chemotherapy and loco regional therapies (TACE, RFA) to reduce masses but increased survival rate has not yet been shown[2].

Figure 1 Distal cholangiocarcinoma during endoscopic retrograde cholangiography.

The main onset of CC is unpainful icterus in > 90% of patients and preoperative biliary drain (endoscopic or percutaneous), has been introduced because jaundice is thought to increase the risk of postoperative complications, but the advantages of this procedure are still unclear[10]. Moreover, in patients who will undergo neo-adjuvant therapy the work-up preceding chemotherapy includes biliary stenting. In the last decades advances in stenting materials and acknowledgement of the benefits in the post-surgical outcome due to pre-operative biliary drainage has led endoscopic retrograde cholangiography (ERC) to a pivotal role in the work up of CC, both in patients amenable to surgical intervention and in those unfit for surgery.

EPIDEMIOLOGY

The reported incidence in the United States is one or two cases per 100000 person/year, also in Europe is 1.5 per 100000 person/year, and it accounts for approximately 3% of all gastrointestinal malignancies. CC is the most common primary malignancy of the liver after hepatocellular carcinoma. An increase in intrahepatic CC mortality has been registered worldwide particularly in western compared with central and northern Europe. The increased incidence of intrahepatic CCs may in part be attributed to new diagnostic methods for obstructive jaundice allowing to identify biliary malignancies which previously would have gone undetected. In spite of this, the rising incidence of intrahepatic CC has not been associated with an increased proportion of early stage or small size lesions[11-15].

Perihilar disease represents about 50%, distal disease 40% and intrahepatic disease less than 10% of CC cases. Age-adjusted rates of CC are reported to be the highest in Hispanic and Asian populations (2.8-3.3 per 100000 person/year) and lowest in non-Hispanic white people and black people (2.1 per 100000 person/year)[2].

RISK FACTORS

The main risk factors are considered primary sclerosing

cholangitis (PSC) and choledochal cysts. The per-year cumulative risk of CC in patients with PSC is 1.5% after the development of jaundice and the prevalence of CC in patients with PSC ranges between 8% and 40%. A recent study from the Netherlands showed that the risk of CC for patients with PSC is 9% after 10 years from the time of the diagnosis[13]. However for the majority of patients a specific risk factor has not been identified. Recently, cirrhosis and viral hepatitis have also been proposed as potential risk factor, particularly for intrahepatic CCs[2]. Another risk factor for the development of CC are choledochal cysts (incidence of CC is between 10% and 20%), significantly reduced by early diagnosis and surgical ablation[15]. The carcinogenetic pathway is not clear although biliary stasis and reflux of pancreatic fluids are suspected through chronic inflammation way[1]. Unfortunately, CC can also occur years after resection of the cyst suggesting some genetic abnormality predisposing to the development of biliary neoplasia[16].

MANAGEMENT

CC have an remarkably poor five-year survival rate estimated from 5% to 10%. Some difference could be detected if survival is stratified by location of the lesion: the percentage of patients amenable of surgical resection is higher if the location is distal CCs compared to proximal (intrahepatic and perihilar) tumors. Nakeeb *et al*[17] published a large series about resectability rates for distal, intrahepatic, and perihilar lesions: 91%, 60%, and 56%, respectively[17]. Moreover patients who undergo a potentially curative resection, at pathology examination achieve tumor-free margins barely in 20% to 40% of proximal and 50% of distal location[18]. These percentage are even lower if a proximal tumor-free margin of at least 5 mm is requested as a curative criteria.

Surgery data for CCs have increased over year, largely owing to more aggressive surgery strategies and extended criteria for resectability.

Criteria for resectability of CC in the United States include[19]: (1) absence of retro-pancreatic and celiac nodal metastases or distant liver metastases[20]; (2) absence of portal vein or main hepatic artery involvement; (3) absence of extrahepatic adjacent organ invasion; (4) absence of spread disease; however, resectability is finally determined at surgical exploration, particularly with perihilar tumors[21]. Due to their location within the upper hepatoduodenal ligament, these tumors often extend into the liver and major vascular structures, and preoperative evaluation of resectability is often difficult. Thus, surgical exploration is indicated for proximal bile duct carcinomas whenever feasible.

Whether preoperative biliary decompression using an endoscopically or percutaneously placed stent should be carried out in patients who present with obstructive jaundice is still controversial and will be discussed below. Obstructive jaundice is the most common presenting symptom of CC. If biliary drainage is advantageous or not is still under debate. Cholestatic malabsorption, liver dysfunction, and biliary cirrhosis develop rapidly with unresolved obstruction and severe liver dysfunction is one of the main factors that increase postoperative morbidity and mortality following surgical resection[21].

The European Society of Gastrointestinal Endoscopy (ESGE) focused his attention on the treatment options in order to select the most appropriate procedure (with or without sphincterotomy) and stent choice (plastic or metal, short or long) on the basis of patient's disease stage and tumor location.

ENDOSCOPIC TREATMENT IN PATIENTS ELIGIBLE FOR SURGERY

Preoperative biliary drainage was introduced to improve the postoperative outcome, for the reason that patients with jaundice had an increased risk of postoperative complications[10-22]. In various experimental studies and retrospective case series, preoperative biliary drainage reduced morbidity and mortality after surgery[23-25]. Nevertheless, two meta-analyses of randomized trials and a systematic review of descriptive series showed that the overall complication rate in patients undergoing preoperative biliary drainage was higher than in those who were referred straight to surgery[26]. In patients, fit for surgery for malignant common bile duct (CBD) obstruction, introduction of a plastic biliary stent followed by postponed surgery was associated with a higher morbidity compared with surgery within 1 wk. This was partly explained by complications associated with the biliary drainage procedure itself. Nevertheless, in many institution preoperative biliary drainage has been incorporated into the work-up of cancer of the pancreatic head or distal CBD[27]. In 2010 van der Gaag *et al*[10] conducted a large multicenter randomized trial in which 202 patients were randomized to receive whether preoperative biliary drainage followed by surgery within 4-6 wk, or surgery alone within 1 wk of diagnosis. Serious complications were registered in 39 percent in the immediate surgery group and 74 percent in the group with biliary drainage (RR = 0.54, $P < 0.001$)[28]. Neither mortality nor length of hospital stay were reduced in patients who underwent preoperative drainage. Moreover, the presence of a stent within the biliary tree could decrease the accuracy of diagnostic imaging to predict tumor resectability and the surgeon's ability to determine the proximal tumor extent during intervention.

The ESGE recommends preoperative biliary drainage only in patients who will undergo neo-adjuvant therapies or in patients with biliary sepsis, or in patients with troublesome itching or predicted delay in surgical intervention[29-50].

How to achieve biliary drainage: endoscopically or *via* a percutaneous approach? Retrospective series and at least two prospective trials conducted in patients with

obstructive jaundice from a malignant hilar obstruction (mainly proximal CCs or gallbladder cancer) suggest that successful palliation of jaundice is more likely and the incidence of post-procedure cholangitis may be lower with the percutaneous as compared to the endoscopic approach[31-33].

Endoscopic biliary drainage can be obtained using either plastic or self-expandable metal stents (SEMSs). Many stents (plastic and metal, both covered and uncovered), are available and both produce similar short-term results with respect to clinical success, morbidity, mortality, and improvement in quality of life[50]. A systematic review concluded that neither stent type offered a survival advantage[34]. Accordingly, in patient candidate for surgery the choice of stent should be guided by tumor location and extension.

The use of a plastic stent is inexpensive and effective, and the stent can be easily removed or replaced. Plastic stents, however, eventually develop occlusion by sludge and/or bacterial biofilm, and maintaining biliary drainage with plastic stents usually requires repeated endoscopic procedures. Plastic stents are available in multiple diameters ranging from 7 to 11.5 French, though 10 French stents are the most commonly used for distal common bile duct obstruction[35]. SEMSs provide a larger opening diameter than plastic one thus enabling prolonged patency and rapid biliary drainage[50]. However, the cost of metal stents is considerably higher and their removal may be challenging. The indications for using SEMSs in patients candidate to surgery is not well established yet. The main reason for the preferential use of plastic stents in patients with pancreatic cancer was the notion that uncovered SEMS could hinder pancreatoduodenectomy by interfering with transection of the bile duct proximal to the neoplasia[36]. With growing experience it has been shown that, when 2 cm or more of the common hepatic duct can be exposed proximally to the SEMS, the surgical procedure is not more complex than in the presence of a plastic stent[35].

Which kind of metal stent? SEMS models have been significantly developed and changed in the last decade: out of five types in use ten years ago, only single one is still available[29-37]. The distinguishing features of the various available SEMSs are prices, shortening ratio, radio-opacity, covering, radial force, flexibility, size of open cells of the mesh, anchoring mechanism and design of the tip[29-37]. *In vitro* measurements of radial expansion force and of flexibility have shown markedly different results between the various SEMSs, including covered and uncovered models of otherwise identical SEMSs[38]. The opening procedure shorten SEMSs by 0%-50%: different models with different shortening ratio are available. If the stricture is long and narrow the deployment could be difficult and irregular. Large open cells in the mesh may allow tissue to ingrow into the stent lumen, getting an inefficacious biliary drainage either immediately after the insertion or during follow-up[39-41]. Some special SEMS models, studied for hilar strictures, have a section with larger mesh cells in order to allow the introduction through the mesh of a new stent to reach another biliary branch[29]. In case of covered SEMSs, anti-migration mechanisms are particularly important: these may include flared ends or external fins, but some complications have been registered like bleeding of the bile duct wall caused by decubitus ulcers[42]. Recently models with soft ends and slip-knot to facilitate removal have been commercialized reducing the risk of bleeding or perforation if the wires are sharp and not fused.

ENDOSCOPIC TREATMENT IN PATIENTS WITH LOCALLY ADVANCED DISEASE

The long-term prognosis in CC patients who have undergone potentially curative surgical resection remains poor: these discouraging results have prompted interest in the use of neo-adjuvant therapy in patients amenable to surgery in order to improve survival. Such a strategy has also been proposed in locally advanced cases aiming to downstage the disease to allow surgical resection. This topic is valid for distal as well as for hilar CC. Recently in case of bilateral extension beyond the secondary radicles curative resection has been proposed after application of neoadjuvant therapy PDT oRFA (its applications and results will be discussed later).

The choice of the best stent to be used in this selected patient is less controversial than in those eligible for surgery. The efficacy of plastic stents is generally poor: more than one half of patients treated with plastic stents during neo-adjuvant therapy requires repeated stent replacement owing to stent occlusion or cholangitis[43]. Several studies have demonstrated that the use of SEMSs leads to improved outcome during neo-adjuvant therapy. Aadam *et al*[44] reported a 7 times higher complications rate and a 3 times higher hospitalization rate in patients treated with plastic stents as compared with patients treated with metal stents.

Uncovered and covered SEMSs are available. Uncovered SEMSs have a mesh design that allows them to be embedded in the biliary duct wall but it also makes them susceptible to tissue in-growth, which can lead to occlusion in as many as 20% of cases. Covered SEMSs were designed to prevent tissue in-growth but, as expected their use is associated with an increased rates of migration[45]. In an effort to guarantee patency and decrease rates of migration, partially covered SEMSs have been developed. In a recent meta-analysis, Saleem *et al*[46] concluded that covered SEMSs supply a significantly longer patency than uncovered SEMSs (average 60 d), but at the price of a higher migration rate[46-48]. Similar rates of cholecystitis were also found (approximately 2% in each group). Through subgroup analysis, Saleem *et al*[46] did not find any difference in rates of migration or stent patency comparing partially covered SEMSs to fully covered SEMSs. Contrastingly, in a retrospective cohort study analyzing the outcome

of 749 patients by Lee *et al*[47] no difference in stent obstruction was found (covered SEMSs 35%, uncovered SEMSs 38%) . While obstruction due to tumor in-growth was more frequent in patients treated with uncovered SEMSs (76% *vs* 9%, $P < 0.001$), other mechanisms of obstruction occurred in patients treated with covered SEMSs, including sludge formation and food debris. Conversely, higher rates of migration (36% *vs* 2%, $P < 0.001$) and of acute pancreatitis (6% *vs* 1%, $P < 0.001$) were found in patients treated with covered SEMSs[47]. This study was retrospective and open, and follow-up was not standardized. In a recent study, Kitano *et al*[48] used a covered SEMS modified to reduce migration. The anti-migration characteristics consisted of low axial forces and uncovered flare ends, and was compared to uncovered SEMSs of similar design. One hundred and twenty patients were included in this prospective randomized multicenter study and the covered SEMS group had a substantial longer stent patency (mean of 219.3 d *vs* 166.9 d, $P = 0.047$) and less need for re-intervention (23% *vs* 37%, $P = 0.08$) compared to uncovered SEMSs. The tumor ingrowth was also lower in the covered SEMS group (0% *vs* 25%, $P < 0.01$)[47,48].

Even if a lower complication rate and a lower hospitalization staying has been described in patients with SEMS compared with plastic stents, the management of long standing metallic stent is challenging due to ingrowth of neoplastic tissue. Usually patients with positioned SEMS underwent neoadjuvant therapy to achieve a tumor downstaging and even if a 5-year survival rate is not influenced a prolonged survival is described and stent obstruction occurs frequently. Management of stent obstruction is challenging especially in hilar CC when previous bilateral SEMS have been positioned, due to the difficulties in bypassing the stent with the guidewire without enter the stent mesh. If not possible an option could be the ballon dilation of stent mesh.

ENDOSCOPIC TREATMENT IN PATIENTS WITH ADVANCED DISEASE

Placement of a stent is currently considered the treatment of choice for palliation of malignant obstructive jaundice in patients with advanced CC since it is associated with similar rates of jaundice relief and survival but less morbidity compared to the surgical approach[49-59]. Successful endoscopic deployment of a stent (or multiple stents as needed to span the malignant stricture) is possible in 70% to 100% of patients. Pre-procedure CT and/or MRI is often used in an attempt to identify the dominant biliary system in the event that only one side can be drained endoscopically.

Endoscopic stenting has been compared to the percutaneous approach. Retrospective series and trials conducted in patients with obstructive jaundice from a malignant hilar obstruction (mainly proximal CCs or gallbladder cancer) suggest that successful palliation of jaundice is more likely and rates of early cholangitis may be lower with the percutaneous as compared to the endoscopic approach[60,61]. However, other complications may be more frequent (*e.g.*, bile leaks and bleeding), potentially increasing morbidity and mortality. Furthermore, percutaneous stents usually imply an open external drainage, at least initially, and this is often inconvenient to the patient. As a result, in most institutions an initial endoscopic attempt at drainage is usually preferred whenever possible.

Figure 2 Endoscopic retrograde cholangiography with a plastic stent in the right hepatic duct. However the left hepatic duct remains dilated.

Palliative endoscopic biliary decompression can be achieved using either plastic or SEMSs. In the last two decades, SEMSs have been increasingly used and have been demonstrated to be more effective than plastic stents allowing a more rapid biliary drainage and consequently a lower incidence of septic complications since the first procedure[51,52]. A systematic review concluded that none stent improves survival rate however uncovered metal stents have a lower risk of causing cholecystitis and pancreatitis and migration rate is significantly lower than in covered group[31].

Whether to use unilateral or bilateral stents in patients with hilar obstruction is debated. The issue should be to drain as much as possible but this does always mean that you need to put a stent in every single duct. In many cases, unilateral stent placement will be sufficient to relieve jaundice and frequently, a dominant duct could be identified during ERC procedure, as the more effective to be drained (Figure 2)[32]. However, unilateral drainage alone may not relieve jaundice completely and may increase the risk of cholangitis especially if contrast medium have been injected and not drained. Studies comparing these approaches have reached variable and dubious conclusions. Many endoscopists place bilateral stents (plastic or metal); certainly a minimum of two stents (left and right branches) is need in an attempt to maximize biliary drainage (Figure 3). The choice to use more than two stents is linked to patient disease features and endoscopist skill.

RADIOFREQUENCY ABLATION

Radiofrequency ablation (RFA) has been used to treat

Figure 3 Use of covered self-expandable metal stent in patients with hylar cholangiocarcinoma.

liver malignancies since the early 1990s[61-65]. More recently this technique has been applied in malignant biliary strictures[62].

Habib TM Endo-HPB EMcision is an endoscopic bipolar catheter studied to be introduced through biliary malignant strictures, so that radiofrequency energy can be delivered locally before stent positioning. Potential advantages of the device use could be longer stent patency by ease down tumor growth. Endo-HPB is a 8 F, 1.8 m coaxial over the wire catheter that is designed to be inserted through a 3.2 mm working channel of the endoscope. At the distal end of the catheter, two ring electrodes spaced 8 mm apart produces a heating zone length of approximately 25 mm.

RFA in bile duct appears to be safe however its efficacy in long term and its role, alone or combined with SEMS is unclear. Sharaiha *et al*[64] recently compared RFA combined with SEMS with SEMS alone in 66 patients. Twenty-six were treated with RFA and SEMS and 40 only with stent placement. The author confirms a statistically significant improvement in malignant strictures diameter after RFA treatment[63-65]. Randomized controlled trials are needed.

ALTERNATIVE STENT DESIGN AND STRATEGIES

Recently Shah[65], proposed drug-eluting stents designed to improve SEMS patency by delivering a chemotherapeutic agent such as paclitaxel to prevent tumor in-growth and stent occlusion[66]. Unfortunately, in a multicenter prospective study comparing drug-eluting covered SEMSs with covered SEMSs no significant difference in stent patency was found[67].

PHOTODYNAMIC THERAPY AND DRUG ELUTING STENT

Photodynamic therapy (PDT) is a new palliative technique for malignant bile duct stenosis that seems to improve pain relief, increase biliary patency and increase survival.

Recently Bae *et al*[2] proposed a photosensitizer-embedded self-expanding metal stent (PDT-stent) which provides a photodynamic treatment without the need of systemic injection of photosensitizer and the treatment could be repeated more than one time due to the incorporation of the polymeric photosensitizer into the mesh of the stent. Photo-fluorescence imaging of the PDT-stent demonstrated homogeneous distribution of polymeric Pheo-A (PPA) on stent surface and the stent maintained its photodynamic power at least for 8 wk, for repeated PDT procedure if necessary after stent positioning. The PDT-stent after light exposure created cytotoxic free radical such as singlet oxygen in the close tissues, inducing destruction of neoplastic cells on animal models[66,67].

EUS GUIDED BILIARY DRAINAGE

Endoscopic biliary drainage with stent positioning is technically successful in > 90% of procedure. In the case of failure, endoscopic ultrasound (EUS)-guided biliary drainage has recently emerged as an effective alternative method providing technical success in > 80% of cases[49]. EUS-guided biliary drainage was first reported in 2001 by Giovannini *et al*[67] and can be approached into 3 different ways: (1) EUS-guided transluminal biliary drainage including choledoco-duodenostomy and hepatico-gastrostomy; (2) EUS-rendezvous technique; and (3) EUS-antegrade approach[67,68].

For EUS-guided transluminal biliary drainage, the biliary duct is punctured from the proximal duodenum with a 19 G fine needle aspiration (FNA) under EUS guidance followed by cholangiography. Progressively a guidewire is driven into the biliary system and dilation of the needle way is carried out. After fistula creation with a cystotome, or a bougie dilator, the stent is deployed between the biliary duct and the duodenal lumen for biliary drainage.

In EUS-rendezvous technique, the biliary duct is approached under EUS and X-ray guidance *via* 19 G FNA needle. Progressively, a guidewire is driven into the biliary system then through the bile duct, through the ampulla within the duodenum. After guidewire positioning, ERCP is performed using guidewire and the guidewire is retrieved, once biliary cannulation is carried out or the stenosis has been exceeded. Therefore, EUS- rendezvous technique is feasible only in patients in which the endoscopic access to the ampulla is preserved[68].

In EUS-anterograde approach, the intra-hepatic biliary duct is accessed from the small bowel with creation of a temporary fistula between the small bowel and the intra-hepatic biliary duct then the stent placement is achieved through the fistula. This technique is appropriate for patients with surgically altered anatomy or duodenal obstruction which prevent ampullary access.

Published studies regarding choledoco-duodenostomy

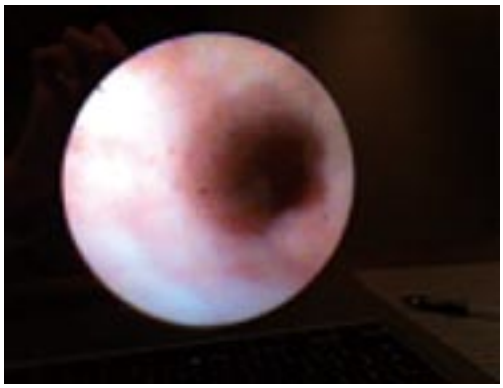

Figure 4 Visualization of biliary epithelium during SpyGlass.

and hepatico-gastrostomy show technical success rates of 94% and 87% with early complication rates of 19% and 27%, respectively, despite the fact that different biliary access and fistula dilation methods have been utilized. Regarding stent type, covered SEMS have generally been preferred over plastic stents, especially in more recent studies. Radial expansion of covered SEMSs can reduce risk of complications such as bile peritoneal leak or pneumoperitoneum because the fistula is immediately plugged by the covered SEMS. On the other hand, stent migration is reported after endoscopic procedure. For this purpose, the development of stents specifically designed for these procedures could further improve the results.

One of the most challenging aspects of EUS-rendezvous technique is the guidewire manipulation, which requires skill, tact sensitivity and good cooperation with a second operator[66]. Similarly, EUS-antegrade approach requires careful guidewire manipulation, however a major care is the risk of bile leak into the peritoneal cavity through the dilated fistula even if no report of biliary peritonitis have been issued, and the overall success and complication rates are 77% and 5 %, respectively[69-73].

NEW TECHNIQUES

Cholangioscopy

Peroral cholangioscopy, "mother-baby" technique, was utilized in the mid-1970s for the diagnosis and definition of bile duct narrowing. Nevertheless this technique revealed many limitations in visualization of the wall and required the cooperation of two skilled operators[74,75]. The "SpyGlass system" (Boston Scientific Corp, Natick, MA, United States) introduced in 2006 has enlarged the role of cholangioscopy from a diagnostic to a therapeutic one. The new system has overcome the need of two endoscopists and it has been launched as a single endoscopist cholangioscope. It allows the direct visualization of biliary tree (Figure 4) and consequently its use in the diagnostic work up of CC is well established. Sethi *et al*[74] reported a diagnostic accuracy of SpyGlass around 57% and these data were confirmed also in other series with an overall diagnostic accuracy, in differentiating neoplastic *vs* non neoplastic lesions, varied from 77% to 90%[75-79]. Although it is considered limitative to banish a cholangioscope to a diagnostic role in CC work up, more data are needed about its role in therapeutic endoscopy and biliary drainage. One of the main indications is the lithotripsy for difficult to remove, biliary stones[80]. Recently Dong Choon Kim described the use of an ultraslim endoscope (GIF-XP260N; Olympus, Tokyo, Japan) for intraductal stones fragmentation under endoscopic visualization[81].

Fluorescence in situ hybridization

Fluorescence *in situ* hybridization (FISH) assesses the presence of chromosomal aberrations, in number or structures, and uses fluorescence-labeled probes to evaluate increases or decreases in chromosome number if referred to numerical abnormalities or to specific structural abnormalities in case of clonal diversity[82,83]. This technique is performed on ERC brushing smears.

Previous studies have demonstrated that FISH polysomy combined with cytology improves sensitivity. Some studies have considered the positive FISH results based on polysomy only, whereas some have considered trisomy or tetrasomy as a positive test results as well. Recently a review was published by Navaneethan *et al*[82] with a pooled sensitivity and specificity was 51% and 93% in detection of CC in patients with PSC. Vasilieva *et al*[83] in 2013 published data about the use of structural abnormalities as markers of clonal diversity and different clinical features of the disease. However more data are needed, the use of fish does not increase sensitivity significantly. A future role of the FISH will be the possibility to delineate the oncogenesis, to understand the response or not to chemotherapy[83,84].

CONCLUSION

Cholangiocarcinoma and bile duct tumors are an heterogeneous group of tumor with different biological behavior and prognosis according to their location and growth pattern. CC presents a special challenge in gastroenterology, oncology, and visceral surgery because of the difficulty in establishing the diagnosis, local complications in the biliary pathways, and a high recurrence rate after resection. Diagnosis is usually defined in advanced disease stage, due to paucisintomaticity of tumor and to low sensitivity of imaging technique for detection of lesions at early stage. The only curative treatment for CC is surgery, but 40%-85% of all patients have recurrent disease even after radical excision. Because of this high recurrence rate and because the majority of patients undergo palliative therapy (chemotherapy or endoscopic therapy) to try to downstage the tumor and adjuvant treatments are now under intense discussion. Moreover because of the low prevalence of the disease, there have been only a few studies of palliative chemotherapy for CC. On the basis of one positive phase 3 study, chemotherapy with

gemcitabine and cisplatin is considered the standard and now plays an established role in palliative care[84].

Endoscopy, as explained in this review has gained in the last decades a key role in the work up of CC, both in patients amenable to surgical intervention as well as in those unfit for surgery or not amenable to immediate surgical curative resection owing to locally advanced disease. Endoscopy allows successful biliary drainage and stenting in more than 90% of cases. The development of new stents, metallic, covered, with different mesh materials, different mesh shape is a constant work in progress to reduce complications in patients with advanced disease, to avoid repeated endoscopic procedure and to improve long term results. Moreover in the last two years new stent prototype able to release drugs and/or photodynamic therapy have been commercialized with promising results but very few data are available, not enough to be validated. When endoscopy fails, endoscopic ultrasound-guided biliary drainage represents an effective alternative method affording successful biliary drainage in more than 80% of cases. Also in this field new dedicated stents fit for trans-duodenal biliary drainage or trans-hepatic biliary drainage are under construction.

This a new field that need constant updating and future studies should address the efficacy of combined local and systemic treatments.

In conclusion the final messages are: (1) The benefit of adjuvant chemotherapy has not yet been confirmed and require further investigation; and (2) Endoscopic biliary drainage by means of ERC is an integral component of the treatment of CC.

Abstract

Achalasia is an oesophageal motor disorder which leads to the functional obstruction of the lower oesophageal sphincter (LES) and is currently incurable. The main objective of all existing therapies is to achieve a reduction in the obstruction of the distal oesophagus in order to improve oesophageal transit, relieve the symptomatology, and prevent long-term complications. The most common treatments used are pneumatic dilation (PD) and laparoscopic Heller myotomy, which involves partial fundoplication with comparable short-term success rates. The most economic non-surgical therapy is PD, with botulinum toxin injections reserved for patients with a higher surgical risk for whom the former treatment option is unsuitable. A new technology is peroral endoscopic myotomy, postulated as a possible non-invasive alternative to surgical myotomy. Other endoluminal treatments subject to research more recently include injecting ethanolamine into the LES and using a temporary self-expanding metallic stent. At present, there is not enough evidence permitting a routine recommendation of any of these three novel methods. Patients must undergo follow-up after treatment to guarantee that their symptoms are under control and to prevent complications. Most experts are in favour of some form of endoscopic follow-up, however no established guidelines exist in this respect. The prognosis for patients with achalasia is good, although a recurrence after treatment using any method requires new treatment.

Key words: Achalasia; Endoscopic treatment; Dilation; Botulinum toxin; Myotomy

Core tip: We propose a treatment and monitoring algorithm for achalasia based on the most relevant published evidence and an exhaustive summary of all the available endoscopic techniques.

INTRODUCTION

Achalasia is a primary oesophageal motor disorder of unknown aetiology characterised manometrically by insufficient relaxation of the lower oesophageal sphincter (LES) and a loss of oesophageal peristalsis[1] secondary to the degeneration of the myenteric plexus[2]. It should be suspected in patients who present with dysphagia, regurgitation of undigested food debris, respiratory symptoms, chest pain, and weight loss[3]. It is described at any age, but occurs most frequently between the ages of 20 and 40. There does not appear to be any association with sex or ethnicity. The annual incidence is 1 in 100000 persons and the prevalence is 10 in 10000[4,5]. Following clinical suspicion and diagnostic confirmation by means of a barium swallow and manometry, the indication of oesophagogastroduodenoscopy (EGD) in the initial phase is essential for differential diagnosis, ruling out pseudoachalasia due to malignant neoplasms and the presence of oesophageal squamous cell carcinoma as complications of achalasia. Diagnosis using high-resolution manometry and multi-channel intraluminal impedancemetry appears to have a higher diagnostic sensitivity than conventional manometry in diagnosing this disease. It also allows the identification of subtypes: Type I is associated with absent peristalsis and no discernible esophageal contractility in the context of an elevated integrated relaxation pressure (IRP). Type II is associated with abnormal esophagogastric junction (EGJ) relaxation and panesophageal pressurisation in excess of 30 mmHg. Type III achalasia is associated with premature (spastic) contractions and impaired EGJ relaxation[6].

EGD forms an essential part of the diagnostic algorithm of achalasia, although in the earliest stage it has a low sensitivity for detecting this condition as up to 40% of patients with achalasia will have a normal endoscopy[7]. The presence of oesophageal dilation on the oesophagogram, a narrowing of the oesophageal junction into a "bird beak" shape, aperistalsis, and difficulty in evacuating the barium column from the oesophagus support the diagnosis[4]. The objective of treatment is to relieve the symptoms, improve oesophageal evacuation, and prevent the development of complications. Therapeutic options include medical treatment, endoscopic treatment, including pneumatic dilation (PD) and botulinum toxin injection (BTI), and surgical LHM treatment[5]. Other treatments with a promising future which are currently being researched are POEM, oesophageal stents, and ethanolamine injection.

ENDOSCOPIC THERAPY FOR ACHALASIA

Pharmacological endoscopic therapy

BTI (Botox, Allergan, Inc.) has been the most frequently used pharmacological endoscopic treatment for achalasia since 1995. Botulinum toxin is a neurotoxin which blocks the release of acetylcholine from nerve endings by cleaving the SNAP-25 protein. This causes a chemical denervation of the LES muscle, which can last several months, reducing its basal pressure[8,9]. The technique involves injecting 80 to 100 U of toxin in four quadrants (20-25 U in each) using a sclerotherapy needle, at a distance of 1 cm above the squamocolumnar junction. Higher doses have not been shown to be more efficient[10]. The initial response rate is very high, approximately 80%-90% in the month of treatment, but the therapeutic effect disappears over time such that < 50% of patients are asymptomatic after one year of monitoring[10-12]. This suggests that repeated treatments with the toxin are required every 6-12 mo. The predictive factors of a better response to treatment with BTI are: age > 40 years, achalasia type II, and a decrease in base line pressure of the LES after treatment[12]. BTI has not been shown to halt progressive oesophageal dilation, so it does not prevent long-term complications of achalasia. It is a simple, safe and effective technique with few side effects, although chest pain following injection has been described in 16%-25% of cases. Complications such as mediastinitis or allergic reactions to egg protein are rare, and systematic neurotoxicity with generalised paralysis does not occur due to the low doses used. However, repeated botulinum toxin treatments cause an intramural inflammatory reaction at the level of the LES as well as submucosal fibrosis which may make it more difficult to carry out subsequent surgical myotomy[13-15]. Treatment with BTI should therefore be reserved exclusively for patients of advanced age, those with high surgical risk, severe comorbidities, short life expectancy, and those who are not candidates for PD or surgical myotomy or on a waiting list for surgery[16].

PD

PD is the most effective non-surgical procedure in the treatment of achalasia[4,17]. The aim of dilation treatment is to rupture the muscle fibres of the LES by means of the force exerted by air balloons positioned and inflated at this level. Both the use of bougies as well as standard

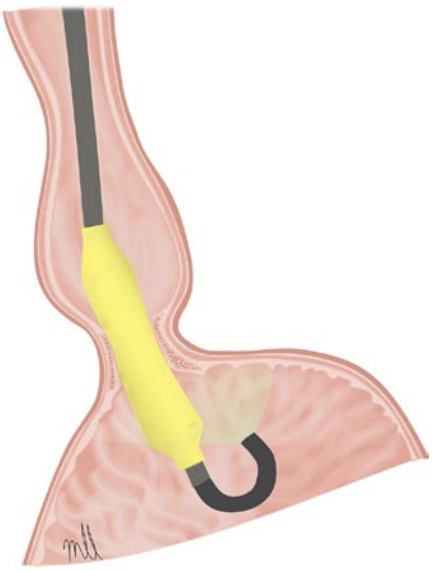

Figure 1 Witzel dilator.

balloon dilation through the endoscope channel (TTS balloon) have not been shown to be particularly effective in achieving this goal, which is necessary to significantly relieve symptoms[4]. The most commonly used dilation treatment for this disease is Rigiflex balloon dilation. Another type of balloon dilation used less frequently is the Witzel dilator, which has also been shown to be effective although it is less widely used and fewer papers have been published on it[18,19].

Pneumatic dilation with a Witzel balloon: Pneumatic dilation with a Witzel balloon is a relatively safe method of treating achalasia with a similar rate of complication to Rigiflex dilation, and a high level of efficacy in the medium to long term[18-20]. The Witzel dilator is a 15-cm polyurethane balloon with a maximum diameter of 4 cm, which is inserted attached to the endoscope until it is positioned at the level of the cardia using direct vision and retroflexion (Figure 1). According to the technique recommended by Alonso Aguirre[20] the balloon is inflated to 200 mmHg for 1 min and, depending on patient tolerance (if the dilation is performed under conscious sedation), it is inflated again once or twice to a maximum pressure of 200 or 300 mmHg. If the dilation is performed under deep sedation, the balloon is inflated to 200 mmHg for 2 min. In a study published for our centre in 2009[18], we observed a success rate of 85% after the first and second dilations (only required in 23% of cases). During the first 5 years of follow-up, 80% maintained the response, and the proportion decreased to around 60% after 10 years. The only variable related to a positive response in the long term was age (> 40 years). A small number of complications were reported: perforation in 4.2%, all treated conservatively, and the appearance of gastro-oesophageal reflux (GER) in the 10% who responded to treatment with proton pump inhibitors (PPI).

Dilation with Rigiflex balloon: The procedure has been standardised with the use of the Microinvasive Rigiflex balloon system (Boston Scientific Corp, Massachusetts, United States). These polyethylene balloons are available in 3 diameters (30, 35, and 40 mm), mounted on a flexible catheter which is positioned in the oesophagus using a guide placed with the help of an endoscope. Balloon inflation at the level of the LES can be controlled using radiology, radiopaque marking, or endoscopy (Figure 2).

The protocol for inflating the balloon varies in function from centre to centre. In general, the balloon is inflated gradually until it reaches a pressure of approximately 7-15 psi, which is maintained for 15-60 s. Using radiology, it is possible to check how the central notch on the balloon, which corresponds to the LES, disappears as the balloon is progressively inflated[21]. This is the most important factor in order for the expansion to be effective, rather than the duration of balloon inflation[22]. Following PD, some authors recommend ruling out perforation by carrying out a radiological check using Gastrografin followed by a barium oesophagogram[4,23]. This technique can usually be performed on an outpatient basis. The patient may be discharged after 6 h, once complications have been ruled out[4,21]. According to some authors, it is possible to choose whether to perform a single dilation session[24], or to carry out successive dilations, progressively increasing the diameter of the balloon in each session (beginning with 30, then 35, and finishing with 40 mm)[25], with 4-6 wk between sessions, based on alleviation of symptoms, reduction of manometric pressure in the LES[24,26], or the improvement of oesophageal evacuation[27,28]. Overall, the results of the studies published show that PD is effective, with response figures of 40%-78% at 5 years and between 12%-58% at 15 years[29-31]. By using the strategy recommended in the clinical practice guidelines[4], higher response rates of up to 97% at 5 years and 93% at 10 years can be achieved[32]. The predictive factors for a failure of treatment with PD are: young patients (age < 40 years)[18,33,34], male sex, dilation using a 30-mm balloon, presence of pulmonary symptoms, failure of treatment after one or two dilation sessions[24,29,35,36], post-treatment determination of a pressure measurement in the LES > 10-15 mmHg, failure of the balloon to relax completely[37], or delayed oesophageal evacuation in a barium oesophagogram carried out in vertical position[26,38-41]. PD is the most cost-effective treatment for achalasia for a period of 5 to 10 years after the procedures[42,43]. Candidates for PD should be those for whom surgery is not contraindicated as a definitive treatment, given that the most severe complication for this technique is oesophageal perforation, which occurs in approximately 1.9% (range 0%-16%)[28,39]. Many perforations tend to occur after the first dilation and are believed to be related to incorrect positioning and balloon relaxation during dilation[44]. Early diagnosis

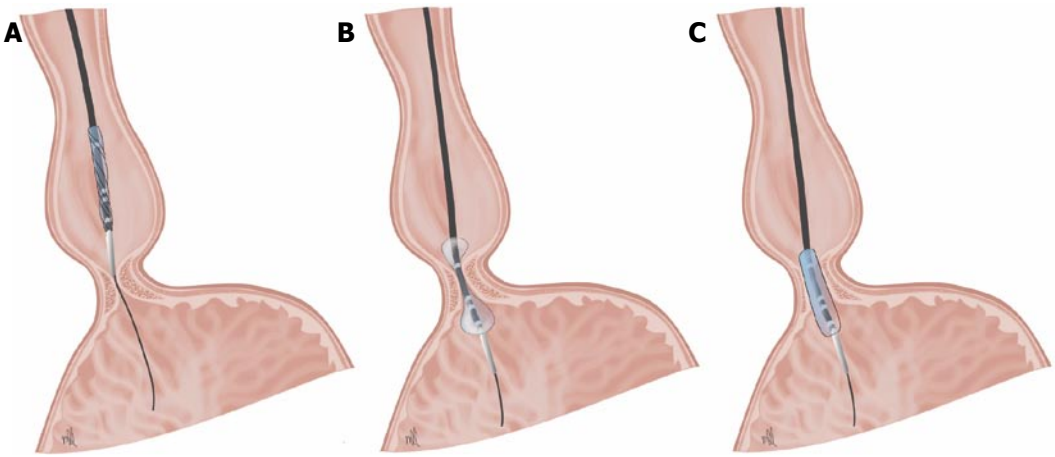

Figure 2 Dilation with Rigiflex balloon positioned at the level of the lower oesophageal sphincter. A: Step 1: positioning the balloon in the esophagogastric junction (EGJ); B: Step 2: deflated balloon in the EGJ; C: Step 3: inflated balloon in the EGJ.

of this complication favours an improved course. Small perforations can be managed conservatively with parenteral nutrition and antibiotics[45], however perforations which are larger, symptomatic, or with suspected contamination of the mediastinum must be repaired surgically *via* thoracotomy[4,21]. Other complications include GER, which is generally mild and transient, appears in 15%-35% of patients, and usually responds to treatment with PPI[46]. Serious GER complications following dilation are rare. Mild but frequent complications include chest pain, aspiration pneumonia, bleeding, fever, tearing of the oesophageal mucosa without perforation, and oesophageal haematoma.

Comparison of the different therapeutic modalities

Botulinum toxin *vs* pneumatic dilation: The results of individual randomised controlled trials comparing BTI and PD have shown that there are no significant differences between the two techniques in terms of remission of symptoms in the short term (4-6 wk), but there is a rapid relapse 6-12 mo after BTI. The success rate in the year of treatment varies from 65.8%-70% for PD and 24%-36% for BTI. However, it can be concluded that PD is more effective in the long term than BTI[11,47-50].

Botulinum toxin *vs* laparoscopic Heller myotomy: There are few studies comparing BTI with LHM. The study by Zaninotto *et al*[51] reports comparable efficacy at 6 mo, although at 2 years only 34% of patients treated with BTI remain asymptomatic, as compared with 87.5% of patients treated with LHM[51].

Role of combination therapy: Therapy with BTI in combination with any other type of endoscopic or surgical treatment for achalasia can increase the response rate. Although it is still not routinely recommended in clinical practice[52], Mikaeli *et al*[53] published a higher remission rate during follow-up in patients who had first been treated with toxin and then with PD (77%) compared to those who had only received treatment with PD (62%)[53]. Other authors have reported a higher percentage of remission after 2 years in those who had received PD first followed by BTI (56%) compared to those who had only received dilation (35.7%), or only toxin (13.79%)[54].

Pneumatic dilation *vs* laparoscopic Heller myotomy: The question of whether to choose surgical treatment or PD as the primary treatment option when treating achalasia remains controversial today. Numerous studies use the strategy of repeating dilation sessions depending on the symptomatic response, if there is no improvement in the manometric tests or in the evacuation of barium contrast. This strategy enables the response rates to be increased to levels comparable with those obtained with LHM[32,55,56]. The only randomised comparative study between PD and surgery, carried out by the European Achalasia Trial Investigators Group in 2011[57] showed similar results for both techniques with a follow-up period of 2 years. 201 patients were randomised to receive dilation with Rigiflex (n = 95) or LHM with partial fundoplication (n = 106). The success rate was comparable for both techniques after 1 year and after 2 years: 90% and 86% respectively for PD, and 93% and 90% for LHM (P = 0.46). The meta-analysis published in 2009 by Campos *et al*[49] includes non-randomised studies of case series. They reported overall response figures of 68% in the 1065 patients dilated with Rigiflex and 89% in the 3086 patients who underwent surgery. In a study by the Cleveland Clinic (Cleveland, OH, United States)[28], 106 patients were treated with PD and 73 patients with LHM. The success rate, based on clinical data or necessity of re-treatment, was similar for both groups: 96% for dilation *vs* 98% for surgery after 6 mo, decreasing to 44% *vs* 57% after 6 years. The advantages of endoscopic treatment are that it includes the possibility of outpatient care, is less invasive than surgery, involves fewer complications and less risk of subsequent reflux and haemorrhage. However,

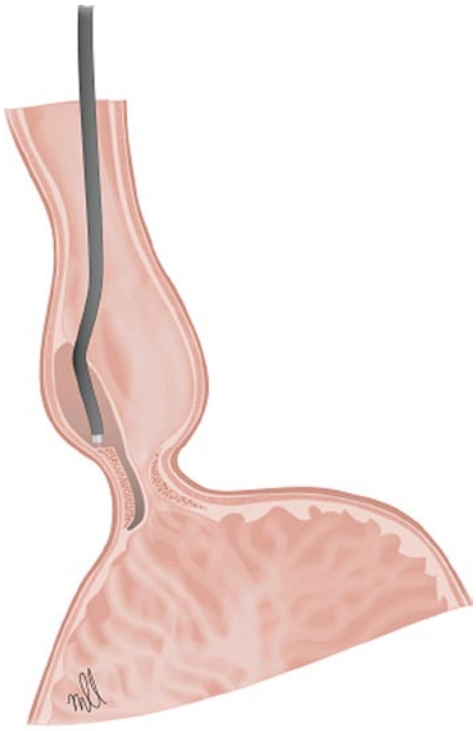

Figure 3 Peroral endoscopic myotomy.

in addition to the fact that more than one treatment session is frequently required, there are still no studies with long-term follow-up which have demonstrated the superiority of PD[21,58]. A recent meta-analysis published by Weber *et al*[59] found that both techniques, PD and LHM, were effective in the treatment of achalasia, however myotomy was found to be more durable[59]. There is some controversy around whether the initial PD obstructs the subsequent performance of laparoscopic myotomy[58,60]. The type of treatment must be selected consensually, taking into account the preferences of the patient as well as the experience of each centre[1,61]. These techniques should preferably be carried out by centres with a high volume and experience in LHM[58].

New treatments for achalasia

Peroral endoscopic myotomy: POEM is a minimally invasive procedure carried out *via* endoscopy. It combines the surgical principles of laparoscopic myotomy with the latest advances in endoscopic submucosal dissection[62].

The technique is performed under a general anaesthetic with endotracheal intubation and the patient in supine position. A liquid diet is indicated for 24-48 h prior to the procedure and antibiotic prophylaxis is administered on the day of the intervention, which is maintained during hospitalisation and in some cases for up to 7 d. Different authors agree on the use of CO_2 insufflation to minimise the risk of pneumomediastinum and air embolism. A submucosal injection of 10 mL of saline solution with 0.3% indigo carmine is administered in the central oesophagus, about 13 cm away from to the EGJ, in a 2 o'clock position. A longitudinal incision of 2 cm is made above the surface of the mucosa to gain access to the submucosal space (Figure 3). Thus a descending anterior submucosal tunnel through the EGJ is created, which reaches approximately 3 cm into the proximal stomach. Once the submucosal tunnel is complete, the circular muscle fibres are cut 2-3 cm in distal direction from the access to the mucosa, approximately 7 cm above the EGJ. Myotomy continues distally until it reaches the gastric submucosa, and extends about 2-3 cm in distal direction to the EGJ. Once the circular muscle fibres in the lower part of the oesophagus have been identified and cut, the site of access to the mucosa is closed using haemostatic clips[63].

The first reference to endoscopic myotomy for achalasia appears in 1980 in a case series published by Ortega *et al*[64]. Later, as endoscopic surgery through natural orifices (NOTES) progressed, Pasricha *et al*[12] demonstrated its feasibility using a porcine model. The technique was adopted in clinical practice in 2010 by Inoue *et al*[65]. The study evaluated 17 patients, aiming for a significant reduction in the index of symptoms of dysphagia in all of them (average score from 10 to 1.3; $P = 0.0003$), as well as the basal pressure of the LES (from 52.4 to 19.9 mmHg; $P = 0.0001$). The operating time ranged from 100 to 180 min, with an average myotomy length of 8.1 cm. No serious complications related to the procedure were described. One patient presented with a complication of pneumoperitoneum. After a follow-up of 5 mo, only one patient reported symptoms of reflux, which were shown in gastroscopy to be an oesophagitis Los Angeles Grade B, which was treated satisfactorily by taking a protein pump inhibitor[65,66]. In 2011, Swanström *et al*[67] published their experience with POEM in 5 patients. No leaks were detected in a barium oesophagogram 24 h after the procedure, nor were any complications described immediately post-operation, with all patients presenting a rapid relief of dysphagia without reflux symptoms[66,67]. In 2012, von Renteln *et al*[68] presented the results of the first prospective POEM trial in Europe. The myotomy was performed in 16 patients achieving a clinical response of 94% after 3 mo. The LES pressure was reduced from 27.2 to 11.8 mmHg ($P < 0.001$), with no patients developing reflux symptoms after the treatment[63,68]. Some authors have studied the applicability of the techniques to patients previously subjected to endoscopic treatment (BTI, PD). Sharata *et al*[69] demonstrated clinical success in this context in 12 patients. Only one case of intramural bleeding, which required a new endoscopy for haemostasis, and one case of dehiscence of the mucosectomy, which was treated with haemostatic clips, were described. All patients demonstrated symptomatic relief, with an average decrease in the Eckardt score from 5 to 1. Comparing these results with those of the 28 patients without previous endoscopic treatment, no significant differences were found to exist between the two groups[66,69]. In 2012, Zhou *et al*[70] published their experience with 12 patients with a history of

LHM in which they successfully performed endoscopic myotomy. No serious complications with the technique were described, achieving an average improvement in the index of symptoms from 9.2 to 1.3 ($P < 0.001$). The basal pressure of the LES was reduced from 29.4 to 13.5 mmHg ($P < 0.001$). Only one patient reported reflux symptoms, presenting a positive response to intermittent treatment with PPI[66,70].

The first study to retrospectively compare POEM and surgical myotomy was published in 2013. No significant differences were observed in terms of the length of the myotomy, complication rate, or hospital stay[63,71]. Bhayani *et al*[72] have recently presented the results of a study in which 101 patients were prospectively included, 64 treated with Heller myotomy and 37 with POEM. The authors conclude that the two techniques are comparable in terms of efficacy and safety, with similar results in post-operative manometry and pathological acid exposure, as assessed on an outpatient basis using a pH meter[72].

In summary, POEM is posited as a useful technique, although it is an expensive procedure which requires significant expertise. The studies published show excellent results in the short term as far as dysphagia relief and improvement of the manometric pressure data for the LES are concerned. The complication most frequently described is pneumoperitoneum, which can generally be resolved by conservative means. The presence of GER following POEM ranges between 5.9% and 46%, depending on the series, but in general it is a question of mild symptoms which can be adequately controlled with medical treatment. On the basis of the published data, it is no surprise that the majority of experts on POEM, including surgeons with extensive experience in surgical myotomy, appreciate the advantages of achieving results like those for LHM by minimally invasive means. Endoscopic myotomy could eventually become a first-line treatment for achalasia, except for those with significant comorbidity or advanced achalasia at the megaoesophagus stage. This technique is not a future anymore, but a present. However, new randomised studies are needed which will allow us to evaluate POEM in the long term and to compare the technique with the remaining treatment modalities.

Oesophageal prostheses: Self-expanding metallic prostheses have been used safely and effectively to treat malignant pathologies of the oesophagus and tracheoesophageal fistula, oesophageal perforations, and anastomotic leaks. However, given the high risk of complications (migration, perforation, indentation, and restenosis), its use in benign pathology is more controversial. Various authors have defended the use of removable prostheses in the management of benign stenosis of the oesophagus, arguing that it constitutes a reasonable alternative in the treatment of patients with achalasia[73,74]. The ideal prosthesis would be placed at cardia level to keep open the EGJ, thus limiting gastroesophageal reflux[75].

In 2009, Zhao *et al*[76] published their experience in 75 with a diagnosis of achalasia who were treated with the temporary placement of a self-expanding metallic prosthesis of 30 mm in diameter, with a follow-up of 13 years. The placement of the prosthesis is guided by a fluoroscopy and is extracted *via* gastroscopy 4-5 d later. The procedure was performed successfully in all patients, achieving a clinical response of 100% one month after removing the prosthesis and 83.3% in the follow-up of over 10 years. No perforations or mortalities associated with the treatment were reported, with the percentage of migration of the prosthesis at 5%, reflux at 20%, and chest pain at 38.7%. The authors conclude that the use of a temporary self-expanding metallic prosthesis is a safe and effective approach in the treatment of achalasia, with a satisfactory long-term clinical remission rate[76]. In 2010, Cheng *et al*[73] compared the efficacy of different self-expanding metallic prostheses in the long-term treatment of achalasia. They designed a study with 90 patients and separated them into three groups according to the diameter of the prosthesis used (20, 25, and 30 mm). They concluded that the prosthesis with a diameter of 30 mm is associated with a lower incidence of migration and with higher clinical response rates, comparable in the short term with those described for surgical myotomy[73]. The same authors published a prospective randomised study in 120 patients, in which they evaluated the long-term efficacy of a specially designed, partially covered and removable metallic prosthesis, and compared it with PD. They achieved a success rate over 10 years of 83% with the 30-mm prosthesis, while the response rate for the 20-mm prosthesis and PD was 0%[75,77].

Although the results seem promising, they reflect the experience of a single centre, which is why this technique should not be generally recommended. Further randomised studies are required which evaluate its long-term efficacy and safety[75].

Treatment of achalasia with sclerotherapy: Ethanolamine oleate: The injection of a sclerosing agent such as ethanolamine oleate at the level of the LES could be an alternative therapy for patients with refractory achalasia who are not candidates for PD or surgery. Its effect is based on the local inflammatory effect of this substance, but there are still insufficient studies and it is only to be recommended in selected cases[78,79].

THERAPEUTIC MANAGEMENT ALGORITHM

Achalasia therapy is based on achieving the relaxation or mechanical disruption of the LES. Since achalasia is a rare disease, there are few randomised and controlled clinical trials which would enable us to define

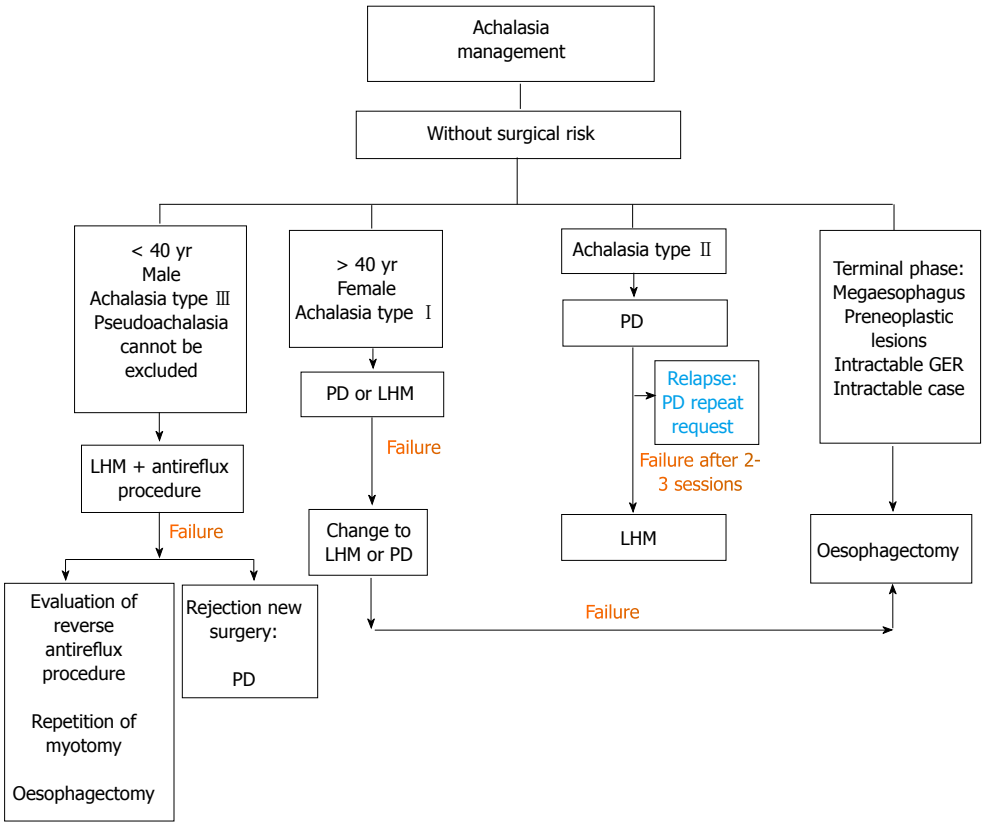

Figure 4 Management algorithm in patients without surgical risk. PD: Pneumatic dilation; LHM: Laparoscopic Heller myotomy.

the optimum strategy. Furthermore, the safety and maintenance of efficacy of the different treatment options vary greatly.

The choice of initial treatment of achalasia is complex and all options are determined by the combination of numerous factors such as the age of the patient, sex, surgical risk, comorbidity, type of achalasia[7], patient preferences, oesophageal anatomical distortion, and the experience of the hospital. Moreover, identifying factors which predict the success of the therapies can inform our recommendations. In Figures 4 and 5, we propose an algorithm for the management of this disease based on the most recent published recommendations[3-5,21,58,80,81]. In general, LHM is the most durable technique in the long term for treating achalasia, however PD is the non-surgical procedure of choice, and it is the most cost-effective strategy. Both techniques are recommended as an initial therapy for treating achalasia in healthy patients who can undergo surgery (Figure 4). The success rate in the short term is comparable for the two techniques.

PD is the most economical non-surgical option, primarily for type Ⅱ. The subtype of achalasia, diagnosed using high-resolution manometry at the beginning of the study, can predict the response of the treatment[58]. Thus we have seen that the success rate with PD is significantly higher for achalasia type Ⅱ (96%) than for type Ⅰ (56%) and type Ⅲ (29%)[82]. The sessions are repeated according to an "on demand" strategy, based on the recurrence of symptoms, and long-term remission can be achieved with it. Criteria for failure include a lack of symptom relief after 2-3 sessions or following the use of the largest diameter balloon chosen. In these cases, the patient must undergo surgery (Figure 4). In high-risk patients, PD can be a reasonable alternative if carried out in hospitals with surgical experience, because of the possibility, however infrequent, of perforation (Figure 5).

Surgical myotomy, using the technique described by Heller a century ago, is the most effective treatment option in the long term[83]. In the last 20 years, this procedure has been carried out safely and successfully using the minimally invasive laparoscopic approach[84], and more recently using robotic assistance. In the majority of cases, it is recommended to also use an anti-reflux fundoplication technique, preferably partial (Dor anterior or Toupet posterior) owing to the fact that it results in significantly lower rates of post-operative dysphagia. It is the procedure of choice in adolescents and young adults, especially male[85], in cases where pseudoachalasia cannot be ruled out and, possibly, in patients with achalasia type Ⅲ (Figure 4)[82], patients with pulmonary symptoms, and those who have not responded to initial treatment with one or two sessions of dilation[37,58,86,87]. The predictors of a poor response after surgery include severe pre-operative dysphagia and preoperative low pressure of the LES (< 30-35 mmHg)[88]. The main predictor of patients

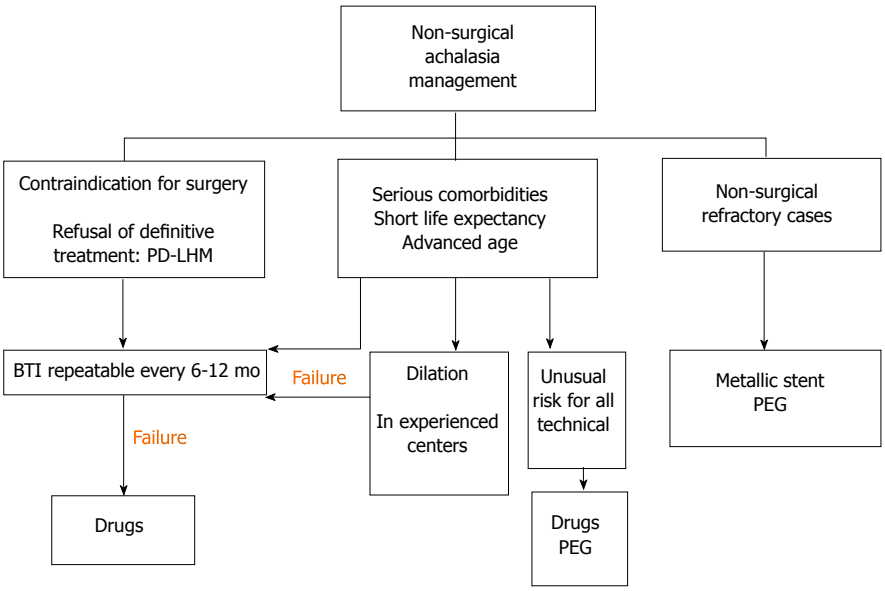

Figure 5 Non-surgical management algorithm. PEG: Percutaneous endoscopic gastrostomy; BTI: Botulinum toxin injection; PD: Pneumatic dilation; LHM: Laparoscopic Heller myotomy.

who will require an additional intervention after the Heller myotomy is an oesophageal dilation of > 6 cm (megaoesophagus) in diameter prior to surgery.

Robotic surgery (Da Vinci® Surgical System, Intuitive Surgical, Mountain View, CA) has been used to treat achalasia as it meets the limitations of conventional laparoscopic surgery, making it more ergonomic for the surgeon and minimally invasive. This involves a computer-assisted surgical device with remote handling. The benefits of amplifying the three-dimensional image enable complex surgical procedures such as fundoplication LMH to be performed more accurately, helping to prevent oesophageal perforation, and to identify residual circular muscle fibres[89].

BTI is the first-line treatment for patients of advanced age, those with severe comorbidities, those with a short life expectancy[16], or those on a waiting list for surgery (Figure 5). It is recommended for patients who are not eligible for more definitive therapies (PD or LHM). Pharmacological treatment with nitrates, calcium channel blockers, and "nitric oxide donors" (sildenafil) may reduce pressure in the LES, but the efficacy is generally unsatisfactory and incomplete. It is recommended for patients who do not want or cannot undergo a more definitive treatment and for whom BTI has failed (Figure 5). Sublingual nifedipine is the most widely used drug. In a review, Cochrane, Wen *et al*[87], identified only two randomised studies evaluating clinical success of nitrates in achalasia and concluded that they cannot give solid recommendations for use. In our experience, it can be a treatment option prior to the extension of the myotomy or the election of oesophagectomy. BTI and medical treatment should only be used in high-risk patients (Figure 5), and as an intermediate step prior to other, more durable treatments[3].

POEM is a new treatment[90] which has shown good results in the short term, including following a myotomy with anterior fundoplication[91]. It is profiled as a viable option for patients following the failure of a myotomy, in the absence of more controlled studies, long-term results, and comparison with current techniques.

Despite the improvement in symptoms offered by PD and LHM, 10%-15% will present progressive deterioration of the oesophageal function, and up to 5% may require an oesophagectomy in the terminal stage when they do not respond to any treatment (Figure 4)[92]. The ideal method of reconstruction following oesophagectomy has not yet been established, the options being gastric, colonic, or jejunal[3]. The treatment option for refractory achalasia is (Figure 5)[93] the minimally invasive Ivor-Lewis oesophagectomy. The success rate is close to 90%, although there is a significant risk of respiratory complications, anastomotic strictures, and leaks, dumping syndrome, regurgitation, and bleeding. The placement of percutaneous endoscopic gastrostomy (PEG) can be considered a suitable alternative in patients with an unusually high risk for other techniques. However, it does not tend to reduce the symptoms or risks of aspiration of salivary retention.

ROLE OF ENDOSCOPY IN THE DIAGNOSTIC THERAPEUTIC PROTOCOL OF ACHALASIA

Evaluation to guide treatment

The success of the treatment must be documented using objective parameters. Since there are deficiencies in the correlation between the latter and clinical symptoms, an adequate strategy includes periodic monitoring to detect symptomatic recurrences at an early stage. The symptoms can also reappear due to an initial incomplete myotomy, the growth of new muscular

fibres, or stenosis. The first clinical evaluation should be performed at an early stage (1-3 mo) after the initial intervention, and every 1-2 years thereafter[88]. The most widely used system for scoring symptoms is the Eckardt score[94]. The Eckardt score (maximum score, 12) is the sum of the symptom scores for dysphagia, regurgitation, and chest pain (0, absent; 1, occasional; 2, daily; and 3, each meal), and weight loss (0, no weight loss; 1, < 5 kg; 2, 5-10 kg; and 3, > 10 kg). This register allows new explorations, barium oesophagram, and EGD to be indicated. In addition, regular monitoring is important not only to ensure clinical control, but also to decide on the need for retreatment and to prevent complications at a later stage. Regardless of the subtype of achalasia, the long-term positive response variable most widely used in Europe is post-treatment LES pressure < 10 mmHg[24,88,95]. Other centres use the timed measurement of the barium column after the PD as a predictor of success. In this respect, a decrease by > 50% with respect to the basal pressure within 1 min is associated with a clinical improvement[41,96]. Some institutions perform oesophageal manometry intraoperatively or immediately after the dilation[97,98]. However, the pressure of the LES could be falsely raised as a result of oedema or intramural haematoma following the intervention. There is a new method for the intraoperative evaluation of the diameter of the EGJ (EndoFLIP). It is an endoluminal probe, which produces functional images of the diameter of the EGJ in real time using impedance planimetry. However, more studies are needed to determine the best parameter for retreatment[99]. There is no treatment for the neural lesion considered to be responsible for achalasia, which is why oesophageal peristalsis is rarely normalised following any of the therapies. However, some cases have been described in which recovery of peristalsis occurs, both following myotomy and following dilation[100-104]. Different authors have associated this with close monitoring of patients and the early indication of treatment, thus avoiding progression to advanced stages with oesophageal atony.

Endoscopic surveillance of complications

The primary role of endoscopy is to detect, prevent, and treat immediate and long-term complications deriving from the disease itself and the therapies applied. Endoscopy immediately after an endoscopic intervention is only indicated for the treatment of complications arising from the techniques used. However, there are currently no guidelines for monitoring squamous cell carcinoma or other late complications such as oesophageal and peptic stenosis, or megaoesophagus. More data are needed to determine which follow-up guidelines will improve the overall result in this disease, since prospective monitoring studies over > 30 years have shown a benefit in long-term survival in only 13% of cases[105].

The most prevalent complications in the long term when the treatment has been effective are mainly due to GER, which occurs in almost 25% of patients after a follow-up of > 15 years[106]. Following PD, the symptoms are generally relieved and temporary, and can be easily controlled with PPI. However, more severe complications have been described following surgery, including the incidence of reflux symptoms of 18% (range 5%-55%)[49]. These complications can be markedly reduced by adding a Dor fundoplication to the LHM[107]. The second most frequent complication is the progressive dilation of the oesophagus which leads to sigmoid megaoesophagus, and appears in 10% of cases of > 10 years of progression[88]. The most feared complication is oesophageal cancer, the prevalence of which ranges from 0.4%-9.2%, squamous cell cancer being more frequent[108-111] than Barrett's adenocarcinoma (associated with GER after myotomy). In this case, and although more studies are required, the majority of experts, including the latest guidelines from the American Society of Gastrointestinal Endoscopy[112], advocate some form of endoscopic surveillance 15 years after the initial diagnosis, and in patients with oesophageal stasis[5,113], but the subsequent monitoring interval has not been defined.

CONCLUSION

Achalasia is a primary oesophageal disorder for which there is no curative treatment. Pneumatic dilation and surgical myotomy are recommended initial therapies in healthy patients because they offer the best results in the long term. Botulinum toxin injection and medical treatment have transitory effects, and should be reserved for high-risk patients or as an intermediate measure before more definitive treatment. Other new options without definitive location in the therapeutic algorithm are peroral endoscopic myotomy, metallic stents, and ethanolamine injection. In refractory cases and in terminal stages, oesophagectomy is an option. Follow-up after the treatment is indicated to detect recurrences, indicate retreatment, and prevent late complications.

Abstract

Biliary tract diseases are the most common complications following liver transplantation (LT) and usually include biliary leaks, strictures, and stone disease. Compared to deceased donor liver transplantation in adults, living donor liver transplantation is plagued by a higher rate of biliary complications. These may be promoted by multiple risk factors related to recipient, graft, operative factors and post-operative course. Magnetic resonance cholangiopancreatography is the first-choice examination when a biliary complication is suspected following LT, in order to diagnose and to plan the optimal therapy; its limitations include a low sensitivity for the detection of biliary sludge. For treating anastomotic strictures, balloon dilatation complemented with the temporary placement of multiple simultaneous plastic stents has become the standard of care and results in stricture resolution with no relapse in > 90% of cases. Temporary placement of fully covered self-expanding metal stents (FCSEMSs) has not been demonstrated to be superior (except in a pilot randomized controlled trial that used a special design of FCSEMSs), mostly because of the high migration rate of current FCSEMSs models. The endoscopic approach of non-anastomotic strictures is technically more difficult than that of anastomotic strictures due to the intrahepatic and/or hilar location of strictures, and the results are less satisfactory. For treating biliary leaks, biliary sphincterotomy and transpapillary stenting is the standard approach and results in leak resolution in more than 85% of patients. Deep enteroscopy is a rapidly evolving technique that has allowed successful treatment of patients who were not previously amenable to endoscopic therapy. As a result, the percutaneous and surgical approaches are currently required in a minority of patients.

Key words: Biliary stricture; Bile leakage; Liver transplantation; Endoscopic retrograde cholangio-pancreatography; Plastic stents; Fully-covered self-expandable metal stents

Core tip: One third of liver transplant recipients are

affected by biliary tract complications which are the major source of morbidity in these patients. Biliary-biliary (as opposed to bilio-enteric) anastomoses are first treated by endoscopy, with resolution of > 85% and > 75% of cases in deceased and living-donor transplant recipients, respectively. New stenting protocols and new designs of fully covered self-expandable metal stents are at the frontline of efforts aiming to reduce patient burden during treatment. Here, we discuss the latest developments in the endoscopic approaches to these complications.

INTRODUCTION

Liver transplantation (LT) has become a standard of care in patients with end-stage liver disease. After LT, approximately one third of patients are affected by biliary tract complications and these result in significant morbidity and decreased patient survival[1]. Due to the scarcity of organ donors and the increasing number of patients waiting for LT, living donor liver transplantation (LDLT) has emerged as an alternative to deceased donor liver transplantation (DDLT). Even though surgical techniques are constantly improving, biliary complications are more frequent following LDLT compared with DDLT[2]; LDLT also remains characterized by its technical complexity and ethical controversies.

Biliary complications following LT include biliary leaks, strictures, choledocholithiasis and other less common conditions[3,4]. Approaches commonly used for treating biliary complications involve endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC) and surgery. ERCP is commonly regarded as the first choice treatment modality in most circumstances; if it fails PTC is often used, reserving surgery for severe complications or refractory conditions not manageable by less invasive techniques[5-8].

Here we review the literature focusing on the endoscopic management of biliary complications, the different strategies for treating strictures and biliary leaks and summarize their outcomes.

ETIOLOGY, RISK FACTORS AND DIAGNOSIS

Biliary reconstruction in LT

It is essential for endoscopists to have a clear comprehension of the different types of surgical reconstruction during LT. Biliary reconstruction is performed at the end of LT, once all vascular anastomoses have been completed. An end-to-end choledoco-choledocal anastomosis is the first choice procedure in most institutions following whole organ LT in patients with healthy native bile ducts of suitable caliber[6,9]. This technique produces physiological bilioenteric continuity, preserves the function of the sphincter of Oddi and allows for potential future endoscopic treatment of biliary complications. Bilioenteric reconstruction (Roux-en-Y hepaticojejunostomy) is performed in cases of previous biliary tract disease (*e.g.*, sclerosing cholangitis, biliary atresia), large disparity in size or small caliber of the bile ducts, and may be preferred in cases of retransplantation because of inadequate recipient duct length[10]. Due to the shortage of cadaveric livers, LDLT has gained popularity in adult patients. With LDLT, the living donor's right or left lobe or the left lateral segment is transplanted. Ductal anastomoses are more difficult to perform than in DDLT due to the small caliber of the intrahepatic ducts. In reduced size split-liver transplantation, a liver from a dead donor is splitted into two organs to permit two recipients to receive a graft; the anastomoses of both right and left lobe are alike to those of LDLT.

Risk factors for biliary complications

Biliary complications may be promoted by multiple risk factors related to recipient, graft, operative factors and post-operative course: (1) among recipient-related factors, advanced recipient age and more advanced liver function impairment contribute to the development of biliary complications[11,12]; (2) among graft-related factors, prolonged cold and warm ischemia time, extended donor criteria grafts and donation after cardiac death, as opposed to brain death, are associated with a higher incidence of ischemic-type biliary lesions (ITBL)[13,14]. Nonetheless, a recent report by Vanatta *et al*[15] showed that, by carefully selecting donors and recipients, overall patient and graft survival as well as the incidence of ITBL were similar following donation after cardiac *vs* brain death[15]; (3) operative risk factors are different for DDLT and LDLT for various reasons: LDLT by itself is an important risk factor for biliary complications due to the small duct size, the presence of multiple biliary duct outlets and the devascularization of the bile ducts during hilar dissection of the graft[16-18]. In DDLT, T-tube placement for duct to duct (DD) reconstruction allows minimizing the incidence of anastomotic strictures[19] and it is unequivocally recommended by some authors[20]; however, this results in biliary leakage following T-tube removal in 5%-33% of cases[19]; (4) during the postoperative course, early hepatic artery thrombosis may lead to the severest forms of non-anastomotic strictures, at multiple sites of the donor biliary system, because blood supply to the bile ducts is fragile. This may result in partial or total biliary necrosis with the formation of typical biliary casts and multiple intraluminal filling defects at

cholangiography[5,21]; and (5) other documented factors, including ABO incompatibility, cytomegalovirus infection and chronic/acute rejection episodes have been reported to be potential risk factors for biliary complications in historical publications; more recently these factors have been strongly associated with non-anastomotic, rather than anastomotic, complications[22-24].

Diagnostic approach

The clinical presentation of biliary complications varies considerably; patients could present no symptom at all, jaundice, abdominal pain, biliary leak or cholangitis. In asymptomatic LT recipients, a biliary complication usually is first suspected because of elevations of serum bilirubin, alkaline phosphatase, and/or gamma-glutamyl transferase levels. In the case of cholestasis, the initial diagnostic step is to discriminate obstructive *vs* nonobstructive causes, like LT rejection (acute or chronic), recurrence of primary disease and drug-induced cholestasis.

The initial evaluation should include a liver ultrasound (US) with a Doppler evaluation of the hepatic vessels, due to the frequent association of biliary complications with the presence of hepatic artery thrombosis or stenosis[6,25]. If hepatic artery stenosis or occlusion is suspected by Doppler US, multidetector computed tomography should be used as the second-line modality of choice for the rapid assessment of major vascular complications requiring pre-treatment confirmation. If hepatic artery thrombosis is confirmed, angiographic intervention should be performed urgently to re-establish hepatic artery flow[26,27]. Magnetic resonance cholangiopancreatography (MRCP) has substantially facilitated the accurate recognition of biliary tract complications (sensitivity and specificity of 93%-97% and 92%-98%, respectively, compared with ERCP as the reference standard)[28-31]. MRCP provides the endoscopist with a map of the whole biliary tract and, unlike ERCP, consistently demonstrates ducts even upstream from a tight stricture, therefore it is especially useful for hilar or intrahepatic anastomotic strictures. When findings at MRCP were compared to other approaches, including ERCP, PTC, and surgery to diagnose post-LT biliary complications, the sensitivity, specificity, positive predictive value, and negative predictive of MRCP were 98%, 94%, 94%, and 98%, respectively[31]. Its main disadvantages include a low sensitivity in the case of sludge or small stones (< 5 mm). MRCP is noninvasive and is the technique of choice for diagnosing post-LT biliary complications.

Etiology and types of biliary strictures

Post-LT biliary strictures are usually classified as anastomotic strictures (ASs) or non-anastomotic strictures (NASs), also called ischemic type biliary strictures (ITBS)[32-34]. Biliary strictures complicate around 2%-14% of LT and can be categorized in to early or late (occurring within or after the first month following LT, respectively). Strictures which appear soon after LT are commonly referable to technical problems, whereas late strictures are generally attributable to vascular insufficiency and problems with healing and fibrosis. In a recent systematic review, 1844 (12.8%) of 14359 LT patients had biliary strictures. The appearance of a stricture varies widely, from 7 d to 11 years after LT[35].

Anastomotic strictures: ASs can present at any time after transplantation but most of them are diagnosed within one year following LT with a mean interval between LT and diagnosis of 5-8 mo. ASs complicate around 6%-12% and 34% of deceased and living donor LT procedures, respectively[33,36,37]. ASs pathogenesis is believed to include inadequate mucosa-to-mucosa anastomosis, local tissue ischemia, and the fibrotic nature of the healing process[33,38]. ASs are solitary and short in length (Figure 1A and B). They may involve a choledocho-jejunostomy or a choledocho-choledochostomy; they are considered clinically relevant only if cholestasis or cholangitis are present. A slight and transient narrowing of the biliary lumen occurs frequently within the first one to two months following biliary anastomosis due to postoperative edema and inflammation, but it is uncertain how many of these cases progress to clinically significant ASs (Figure 1A)[33]. ASs can generally be effectively treated by endoscopic means and do not decrease graft or patient survival.

Non-anastomotic strictures: Post-LT strictures are classified as NASs if they are located more than 5 mm proximal to the anastomosis (Figure 1D). They account for 10% to 25% of all strictures complicating LT, with an incidence in the range of 0.5% to 10%[19,38-40]. NASs are considered to derive from ischemic damage to the duct as it may occur following hepatic artery thrombosis. Conditions associated with NASs include a prolonged ischemia time (cold and warm), transplantation after cardiac death donation, prolonged vasopressor support for the donor, ABO-type incompatibility, primary sclerosing cholangitis, autoimmune hepatitis or hepatitis C virus infection in the recipient[41-48]. Furthermore, nowadays a wider acceptance of older and extended criteria donors has been suggested to contribute to an increased incidence of NASs[19]. True NASs, usually referred to as ITBSs, characteristically are diffuse and include the hilum and sectorial or segmental intrahepatic branches. The treatment of NASs is technically more difficult than that of ASs and, in the case of hepatic artery thrombosis, the endoscopic treatment is mostly ineffective if the arterial blood flow cannot be restored.

Etiology and types of biliary leaks

Biliary leakage is the second most common complication after LT, with an incidence of 2%-21%[19,49,50]. In a recent meta-analysis, the rate of biliary leakage after LT

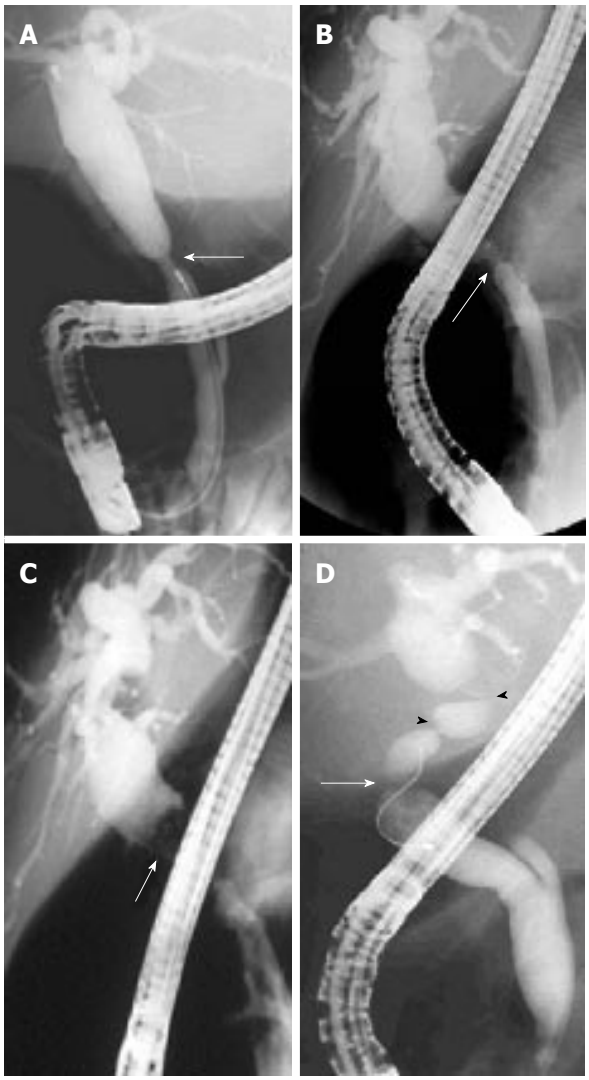

Figure 1 Biliary strictures at endoscopic retrograde cholangiopancreatography. A: Early and incipient anastomotic stricture (arrow) with upstream biliary dilation; B and C: Late and high-grade anastomotic stricture (arrow) > 1 year after deceased-donor liver transplantation, with a large stone located upstream from the stricture (arrow); D: Combination of anastomotic (arrow) and non-anastomotic (arrow heads) strictures.

was 8.2%, without significant difference between DDLT (7.8%) and LDLT (9.5%)[35]. Leakage may develop at the level of the anastomotic site, from the cystic duct remnant, from the cut surface of partial liver grafts in the case of LDLT, and following T-tube removal (Figure 2). Bile leaks can be classified into two categories: early bile leaks, which present within 4 wk following LT (these usually occur at the anastomotic site and are often related to technical issues, not to the type of biliary reconstruction), and late bile leaks, which present beyond this time (they are usually related to T-tube removal, resulting from delayed T-tube tract maturation possibly related to immunosuppression). A bile leak should be suspected in any patient who develops abdominal pain, fever or any sign of peritonitis following LT, especially after T-tube removal. Bile leaks can derive in collections of fluids and abscesses that might be related to strictured or disconnected ducts. Depending on the size of the leakage and the clinical presentation, bile leaks can be managed conservatively, nonsurgically or surgically[4,51].

Etiology and type of intraluminal biliary filling defects

Stones, sludge and casts occur in approximately 5% of patients after LT, with stones accounting for 70% of the cases. Biliary stone disease is associated with disorders that can reduce the flow of bile such as ASs or NASs. In addition, medications such as cyclosporine may play a role in bile lithogenicity by inhibiting bile secretion and promoting functional biliary stasis. Sludge is described as a thick collection of mucus, calcium bicarbonate and cholesterol crystals, which, when left untreated, can transform into biliary stones (Figure 3A).

Casts refer to the presence of multiple hard pigmented dark material that mold the bile ducts (Figure 4). These are thought to develop due to bile duct mucosal damage related to obstruction, ischemia, or bacterial infection. A history of hepatic artery thrombosis and a prolonged cold ischemia time are associated with debris formation[52-54]. This disorder occurs in 2.5% to 18.0% of LT recipients[32,54]. Casts are associated with increased morbidity, graft failure, retransplantation and mortality.

Sphincter of oddi dysfunction

Sphincter of oddi dysfunction (SOD) describes a clinical syndrome of biliary or pancreatic functional obstruction that may be responsible for cholestasis, pain, or pancreatitis.

It is hypothesized that, in the post-LT setting, denervation of the ampulla (secondary to surgical intervention) might generate a hypertonic sphincter, resulting in increased intraductal biliary pressure. This complication has been reported in 2% to 7% of patients who have undergone LT[55,56]. Typically, patients present with cholestasis, dilation of the distal bile duct and no obstacle detected at cholangiography.

ENDOSCOPIC MANAGEMENT

Managing post-LT biliary complications needs a multidisciplinary team involving transplant surgeons, hepatologists, endoscopists, and interventional radiologists. Endoscopic therapy is the first line therapy in most cases with a duct-to-duct anastomosis. With recent developments in enteroscopy, many patients with Roux-en-Y hepaticojejunostomy can also be treated endoscopically[57], with PTC being mostly reserved for the salvage of failures. The spectrum of endoscopic therapies includes biliary sphincterotomy, balloon dilation of strictures, basket and balloon extraction of stones, sludge, and casts, and the placement of one or multiple, side-by-side, biliary plastics stents. Additionally, cholangioscopy allows the characterization of strictures by observation and tissue sampling, and therapy of difficult casts or stones by intraductal lithotripsy[58-62]. Endoscopic therapy is usually highly successful and has a low incidence of procedure-related complications,

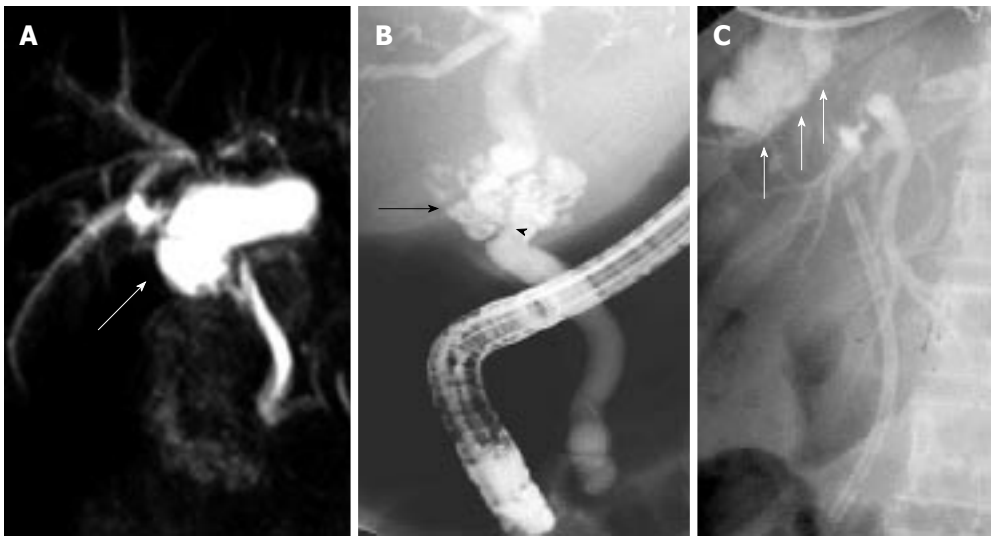

Figure 2 Biliary leaks. A: Biloma (arrow) resulting from anastomotic leakage early after liver transplantation as shown at magnetic resonance cholangiopancreatography; B: Anastomotic leakage (arrow) at the level of an anastomotic stricture (arrow head) early after liver transplantation as shown at endoscopic retrograde cholangiopancreatography (ERCP); C: Multiple leak sites from the cut surface in a split liver transplantation patient (arrows) as shown at ERCP with a plastic biliary stent in place.

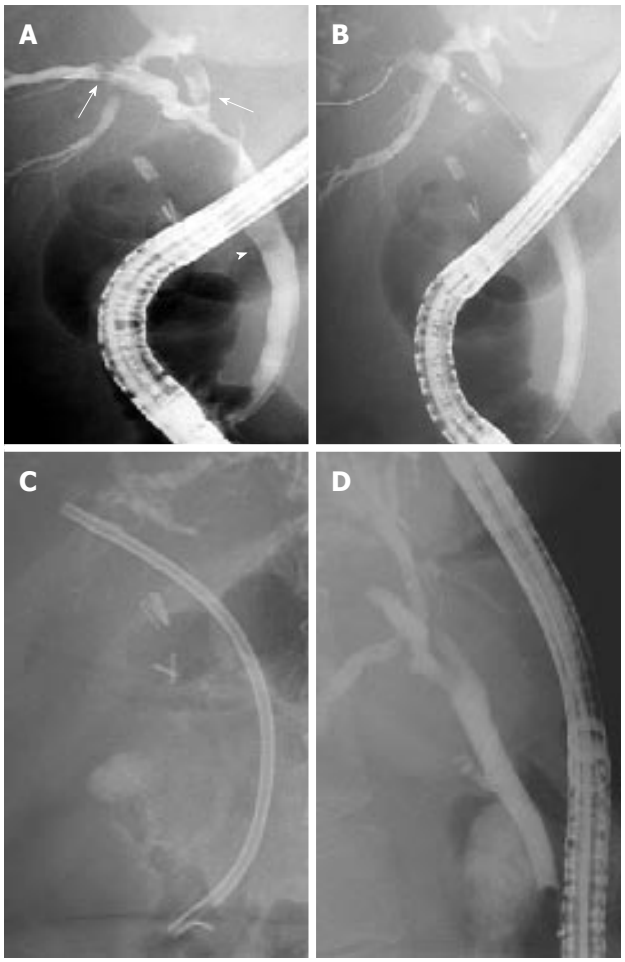

Figure 3 Endoscopic treatment of an anastomotic biliary stricture with upstream sludge and downstream stone after living donor liver transplantation. A: Anastomotic biliary stricture with upstream sludge (arrows) and downstream stone (arrowhead); B: Stricture dilation using a 10-mm in-diameter balloon; C: 10-F plastic biliary stent in place; D: Absence of residual stricture at late follow-up.

reserving surgery as a last option intervention if endoscopic and/or percutaneous treatment is not feasible or is ineffective.

Biliary leaks

Traditionally, post-LT biliary leaks have been treated surgically with anastomotic revision or conversion to a Roux-en-Y hepaticojejunostomy if a duct-to-duct anastomosis is not technically feasible. With advances in endoscopic therapy, ERCP has now become the initial therapeutic option in the management of biliary leaks. Usually the leakage of bile is treated through biliary sphincterotomy followed by the placement of a transpapillary stent (Figure 2C) for 2 to 3 mo (in contrast to post-cholecystectomy leaks, where the stent can be removed in 4 to 6 wk) with the aim of ensuring the proper healing of the leaks. Prolonged stenting is advised because healing may be delayed by immunosuppressors. If the leak is associated with a biliary stricture, this can be prudently dilated before inserting one or more plastic stents upstream from both the stricture and the leak[63]. Biliary stenting provides faster leak resolution than sphincterotomy alone and it is equally effective whether sphincterotomy is performed or not. At the time of stent removal, a careful anatomical evaluation should be performed and duct cleansing should always be performed because biliary abnormalities (mostly sludge, stones, or persistent leak) can be found at this time in a significant proportion of patients[64]. Endoscopic therapy solves the leakage of bile in more than 85% of patients[38,63-66]. Recently, fully covered self-expandable metal stents (FCSEMS) have been used in a pilot study of 17 LT recipients with biliary leaks[67]. FCSEMS offered minimally invasive and low-morbidity short-term control of leaks but it resulted in a relatively high stricture rate. In this series of 17

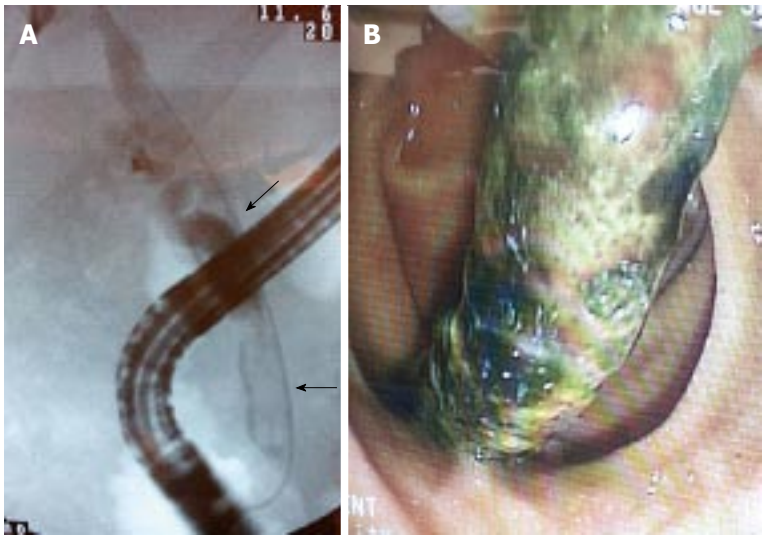

Figure 4 Elongated intraductal filling defects in the choledocus and common hepatic duct suggestive of biliary casts (arrows) (A) and endoscopic view of the successfully removed cast (B).

patients, 8 (47%) patients developed common bile duct strictures following FCSEMS removal; of these, 6 (35%) required repeat endoscopic treatment for a clinically significant stricture, therefore the use of current FCSEMS models cannot be recommended in the post-LT population. In specific situations, endoscopic therapy can be impossible or fail, for example, in the case of large anastomotic leaks associated with hepatic artery compromise or surgically altered anatomy (Roux-en-Y anastomosis). These patients will most often require surgical management.

Biliary strictures

Anastomotic strictures: No standard protocol has emerged for the endoscopic therapy of ASs. By analogy with the more frequent postcholecystectomy biliary stricture, endoscopic therapy of ASs usually requires biliary sphincterotomy plus balloon dilatation (BD) and stent placement (Figure 5). The use of BD alone in early onset anastomotic strictures (the first 2 mo following LT) may be effective. However, despite good initial success, BD alone led to a high rate of recurrent stricture formation[68]. Therefore, the combination of BD and stenting is a more adequate approach[33,65,68-71].

Multiple 10-Fr plastic stents are usually maintained until stricture resolution or for a minimum of 12 mo, with stent exchange scheduled every 3-4 mo to reduce the chance of stent blockage and cholangitis. In a recent systematic review that included 440 LT-related ASs treated with multiple simultaneous plastic stents[72], the mean AS resolution rate was approximately 85% for early as well as late ASs. Higher ASs resolution rates (97% *vs* 78%) and lower ASs recurrence rates (1.5% *vs* 14%) have been reported with stenting durations > 12 mo *vs* < 12 mo. This was observed despite the fact that shorter stenting durations were applied for early *vs* late ASs. Most cases of ASs recurrence were successfully managed with repeat plastic stenting.

Recently, different strategies of AS treatment have been described to decrease patient burden: (1) long-term maximal stent therapy with stent exchange only when signs or symptoms of biliary obstruction are detected: this strategy has allowed minimizing the number of ERCPs needed to treat ASs without compromising success or patient safety. With this protocol, complete AS resolution was reached in 94% of patients and recurrence rate at a median follow-up of 11 mo was 3%[73]. The authors reported in a total of 83 patients 2 cases of post-ERCP pancreatitis, 2 cases of periprocedural bacteremia but no episodes of cholangitis caused by stent occlusion; (2) stent exchange every 2 wk: ERCP with rapid-sequence balloon dilation followed by stenting with multiple stents over a short time period[74]. With this approach, mean stenting duration was 107 d and long-term stricture resolution was achieved in 33 (87%) of 38 patients; ERCP-related complications occurred in 2 (5%) patients. During a mean follow-up of one year after stent removal, 5 (13%) patients had a stricture recurrence, successfully retreated by endoscopic means in 4 cases; and (3) temporary placement of covered self-expandable metal stent (SEMSs). Covered SEMSs offer the advantage of longer stent patency and larger nominal diameter compared with a single plastic stent. Covered SEMSs should be maintained in place for a minimum of 3 mo as shorter stenting durations result in lower ASs resolution (72% *vs* 90%)[75-79]. In the systematic review cited above[72], covered SEMSs had a much higher stent migration rate (16%) compared with simultaneous multiple plastic stenting. Furthermore, covered SEMS carry a low but real risk of tissue ingrowth and stent impaction. Therefore, the authors concluded that current evidence does not suggest a clear advantage of SEMS use over multiple simultaneous plastic stenting in the management of ASs. In a large prospective study that was not included in the systematic review[80], the AS resolution rate using FCSEMSs was 68% of 42 LT patients and the migration rate was 17% and 75% at 3 and 6 mo, respectively. In this study, cholangitis was reported in 24% of patients with LT-related ASs and it

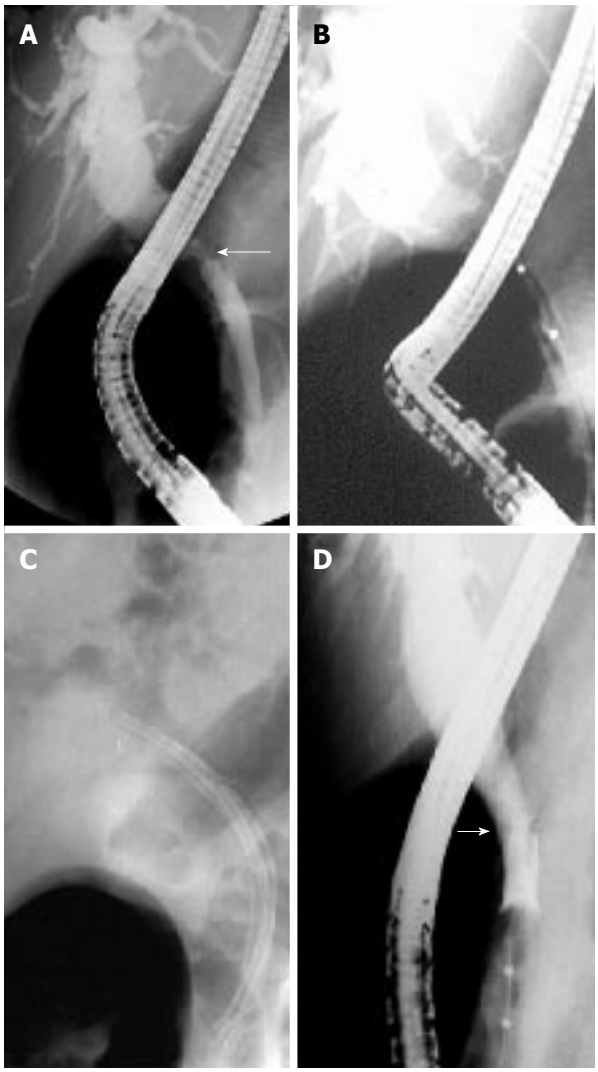

Figure 5 Endoscopic treatment of an anastomotic biliary stricture after deceased donor liver transplantation. A: Late, high-grade, anastomotic stricture (arrow) with a stone partially concealed by the endoscope; B: Stricture dilatation with a 4-mm in-diameter balloon; C: Three 10-Fr plastic stents in place, no residual stone; D: Balloon occlusion cholangiogram showing stricture disappearance at the end of treatment (arrow).

was strikingly associated with stent migration. Finally, a recent randomized trial compared a new design of FCSEMS *vs* multiple simultaneous plastic stenting in 20 patients with LT-related ASs[81]. ASs resolution rates were similar with both stent models but complication rate and hospital stay duration were non-significantly higher with the plastic stent *vs* FCSEMS, suggesting that some FCSEMS designs that effectively prevent stent migration might be a cost-effective alternative to plastic stenting.

Endoscopic management of ASs seemed to be more challenging in LDLT *vs* DDLT due to the complexity of duct-to-duct anastomosis. However, using an aggressive strategy of maximal endoscopic stent placement, two studies reported high (75%-100%) AS resolution rates in LDLT patients[82,83]. The long-term resolution rates of biliary leaks and/or strictures reported in selected retrospective studies are summarized in Table 1[37,82-87].

[1]Combination of percutaneous transhepatic biliary drainage plus endoscopic retrograde cholangiopancreatography (ERCP) in 9 patients and inside stents technique; [2]Combination of percutaneous transhepatic biliary drainage plus ERCP in 6 patients. NR: Not reported.

Factors identified as independent predictors of failed endoscopic treatment of LDLT-related ASs include higher LT recipient age, longer operation duration, and a pouched morphology of the AS[84,88]. Recurrent ASs occur in approximately 21% of patients and may be retreated by endoscopy[83]. PTC plays an important role when a guide wire cannot be inserted through the anastomotic stricture at the time of ERCP (*e.g.*, disconnected duct, some refractory angulated or twisted strictures). For these patients, the rendez-vous technique (PTC + ERCP) may be useful to insert a stent above the stricture. This approach has been demonstrated to be feasible and relatively safe for the management of biliary strictures complicating LDLT with duct-to-duct anastomosis[89]. The endoscopic treatment of some ASs can be unsuccessful and may need long-term stenting or surgical hepaticojejunal anastomosis[87,90].

Non-anastomotic strictures: The endoscopic therapy of NASs or ITBSs often involves the hilum and intrahepatic ducts and is notably more demanding than the therapy of ASs. The stenosis at the level of the sectorial or segmental branch ducts can result in a cholangiographic appearance that simulates primary sclerosing cholangitis. It is challenging to make general recommendations for managing NASs and treatment should be individualized. Treatment success depends upon stricture grade, number, and location. Extra-hepatic strictures generally respond better to therapy and altogether, in the few published reports of endoscopic treatment, the success rates ranged between 50% and 70%[50,91]. Finally, a few patients (especially the ones with complex ischemic intrahepatic strictures) may need surgical revision or retransplantation.

In patients who have undergone Roux-en-Y hepaticojejunostomy, a potential alternative to PTC is the use of various techniques of enteroscopy. In 25 pediatric patients with hepaticojejunal anastomoses, the bilioen-

teric anastomosis could be reached in 17 patients, a stent could be placed in 9 patients and AS resolution was obtained in 5 (20%) patients, showing the difficulty of this procedure[92]. In a series of 44 adults with choledochojejunal AS following various hepato-biliary-pancreatic surgery, temporary stenting (including stent removal) was achieved in 32 (73%) patients and restenosis occurred in 7/32 patients[93].

Other complications

Biliary stones, sludge and casts: In LT recipients, the endoscopic management of stones is similar to that performed in the nontransplant setting although the approach may be complicated by the presence of a stricture downstream from the stone. In such circumstances, delayed stone extraction (following biliary stenting) or advanced endoscopic techniques like intraductal lithotripsy or direct choledocoscopy may be required to achieve stone removal. In patients with serious coagulation disorders or thrombocytopenia where sphincter ablation may be relatively contraindicated, balloon dilatation of the intact sphincter can be applied.

For biliary casts, the endoscopic approaches are alike to those utilized in stone disease. However, the success rate is significantly lower owing to the multiplicity of filling defects located in intrahepatic bile ducts[39]. Treatment usually requires multiple ERCPs, possibly complemented with PTC and it may require retransplantation in a significant proportion of cases[39,94] Cholangioscopy might aid to discriminate biliary casts from strictures[59].

Sphincter of Oddi dysfunction and papillary stenosis

As for SOD in the non-LT setting, biliary sphincterotomy is the common treatment and provides a high success rate[39]. The question of whether these patients are at similar risk of post-ERCP pancreatitis as those who are affected in the non-LT setting has not been formally studied; however it seems reasonable to consider prophylactic pancreatic stenting in addition to standard rectal administration of NSAIDs when performing sphincterotomy in these patients[95].

SUMMARY

Biliary complications remain a burden in LT patients and continue in some cases to be a challenging aspect of the multidisciplinary care of LT patients. As biliary complications are the most frequent complication following LT, the index of suspicion for requesting further investigations should be low. MRCP is the most useful examination to establish the diagnosis, especially because the low sensitivity of US may be more detrimental in LT as compared to the average patient. Successful endoscopic treatment is achieved in most cases, with the notable exceptions of ASs in LDLT patients, NASs and biliary casts. For ASs, temporary simultaneous multiple plastic stenting for a minimum of 12 mo (except in some cases of early AS) remains the standard of care; FCSEMS have yielded disappointing results up to now. In patients with choledocojejunostomy, deep enteroscopy techniques may allow successful treatment but success rates are lower. Nowadays PTC and surgery are reserved for a small minority of patients.

Abstract

The endoscopic approach for biliary diseases in patients with surgically altered gastrointestinal anatomy (SAGA) had been generally deemed impractical. However, it was radically made feasible by the introduction of double balloon endoscopy (DBE) that was originally developed for diagnosis and treatments for small-bowel diseases. Followed by the subsequent development of single-balloon endoscopy (SBE) and spiral endoscopy (SE), interventions using several endoscopes for biliary disease in patients with SAGA widely gained an acceptance as a new modality. Many studies have been made on this new technique. Yet, some problems are to be solved. For instance, the mutual unavailability among devices due to different working lengths and channels, and unestablished standardization of procedural techniques can be raised. Additionally, in an attempt to standardize endoscopic procedures, it is important to evaluate biliary cannulating methods by case with existence of papilla or not. A full comprehension of the features of respective scope types is also required. However there are not many papers written as a review. In our manuscript, we would like to evaluate and make a review of the present status of diagnostic and therapeutic endoscopic retrograde cholangiopancreatography applying DBE, SBE and SE for biliary diseases in patients with SAGA for establishment of these modalities as a new technology and further improvement of the scopes and devices.

Key words: Double balloon endoscopy; Single balloon endoscopy; Spiral endoscopy; Endoscopic retrograde cholangiopancreatography; Roux-en-Y reconstruction

Core tip: This study is a review of the status of diagnostic and therapeutic endoscopic retrograde cholangiopancreatography using several endoscopic methods in patients with surgically altered gastrointestinal

anatomy, evaluating the results from multiple centers over the world. The descriptions of features of the respective endoscopes including the introduction of new endoscopes are summarized. Assessment of the procedures is concretely made by type of reconstruction methods and by type of applied endoscopes, which suggests the present and future challenges to be overcome.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is now one of the most effective diagnostic and therapeutic modalities in patients with biliary diseases. The success rate is > 90% for patients with normal anatomy[1,2], however, ERCP in patients with surgically altered gastrointestinal anatomy (SAGA) is far more challenging because of the inability of the endoscope to reach the blind end due to the long bowel passage, and of the complicated angulation. Some acute angled surgical limbs preclude the scope maneuverability and hinder the scope advancement.

The success of ERCP in patients with SAGA is affected by methods of surgical operations[3], and it often fails despite all the efforts. Consequently, many patients with SAGA are indicated for surgical or percutaneous operations, which is more invasive with greater risk of complications for patients than endoscopic therapy[4]. As an alternative procedure, percutaneous transhepatic cholangiography (PTC) is widely accepted, though is technically limited in such cases as; the absence of the dilated intrahepatic ducts, a contraindication due to the abdominal dropsy or compromised coagulation. In addition, PTC cannot establish an access to the pancreatic duct system[4]. Then surgery is left as the only alternative[5], though it brings about greater adverse events, longer hospital admission, and increased financial costs. Thus, the endoscopic interventional approaches have come to be preferred.

Since Katon *et al*[6] introduced the first endoscopic approach to Billroth-Ⅱ gastrectomy in 1975. In the late 1990s early 2000s, a number of papers studied on ERCP by using forward-viewing endoscopes or standard side-viewing duodenoscopes in various attempts, and the success rates widely ranged in 50%-92%[7-12]. As for Roux-en-Y reconstruction, Gostout *et al*[13] first reported the endoscopic approach in 1988. Since then, many attempts had been made by using duodenoscopes, pediatric colonoscopes, and oblique-viewing endoscopes, though the success rate was 33%-67% which was not satisfactory[12,14-16]. However, the advent of recently developed balloon assisted endoscopy (BAE) and spiral endoscopy (SE) radically gained the efficacy of endoscopic interventions in post-operative patients with not only Billroth-Ⅱ gastrectomy but also with Roux-en-Y reconstruction.

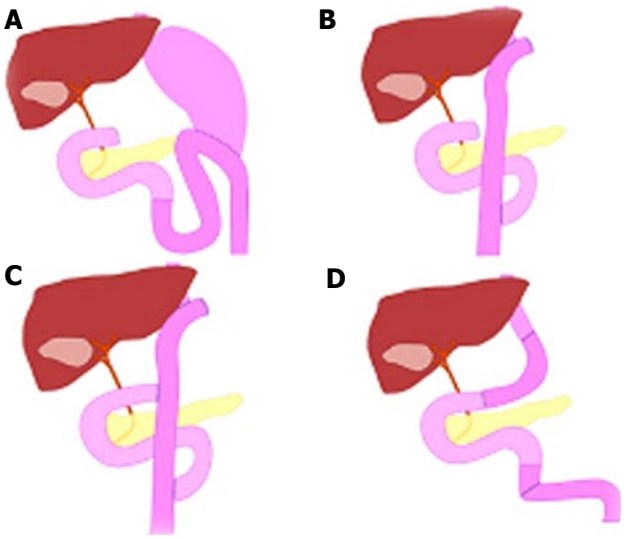

Figure 1 Schema of types of surgical anatomic reconstruction from gastrectomy. A: Billroth Ⅱ reconstruction; B: Roux-en-Y reconstruction; C: Double-tract reconstruction; D: Jejunal pouch interposition.

SURGICALLY ALTERED ANATOMY

In Japan, pancreaticoduodenectomy for treatment of pancreatic carcinoma and a total or partial gastrectomy for treatment of gastric diseases are often encountered. There are four common types of surgical anatomic reconstruction from gastrectomy; Billroth-Ⅱ reconstruction, Roux-en-Y reconstruction, double-tract reconstruction and jejunal pouch interposition (Figure 1). The number of Billroth-Ⅱ reconstruction has decreased due to the effective treatment of peptic ulcer disease whereas that of Roux-en-Y reconstruction has increased due to the recent spread of laparoscopic surgery. There are three common types of surgical anatomic reconstruction from pancreaticoduodenectomy; the Whipple Method, the (modified) Child surgery, the Cattell Method, and the Imanaga Method (Figure 2). Currently in Japan, the modified Child surgery is the first line reconstruction method for pancreaticoduodenectomies.

In United States in contrast, Roux-enY gastric bypass (RYGB) for morbid obesity[17-20], hepaticojejunostomy for living donor liver transplantation (LDLT)[21,22] or treatment of biliary injury or disease[23,24], and pancreaticoduodenectomy for ampulla neoplasia and pancreatic carcinoma[25,26] are more frequently encountered types of surgically altered anatomies. Because the severe morbid obesity is rarely encountered in Japan, RYGB for obese is not common and neither is hepaticojejunostomy for LDLT.

ENDOSCOPES

The invention of deep endoscopy has revolutionized the management of patients with mid-small-bowel diseases. Since the first introduction of double-balloon endoscopy (DBE) by Yamamoto[27] in 2001 (Figure 3), two additional techniques have become available, single-balloon endoscopy (SBE)[28,29] (Figure 4) and spiral endoscopy (SE)[30,31] (Figure 5). DBE and SBE entail a similar mechanism of advancement consisting of sequential bowel pleating by a push-pull technique that uses a balloon-fitted overtube with or without a second balloon inserted over the tip of a dedicated endoscope. The maneuver of the balloon or balloons in combination helps to hold and fix the intestine allowing the deep insertion by shortening the intestine. The inserting method of DBE (Figure 6) and SBE (Figure 7) is as shown in schemas. This technique enables the scope advancement selectively or retrogradely to reach the blind end in altered gastrointestinal anatomy with a high success rate. In contrast, SE is based on a different concept of insertion that pleats small bowel onto the endoscope to advance it through the lumen useing a rotating overtube [Discovery SB overtube (DSB); Spirus Medical, Inc., Stoughton, MA, United States]. This technique uses a spiral or raised helix-fitted overtube coupled with the endoscope, advanced as a unit into the small bowel by continuous rotation of the overtube in a manner similar to use of a corkscrew. An inner sleeve allows the independent motion of the overtube from the endoscope during advancement and withdrawal. The main difference between BAE and SE is that the latter uses a more or less continuous pleating of the small bowel by a clockwise rotation of the overtube rather than the push-pull technique. Unfortunately, SE is not currently commercially available.

Figure 5 Spiral endoscopy. Discovery SB overtube over the snteroscope.

Characteristic of DBE

There are two types of DBE. One is with a 2.2 mm working channel for observations, introduced in 2003. The DBE, EN-450P (FUJIFILM, Osaka, Japan) and the other is for treatments with a 2.8 mm working channel. For the treatment-type scope, it can be sorted into two types. The first type was introduced in 2004, the standard type DBE, EN-450T5 (FUJIFILM, Osaka, Japan) with a 2.8 mm working channel and a 200 cm working length. The second type is the short type DBE, EC-450BI5 (FUJIFILM, Osaka, Japan) with a 2.8

mm working channel and a 152 cm working length that was introduced in 2005 as a colonoscope, and subsequently in 2011 another short type DBE EI-530B (FUJIFILM, Osaka, Japan) was introduced with a 2.8 mm working channel and a 152 cm working length as a pancreatobiliary scope. The short type DBE with the 152 cm working length is preferred and used rather than the standard type DBE with the 200 cm working length to perform ERCP in patients with (SAGA), because the 152 cm working length of the short type DBE allows the availability of almost all the ERCP-related devices, whereas the 200 cm working length limits the use of those devices.

In 2013, the treatment-type scope (EN-580T; FUJIFILM, Osaka, Japan) with a 3.2 mm working channel was introduced after further improvement, though it remained as the standard type with a 200 cm working length. For the use in ERCP in patients with SAGA, further development of short type DBE is strongly expected.

Characteristic of SBE

In 2007, Olympus introduced the standard type SBE (SIF-Q260; Olympus Medical Systems, Tokyo, Japan) with a 2.8 mm working channel and a 200 cm working length. Currently in Japan, only the standard type SBE is commercially available. Though, the short type SBE with a 3.2 mm working channel and a 152 cm working length (SIF-Y0004; Olympus Medical Systems, Tokyo, Japan), has been newly developed as the first-generation prototype. Some papers have been already written about the use of this scope for ERCP reporting that the 3.2 mm-working channel of the short type SBE allowed a smooth pushing-in and pulling-out action of devices, facilitating the employment of devices including a covered metallic stent that had been not applicable with the 2.8 mm working channel, which consequently enabled almost all the treatments that were equivalent to those of the conventional ERCP[32-35]. Additionally, the short type SBE (SIF-Y0004; Olympus Medical Systems, Tokyo, Japan) has been recently introduced as the second-generation prototype. This new endoscope is equipped with a passive bending part. This device helps the scope to pass and advance smoothly in the small intestine, which makes a special feature of this scope, as well as the 3.2 mm working channel that facilitated almost all the treatments equivalent to those of conventional ERCP. Some papers have been already written about ERCP using this scope[34,35], implying that deep insertion to the blind end using the second-generation prototype was easier than that using the first-generation prototype. With the equipment of this new device, the excelling performance in deep insertion to the blind end seems to be highly expected. Characteristics of BAE are summarized in Table 1.

ENTERING THE AFFERENT LIMB BY TYPE OF SURGICAL RECONSTRUCTION

The method of insertion to the blind end differs according to the type of surgical reconstruction. A full comprehension of every feature of respective reconstruction method is essential.

Billroth Ⅱ gastrectomy

In a case with Billroth Ⅱ gastrectomy, there are short afferent loop (SAL) and long afferent loop (LAL). The latter contains a jejunojejunostomy called the Braun anastomosis between the afferent and the efferent limbs. As for SAL, the angulation of gastrojejunostomy is acute, and it is difficult to identify the intestinal orifice that is possibly-be-the afferent limb, as well as to insert. The afferent limbs often appear in the upper left direction over the normal anastomosis in the monitor with its lumen closed. Generally, identification of the afferent limb is challenging due to the complicated angulation of gastrojejunostomy, however once the scope is inserted, the blind end can be reached using conventional scopes such as duodenoscopes or forward-viewing endoscopes in a short time owing to the short length of afferent limb. Ciçek *et al*[36] reported that the success rate of reaching the blind end in patients with simple Billroth Ⅱ gastroenterostomies using the duodenoscope was 83%.

In LAL, identification of the afferent limb is easy and the angulation is obtuse, which facilitates the scope insertion to the afferent limb because two intestinal orifices should be visible from the gastric lumen and either can be inserted easily. However due to the

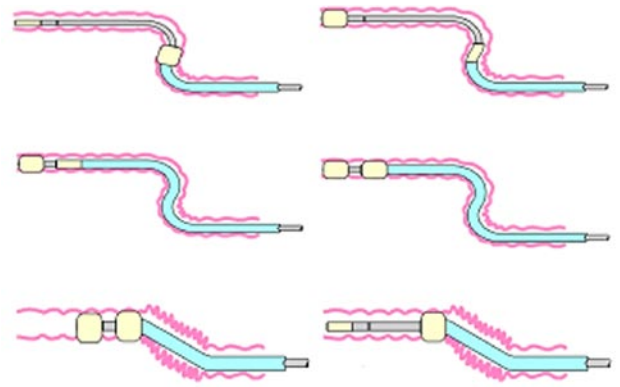

Figure 6 Schema of double-balloon endoscopy insertion.

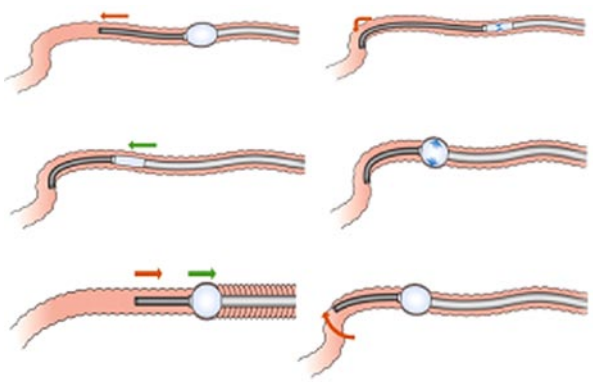

Figure 7 Schema of single-balloon endoscopy insertion.

longer length of the afferent limb it requires a longer duration to reach the blind end. It also precludes the advancement to the blind end. Thus, deep insertion using the conventional scopes is quite difficult.

In patients with both a Billroth Ⅱ gastroenterostomy and an additional Braun anastomosis, Çiçek *et al*[36] reported that the success rate was lowered to 29% for reaching the blind end. Whereas, Wu *et al*[37] reported the success rate of reaching the blind end in patients with both a Billroth Ⅱ gastroenterostomy and an additional Braun anastomosis was 90% even by using duodenoscopes by inserting the middle entrance of the lumen. Lin *et al*[38] reported the success rate of reaching the blind end using a duodenoscope was 69%. Furthermore in all the unsuccessful cases DBE was employed for the reattempted session and could successfully access the blind end. Also, in our previous report using short type DBE, the success rate of reaching the blind end was 100%[39]. In cases with Braun anastomosis, we would also attempt the insertion to the middle entrance as Wu *et al*[37] reported. The Braun anastomosis shows like a maze. It is often considered as a disadvantage for endoscopic insertion, however when the efferent limb was entered by error, the scope can always return from the Braun anastomosis to the efferent limb. Applying the technique to insert the middle entrance, the Braun anastomosis is not necessarily a disadvantage for the scope insertion, rather can be an advantage.

Roux-en-Y reconstruction

In a case with Roux-en-Y reconstruction, identification of the afferent limb in Y anastomosis is very difficult. Also, the insertion is possibly hindered by the acute angulation of the afferent limb and the severe adhesion as a consequence of the long intestine to the blind end. In comparison with the cases of Billroth Ⅱ gastrectomy, entering the afferent limb in cases with Roux-en-Y reconstruction is considered much more difficult. There are three challenges to be overcome for a successful insertion in cases with Roux-en-Y reconstruction.

The first challenge is identification of the afferent limb. It is difficult to identify the afferent limb in jejunojejunal anastomoses. Because of the maze-like feature of that area, endoscopists often lose their way or misjudge the orientation. Recently, Yano *et al*[40] reported a method using an intraluminal injection of indigo carmine to identify the afferent limb. The success rate was 80%, which suggests it should be helpful in identification of the afferent limb. However, the success rate based on our experience was approximately 50%. (unpublished observations) The divergence of the results could be reasoned that Yano *et al*[40] performed the procedure with the patient in a left-lateral position, whereas we performed in a pronation. Different postures in patients could have caused the divergence between the results.

The second challenge is the management of the complicated angulation in jejunojejunal anastomosis and the length of the afferent limb. It requires endoscopist's experience and skill to control the of sharp angulation of jejunojejunal anastomosis in order to reach the afferent limb, which in some patients forms an angle of up to 180 degrees. Shah *et al*[41] reported the success rate of deep insertion could be raised by change of patient's position from the typical semi-prone to a left-lateral or supine position during the procedure. Roux-en-Y gastric bypass (RYGB) is a particularly challenging postsurgical anatomy in terms of the length of the afferent limb. It consists of the long limb (often > 100 cm) that is traversed from the gastrojejunal orifice to the jejunojejunal anastomosis to reach the afferent small-bowel limb[14]. This reconstruction method is frequently performed in the United States for morbid obesity. Therefore, it was reported laparoscope-assisted ERCP was more efficient than endoscope-assisted ERCP for RYGB[42,43]. The RYGB is infrequently performed in Japan. We assume that the primary disease and application of surgery method differ to some extent in gastrointestinal anatomy between the United States and Japan.

Adhesions are the third challenge, which are frequently observed in patients with SAGA. In Japan, lymphadenectomy of malignant tumors is likely to be performed, which often results in post-surgical severe adhesion. They often preclude the scope advancement, and if scope insertion to this lesion is forced by power, it increases a risk of perforation and bleeding. Therefore

a careful maneuver and the discretion to withdraw are necessary for endoscopists.

In order to challenge these three obstacles, various attempts have been made and reported. Hintze *et al*[12] reported that the success rate of reaching the ampulla in Roux-en-Y anastomoses was 33%, compared with 92% in Billroth Ⅱ anatomy. Wright *et al*[14] reported a use of colonoscopy to access the biliary orifice and a guide wire for a duodenoscope to attempt ERCP in 15 patients with long-limb Roux-en-Y anastomoses. Kikuyama *et al*[16] used the oblique-viewing endoscope in couple with an overtube and reported a high success rate, though it was based on the small case series. Generally the results were not sufficiently practical or satisfactory.

Recently, two multicenter studies have been reported on the use of overtube-assisted endoscopy in the United States. One multicenter study[41] observed 129 patients (180 procedures) focusing only on Roux-en-Y reconstruction, and reported that the success rate of reaching the papilla or the hepaticojejunostomy site was 71% using several scopes such as DBE, SBE and SE. They concluded there was no divergence in the result caused by the type of applied scopes, however, in the 3/4 of unsuccessful cases where endoscopy-ERCPs failed were simply due to the failure of reaching the blind end, which suggested that the success of endooscopy-ERCPs were significantly affected by the result of the deep insertion to the blind end. It indicates that insertion to the blind end is quite challenging and prerequisite for performing ERCP in cases with Roux-en-Y reconstruction. The other multicenter study[44] focused on ERCP in 79 patients using the short-type DBE for several anatomical variations. The success rate of reaching the blind end was 90% (based on success rates of 82% for Roux-en-Y gastric bypass, 95% for pancreatoduodenectomy, and 100% for Billroth Ⅱ gastrectomy, hepaticojejunostomy, Roux-en-Y hepaticojejunostomy, Roux-en-Y gastrojejunostomy, choledochojejunostomy, and Roux-en-Y pancreaticojejunostomy). They reported a very high success rate of 90% to reach the papilla or the hepaticojejunostomy site applying only the short type DBE. They raised two points as reasons for their good result owing to several advantages regarding the short DBE, which is quite agreeable: (1) DBE might have better maneuverability than the long conventional DBE, which is especially useful in patients with post-surgical severe adhesions; and (2) DBE allowed endoscopists to apply a power pressure more effectively to the endoscope, which might have raised the success rate of reaching the papilla or anastomosis.

REACHING THE BLIND END WITH OVERTUBE-ASSISTED ENDOSCOPY

Reaching the blind end with BAE

SBE and DBE are based on the same concept of insertion. The difference is the presence or absence of the balloon at the tip of the endoscope. The absence of a balloon fitted to the tip of the endoscope impairs the stability in case with severe adhesions around the blind end. The slippery feature of intestine prevents the tip of the endoscope from being fixed still and orienting into the required direction to follow the overtube, which eventually hinders the deep advancement of overtube. Tsujikawa *et al*[28] suggested that the DBE was advantageous in cases with sharp angulations of the small intestine, because the balloon on the tip of the DBE could help pass around such angulations better than the hook-shaped tip of the SBE. In comparison with DBE, it is assumed that SBE is more disadvantageous in a performance of deep insertion. Shah *et al*[41] reported the success rates of reaching the blind end in patients with Roux-en-Y gastric bypass using standard type SBE (n = 22) or DBE (n = 15), using both the standard and the short type DBE, was 73% in the SBE group and 87% in the DBE group. It suggested that DBE showed a better performance in deep insertion to the blind end. However, the new short type SBE with the passive bending part has been introduced in order to improve the success rate of insertion to the blind end. Obana *et al*[33] reported the success rate of insertion to the blind end using the short type SBE without the passive bending part was 73%, which was relatively low. Recently we have reported the success rate using the short type SBE with the passive bending part was 92%[34]. We assume that the success rate of deep insertion to the blind end might have been raised by the use of short type SBE equipped with the passive bending part. Today several challenges are yet to be overcome for deep insertions using BAEs into the blind end.

Reaching the blind end with SE

SE is based on the totally different concept of insertion from that of BAE. Previous small studies have suggested that SE allow more efficient advancement into the small bowel than BAE, however, there are not much paper written regarding the insertion to the blind end in patients with (SAGA) using SE. Therefore, sufficient data are not available to evaluate the SE in point of success rate of deep insertion, complication morbidity and efficacy. To evaluate the efficacy and the safety of this method, more studies and assessment in a larger number of cases are necessary.

OVERTUBE-ASSISTED ERCP

Many studies of DBE-assisted ERCP have been made since 2007[39,41,44-61]. And studies of SBE-assisted ERCP were subsequently introduced in 2009[62-69], followed by the studies of SE-assisted ERCP in 2011[70-72]. As the DBE was introduced prior to the development of the SBE and SE, there existed more number of reports of successful ERCP using DBE in patients with PD than that of the SBE and SE. In comparison of the results before and after the advent of BAE and/or SE, it is obvious that

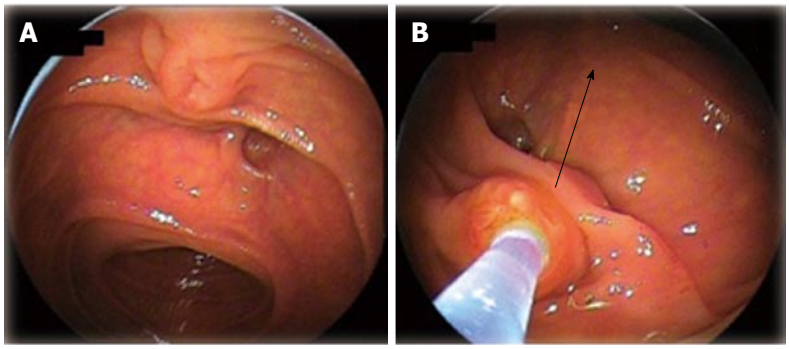

Figure 8 Biliary cannulation using double-balloon endoscopy in a patient with papilla. A: Papilla when the blind end was accessed; B: Locating papilla in 6 o'clock direction in the monitor, and performing cannulation adjusting the axis of catheter into 12 o'clock direction along the biliary duct.

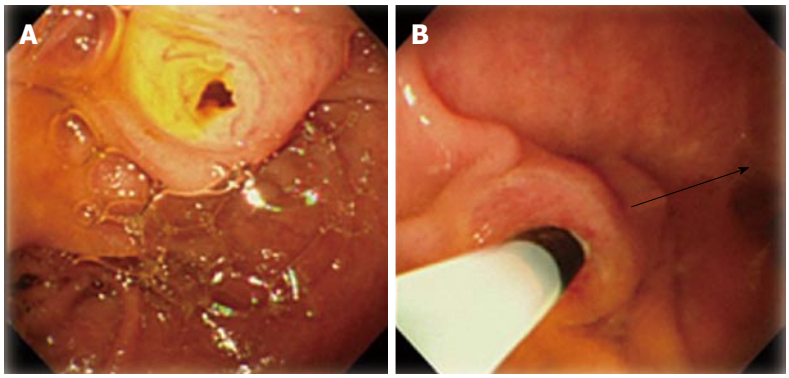

Figure 9 Biliary cannulation using single-balloon endoscopy in a patient with papilla. A: Papilla when the blind end was accessed; B: Locating papilla in 8-9 o'clock direction in the monitor, and performing cannulation adjusting the axis of catheter into 3 o'clock direction along the biliary duct.

the success rate has radically improved to a satisfactory level.

DBE-assisted ERCP

There are a lot of studies on DBE-assisted ERCP with wide ranging results. The success rate of ERCP-related interventions varied 60%-100%[39,41,44-61], which was probably because many studies were based on a small number of cases. We have reported a large case single center study[39], as a single center study in which we evaluated 103 procedures DBE-assisted ERCP by type of reconstruction method in 68 patients. The overall success rate for ERCP was 95% (based on success rates for Roux-en-Y reconstruction, Billroth Ⅱ reconstruction, and pancreatoduodenectomy of 91%, 100%, and 100%, respectively). In all successful ERCP cases, endoscopic therapeutic interventions were successfully accomplished. One multicenter study[41] reported the overall ERCP success rate was 63%. The success rate of ERCP using SBE and DBE was similar between Roux-en-Y gastric bypass and other long-limb surgical bypass. It also reported that the success rate of ERCP in cases where the blind end was successfully reached was 88%, which was satisfactory though they explained the success rate was lowered because many cases had contained papilla. Itoi *et al*[63] reported the success rate of ERCP using the standard type SBE was 72.3% mentioning that the biliary approach in patients with naïve papilla was difficult[63]. It is agreeable, however, in our previous study[39], the success rate of cannulation into papilla was 97%, suggesting the different type of applied scopes could affect the divergence of the results. For instance, because the position of the working channel of DBE is located at 6:30, an attempt to bring the papilla in a 6 o'clock direction in monitor will allow a down-angled maneuver that helps to fix the papilla still by a direct power pressure, which facilitates a stable cannulation (Figure 8). Whereas, the position of the working channel of SBE is located at 9 o'clock, which makes difficult to fix the papilla, precluding a stable cannulation as a consequence (Figure 9). Whereas Shah *et al*[41] concluded the type of scopes did not affect their result, though they used mostly the standard type DBE and SBE with the 200 cm working length in many cases. Namely, it could be inferred that not only using the DBE but the short type was the best appropriate scope for cannulation in cases with papilla. Siddiqui *et al*[44] reported the overall ERCP success rate using only the short-type DBE was 90% raising a reason for the excellent result as; the short DBE allowed the use of commercially available ERCP cannulas for performance of wire-guided cannulation, and therapeutic instruments could be applied to carry out successful therapeutic treatments.

SBE-assisted ERCP

Dellon *et al*[64] evaluated a use of the standard type SBE for diagnostic and therapeutic ERCP. They observed 4 patients with Roux-en-Y anatomy in total. (1 patient with RYGB, 2 patients with Roux-en-Y anatomy caused by bile duct injury, and 1 patient with Roux-en-Y anatomy after liver transplantation). The overall success rate of the therapeutic ERCP on the first session was 50%. In this report, the standard type SBE with 200 cm working length that was only applicable to limited variety of devices was used for the therapeutic ERCP,

Table 2 Review studys evaluating endoscopic retrograde cholangiopancreatography using several enteroscopy in patients with altered gastrointestinal anatomy

Ref.	No. of cases	Type of scope	Enteroscopy success (%)	Success rate of ERCP	Overall ERCP success (%)

ERCP: Endoscopic retrograde cholangiopancreatography; DBE: Double balloon endoscopy; SBE: Single-balloon endoscopy.

which could have caused the unsatisfactory success rate of SBE-assisted ERCP.

However, along the recent development of the short type SBE, several reports have been made on the short type SBE-assisted ERCP. The overall success rate of ERCP was 78%-90%, which was higher than that of ERCP using the standard type SBE. It could be reasoned that the 152 cm working length allowed the use of more variety of available devices.

SE-assisted ERCP

Although only published in abstract form, some studies on SE-assisted ERCP have been made. In a multi-center study, Shah *et al*[41] reported 129 patients with surgically altered anatomy who underwent ERCP using SBE (*n* = 15), DBE (*n* = 22), and SE (*n* = 13). The ERCP success rates of each method were 60%, 63%, and 65%, respectively. Lennon *et al*[70] discussed the comparison of SE and SBE. They concluded there was no significant difference between SE and SBE, and their overall ERCP success rate was 44%.

A review of studies evaluating overtube assisted ERCP in patients with (SAGA) *via* various techniques is summarized in Table 2.

COMPLICATIONS

It is assumed that the morbidity of complications is affected by type of applied endoscopes and by method of surgical reconstruction. The common complications for overtube-assisted ERCP are comparable with those of conventional ERCP such as bleeding, perforation, and post-ERCP pancreatitis. There are few studies made only in a small case series, however, the actual rates of perforation, bleeding, and pancreatitis associated with overtuve-assisted ERCP is unknown.

Performing ERCP in Patients with SAGAposes a greater risk of complications than in patients with NGA[73,74]. The risk of retroperitoneal perforation in patients with Billroth II surgery has been reported as high as 7%-10%[74]. Regarding Roux-en-Y reconstruction, our previous study retrospectively observed 55 procedures, reporting that procedural complications developed in 5 of 55 procedures (9%)[39]. Shah *et al*[41] retrospectively observed 129 patients, reporting that procedural complications were observed in 16 of 129 patients (12%), including pancreatitis (mild = 4, severe = 1), mild bleeding (*n* = 1), abdominal pain requiring hospital admission (*n* = 3), and throat pain requiring physician contact (*n* = 4). Two perforations were also observed and 1 case of death occurred. However, apart from those, studies based on only small case series can be found[75,76]. In order to evaluate the safety and efficacy of the procedure, it is necessary to analyze and evaluate data of complications out of large case studies from multiple centers prospectively, particularly for Roux-en-Y reconstruction.

CONCLUSION

The endoscopic approach to PD in patients with (SAGA) has radically become practical. Development of new modalities such as DBE, SBE, and SE is in progress as a consequence of an increased demand for the endoscopic interventions. For the safety and a higher success of the procedures, further development of the scopes and devices, standardization of technical maneuverability, establishment of guidelines in decision making of indicated and contraindicated cases, and assessment of complications from a larger multi-center study are necessary.

Abstract

Endoscopic ultrasound (EUS) has emerged as an important diagnostic and therapeutic modality in the field of gastrointestinal endoscopy. EUS provides access to many organs and lesions which are in proximity to the gastrointestinal tract and thus giving an opportunity to target them for therapeutic and diagnostic purposes. This modality also provides a real time opportunity to target the required area while avoiding adjacent vascular and other structures. Therapeutic EUS has found role in management of pancreatic fluid collections, biliary and pancreatic duct drainage in cases of failed endoscopic retrograde cholangiopancreatography, drainage of gallbladder, celiac plexus neurolysis/blockage, drainage of mediastinal and intra-abdominal abscesses and collections and in targeted cancer chemotherapy and radiotherapy. Infact, therapeutic EUS has emerged as the therapy of choice for management of pancreatic pseudocysts and recent innovations like fully covered removable metallic stents have improved results in patients with organised necrosis. Similarly, EUS guided drainage of biliary tract and pancreatic duct helps drainage of these systems in patients with failed cannulation, inaccessible papilla as with duodenal/gastric obstruction or surgically altered anatomy. EUS guided gall bladder drainage is a useful emergent procedure in patients with acute cholecystitis who are not fit for surgery. EUS guided celiac plexus neurolysis and blockage is more effective and less morbid vis-à-vis the percutaneous technique. The field of interventional EUS is rapidly advancing and many more interventions are being continuously added. This review focuses on the current status of evidence vis-à-vis the established indications of therapeutic EUS.

Key words: Endosonography; Pancreatic pseudocyst; Celiac plexus; Choledochostomy; Cholecystostomy; Photochemotherapy; Abdominal abscess; Common bile duct; Pancreatic duct; Endoscopic ultrasound-guided fine needle aspiration

Core tip: Therapeutic endoscopic ultrasound (EUS) has found role in management of pancreatic fluid collections, biliary and pancreatic duct drainage in cases of failed endoscopic retrograde cholangiopancreatography, drainage of gallbladder, celiac plexus neurolysis/blockage, drainage of mediastinal and intra-abdominal abscesses and collections and in targeted cancer chemotherapy

and radiotherapy. The field of interventional EUS is rapidly advancing and many more interventions are being continuously added. This review focuses on the current status of evidence vis-à-vis the established indications of therapeutic EUS.

Endoscopic ultrasound (EUS) is an important diagnostic and therapeutic technique in the field of gastroenterology. The ability to visualise and access organs in vicinity of the gastrointestinal tract has opened this exciting field with many interventional EUS procedures now overtaking conventional approaches for treatment of various gastrointestinal diseases. While advances have been made in all aspects of diagnostic and therapeutic EUS, the present review will focus on advances in therapeutic EUS and use of EUS in drainage of pancreatic collections, celiac plexus neurolysis, biliary/pancreatic duct drainage, and in the drainage of intra-abdominal abscesses.

EUS GUIDED DRAINAGE OF PANCREATIC FLUID COLLECTIONS

Pancreatic fluid collections

Acute and chronic pancreatitis can be complicated by collections of varying nature composed of pancreatic juice and varying amounts of necrotic debris in patients with acute necrotising pancreatitis[1]. The morphological characteristics of pancreatic collections complicating acute pancreatitis seem to change with time and the amount of solid necrotic debris lessens with time[2]. Pancreatic fluid collections need to be drained if they get infected or become symptomatic and cause abdominal pain, gastric outlet obstruction or biliary obstruction. Radiological, surgical and endoscopic approaches have been used to drain pancreatic collections[3,4]. Broadly, collections needing drainage early in the course of illness when a wall has not yet formed are drained *via* percutaneous interventions while endoscopic drainage is feasible late in the course when wall has formed[5]. The distinction between the types of collection is important before drainage as the nature and outcome of drainage depend to a large part on the amount of solid debris present in the pancreatic fluid collections (PFCs)[6-8]. While non-necrotic collections have an excellent outcome with endoscopic drainage, the fate of necrotic collections is not as good. In one report while treatment success was 93.5% in pseudocyst drainage it was much lower at 63.2% for drainage of walled off necrosis[9]. Morphologic features like size and amount of debris predict the number of procedures needed as increasing size and amount of debris predict more number of procedures[8].

Endoscopic drainage vs EUS-guided drainage

While many centres continue to perform pancreatic pseudocyst drainage endoscopically, there is some evidence to suggest that EUS-guided drainage may be preferable. Two randomised trials have indicated a higher technical success especially in non-bulging lesions (Table 1)[10,11]. EUS-guided drainage is preferable in certain other clinical scenarios like presence of portal hypertension, collaterals around the collection, and presence of calcification in the wall[14,15]. A meta-analysis of available studies suggest that the technical success rates are higher for EUS guided drainage but the short term and long term results appeared to be similar[12]. In one of the report comparing the endoscopic and EUS guided drainage, median hospital stay was reported as similar with the two modalities[11]. Both reports indicate that the procedure time was not significantly different with either of the modality[10,11].

EUS guided drainage of PFCs

The drainage using EUS is done by using a linear echoendoscope which is advanced into the stomach or duodenum. The window is assessed using colour Doppler for any regional vascularity as well as the distance between the gastrointestinal tract wall and the cyst is measured. A 19 gauge EUS fine needle aspiration (FNA) is utilised to access the collection and contents aspirated for visual assessment as well as for analysis (cultures, amylase and carcinoembryonic antigen levels). Following this a guidewire is coiled into the cyst cavity and the tract is dilated[6,7,16]. Following this various modifications are available for the drainage of PFCs including single or multiple stentings, multistep procedure with initial nasocystic drain followed by placement of stent or insertion of fully covered self-expanding metallic stents[17]. Also, after resolution of PFC, removal of transmural stents may result in recurrence of PFCs[18]. Long term indwelling plastic stents, especially in patients with disconnected duct, is a preferred approach currently in these patients[19]. Multiple authors have reported good results of EUS guided drainage and Table 2 shows important studies reporting outcomes with EUS-guided drainage of PFCs[20-36].

Innovations

Use of metallic stents: Use of self expanding metallic stents (SEMS) has recently been advocated as they may provide a better drainage because of wider diameter and thus a quicker resolution of the symptoms[37]. Various removable stents with anti-migration features have been introduced for drainage of PFCs. Fully covered stents with dumbbell like shape have been introduced which provide lumen apposition and have lesser chances of migration[38]. Various innovations like insertion of plastic pigtail stents to prevent migration

Table 1 Comparison between endoscopic *vs* endoscopic ultrasound-guided drainage of pancreatic pseudocysts

Ref.	Patients and methods	Results
Park *et al*[10]	Randomised trial of conventional *vs* EUS guided drainage of pancreatic pseudocysts (n = 60)	EUS guided drainage has higher technical success (94% *vs* 72%). EUS preferable in non-bulging collections. Complications and pseudocyst resolution similar
Varadarajulu *et al*[11]	RCT of conventional *vs* EUS guided drainage (n = 15 each)	Higher technical success in EUS guided procedure (100% *vs* 33%) with lesser complications
Kahaleh *et al*[12]	Conventional drainage in bulging pseudocysts and absence of portal hypertension *vs* EUS guided in rest (n = 99)	No differences in short term or long term success and similar complications
Barthet *et al*[13]	Algorithm based approach of transpapillary (for small), EUS guided (nonbulging) or Conventional drainage of pseudocysts	EUS guided approach needed for atleast half of the patients

EUS: Endoscopic ultrasound; RCT: Randomized controlled trials.

Ahn *et al*[27]	47 patients with pseudocyst	Technical success: 89% Clinical success: 100%
Will *et al*[28]	132 patients: 31 pseudocysts (n = 32), 115 abscesses/WON	Technical success: 97% Clinical success: 96%
Seewald *et al*[29]	70 patients: including pseudocyst, WON, abscess	Technical success: 97.5% Clinical success: 83%
Puri *et al*[30]	40 patients with pseudocyst	Technical success: 100% Clinical success: 97%
Kato *et al*[31]	67 patients with pseudocyst	Technical success: 88% Clinical success: 83%
Künzli *et al*[32]	108 patients	Technical success: 97% Clinical success: 84%
Siddique *et al*[33]	87 patients with WON	Technical success: 99% Clinical success: 73.5%
Hocke *et al*[34]	30 patients with WON	Technical success: 96.7% Clinical success: 83.4%
Jürgensen *et al*[35]	35 patients with WON	Technical success: 100% Clinical success: 97%
Yasuda *et al*[36]	57 patients with WON	Technical success: 100% Clinical success: 75%

WON: Walled off necrosis; EUS: Endoscopic ultrasound; PFCs: Pancreatic fluid collections.

have been employed with these stents[39]. The major benefit of SEMS is likely to be in walled off necrosis (WON) as they may provide ease of repeated access for necrosectomy, however this remains to be proven in prospective studies. Table 3 depicts the studies where metallic stents were used in management of PFCs.

Non-fluoroscopic drainage: It has been demonstrated that EUS-guided drainage is feasible even without fluoroscopic control[6,48]. Seicean *et al*[48] have demonstrated the utility of EUS in drainage of PFCs in 24 patients and documented complete resolution in 83.3% cases. However difficulty arose in PFCs with thickened wall for which fluoroscopic control was recommended by the authors. We have also demonstrated the efficacy of EUS in draining non-bulging PFCs in 20 patients in absence of fluoroscopic control. Only one patient needed percutaneous intervention amongst these 20 patients[6]. In another report of EUS guided drainage of 22 patients with PFCs, drainage was technically feasible in 19 patients even in absence of fluoroscopy. Success after single procedure was noted in 59% patients[49].

Creation of multiple drainage routes: In management of walled off necrosis, creation of a single enteral opening may not provide adequate drainage of the collection. In this regard it may be better to have multiple access sites into the cavity which may help in improving drainage and irrigation of the cavity. Dual modality drainage involving percutaneous and endoscopic drainage simultaneously has been advocated for achieving this end[50]. A purely endoscopic procedure: EUS guided multi transluminal gateway technique has been evaluated and reported to have a high success (91.7%) vis-à-vis convention drainage (52.1) in a non-randomised study[51]. Prospective reports validating this approach are awaited.

Forward viewing echoendoscope: A multicentre randomised trial reported use of a forward viewing echoendoscope for drainage of PFCs. The technical success rates, mean procedure times, ease of access and complication rates were similar to the oblique-viewing echoendoscope indicating lack of any benefit with use of forward viewing echoendoscope for drainage of PFCs[52].

Others

Access to the cavity may be difficult in patients with thick wall between the gastric/duodenal lumen and the cavity and therefore the tract may be difficult to dilate. To overcome this use of wire guided bent needle knife to obtain a wide access has been used[53]. A double guidewire technique utilising a double lumen catheter has been advocated to avoid the hassle of repeated need for cannulation of pseudocyst for placing multiple endoprosthesis[54]. A modification of the dual-lumen biliary brush catheter has also been used to place multiple guidewires into the cyst cavity and thereby allowing placement of multiple stents[55]. A novel exchange free access device has also been used for EUS guided drainage of PFCs and has an inner trocar for puncture and an outer dual balloon for dilatation of the tract reducing the need for multiple exchanges[56,57]. Numerous other innovations like use of hydrogen peroxide and streptokinase have been used but comparative data vis-à-vis control group is not yet available[58,59].

Drainage of PFCs is an important therapeutic application of EUS with excellent technical and clinical outcomes. We believe that merely dividing walled off PFCs into pseudocysts and WON may be too simplistic and it would be better to have three subgroups including acute postnecrotic pseudocyst (< 10% solid debris), walled off liquid necrosis (10%-40% solid content) and walled off solid necrosis (> 40% solid debris) as this has implications on management and success of endoscopic drainage[60]. We have previously shown that the amount of necrosis predicts the therapy needed in PFCs. Whilst those with < 10% debris need only one session of drainage, those with 10%-40% solid debris needed ≥ 2 sessions and the group with even higher (> 40%) debris needed direct endoscopic debridement or surgical necrosectomy[8]. Based on this, we follow an algorithmic approach (Figure 1) for management of PFCs at our institution.

EUS GUIDED BILIARY ACCESS

Endoscopic retrograde cholangio-pancreaticography (ERCP) is the standard approach to drain an obstructed biliary tract but may fail due to a number of factors like inaccessible papilla or a failure to cannulate it. In these situations, radiological or surgical drainage is needed. EUS guided biliary drainage is emerging as an alternative to a failed ERCP[16]. EUS guided approaches include transmural drainage (hepaticogastrostomy or choledochoduodenostomy), a rendezvous procedure or an antegrade approach[61]. EUS guided transluminal drainage (EUS-TLD) is achieved by bile duct puncture from the stomach or the duodenum using EUS-FNA needle. Occasionally choledochoantrostomy or hepaticoesophagostomy has also been described for achieving biliary drainage[62-64]. After obtaining a cholangiogram a guidewire is placed into the biliary system and the tract dilated followed by insertion of stent to achieve drainage of biliary system into the stomach or the duodenum. While duodenal station is used to achieve access into the common bile duct, gastric station allows access to the left lobe intrahepatic biliary radicals[61]. Access to right sided biliary system has also been described[65]. Table 4 depicts the major reports of EUS guided transluminal access to biliary

system. EUS guided rendezvous is achieved by creation of a temporary access to the biliary tree using EUS guided approach in patients with failed cannulation but with accessible papilla. The guidewire is then negotiated across the obstruction into the duodenum through the papilla and is then retrieved using snare and thereby providing a conduit for further ERCP[61]. This approach is, therefore, useful in failed ERCP but accessible papilla. The approach from the stomach and first part of duodenum is considered to be stable but the ampullary direction of guidewire is achieved best from the stomach and second part of duodenum[61]. Table 5 depicts the major reports of EUS guided rendezvous procedures and their outcomes. EUS guided antegrade approach is the use of temporary EUS guided access created from the duodenum or stomach for placement of stents or balloon dilatation without the scope reaching the papilla. The reported success rate for this procedure is 77% and the complication rate is 5%, however large studies are lacking[61].

EUS-TLD is associated with significant complications including perforation, bile leak, bleeding, and stent dysfunction or migration. The use of EUS-TLD has also been reported to be as efficacious as transpapillary drainage in patients with previous duodenal stents with a higher stent patency rate with EUS-TLD[84]. SEMS are preferred over plastic stents as they provide a larger diameter and therefore are likely to remain patent for longer periods and the risk of bile leaks is likely to be less with SEMS. SEMS also make a reinsertion of stent easier as stent can be placed into the previous SEMS[85]. Both EUS-TLD and placement of duodenal SEMS in patients with obstructive jaundice and duodenal obstru-

ction due to unresectable periampullary lesions has been reported as a single step procedure with use of linear echo-endoscope[86].

EUS guided approaches have also been compared with percutaneous approach for biliary drainage. In a randomised study comparing percutaneous and EUS guided approaches in 25 patients with unresectable biliary obstruction, the technical success, clinical success, cost and complications were similar amongst both the groups suggesting that either could be used as an alternative for biliary drainage[87]. However a recent report comparing 51 patients who underwent percutaneous transhepatic biliary drainage (PTBD) with 22 patients who underwent EUS-TLD indicated that the technical success was higher for PTBD. The authors however recommended EUS-TLD as the initial procedure of choice as it needed lesser re-interventions reducing costs of therapy as also a lower adverse event rate[88]. In a similar report where 50 patients were retrospectively evaluated success of internal stenting as well as complication rates were more favourable in the EUS-TLD group. While internal stenting could be achieved in 92% patients in EUS-TLD group, it could be achieved only in 46% of PTBD group[89]. Amongst EUS guided approaches, transhepatic access seems to increase the risk of complications vis-à-vis transduodenal access of the biliary tree[78]. An approach has been suggested for the use of various EUS guided methods for achieving biliary drainage in different clinical settings. If ampulla is inaccessible, EUS-TLD is the initial choice. If papilla is accessible rendezvous should be attempted but if it is not possible to cross the lesion/stricture then EUS-TLD can be undertaken. Antegrade approach may be better suited for surgically altered anatomy where the procedure is needed for benign lesions[61].

EUS GUIDED GALL BLADDER DRAINAGE

The emergent gall bladder drainage is usually done radiologically but availability of EUS has made it possible to drain the gall bladder endoscopically. This may be indicated in situations like acute cholecystitis in patients who are unsuitable for surgery and have not improved with antibiotics[90]. In a systematic review of endoscopic drainage of gallbladder using nasogallbladder drainage in 194 patients and gallbladder stenting in 127 patients the technical success rates were 81% and 96%, clinical success rates were 75% and 88% and complication rates were 3.6% and 6.3%, respectively[90,91]. In a randomised study of patients with acute cholecystitis who were assigned to undergo either an EUS guided drainage or a percutaneous drainage of gall bladder the technical success rates were similar as were the complication rates suggesting that EUS guided approach is feasible for gall bladder drainage with outcomes comparable to the percutaneous approach[92]. Major reports (> 10 patients) on EUS guided drainage of gall bladder are shown in Table 6.

Table 6 Endoscopic ultrasound guided gall bladder drainage for acute cholecystitis

Ref.	Number	Technical success	Clinical success	Complications
Jang *et al*[92]	30	97%	100%	7%
Lee *et al*[93]	9	100%	100%	11%
Song *et al*[94]	8	100%	100%	37%
Jang *et al*[95]	15	100%	100%	13%
de la Serna-Higuera *et al*[96]	13	85%	85%	15%

Gall Bladder drainage can be achieved by use of either plastic or metallic stents or use of naso-gallbladder drains[94,95]. The complications may include bile leak, perforation and pneumo-peritoneum. In a report evaluating long term outcomes in 56 patients with acute cholecystitis who had underwent EUS guided gallbladder drainage the stent patency was 86% over 3 years. Four patients had late adverse events including distal stent migration in 2 patients and acute cholecystitis due to stent occlusion in 2 patients. The stent occlusions were treated endoscopically[97]. A single step procedure for insertion for lumen opposing metallic stent using AXIOS system has also been reported[98]. EUS guided gallbladder drainage has also been used as an approach for drainage in unresectable pancreatic cancer with use of anti-migratory fully covered metallic stents[99]. EUS guided gall bladder drainage may be of value in situation where a percutaneous procedure is dificult or more risky (presence of ascites and coagulopathy) but comes at an increased risk associated with sedation in patients with various comorbidities and the risk of bile leak.

EUS GUIDED PANCREATIC DUCT DRAINAGE

EUS guided pancreatic ductal (PD) drainage may be indicated for patients with failed transpapillary

drainage like in failed cannulation of non-negotiable strictures in chronic pancreatitis or pancreatic fistulae or pancreaticogastric or pancreaticojejunal stenosis after pancreatic surgery[100]. Both trans-enteric stenting and rendezvous procedures can be accomplished after EUS guided access to the pancreatic duct has been obtained. Once an access has been achieved using EUS-FNA needle and a guidewire is placed into the PD, and dilatation of the tract is done. SEMS are not used to drain the pancreatic duct for the associated risk of obstructive pancreatitis due to blockage of the side branches of the pancreatic duct. Complications associated with EUS guided PD drainage include leakage of pancreatic juice, pancreatitis, perforation or bleeding[101,102]. In a systematic review of 9 studies including 205 patients the pancreatic duct drainage was successful in 58%-100% with clinical success in 74% and a complication rate of 20%[102]. Success rates were lesser in a nationwide retrospective study form Spain[75]. Both rendezvous and transenteric drainage has been reported to have similar efficacy although it may be difficult to do a rendezvous in tight strictures[103,104]. The EUS guided PD access can be utilised for taking brushings to confirm malignancy in pancreatic stricture[105]. Access may be easier to obtain in dilated duct[104]. Some data is available about long term clinical success which indicates that at a median follow-up of 37 mo pain relief was present in 72% patients[106]. Another report indicated complete pain relief in 83% of patients[107]. It is important to suspect underlying malignancy in those with lack of pain relief[108]. Anterograde pancreatic drainage including stricture dilatation and removal of stone has also been reported[109,110]. To summarise EUS guided pancreatic duct drainage can be of use in rescue management of failed ERCP or in patients with surgically altered anatomy but the technique is still evolving and better accessories are needed.

USE OF EUS IN MANAGEMENT OF MALIGNANT DISEASE

Brachytherapy

Recently EUS guided brachytherapy has also been evaluated with radioactive seeds being placed into the tumour of interest under EUS guidance with the help of linear echoendoscope[111,112]. The most popular radioactive seeds are Iodine 125, palladium 103 and iridium 192. In pancreatic cancers where the cells divide quite rapidly, iodine is the radioactive material of choice as it has got a long half life of 60 d. The radioactive spill over the region of interest is definitely an issue of concern but in human tissue the penetration distance of the radiation into surrounding tissue is very small. The seeds of EUS guided brachytherapy were sowed by Sun *et al*[111] with their study in pigs. Sun *et al*[111] published the use of iodine 125 in unresectable pancreatic cancer in 15 patients. The result revealed a median survival of 10.6 mo with 27% patients having partial tumour response[111]. In another study in 22 patients with advanced pancreatic cancer where combination of gemcitabine and Iodine 125 brachytherapy was used, the overall survival rate didn't improve[112].

Fiducial marker placement

For external beam radiation to the cranium, bony landmarks are used for guiding the therapy while in intraabdominal malignancy fiducial markers are placed inside the tumour for guiding therapy. These markers are radioactive spheres, coils or seeds. Earlier fiducials were placed under surgical or radiological guidance but with advent of interventional EUS, these fiducials can be placed under EUS guidance also. Pishvaian *et al*[113] reported EUS guided fiducail placement in 13 patients with technical success achieved in 11/13 patients. An average of 3-4 fiducials were placed in each patient. There have been multiple studies where EUS guided fiducials have been placed successfully in pancreatic cancers, esophageal cancers and neuroendocrine tumours[114-116]. To compare the 2 types of fiducials a study was conducted in 39 patients with advanced pancreatic cancer. Traditional fiducials of 5 mm length and viscoil fiducials of 10 mm length were compared. It was observed that traditional fiducials had better visibility scores as compared to viscoil fiducials and the migration rate between the two types of fiducials was similar[117].

EUS guided ethanol ablation

Ethanol causes cell death by membrane lysis, vascular occlusion and protein denaturation and has been used for ablation of solid and cystic lesions of thyroid, liver, adrenals, *etc*. EUS guided ethanol ablation has been used recently for ablation of pancreatic lesions, neuroendocrine tumors (NETs) and metastatic abdominal lesions. EUS guided fine needle injection therapy using alcohol is safe and better than percutaneous approach as it is delivers alcohol to target tissue with more accuracy, identify surrounding structures and perform injection therapy in real time monitoring.

In a study by Gan *et al*[118] including 25 patients with pancreatic cysts who underwent ablation with variable concentrations of alcohol (5%-80%), the results revealed complete resolution in 8 patients and epithelial ablation in 5 patients who underwent surgery. In another study ethanol injection was compared with saline injection alone. In this study 25/42 patients were initially treated with alcohol and rest 17 with saline. After 3 mo, patients in both the groups were treated with ethanol injection. The results showed that 80% ethanol injection resulted in a greater decrease in size as compared to saline injection. Nine patients who were followed up for 2 years had no recurrence of cyst[119]. In another study of 42 patients with cystic tumours of the pancreas who were initially injected with 99% ethanol followed by paclitaxel. Complete resolution

Table 7 Antitumour agents, their composition and area of use

Name of the agent	Drug	Ref.	Reported use
CYTOIMPLANT	Allogenic mixed lymphocyte culture	Chang *et al*[130]	Advanced pancreatic cancer
TNFerade	cDNA expressing TNF-α (adenovector)	Hecht *et al*[131], Chang *et al*[132] and Citrin *et al*[133]	Pancreatic, esophageal and rectal cancer
ONY X-015	Adenovirus	Mulvihill *et al*[134]	Advanced pancreatic cancer
Oncogel	Paclitaxel and ReGel	Linghu *et al*[135], Matthes *et al*[136] and Vukelja *et al*[137]	Pancreatic, esophageal cancer
Gemcitabine	Gemcitabine	Levy *et al*[138]	Advanced pancreatic cancer
DC's	Dendritic cells	Irisawa[139], Hirooka *et al*[140]	Advanced pancreatic cancer

was achieved in 29 patients. No complications were observed[120]. EUS guided ethanol ablation of pancreatic neuroendocrine tumours has been reported in patients who are not good candidates for surgery either because of age or comorbidities. There have been published reports where even multiple NETs have been injected with alcohol and ablation has been achieved with patient remaining symptom free post injection. But there is a risk of recurrence and metastasis. So long term follow up studies are required to adequately define the role of ethanol ablation in NETs[121-125].

Multiple metastatic lesions have also been ablated with EUS guided ethanol injection but its role in these situations need to assessed in larger studies. These include hepatic metastases from carcinoma colon, pelvic lymph nodal metastases from rectal cancer, left adrenal metastases from non-small cell carcinoma lung, hepatic metastases from pancreatic carcinoma and ablation of a gastrointestinal stromal tumour in a patient whose comorbidities precluded surgery[126-129].

Delivery of antitumor agents

Pancreatic carcinoma has got a poor response to chemotherapeutic agents and radiation. In presence of locally advance disease and borderline resectability, neoadjuvant chemotherapy has been tried, but it carries a poor response rate as the tumour is hypovascular and produces a desmoplastic reaction around it leading to poor delivery of drugs. So various local antitumour agents have been tried in patients with advanced pancreatic carcinoma for palliation and in locally advanced lesions for downstaging before surgery (Table 7).

The problem with all these studies is that they were small and all these agents in this role are still in experimental stage. So we need much more large prospective studies before these techniques can be put into clinical practice.

Tumour ablation

Thermal injury leading to coagulation necrosis has been the principle of radiofrequency ablation (RFA). This principle has been exploited for treatment of solid tumours like hepatocellular carcinoma (HCC) and liver metastases. Percutaneous, open or laparoscopic approach have been associated with morbidity and mortality. Recently EUS guided RFA has been performed under real time guidance in porcine models. Studies of EUS RFA done in porcine models have used the technique for ablation of lymph nodes and pancreatic lesions[141,142]. Majority of pigs tolerated the procedure well except for few complications.

EUS photodynamic therapy

Photodynamic therapy is another modality for tumour ablation. Here a photosensitizer drug is injected and application of light is done to the area of interest. The tumour cells are killed by direct cytotoxic effects, vascular changes and inflammatory reaction[143,144]. A study in porcine models where EUS guided photodynamic therapy has been done to liver, pancreas and kidney showed that 100% necrosis was seen in pancreas only[145].

EUS guided laser therapy

It is an evolving technique and recently a case was reported where EUS guided laser ablation of a left lobe HCC was performed using 22 G needle and patient was followed up for 2 mo with no recurrence of the lesion[146].

EUS-GUIDED INRAABDOMINAL ABSCESS DRAINAGE

EUS guided internal drainage of abdominal and pelvic abscesses has emerged as an alternative to traditional percutaneous drainage. Abscesses in areas close to the gastrointestinal lumen including mediastinum, lesser sac, perihepatic and subphrenic space, and pelvis can be drained using EUS guidance. The procedure involves the usual steps described earlier for PFC drainage: access using 19 G EUS-FNA needle, use of guidewire, dilatation of tract and placement of drainage catheter or pigtail stents. The suggested dilatation diameters for esophagus is 6 mm, for colon and jejunum is 6-8 mm, for duodenum 8-10 mm and in stomach 8-15 mm[147]. Table 8 shows various reports of EUS guided drainage of pelvic abscesses.

Mediastinal abscesses have also been drained under EUS guidance including placement of lumen opposing stents[154,155]. A few reports have also involved aspiration of splenic abscess in setting of pancreatitis[156,157]. Liver abscess have also been drained using EUS guidance

Table 8 Endoscopic ultrasound guided drainage of pelvic abscesses

Ref.	Number	Site	Technical success	Clinical success	Complications
Hadithi *et al*[148]	8	Abdominal (pelvic)	100%	100%	0
Puri *et al*[149]	30	Pelvic (4 prostatic)	93.3%	83.5%	0
Ramesh *et al*[150]	38	11 transcolonic, 27 transrectal	100%	87%	10.5%
Puri *et al*[151]	14	Pelvic	100%	93%	0
Varadarajulu *et al*[152]	25	Pelvic	100%	96%	0
Giovannini *et al*[153]	12	Pelvic	100%	75%	25%

and placement of lumen apposing stent has also been done[158,159].

EUS GUIDED CELIAC PLEXUS BLOCK

Percutaneous celiac plexus neurolysis (CPN) has been used for management of pain in pancreatic cancer and sometimes for chronic pancreatitis. EUS guided CPN has emerged as a more effective technique in recent times[160]. Using the linear echoendoscope at the level of gastroesophageal junction the aorta is located and celiac artery traced. While alcohol is used to obtain CPN, bupivacaine is used for celiac plexus block (CPB). Although triamcinolone is often added to bupivacaine but a randomised study found no benefit with addition of triamcinolone[161]. The average efficacy of CPB for pain relief is around 3 mo. Transient hypotension and diarrhea may occur as side effects of the procedure. The EUS guided technique avoids passage through the vertebrae and muscles at the back as required for a CT guided celiac block and therefore unlikely to have related adverse events like paraparesis[162]. Interestingly, ganglion cells have now been visualised on EUS and it may be better to target ganglions directly[163,164]. In a randomised trial comparing CPN with celiac ganglia neurolysis (CGN), the positive response was higher in the CGN group (73.5% *vs* 45.5%). Half of the patients in CGN group obtained complete relief vis-à-vis 18% in CPN group[165].

Multiple comparative reports have emerged which have compared radiologic *vs* EUS guided CPN. EUS guided CPN provided a more long lasting pain relief (30% up to 24 wk) while with CT guided CPN only 12% had some relief at 12 wk[166]. In a trial comparing one *vs* two injections for pain relief during CPN, no incremental benefit in pain relief was observed with two injections[167]. EUS guided CPB was more efficacious for pain relief in patients with chronic pancreatitis in a randomised comparison with percutaneous CPB[168]. Only a subset of patients with EUS guided CPN obtain complete pain relief and the duration of pain relief is variable. The predictors of pain relief are not established. Also the benefit of performing CPN rather than CPB in chronic pancreatitis is not clear[169].

It is apparent that the availability of interventional EUS has allowed gastroenterologists to make forays into areas which traditionally remained the domain of surgeons and interventional radiologists. With further improvements in accessories and development of EUS-natural orifice transluminal endoscopic surgery, the endosonologist will have to do multiple roles[170].

Abstract

The introduction of wireless capsule endoscopy in 2000 has revolutionized our ability to visualize parts of the small bowel mucosa classically unreached by the conventional endoscope, and since the recent introduction of colon capsule endoscopy, a promising alternative method has been available for the evaluation of large bowel mucosa. The advantages of wireless capsule endoscopy include its non-invasive character and its ability to visualize proximal and distal parts of the intestine, while important disadvantages include the procedure's inability of tissue sampling and significant incompletion rate. Its greatest limitation is the prohibited use in cases of known or suspected stenosis of the intestinal lumen due to high risk of retention. Wireless capsule endoscopy plays an important role in the early recognition of recurrence, on Crohn's disease patients who have undergone ileocolonic resection for the treatment of Crohn's disease complications, and in patients' management and therapeutic strategy planning, before obvious clinical and laboratory relapse. Although capsule endoscopy cannot replace traditional endoscopy, it offers valuable information on the evaluation of intestinal disease and has a significant impact on disease reclassification of patients with a previous diagnosis of ulcerative colitis or inflammatory bowel disease unclassified/indeterminate colitis. Moreover, it may serve as an effective alternative where colonoscopy is contraindicated and in cases with incomplete colonoscopy studies. The use of patency capsule maximizes safety and is advocated in cases of suspected small or large bowel stenosis.

Key words: Small bowel capsule endoscopy; Colon capsule endoscopy; Crohn's disease; Ulcerative colitis; Indeterminate colitis; Postoperative; Ileal pouch-anal anastomosis; Refractory pouchitis

Core tip: Wireless capsule endoscopy is a valuable diagnostic tool for the evaluation of lesions located on the small intestine and large bowel mucosa since the recent introduction of colon capsule endoscopy. It plays an important role in the early recognition of recurrence on postsurgical Crohn's disease patients, offers valuable

information on the evaluation of intestinal disease, and aids significantly in patient management, treatment tailoring and disease reclassification in patients with a previous diagnosis of ulcerative or indeterminate colitis. Patency capsule maximizes safety and is advocated in suspected small or large bowel stenosis.

Mitselos IV, Christodoulou DK, Katsanos KH, Tsianos EV. Role of wireless capsule endoscopy in the follow-up of inflammatory bowel disease. *World J Gastrointest Endosc* 2015; 7(6): 643-651 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i6/643.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i6.643

INTRODUCTION

The follow-up of patients with known inflammatory bowel disease consists in close disease monitoring for the maintenance of clinical remission, early detection of biochemical or clinical relapse and early recognition, as well as prevention, of disease and treatment related complications. Since various studies[1-4] have provided strong evidence that the inflammation of the intestinal mucosa is not firmly associated with patients' symptoms and laboratory markers of inflammation, the treatment goal has evolved to a new concept, the achievement and maintenance of deep remission. Its definition includes the concurrent abatement of symptoms, a score < 150 as measured with Crohn's Disease Activity Index (CDAI), mucosal healing, a term referring to the endoscopic restoration of normal mucosal appearance of a previously inflamed region and the complete absence of ulceration as well as macroscopic and histological signs of inflammation[5], and diminution of inflammatory markers. In the absence of a consensus on mucosal healing definition in ulcerative colitis patients, this could involve the disease's clinical and endoscopic remission[6-8]. In Crohn's disease patients, deep remission is associated with a better health-related quality of life and minimization of disease related complications requiring hospitalization or surgery[6].

Despite its invasive character, colonoscopy is considered the gold standard method for the evaluation of intestinal mucosa lesions as it provides accurate assessment of disease extension and localization, offering the ability of tissue sampling of abnormal mucosal segments. By contrast to colonoscopy, the introduction of wireless capsule endoscopy in 2000[9], a non-invasive well-tolerated diagnostic method, allowed the visualization of parts of the small intestine beyond the reach of conventional endoscopes and also the large bowel mucosa, since the recent introduction of wireless colon capsule endoscopy. Current research does not support the use of colon capsule endoscopy over colonoscopy for the evaluation of mucosal healing and disease activity[10] although results of a recent study[11] demonstrate that colon capsule endoscopy findings can result in changes of the initial diagnosis, in favor of Crohn's disease. The aim of this review is to evaluate the importance of wireless capsule endoscopy in mucosal healing assessment, treatment management and disease reclassification of inflammatory disease patients, their follow-up in the post-operative period, as well as to highlight its possible future roles.

CAPSULE ENDOSCOPY: BENEFITS, DRAWBACKS, LIMITATIONS AND SAFETY

Capsule endoscopy is a non-invasive, well-tolerated method, allowing direct visualization of the small bowel mucosa and having a significant higher diagnostic yield compared to other diagnostic methods[12].

Its main disadvantages (Table 1) are the procedure's higher cost compared to other modalities, the inability of tissue sampling, the significant incompletion rate which in several trials[13-15] is reported to range from 15% to 30%, the risk of aspiration and the risk of capsule retention, which in Crohn's disease patients is estimated to be 2.6%[15] and may require surgery for the removal of the retained capsule.

The use of capsule endoscopy is contraindicated in patients with known stricturing or obstructing disease and in selected cases, radiology may still be necessary to exclude the presence of strictures. It is considered to be a safe technique[16] and the administration of a dissolvable patency capsule to patients with suspected strictures prior to the procedure, provides adequate assessment of the gastrointestinal patency and maximizes safety[17,18]. In cases of known gastroparesis or in patients unable of swallowing, the videocapsule can be administered endoscopically. The relative contraindication of wireless capsule administration in patients with electromedical devises is in question, as according to recent research[19] it is considered safe.

CAPSULE ENDOSCOPY SCORING INDEXES FOR THE ASSESMENT OF MUCOSAL INFLAMMATION

In an effort to maximize objectivity on the interpretation of small bowel capsule endoscopy findings and the need of a common language to report severity of small bowel inflammation, two diagnostic scoring systems have been developed, Lewis score (LS) and Capsule Endoscopy Crohn's Disease activity Index (CECDAI).

Developed by Gralnek *et al*[20] in 2008, LS[20], an incorporated feature of Given's Rapid Reader software, offers a quantitative assessment of inflammation severity using the Capsule Endoscopy Structured Terminology[21] for the description of lesions and a grading system for the assessment of inflammation severity. Capsule transit time is used to divide the small bowel in three tertiles and based on the severity of 3 endoscopic variables - villous edema, ulcers and stenosis - each tertile score is calculated individually. The final score ranges from 8 to 4800 points and is the sum of the tertile with the

Table 1 Advantages and disadvantages of wireless capsule endoscopy

Advantages
Non-invasive well-tolerated method
Allows direct visualization of distal and proximal parts of the small bowel (SBCE) and large bowel mucosa(CCE)
Disadvantages
High cost compared to other modalities
Inability of tissue sampling
Significant incompletion rate (15%-30%)
Risk of capsule retention (2.6%)
Risk of aspiration

SBCE: Small bowel capsule endoscopy; CCE: Colon capsule endoscopy.

greatest score added to the stenosis score. A score below 135 points represents a normal appearing mucosa or clinically insignificant findings.

CECDAI, a quantitative method developed by Gal *et al*[22] in 2008, employs the variables of inflammation, extent of disease and the presence of strictures as well as a grading system for the assessment severity. Small bowel is divided in proximal and distal segments after the midpoint determination with the use of small bowel transit time. Segmental scores are gauged separately by multiplying the inflammation score by the extent-of disease score and adding the stricture score. The sum of segmental scores represents the final CECDAI score. Both scores should be interpreted with regard to the patient's history, as they cannot identify the underlying reason of mucosal inflammation. The use of LS and Capsule Endoscopy Crohn's Disease Activity Index is advocated, as they provide an objective non-invasive method for the evaluation of small bowel inflammation and follow up of Crohn's disease[22-24] and correlate closely with highly sensitive markers of intestinal inflammation such as fecal calprotectin[25], a protein released from neutrophils and inflamed mucosa. Fecal calprotectin is not able to determinate the cause of intestinal inflammation, however fecal calprotectin levels are demonstrated to correlate closely with intestinal inflammation[26-29] and are proved to be a valuable selection tool prior to capsule endoscopy studies as despite the presence of symptoms, patients with fecal calprotectin levels between 50 and 100 μg/g, are shown to have negative for findings studies[30].

THE ROLE OF WIRELESS CAPSULE ENDOSCOPY IN THE ASSESSMENT OF MUCOSAL HEALING AND TREATMENT TAILORING

Clinical remission is not strongly associated with the diminution of inflammatory markers[4] although C-reactive protein (CRP) is demonstrated to be a useful marker in the evaluation of moderate to severe Crohn's disease[31]. Moreover, clinical and laboratory improvement of patients under treatment is not associated with mucosal healing[31]. Patients continue to have small bowel aphthous ulcerations in video capsule endoscopy studies (Table 2) one month after clinical remission and it is estimated that approximately 6 mo are necessary for the complete endoscopic restoration of small bowel mucosa[4,32]. In a multicenter prospective study[3] including 40 patients with known or suspected non-stricturing, non-penetrating Crohn's disease, only one third of the patients who achieved clinical response improved their endoscopic image in capsule endoscopy studies. A cohort of 43 patients with symptomatic small bowel Crohn's disease, under biologic or immunomodulatory treatment, evaluated mucosal healing and deep remission rate on baseline and after 12 and 52 wk on treatment[1,33]. Their baseline demographics, quality-of-life questionnaires, Harvey-Bradshaw index, CRP and fecal calprotectin levels were collected and Capsule Endoscopy Crohn's Disease Activity Index was used to assess ileitis severity. Active small bowel Crohn's disease was present in 39 patients (90%) on baseline and 28 patients (65%) had an endoscopic re-assessment during week 52. Despite the clinical and biochemical improvement, no patient achieved complete mucosal healing on week 12[1]. Twelve patients achieved deep remission on week 52 (42%)[33]. The correlation between capsule endoscopy findings, clinical symptoms (Crohn's Disease Activity Index and Inflammatory Bowel Disease Questionnaire) and laboratory markers of inflammation (CRP) was evaluated in 19 patients with known, moderately active Crohn's disease under treatment[2]. All patients had a proven functional patency to minimize the risk of capsule retention, and small bowel capsule endoscopy studies at baseline, after 4, 12 and 24 wk on treatment. Mucosal inflammation was evaluated with the use of LS. At baseline, no correlation was found between clinical symptoms, markers of inflammation and LS, and capsule endoscopy findings were not associated with patients' symptoms on 4 and 12 wk of treatment, leading to the conclusion that capsule endoscopy is a reliable, independent and objective diagnostic modality for the assessment of mucosal healing and response to therapy, and on the prognosis of prolonged clinical disease remission[32]. In addition, data obtained of two recent retrospective studies[34,35] indicate that capsule endoscopy findings assist on decision making, treatment changes or initiation of new pharmaceutical agents, in a significant proportion of inflammatory bowel disease patients.

THE ROLE OF WIRELESS CAPSULE ENDOSCOPY IN THE POSTOPERATIVE PERIOD OF INFLAMMATORY BOWEL DISEASE PATIENTS

Recurrence

The introduction of biologic therapy for the treatment of inflammatory bowel disease did not eliminate

the need for surgical intervention[36-40]. Eventually, 20%-30% of ulcerative colitis patients[41,42] and up to 75% of Crohn's disease patients[43], will require surgery for the management of uncontrolled inflammatory bowel disease and disease related complications. A common and undesirable postsurgical outcome is the development of disease recurrence. In Crohn's disease patients, recurrence rate increases with time[44] and is demonstrated to be higher in smokers[45], patients with ileocolonic involvement[46], perforating disease[47] and 5-ASA-treated patients with end-to-end anastomosis[44]. The introduction of Rutgeerts endoscopic scoring system[48] has provided a valuable modality for the quantified assessment of postoperative recurrence of the ileocolonic anastomosis or neoterminal ileum, and a valuable prognostic tool of Crohn's disease recurrence[48-50], since endoscopic recurrence precedes the development of symptoms[48] and does not correlate with CDAI[51]. The follow-up of postoperative patients is directed towards recognition of endoscopic recurrence (Table 3), as severe endoscopic recurrence rate is estimated at 50.2% (95%CI: 28-73; range: 30-79) and early identification and initiation of treatment may prevent clinical recurrence[52,53].

In a prospective study of 22 Crohn's disease patients, capsule endoscopy was reported to have comparable results with other noninvasive tests on the detection of recurrence[54]. Moreover, based on the results of a prospective study[55] including 35 patients who had undergone ileocolonic or partial ileal resection, wireless capsule endoscopy was not shown to be superior to ileocolonoscopy for the detection of recurrence on the neoterminal ileus although it enabled the visualization of lesions beyond colonoscope's reach in two out of three patients and aided significantly in the detection of recurrence in two patients missed by ileocolonoscopy. However, capsule endoscopy was the diagnostic modality preferred by patients in a small prospective study[56] including 24, symptom-free Crohn's disease patients under no prophylactic treatment, who had undergone ileocolonic anastomosis. In the same study, the authors concluded that capsule endoscopy was more effective in the detection of a significant number of Crohn's disease recurrence missed by colonoscopy and an effective diagnostic alternative for the visualization of the neoterminal ileum of patients with incomplete colonoscopy studies. Current research supports the use of baseline capsule endoscopy, shortly after the resection, for the detection of true cases of recurrence, as many ulcerations near the anastomotic site are formed due to factors related to surgery, such as disturbed blood flow and sutures[57], but its preoperative use is reported to be of little value for the prognosis of recurrence[58]. The use of wireless capsule endoscopy in suspected or known luminal stenosis is contraindicated[54,57].

Anemia

Based on the results of a small study of 17 ulcerative colitis patients with ileal pouches and persistent iron deficiency anemia[59], the authors concluded that wireless capsule endoscopy is a well-tolerated procedure to provide additional information on the reason of anemia. Patients with persistent anemia, 12 mo after ileal pouch-anal anastomosis (IPAA) or continent ileostomy, were evaluated with upper gastrointestinal endoscopy, pouch endoscopy and videocapsule endoscopy, and they had laboratory screening to exclude celiac disease. The reason of anemia was identified in 5 patients (29.4%). In one patient, arterio-venous malformations of the small bowel were only recognized by capsule endoscopy.

Pouchitis in patients with IPAA

Surgical removal of the colon and rectum with the creation of an artificial pouch, the IPAA, may be the only treatment option for ulcerative colitis patients with medically uncontrolled disease, who are unwilling to receive immunomodulatory or biologic therapy, or suffering from severe disease complications.

Table 3 Key studies on the role of wireless capsule endoscopy on postoperative Crohn's disease recurrence

Patient group	Ref.	No. of patients	WCE findings/(*n*)	Ileocolonoscopy findings/(*n*)
CD	Bourreille *et al*[55]	32	21/(32)	19/(32)
CD	Pons Beltrán *et al*[56]	24	15/(22)	6/(19)
CD	Biancone *et al*[54]	22	16/(17)	21/(22)
CD	Kono *et al*[57]	19	14/(18)	NA

CD: Crohn's disease; WCE: Wireless capsule endoscopy; WCE findings: Number of patients with findings on WCE; WCE (*n*): Total number of patients who had undergone WCE; Ileocolonoscopy findings: Number of patients with findings on ileocolonoscopy; Ileocolonoscopy (*n*): Total number of patients who had undergone ileocolonoscopy; NA: Not available.

Pouchitis is the most common complication, with a cumulative probability of nearly 50% ten years after IPAA performed[60] requiring investigation for the recognition of the underlying cause.

Results based on trials of ulcerative colitis patients with IPAA and symptomatic pouchitis[35,61,62] (Table 4), support the use of capsule endoscopy for the evaluation of small bowel mucosa on the suspicion of Crohn's disease and on differentiating intermediate colitis.

THE ROLE OF WIRELESS CAPSULE ENDOSCOPY ON DISEASE RECLASSIFICATION

Inflammatory bowel disease patients may undergo multiple imaging studies, endoscopic procedures and biopsies before reaching a definitive Crohn's disease or ulcerative colitis diagnosis, while 10%-15% of patients will remain unclassified[63]. Capsule endoscopy has become an important tool for the reclassification of disease (Table 5) in patients with an initial diagnosis of ulcerative colitis or inflammatory bowel disease unclassified/indeterminate colitis. The importance of wireless capsule endoscopy in the diagnostic workup of inflammatory bowel disease was demonstrated in a recent study of 23 known ulcerative colitis patients[64] where small bowel lesions (13 patients, 57%) and erosions (8 patients, 35%) were identified in the majority of them.

Corresponding results from the initial experience with small bowel capsule endoscopy[65] have demonstrated that the identification of small bowel lesions by wireless capsule in patients with isolated colitis, lead to further investigation with ileocolonoscopy with biopsies, and a change of diagnosis in favor of Crohn's disease. In a retrospective trial[62] including 120 patients with known ulcerative colitis or indeterminate colitis undergone capsule endoscopy, 19 patients (15.8%) had findings suggestive of small bowel Crohn's disease involvement. Interestingly, patients with the highest proportion of small bowel disease were those with a history of colectomy (7 out of 21 patients, 33%) compared to the patients who did not undergo colectomy (12 out of 99 patients/12%), indicating the importance of capsule endoscopy studies prior to colectomy in ulcerative colitis patients. Similarly, data obtained from a study of 30 inflammatory bowel disease unclassified patients with negative serology[66] showed that wireless capsule endoscopy findings resulted in disease reclassification in favor of Crohn's disease in five of them. Another significant conclusion of this study was that negative for findings capsule endoscopy studies, do not exclude small bowel Crohn's disease, as further investigation with ileocolonoscopy and biopsies in six patients led to a diagnosis of Crohn's disease in five patients and ulcerative colitis in one patient. In two studies that enrolled pediatric patients[67,68] capsule endoscopy resulted in reclassification of more than half of the ulcerative colitis, inflammatory bowel disease unclassified/indeterminate colitis patients to Crohn's disease.

POSSIBLE FUTURE INDICATIONS OF WIRELESS CAPSULE ENDOSCOPY IN THE FOLLOW UP OF INFLAMMATORY BOWEL DISEASE PATIENTS

Research on the prognostic value of mucosal healing on treatment response[69-72], has shown that assessment of mucosal healing on certain time points can predict the likelihood of prolonged deep remission. The data of 127 patients[73] who had participated in the SONIC trial, were used to estimate the prognostic value of ileocolonoscopy findings on treatment response. Patients Simple Endoscopic Score for Crohn's Disease and the Crohn's Disease Endoscopic Index of Severity were calculated on baseline, after week 26 and week 50. Namely, the endoscopic response and mucosal healing in week 26 identified the patients who would be on corticosteroid-free clinical remission on week 50. The study's results provided confirmatory evidence that assessment of mucosal healing in certain time points during therapy has a significant prognostic value on the response of treatment.

Growing evidence[74-76] in the corresponding literature, indicate the strong association between disease location and disease complications. Patients with ileal

Crohn's disease were shown to have a greater risk of stricturing and penetrating disease development as well as disease progression compared to those with colonic involvement.

There is no supporting evidence for the use of wireless capsule endoscopy on treatment response, on risk stratification and as a prognostic tool for prolonged remission, but given videocapsule endoscopy's non invasive nature and the advantage of detailed imaging of the entire small intestine, it could be a promising tool towards this direction.

Wireless capsule endoscopy could play an important role in the early detection of ulcerative colitis related panenteritis[77], a new and rare entity related to colectomy which typically occurs after colectomy, and its histological picture is not compatible with Crohn's disease. In a small case series of 6 patients[78], the use of ileocolonoscopy identified ulcerative colitis related panenteritis findings in 5 patients, resulting in treatment step-up and clinical improvement. One patient had to be evaluated with capsule endoscopy to confirm small bowel mucosa inflammation leading to the conclusion that video capsule endoscopy could offer an alternative method for the early detection of this rare complication.

CONCLUSION

Wireless capsule endoscopy is a valuable, non-invasive tool for the follow-up of inflammatory bowel disease, offering direct and detailed visualization of the entire intestine. Even though it cannot replace the role of traditional endoscopy, its use is advocated when there is high suspicion of small bowel disease involvement and as an alternative method in incomplete colonoscopy studies or when colonoscopy is contraindicated. Wireless capsule endoscopy's important disadvantages comprise the inability of tissue sampling and the limited, or in selected cases, prohibited application on patients with known stenosis or obstruction of the intestinal lumen, due to the high risk of capsule retention. Unnecessary capsule endoscopy studies can be avoided with the use of fecal calprotectin levels to identify patients who will probably not benefit from the procedure, and the use of patency capsule to identify patients that are likely to experience capsule retention. Lewis Score and Capsule Endoscopy Crohn's Disease Activity Index are validated, objective and reliable scoring systems developed to minimize interobserver agreement and provide a standardized reporting system of small-bowel inflammation. Assessment of mucosal inflammation has a positive impact on treatment tailoring and is proven to be a reliable prognostic tool for disease remission. Videocapsule endoscopy studies in the postoperative period of ulcerative colitis and inflammatory bowel disease unclassified/indeterminate colitis patients provide valuable information on the differential diagnosis of Crohn's disease as well as postoperative complications, and can aid significantly in the early recognition of recurrence for the timely initiation of immunomodulatory or biologic treatment, before obvious clinical and laboratory relapse. Wireless Capsule endoscopy may have potentially significant roles in the prognosis of treatment response as well as the occurrence of potential complications and the early diagnosis of ulcerative colitis related panenteritis, a recently described rare entity, affecting patients with ulcerative colitis after colectomy.

Author contributions: Pérez-Cuadrado Robles E, Esteban Delgado P and Bebia Conesa P contributed equally to this work; Martínez Andrés B, Franulic Guggiana M, Alcaraz Mateos E and Fernández Caballero M designed and performed the research; Rodrigo Agudo JL and Chacón Martínez S analyzed the data; Latorre R, Soria F, Herrerías Gutiérrez JM and Pérez-Cuadrado Martínez E wrote the paper.

Ethics approval: This study was a retrospective and descriptive study without prospective interventions or control group. Thus, we have not considered necessary to submit the manuscript to the Institutional Review Board.
Informed consent: All patients provided written consent to undergo DBE under general anesthesia or deep sedation. However, in this retrospective study of 627 patients with a long span of time (2004-2014) the informed consent to be enrolled in the study was waived. All data are anonymized and there were no prospective interventions.
Conflict-of-interest: None to declare.
Data sharing: Technical appendix, statistical code, and dataset available from the corresponding author at kikemurcia@gmail.com. Consent was not obtained but the presented data are anonymized and risk of identification is low.

Abstract

AIM: To assess the double-balloon enteroscopy (DBE) role in malignant small bowel tumors (MSBT).

METHODS: This is a retrospective descriptive study performed in a single center. All consecutive patients who underwent a DBE with final diagnosis of a malignant neoplasm from 2004 to 2014 in our referral center were included. Patient demographic and clinical pathological characteristics were recorded and reviewed. MSBT diagnosis was achieved either by DBE directed

biopsy with multiple tissue sampling, endoscopic findings or histological analysis of surgical specimen. We have analyzed double-balloon enteroscopy impact in outcome and clinical course of these patients.

RESULTS: Of 627 patients, 28 (4.5%) (mean age = 60 ± 17.3 years) underwent 30 procedures (25 anterograde, 5 retrograde) and were diagnosed of a malignant tumor. Patients presented with obscure gastrointestinal bleeding (*n* = 19, 67.9%), occlusion syndrome (*n* = 7, 25%) and diarrhea (*n* = 1, 3.6%). They were diagnosed by DBE biopsy (*n* = 18, 64.3%), histological analysis of surgical specimen (*n* = 7, 25%) and unequivocal endoscopic findings (*n* = 2, 7.1%). Gastrointestinal stromal tumor (*n* = 8, 28.6%), adenocarcinoma (*n* = 7, 25%), lymphoma (*n* = 4, 14.3%), neuroendocrine tumor (*n* = 4, 14.3%), metastatic (*n* = 3, 10.7%) and Kaposi sarcoma (*n* = 1, 3.6%) were identified. DBE modified outcome in 7 cases (25%), delaying or avoiding emergency surgery (*n* = 3), modifying surgery approach (*n* = 2) and indicating emergency SB partial resection instead of elective approach (*n* = 2).

CONCLUSION: DBE may be critical in the management of MSBT providing additional information that may be decisive in the clinical course of these patients.

Key words: Double balloon enteroscopy; Malignant small bowel tumors; Obscure gastrointestinal bleeding; Gastrointestinal stromal tumor; Occlusion syndrome

Core tip: Malignant small bowel tumors (MSBT) are a heterogeneous and relatively rare group of neoplasms. Double balloon enteroscopy (DBE) may have a critical role in the management of MSBT because of its diagnosis and therapeutic capabilities. DBE procedure may delay or avoid emergency surgery, clarifying the tumor location and characteristics. We have assessed DBE impact in these lesions in a large series of patients of a single referral center.

Role of double-balloon enteroscopy in malignant small bowel tumors. *World J Gastrointest Endosc* 2015; 7(6): 652-658 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i6/652.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i6.652

INTRODUCTION

Small bowel tumors (SBT) are relatively rare, accounting for 3% to 6% of all gastrointestinal neoplasms[1]. Malignant SBTs (MSBT) are described in the 3.6%-14.5% of patients of double balloon enteroscopy (DBE) series[2-4]. The difference in incidence in these studies is because many authors considered benign and malignant tumors and included duodenal neoplasms. MSBT are a heterogeneous group with different predominant histological types within different studies[5-10]. We will focus on malignant primitive SB tumors such as adenocarcinoma, stromal, neuroendocrine, lymphoproliferative and metastatic tumors. Moreover, these lesions may have a poor prognosis in its natural course so that early diagnosis and treatment may be critical[11,12]. These tumors are often diagnosed late because of their nonspecific clinical presentation[13-16], when they have few therapeutic possibilities[17,18].

Obscure gastrointestinal bleeding (OGIB) is the most common clinical presentation in some studies[4,19,20], while a suspected mass is reported to be the first DBE indication by other authors[2,21]. Therefore, MSBT represent a real diagnostic challenge for the physician. DBE is a well-established procedure in diagnosis and treatment of SB disorders. However, there are few data to date reporting DBE role in MSBT[20,22-24]. Our study was conducted to assess the impact of DBE in these neoplasms.

MATERIALS AND METHODS

This is a retrospective descriptive study. All consecutive patients with MSBT who underwent a DBE procedure in our institution were investigated. Patient demographic and clinical pathological characteristics were recorded. MSBT diagnosis was achieved either by DBE directed biopsy with multiple tissue sampling, endoscopic findings or histological analysis of surgical specimen.

DBE procedure

DBE procedure (Fuji Film, Saitama, Japan) was performed by expert endoscopists as described by Yamamoto *et al*[25]. Fujinon EN-450 P5, EN-450 T5 and EN-580T enteroscopes were used. There was no special preparation for the anterograde approach besides an 8-12 h fast. For the retrograde approach, bowel preparation was performed as in colonoscopy. All patients provided written consent to undergo DBE under general anesthesia or deep sedation. Capsule endoscopy (CE) and radiological studies such as CT scan were also considered, when available.

Endoscopists were aware of prior findings reported by CE or other techniques. DBE approach was selected based on the information prior to DBE procedure including previous CE, clinical and/or radiological findings. When the location was uncertain, the oral approach was preferred.

DBE data including indication, approach, endoscopic findings, tumor location, time of the procedure, biopsy histological diagnosis, therapeutics and complications were collected. Tattoo injection was performed to mark the maximum length of bowel inspected or the location

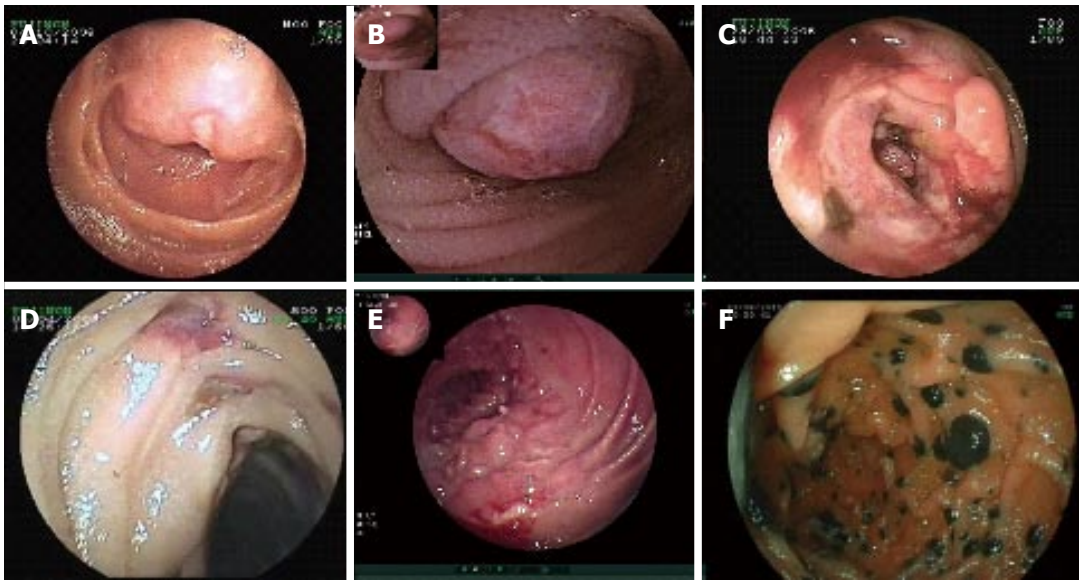

Figure 1 Endoscopic images of different types of malignant small bowel tumors. A: Ulcerated jejunal gastrointestinal stromal tumor; B and C: Stenosing adenocarcinomas; D: Kaposi sarcoma; E: Mucosa-associated lymphoid tissue lymphoma; F: Melanoma.

of the lesion and to guide the elective or emergency surgery.

Finally, we analyzed how DBE procedure influenced MSBT management and outcome. In this sense, avoiding or modifying the elective or emergency surgery approach was considered as the main evaluation criterion.

Descriptive statistics were used to describe clinical pathological features, endoscopic and radiological findings. Categorical variables were calculated as percentages and continuous variables were expressed as mean values (SD).

RESULTS

Of 627 consecutive patients who underwent 880 DBEs from January 2004 to September 2014 at our referral center, 89 (14.2%) were confirmed to have a SBT. Twenty-eight patients (4.5%) (mean age ± SD: 60 ± 17.3 years) underwent 30 DBEs (25 anterograde, 5 retrograde) (median time: 65 min, range 20-160) and were diagnosed of a MSBT. We only include the malignant tumors localized distal to Treitz. There was a male preponderance in gender (*n* = 20, 71.4%).

Patient's characteristics are shown in Table 1. The most common clinical indication was OGIB (67.9%). Patients presented with overt-OGIB (*n* = 9, 32.1%), occult-OGIB (*n* = 10, 35.7%), occlusion syndrome (*n* = 8, 28.6%) and diarrhea (*n* = 1, 3.6%). In addition, 10 patients (35.7%) had weight loss and 6 patients (21.4%) transfusion requirements.

DBE was indicated following CE in 17 cases (60.7%) and this procedure confirmed the MSBT in 14 cases (82.4%). The capsule was retained in 4 cases due to SB stenosis identifying the tumor in two of them and retrieved by DBE in all patients. CT scan (*n* = 8, 28.6%) and other radiological studies (*n* = 2, 7.1%) were previously performed and a suspected mass was identified in 6 cases (21.4%). CT scan also detected a SB complete stenosis in four cases and DBE clarified that only in three of them there was a complete stenosis without overpassing it with the endoscope. Among patients with obstructive symptoms, radiological imaging was the first SB study in 6 (75%) cases and direct DBE was performed in 2 (25%) patients.

DBE directed-biopsy was attempted in 25 patients (89.3%) and benign/reactive mucosa was found in 5 of them (1 midgut neuroendocrine tumor, 1 adenocarcinoma and 3 GIST) so that 20 patients (71.4%) were finally confirmed to have a MSBT by DBE biopsy (Table 2). Two patients (7.1%) had moderate bleeding after DBE biopsy that stopped after endoscopic treatment. Directed-biopsy by DBE was not attempted in 3 patients (10.7%) with GIST (*n* = 1), neuroendocrine tumor (*n* = 1) and metastatic disease (*n* = 1) because of active bleeding that required emergency surgery within GIST and neuroendocrine tumors and because it was considered unnecessary for diagnosis in the other case. In addition, histological analysis of surgical specimen and endoscopic findings lead to diagnosis in 7 (25%) and 1 (3.6%) patients, respectively.

Seven different histological types of MSBT were found. Most of them were located in jejunum (*n* = 20, 71.4%) followed by ileum (*n* = 8, 28.6%). We have only included malignant tumors located between distal to Treitz and terminal ileum. Endoscopic findings of different MSBT are shown in Figure 1.

The most common malignant tumor was GIST (*n* = 8, 28.6%) followed by adenocarcinoma (*n* = 7, 25%). GIST was also the most common MSBT within OGIB patients (36.8%). In two GIST an enteric fistula was identified by DBE with passage of contrast into the peritoneum so that emergency surgery was indicated after tattoo injection. One of them deceased

Table 1 Patient characteristics by histological type of malignant small bowel tumor

	GIST	Adenocarcinoma	Lymphoma	Neuroendocrine tumor
No. patients (% of MSBT)	8 (28.6%)	7 (25%)	4 (14.3%)	4 (14.3%)
Sex (M/F)	7/1	3/4	2/2	4/0
Mean age (SD) (yr)	64 ± 15	59 ± 16	48 ± 22	55 ± 24
Clinical presentation				
Overt-obscure OGIB	4	1	1	1
Occult-obscure OGIB	3	3	2	2
Diarrhea	0	0	0	1
Occlusion syndrome	1	3	1	0
Duodenum/jejunum/ileum	0/7/1	0/6/1	0/3/1	0/0/4

MSBT: Malignant small bowel tumor; GIST: Gastrointestinal stromal tumor; OGIB: Obscure gastrointestinal bleeding.

in the intensive care unit. Another patient with severe anemia and transfusion requirements underwent a DBE that confirmed an ulcerated jejunal GIST with active bleeding. Argon plasma coagulation was successfully performed so that emergency surgery was delayed. The positive detection rate by directed-biopsy within GIST was 57.1%.

Adenocarcinoma was mainly located in jejunum (*n* = 5, 71.4%). One patient underwent DBE because of one CT suspected jejunal mass and chronic anemia. Finally two synchronic jejunal adenocarcinomas were found modifying the surgery approach. Three patients with adenocarcinoma (42.9%) had impassable SB stenosis despite multiples endoscopic maneuvers and an enteral stent was successfully placed in one case[26]. There were 2 patients with liver metastasis at diagnosis and 3 patients did not underwent surgery because of comorbidities. Finally, 4 patients (57.1%) with adenocarcinoma underwent elective surgery.

Among lymphoma tumors (*n* = 4, 14.3%), there were 2 MALT, 1 non-Hodking diffuse large B lymphoma and 1 Burkitt lymphoma. One patient with a jejunal MALT lymphoma had refractory celiac disease. Three patients were treated by chemotherapy and the remaining patient refused treatment.Half of patients (*n* = 2) with neuroendocrine tumors had multiple small tumors besides the main ileal lesion undiagnosed by previous enhanced CT scan.

A jejunal Kaposi sarcoma actively bleeding was identified in a patient with acute overt-OGIB and endoscopic hemostasis was successfully performed. All patients with SB metastasis had the primary lesion already diagnosed (colonic adenocarcinoma, choriocarcinoma, lung adenocarcinoma and melanoma). DBE modified surgical approach in one patient with

Table 2 Final diagnosis and histological analysis by double balloon enteroscopy directed-biopsy

	DBE biopsy	Final diagnosis (% of MSBTs)
MSBT	20/25 (80%)	28
GIST	4/7 (57.1%)	8 (28.6%)
Adenocarcinoma	6/7 (85.7%)	7 (25%)
Lymphoma	4/4 (100%)	4 (14.3%)
Neuroendocrine tumor	2/3 (66.7%)	4 (14.3%)
Metastatic	3/3 (100%)	4 (14.3%)
Kaposi Sarcoma	1/1 (100%)	1 (3.6%)

DBE: Double balloon enteroscopy; MSBT: Malignant small bowel tumor; GIST: Gastrointestinal stromal tumor.

clinical occlusion syndrome suspected because of metastasis in whom a total DBE confirmed that the obstruction was due to adherences.

Tattoo injection was performed in 21 cases (75%) and guided elective (*n* = 8, 28.6%) or emergency surgery (*n* = 5, 17.9%). There was no complication related to therapeutics.

In summary, DBE modified the clinical course and outcome in 7 patients (25%), delaying or avoiding emergency surgery (*n* = 3), modifying surgery approach (*n* = 2) and indicating emergency SB partial resection instead of elective approach (*n* = 2). It's interesting to note that within these 7 patients, in only 3 cases (42.9%) surgery was delayed or avoided due to endoscopic therapy. Two patients with actively bleeding GIST and Kaposi sarcoma in whom argon plasma coagulation was successfully performed and one patient with a stenosing adenocarcinoma who underwent a DBE with an enteral prosthesis placed.

DISCUSSION

Regarding the diagnostic performance of deep enteroscopy in SB tumors, Chen *et al*[3] in an Asiatic retrospective study reported 440 DBEs in 400 patients, diagnosing 67 SB tumors by DBE, with 16.8% overall diagnostic yield. Eleven patients with negative DBE were diagnosed of a SBT by CE or surgery. The positive detection rate among the 78 patients with SBT was higher with DBE than with CT scan (85.9% *vs* 72.9%, respectively). Adenocarcinoma (29.5%), GIST (24.4%) and lymphoma (15.4%) were the most common tumors reported by this author. They were mostly located at the jejunum (60.3%), and the MSBT detection rate was 14.5%. Cangemi *et al*[2], in an American research study, with 1652 DBE performed in 1106 patients reported a SBT detection rate of 12.1%. However, the MSBT rate was about 5%. The most common lesions were neuroendocrine tumor (19.4%), GIST (7.5%) and lymphoma (7.5%).

A study from United States[27] analyzes the impact on incidence and survival rates for SBT after the emergence of CE and deep enteroscopy. In order to assess the potential impact of this technology, they compared

the incidence rates from 1992-2000 and 2001-2009 to determine if there were different diagnostic yields between both periods. SBT remain uncommon in United States, and its incidence significantly increased from 2.5 during the 1992-2000 time frame to 3.1 per 100000/year in the later period of time ($P < 0.004$). The survival was significantly better in the 2001-2009 cohort (52.6% *vs* 63.1% 5-year survival, $P < 0.001$). Stage-specific analysis showed a significant rise in more distant disease only in African-Americans after 2000, which may reflect factors in tumor biology, treatment, and/or access to care of these patients.

In the present study, we reported on 28 patients (4.5%) with MSBTs, all distal to Treitz. When DBE was carried out, there was a suspicion of SBT in all cases. The histological type distribution is quite different between different countries. Adenocarcinoma[3,20,28], neuroendocrine SBT[1,4] and lymphoma[21] have been reported to be the most frequent histological type by different authors. These differences are probably due to the different geographical distributions and clinical presentations of different studies of patient's populations. In our study, GIST was the most common MSBT followed by adenocarcinoma.

DBE allowed histopathological diagnosis in most patients (71.4%), except in GI stromal tumors. The histological detection rate in GIST was low (57.4%) but higher than reported by other authors[22,29]. In addition, there were some extremely rare tumors detected, such as jejunal Kaposi sarcoma.

MSBTs were more common among men (71.4%). These tumors may be presented with complete SB stenosis and/or acute overt OGIB, requiring early management by emergency DBE[30-32] or surgery[33]. This procedure may define the characteristics of SB stenosis or bleeding in order to make a surgery decision and/or perform endoscopic treatment[34,35].

There has been recently reported[5] that in patients presented with OGIB, DBE following a positive CE may be the first option, but direct surgery may also be indicated. Interventional digital subtraction angiography has also been reported to be effective in GIST with bleeding[36].

Among patients with a high clinical suspicion of a SBT in the setting of a negative CE result, radiological imaging or deep enteroscopy are equally indicated. CT scan or MR is the preferred initial test in patients with obstructive symptoms. We have performed a DBE following a positive CE in all cases to have a histological and endoscopic diagnosis.

We are also convinced that the entire exploration of the SB in selected cases such as patients with neuroendocrine tumors may be crucial, because this may impact further management. In our series, we have reported multiple adenocarcinomas or neuroendocrine tumors in the same patient. In addition, the histological analysis may have different diagnostic yields within different lesions of the same MSBT. In other cases, to achieve the primary MSBT location for histological and endoscopic diagnosis may be enough.

Thus, DBE has proven to be accurate in management of MSBT. In our study, DBE modified the outcome of 7 patients (25%), not only because of diagnosis capabilities but also of therapeutics interventions.

However, there were some limitations of our study as the retrospective design and potential referral bias.

In conclusion, DBE is critical in the management of MSBT and may have an impact delaying or avoiding emergency surgery. This procedure clarifies the tumor location and characteristics allowing tattoo injection to guide a possible surgery and provides additional information to other procedures that may be decisive in the clinical course of these patients.

COMMENTS

Background

Malignant small bowel tumors (MSBT) are a heterogeneous group of rare tumors. However, the incidence of these neoplasms is increasing correlated to the expansion of deep enteroscopy and video capsule endoscopy.

Research frontiers

There're different histological subtypes of MSBT with different prognosis and management. The real incidence of each histological type and clinical characteristics are not well-established. Studies to date have reported different distributions of these neoplasms depending on the *geographical area*. Recently, double-balloon enteroscopy (DBE) following capsule endoscopy was confirmed as a valid strategy in patients with a suspected MSBT presenting with obscure gastrointestinal bleeding (OGIB).

Innovations and breakthroughs

Most of studies to date report series from Asia or United States. There're few large European reports of MSBT. In addition, there's no consensus regarding the most common histological type or clinical presentation by different authors. The present study represents a large series of a referral center in DBE. The authors have considered only patients with jejunal of ileal tumors in order to clarify the DBE role in these cases. OGIB was the most common clinical presentation and gastrointestinal stromal tumors the most common type.

Applications

This study clarifies the DBE role in MSBT. The present data might suggest that DBE might impact in about 25% of patients with MSBT by modifying surgery approach.

Terminology

DBE is an endoscopic technique originally described by Yamamoto that allows the entire examination of the small bowel, with two balloons fitted onto the tips of the scope and over tube.

Peer-review

This study clarifies the role of DBE in the management of MSBT on proper scientific level.

Abstract

AIM: To evaluate the determination of the margin of differentiated-type early gastric cancers by using conventional endoscopy.

METHODS: We retrospectively evaluated 364 differentiated early gastric cancers that were endoscopically resected as en-bloc specimens and diagnosed pathologically in detail between November 2007 and October 2008. All procedures were done with conventional endoscopes and all endoscopic samples, before and after indigo carmine dye, were re-evaluated using a digital filing system by one endoscopist. We analyzed the incidence of lesions with unclear margins and the relationship between unclear margins and relevant clinicopathological findings.

RESULTS: The rate of lesions with unclear margins was 20.6% (75/364). Multivariate regression analysis suggested that the factors that make the determination of the margin difficult were normal color, presence of components of flat area (0-IIb), a diameter ⩾ 21 mm, ulceration, and components of poorly differentiated adenocarcinoma in the mucosal surface.

CONCLUSION: As many as 20% of differentiated early gastric cancers show unclear margins. Consideration of the factors associated with unclear margins may help endoscopists to accurately determine the margins of the lesion.

Key words: Early gastric cancer; Conventional endoscopy; Determination of the margin

Core tip: As many as 20% of differentiated early gastric cancers show unclear margins by using conventional endoscopy. Consideration of the factors associated with unclear margins, such as normal color, presence of components of flat area (0-IIb), a diameter ⩾ 21 mm, ulceration, and components of poorly differentiated adenocarcinoma in the mucosal surface, may help endoscopists to accurately determine the margins of the lesion.

INTRODUCTION

Since Gotoda *et al*[1] described the incidence of lymph node metastasis from early gastric cancer and with the development of endoscopic submucosal dissection (ESD), early gastric cancer is often resected endoscopically. When endoscopic resection of early gastric cancers is performed, it is important to accurately determine the margin of the lesion. A vague determination of the location of the margin may allow residual cancer to remain, leading to recurrences and additional resections. Recently, imaged enhanced endoscopy (IEE) procedures, such as narrow band imaging (NBI), auto fluorescence imaging (AFI), or flexible spectral imaging color enhancement (FICE) have been developed; however, these methods have not been adopted everywhere. Therefore, an accurate understanding of the use of conventional endoscopes is still relevant.

In this study, we evaluated the determination of the margin of differentiated-type early gastric cancers by using conventional endoscopes and investigated the factors that may make the margin unclear.

MATERIALS AND METHODS

A total of 381 differentiated early gastric cancers were resected endoscopically between November 2007 and October 2008. We excluded 17 early gastric cancers that could not be evaluated in detail because of piecemeal resection, severe burning effects, or other confounding factors. A total of 364 early gastric cancers were included in this study. We reviewed the clinical records, endoscopic images, endoscopy reports, and pathology reports for every patient and analyzed the incidence of lesions with unclear margins and the relationship between unclear margins and the following clinicopathological findings: age, sex, tumor location, tumor color, macroscopic type, component of flat area, tumor size, ulcer finding, component of poorly differentiated adenocarcinoma in the mucosal surface, and intestinal metaplasia around the lesion.

Endoscopic procedure

All patients drank a solution containing 40000 units of pronase (Pronase MS®; Kaken Pharmaceutical Products, Tokyo, Japan), 4 mL of 2% dimethicone (Gascon®; Kissei Pharmaceutical Co., Tokyo, Japan) and 2 g of $NaHCO_3$ to dissolve mucus and bubbles before examination. All procedures were done with conventional endoscopes (GIF-Q240, Q260, H260; Olympus Optical Co., Tokyo, Japan) and without magnifying endoscopy, NBI, or AFI. All endoscopic images were recorded by using a digital filing system (NEXUS; Fuji Film Medical Co., Tokyo, Japan). All endoscopic images before and after indigo carmine dye (0.2%) were reviewed in this study by using a digital filing system by one individual (S.Y) who has 10 years of experience as an endoscopist.

Definitions

Lesions with an unclear margin were defined as lesions with an undelineated margin or an inaccurate marking. An undelineated margin was determined by reviewing the endoscopic images. The identification by the endoscopist of a difference between the lesion and surrounding mucosa in terms of colors, surface morphology, and a height more than two-thirds the size of the circumference was considered a delineated margin (Figure 1). If it was not possible to make a distinction, it was classified as an undelineated margin lesion (Figure 2). We also evaluated the markings made before resection to recognize the tumor margin. We defined an accurate marking if all markings were made outside of the tumor in the resected specimen (Figure 3A). If not, we defined it as an inaccurate marking (Figure 3B). The tumor color and location were also determined endoscopically. The stomach is anatomically divided into three parts: the upper third (U), middle third (M), and lower third (L). The cross-sectional circumference of the stomach is divided into four equal parts; the lesser and greater curvatures, and the anterior and posterior walls based on the Japanese Classification of Gastric Carcinoma[2]. The main macroscopic type of the tumor was classified based on the Paris classification[3], and the components of flat area (0-IIb) of the tumor, tumor size, ulceration findings, components of poorly differentiated adenocarcinoma in the mucosal surface, and metaplasia around the tumor were determined histopathologically.

Statistical analysis

Statistical analysis were made by using the Student's *t* test for evaluating the patients' ages and the tumor sizes, and by using the χ^2 test with Yate's correction and the Fisher exact test for evaluating any other factors.

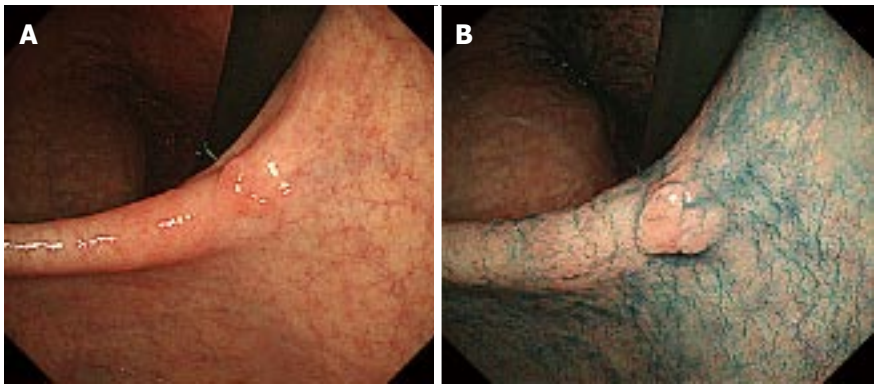

Figure 1 A case of a delineating lesion (0-IIa). Before (A) and after (B) indigo-carmine dye, the margin of the tumor was clear.

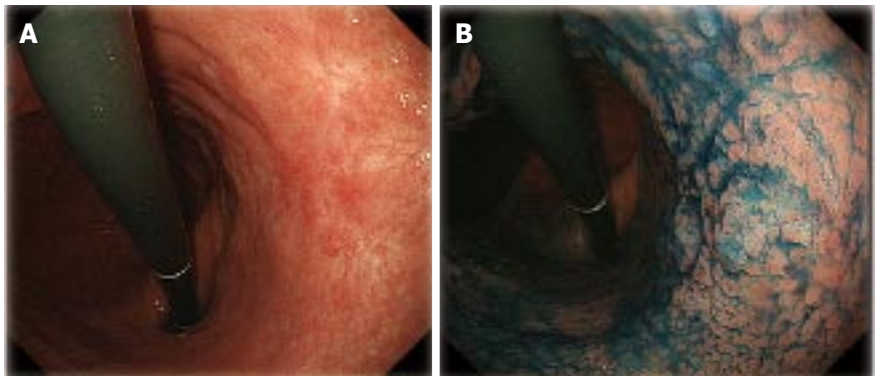

Figure 2 An undelineated margin lesion. A: A case of an undelineating lesion (0-IIc) with ulceration findings; B: After indigo-carmine dye, the margin of the tumor was still unclear.

A level of $P < 0.05$ was considered to be statistically significant. After evaluating the factors that made the determination of the margin difficult, we decided to use logistic regression analysis for further analysis of those factors.

RESULTS

Incidence of lesions with unclear margin

The characteristics of the 364 candidate lesions reviewed during this period are described in Table 1. There were 27 undelineated margin lesions and 337 delineated margin lesions. There were 62 lesions with inaccurate markings and 302 lesions with accurate markings (Table 1). Consequently, 14 lesions were found to have overlapping results. Therefore, there were 75 lesions with unclear margins (Figure 4). The rate of those lesions in this group was 20.6% (75/364).

Factors that made determination of the margin difficult

Factors that had significant correlations with unclear margins were tumor location (three parts), color, components of the flat area (0-IIb), tumor size, ulceration, and components of poorly differentiated adenocarcinoma in the mucosal surface (Table 2). After evaluating those 6 factors by multivariate regression analysis, the factors that made the determination of the margin difficult were normal coloration (OR = 2.095; 95%CI: 1.040-4.217; $P = 0.0383$), components of flat area (0-IIb) (OR = 4.900; 95%CI: 1.610-14.913; $P = 0.0051$), the diameter $\geqslant$ 21 mm (OR = 3.852; 95%CI: 2.165-6.852; $P < 0.0001$), ulceration findings (OR = 2.307; 95%CI: 1.156-4.604; $P = 0.0178$), and components of poorly differentiated adenocarcinoma in the mucosal surface (OR = 6.650; 95%CI: 2.590-17.073; $P < 0.0001$) (Table 3).

DISCUSSION

After ESD was developed, early gastric cancer was often resected endoscopically, especially in Japan. Previously reported[4-6] accuracy rates for the delineation of the margin by using conventional endoscopy were almost 80% to 85%, although the criteria for the determination of the margin were not commonly specified in those reports. In this study, we defined the accuracy rate not only by endoscopic images but also by pathological study of the specimens, and the accuracy rate was almost the same as that shown in previous reports. Asada-Hirayama *et al*[7] reported a similar study to ours, and in their result, the accuracy rate for the delineation of the margin was 92.6%, which was much higher than that seen in previous reports, including our study. However, they evaluated only markings on the resected

specimens and they used not only conventional endoscopes, but also magnifying endoscopes with NBI. Although there was no significant difference in the accuracy between the 2 kinds of endoscopes in their study, this factor might have influenced the margin delineation rates.

Tanabe *et al*[6] reported the factors that make the delineation of the margin difficult as (1) large lesions (> 31 mm); (2) flat lesions or those with a flat area; (3) adenocarcinoma with low-grade atypia; (4) gastric mucin phenotype (G-type) adenocarcinoma or gastric predominant gastric and intestinal mucin phenotype (G > I-type) adenocarcinoma; and (5) carcinoma cells invading the middle to deeper portion of the mucosa under normal covering epithelium. In our study, 2 factors, lesion size and flat area, were almost the same as the factors that Tanabe *et al*[6] reported, and Asada-Hirayama *et al*[7] reported similar results. To achieve a complete resection, we should observe for those factors that demonstrate a more difficult to differentiate margin, and if the lesion might have such characteristics, we should examine the margin more carefully to ensure an accurate determination. Conventional endoscopy can demonstrate the tumor size and ulceration findings, but sometimes it is difficult to identify components of the flat area. To solve this difficulty, IEE, such as a magnifying endoscope, NBI[8,9], FICE[10], and an acetic acid-indigo carmine mixture (AIM)[11], might be useful. Yao *et al*[8] reported magnifying endoscopy with NBI may allow reliable delineation of the lateral extent of carcinomatous tissue, and in this study, a demarcation line was identified in 97 of 100 carcinomas (97%). Additionally, Nagahama *et al*[9] reported that magnifying endoscopy with NBI could determine margins in 72.6% of the lesions that show unclear margin using conventional endoscopes. AIM was developed by Kawahara *et al*[11] and they reported the diagnostic accuracy of AIM observation was 90.7%. In contrast, the diagnostic accuracy of indigo carmine observation was 75.9% in that study. AIM is also easy to use without special equipment. Kadowaki *et al*[12] mentioned that magnifying endoscopy with NBI and acetic acid is easier compared to other magnifying endoscopy methods to recognize the demarcation of

early gastric cancers for non-expert endoscopists as well as expert endoscopists. Utilizing these advanced imaging techniques may make it easier and clearer for all endoscopists to recognize the demarcation of early gastric cancers.

Our study had a few limitations. First, we did not compare endoscopic figures with resected specimens in detail, so there was no evidence that the determination of the margin was completely correct. However, in our study, to evaluate the accuracy as precisely as possible, we strictly determined the criteria of "undelineated margin lesions" using not only endoscopic images but also pathological study of the specimens as well as was done in the study of Nagahama *et al*[9]. Second, our study was a retrospective study, and therefore, the individuals who performed the endoscopic resection and those who re-evaluated the lesions were not the same in almost all cases, and the margins that the 2 endoscopists considered were not same. To solve these 2 limitations, future studies could prospectively demarcate the tumor margin to be able to compare it with the endoscopically resected specimens, and the same endoscopists should evaluate the accuracy of the determination.

In conclusion, approximately 20% of differentiated early gastric cancers showed an unclear margin.

Factors such as normal color, components of flat area (0-IIb), diameter ⩾ 21 mm, ulceration findings, and components of poorly differentiated adenocarcinoma in the mucosal surface can make the determination of the margin difficult. During endoscopic resection, endoscopists should carefully evaluate the margin of the lesion while considering the risk factors for unclear margins.

COMMENTS

Background

When endoscopic resection of early gastric cancers is performed, it is important to accurately determine the margin of the lesion. A vague determination of the margin may result in residual cancer cells, which may cause recurrences and require additional resections.

Research frontiers

Recently, imaged enhanced endoscopy (IEE) procedures, such as narrow band imaging (NBI), auto fluorescence imaging (AFI), or flexible spectral imaging color enhancement (FICE) have been developed. Especially, magnifying endoscopy with NBI may allow reliable delineation of the lateral extent of carcinomatous tissue, and it could determine margins in the lesions that show unclear margin using conventional endoscopes. However, these methods have not been adopted everywhere.

Innovations and breakthroughs

In this study, the authors evaluated the determination of the margin of differentiated-type early gastric cancers by using conventional endoscopy. In order to evaluate the accuracy as precisely as possible, the authors more strictly determined the criteria of "undelineated margin lesions" using not only endoscopic images but also pathological study of the specimens than similar studies.

Applications

The result of this study is an important benchmark to evaluate the new modalities describe above. And when these new modalities are not available, the authors should carefully evaluate the margin of the lesion while considering the risk factors for unclear margins.

Terminology

Endoscopic submucosal dissection is a newly developed technique in the field of endoscopic treatment for gastrointestinal neoplasms because of its high rate of *en bloc* resection. IEE is a dye-based or an equipment-based image enhanced technology to increase the contrast of structures, thus making the mucosal topography, morphology and borders of lesions viewable in finer detail. NBI is one of the equipment-based image enhancement technologies, which improves the contrast of the microvascular structure and fine mucosal patterns in the mucosal surface layer using the narrow-band illumination focused two beams of 415 nm and 540 nm. AFI is one of the equipment-based image enhancement technologies based on the detection of natural tissue fluorescence emitted by endogenous molecules such as collagen, flavins, and porphyrins. FICE is one of the equipment-based image enhancement technologies, which enhance images by extracting spectral images at the desired wavelengths by applying signal processing to the white light generally used by endoscope. An acetic acid–indigo carmine mixture is one of the dye-based image enhancement technologies using both acetic acid for color contrast and indigo carmine for shape contrast.

Peer-review

It is a retrospective study and evaluation of various endoscopic criteria for unclear margins in early gastric cancer may not be perfect. Still this study provides useful guide for future prospective studies to define unclear margins in early gastric cancers.

CASE REPORT

Metallic stent insertion with double-balloon endoscopy for malignant afferent loop obstruction

Masakuni Fujii, Shuhei Ishiyama, Hiroaki Saito, Mamoru Ito, Akiko Fujiwara, Takefumi Niguma, Masao Yoshioka, Junji Shiode

Masakuni Fujii, Shuhei Ishiyama, Hiroaki Saito, Mamoru Ito, Akiko Fujiwara, Masao Yoshioka, Junji Shiode, Department of Internal Medicine, Okayama Saiseikai General Hospital, Okayama 700-8511, Japan
Takefumi Niguma, Department of Surgery, Okayama Saiseikai General Hospital, Okayama 700-8511, Japan

Author contributions: Fujii M, Ishiyama S, Saito H, Ito M, Fujiwara A, Niguma T, Yoshioka M and Shiode J were responsible for the care of the patients; Fujii M, Ishiyama S and Saito H performed endoscopic therapy; Niguma T conducted patient follow-ups; Fujii M, Yoshioka M and Shiode J wrote the manuscript; all authors read and approved the final manuscript.

Ethics approval: Case reports do not require examination by the Okayama Saiseikai General Hospital Institutional Review Board. Ethical considerations were upheld and patient personal information was protected.
Informed consent: All study participants, or their legal guardian, provided written informed consent prior to study enrollment.
Conflict-of-interest: The authors declare that there are no competing financial or personal relationships with other people or organizations that could inappropriately influence the research.

Abstract

Progress in double-balloon endoscopy (DBE) has allowed for the diagnosis and treatment of disease in the postoperative bowel. For example, a short DBE, which has a 2.8 mm working channel and 152 cm working length, is useful for endoscopic retrograde cholangiopancreatography in bowel disease patients. However, afferent loop and Roux-limb obstruction, though rare, is caused by postoperative recurrence of biliary tract cancer with intractable complications. Most of the clinical findings involving these complications are relatively nonspecific and include abdominal pain, nausea, vomiting, fever, and obstructive jaundice. Treatments by surgery, percutaneous transhepatic biliary drainage, percutaneous enteral stent insertion, and endoscopic therapy have been reported. The general conditions of patients with these complications are poor due to cancer progression; therefore, a less invasive treatment is better. We report on the usefulness of metallic stent insertion using an overtube for afferent loop and Roux-limb obstruction caused by postoperative recurrence of biliary tract cancer under short DBE in two patients with complexly reconstructed intestines.

Key words: Afferent loop obstruction; Double balloon endoscopy; Overtube; Metallic stent; Biliary tract cancer

Core tip: Malignant afferent loop and Roux-limb obstruction are intractable complications caused by

postoperative recurrence of biliary tract cancer. Metallic stent insertion using an overtube under double-balloon endoscopy is a safe and feasible treatment option in such cases.

Fujii M, Ishiyama S, Saito H, Ito M, Fujiwara A, Niguma T, Yoshioka M, Shiode J. Metallic stent insertion with double-balloon endoscopy for malignant afferent loop obstruction. *World J Gastrointest Endosc* 2015; 7(6): 665-669 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i6/665.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i6.665

INTRODUCTION

Malignant afferent loop obstruction is a potentially life-threatening adverse event of Billroth II gastrectomy and pancreaticoduodenectomy. The occlusion is generally caused by a recurrent tumor, and often presents as chronic, progressive, partial obstruction[1-3]. This type of complication is expected to increase along with therapeutic advances for malignant tumors, thus necessitating the development of safe, effective treatments.

The general condition of patients with malignant afferent loop obstructions is poor due to cancer progression, and thus a less invasive treatment is preferred. Malignant afferent loop obstructions can be treated with surgery, percutaneous transhepatic biliary drainage, percutaneous enteral stent insertion, or endoscopic therapy[4-6]. Endoscopic stents for digestive tract obstruction are a minimally invasive, useful, and safe treatment[7-9]. The primary obstacle for endoscopic stent treatment in postoperative digestive tract obstruction is the difficulty in approaching the obstructing lesion. Of note, there are reports on the use of double-balloon endoscopy (DBE) for complicated postoperative bowel reconstructions[10,11]. Furthermore, a short DBE, which has a 2.8 mm working channel and 152 cm working length, is useful for endoscopic retrograde cholangiopancreatography in these patients[12]. However, because of the large diameter of the system for delivery of metallic stents (MS) indigestive tract obstructions, they cannot be deployed through the narrow working channel of a short DBE. Therefore, new methods are needed to deploy an MS with DBE.

We report on the usefulness of MS insertion using an overtube under a short DBE for afferent loop and Roux-limb obstruction caused by postoperative recurrence of biliary tract cancer in two patients with complexly reconstructed intestines.

CASE REPORT

Case 1

A man in his sixties underwent Roux-en-Y hepaticojejunostomy because of cholangiocarcinoma. Chemotherapy was performed one year later for recurrence of peritoneal dissemination. Two years after chemotherapy, the patient developed a fever and elevated serum transaminase levels. Laboratory tests were as follows: white blood cell (WBC) counts, 9410/μL (normal: 4500-8500/μL); C-reactive protein, 4.7 mg/dL (normal: < 0.26 mg/dL); total bilirubin, 1.2 mg/dL (normal: 0.2-1.2 mg/dL); γ-glutamyltranspeptidase (γGTP), 256 IU/L (normal: 5-40 IU/L); aspartate aminotransferase (AST), 38 IU/L (normal: 10-35 IU/L); and alanine aminotransferase (ALT), 17 IU/L (normal: 7-42 IU/L). Abdominal computed tomography (CT) showed the reconstructed jejunum that was expanded at the site of hepatectomy, mild expansion of the intrahepatic bile ducts and stenosis of the reconstructed jejunum (Figure 1A). The patient was diagnosed with malignant Roux-limb obstruction due to peritoneal dissemination and cholangitis.

Ultrasound-guided drainage was performed for the dilated jejunal Roux-limb, but repeated inflammatory aggravation with drain obstruction occurred. Therefore, a short DBE was performed with the patient under conscious sedation. The short DBE (EC-450BI5; Fujifilm, Tokyo, Japan) was inserted into the Roux-limb obstruction (Figure 1B), and a 0.035 inch guide-wire (Radifocus; Terumo, Tokyo, Japan) was passed through the site of the stricture. Then, a standard endoscopic retrograde cholangiopancreatography injection catheter (MTW Endoskopie, Düsseldorf, Germany) was inserted, and passage through the stenosis was confirmed by radiography. The guide-wire was exchanged with a 0.035 inch Jagwire (Boston Scientific Co., Natick, MA, United States), and an overtube was left to prevent bowel expansion. The DBE was then removed. Finally, an MS (2.2 cm × 6.0 cm, Wallflex duodenal stent; Boston Scientific Co.) was inserted through the overtube in combination with an over-the-wire technique (Figure 1C) and deployed (Figure 1D). There were no perioperative or postoperative adverse events.

After stent insertion, the patient's cholangitis, general condition, and laboratory tests improved as follows: WBC count, 7960/μL; C-reactive protein, 1.86 mg/dL; total bilirubin, 0.7 mg/dL; γGTP, 96 IU/L; AST, 25 IU/L; and ALT, 19 IU/L. On CT, dilation of the Roux-limb disappeared, and chemotherapy resumed. However, this patient died because of peritonitis carcinomatosa 141 d after stent insertion.

Case 2

A man in his sixties underwent pancreaticoduodenectomy because of Vater's papilla cancer. He developed a fever and jaundice approximately 10 mo after the operation. Laboratory tests were as follows: total bilirubin 9.9 mg/dL; γGTP, 401 IU/L; AST, 273 IU/L; and ALT, 283 IU/L. Abdominal CT showed ascites, dilation of the afferent loop, and a surrounding soft density (Figure 2A). The patient was thus diagnosed with malignant afferent loop obstruction due to peritoneal dissemination and cholangitis.

A short DBE (EC-450BI5; Fujifilm) was performed,

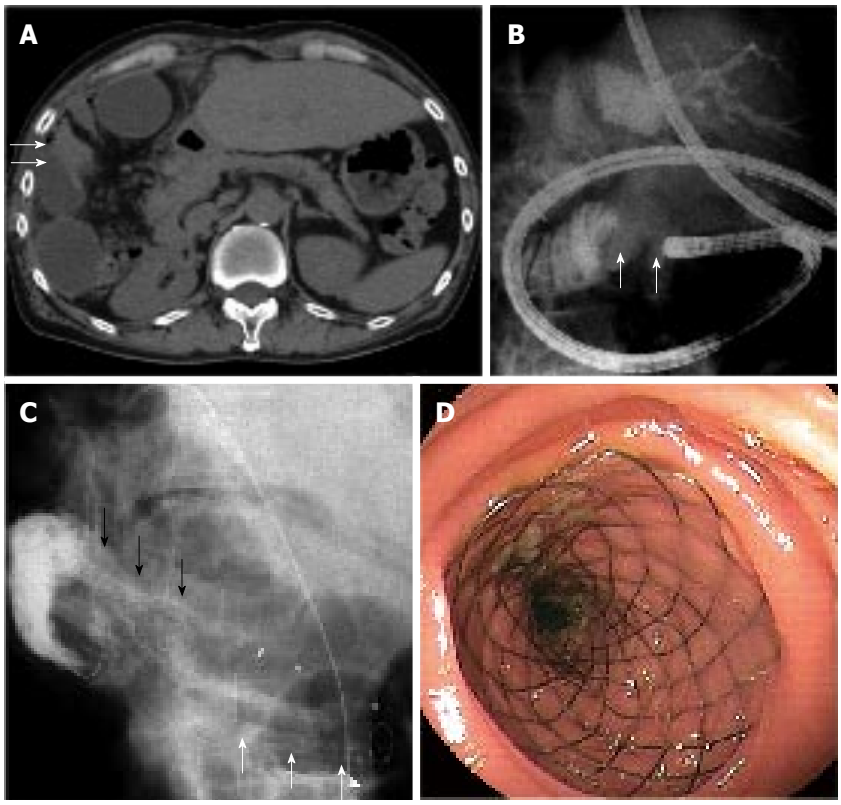

Figure 1 Metallic stent insertion with double-balloon endoscopy for malignant afferent loop obstruction in case 1. A: Abdominal computed tomography showed the reconstructed jejunum that was expanded at the site of hepatectomy, expansion of intrahepatic bile ducts, and the stenosis of the reconstructed jejunum (arrows); B: The stenosis (arrows) was seen when the double-balloon endoscopy (DBE) reached the Roux-limb obstruction; C: An overtube was left to prevent bowel expansion. The DBE was then removed and an metallic stent (MS) (black arrows) was inserted through the overtube (white arrows) in combination with the over-the-wire technique; D: A Wallflex duodenal MS with a diameter of 2.2 cm and a length of 6.0 cm was deployed.

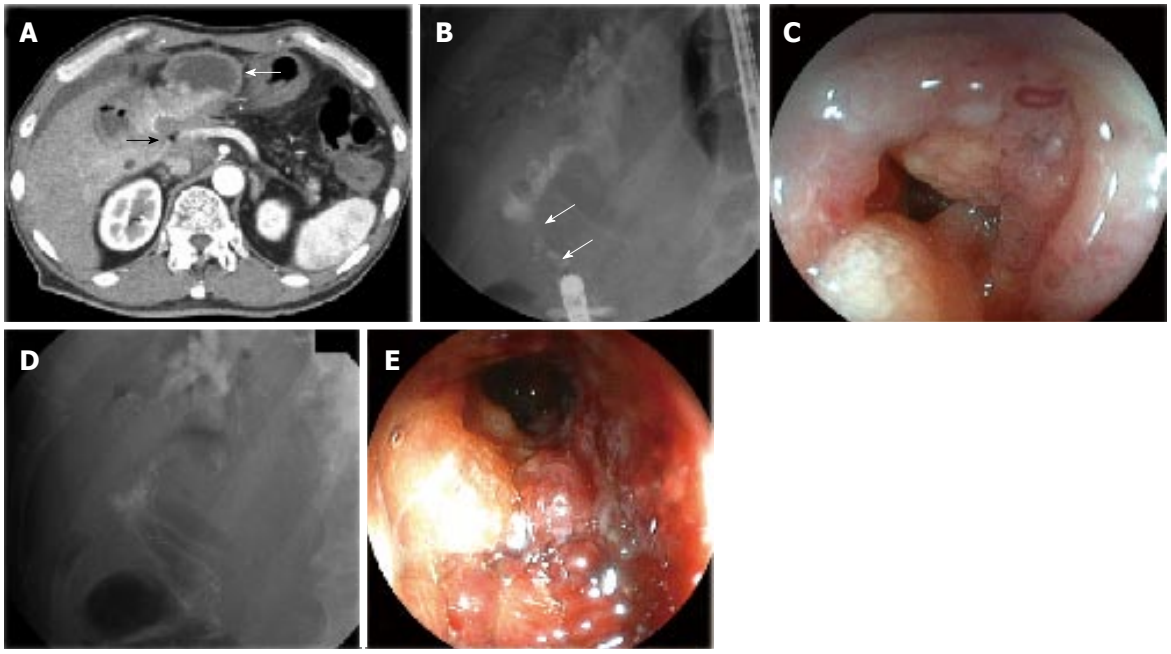

Figure 2 Metallic stent insertion with double-balloon endoscopy for malignant afferent loop obstruction in case 2. A: Computed tomography showed ascites, dilation of the afferent loop (white arrow), and a surrounding soft density (black arrow); B: The double-balloon endoscopy reached the afferent loop obstruction (arrows); C: Stenosis with irregular mucosa was seen; D and E: A Niti-S duodenal metallic stent with a diameter of 2.2 cm and a length of 6.0 cm was inserted and deployed.

which revealed stenosis with irregular mucosa at the afferent loop obstruction (Figure 2B and C). An MS (2.2 cm × 6.0 cm, Niti-S D-type stent; Taewoong Medical Inc., Seoul, South Korea) was inserted and deployed as

described in case 1 (Figure 2D and E). There were no perioperative or postoperative adverse events.

After insertion of the MS, the patient's general condition and laboratory tests improved: total bilirubin, 1.5 mg/dL; γGTP, 296 IU/L; AST, 92 IU/L; and ALT, 77 IU/L. Chemotherapy was resumed, however this patient also died from peritonitis carcinomatosa 140 d after stent insertion.

DISCUSSION

Afferent loop and Roux-limb obstruction are rare adverse events that result in the obstruction of the postoperative intestinal tract. When jaundice and/or fever occur in a postoperative cancer patient with intestinal tract reconstruction, it is important to consider afferent loop or Roux-limb obstruction due to recurrence. Obstructions are typically treated with surgery; however, the general condition of many of these patients is so poor that surgery is not possible. In such cases, insertion of an MS through the stenosis is a useful treatment.

Although percutaneous stent deployment has been reported[13,14], the endoscopic approach allows for direct identification of the stenosis. There are few reports using this method, due to the difficulty in reaching the stenosis with an endoscope, and the need for a scope with a large enough working channel diameter to permit insertion of an MS. In the cases reported here, malignant afferent loop and Roux-limb obstructions were confirmed by DBE and the stenoses were penetrated with a guide-wire. The endoscope was then removed, leaving the overtube to prevent bowel expansion and deploy the MS with an over-the-wire technique. With this method, the stents were safely and easily inserted through the stenoses using a DBE, eliminating the need for a new endoscope. DBE was chosen over a colonoscope in these cases, as it can cause patient discomfort and poses a risk to the patient's health. Stents were safely inserted without a high degree of difficulty and did not produce major adverse events. Moreover, the patients were able to leave the hospital early.

There are other treatments for afferent loop obstruction, such as percutaneous transhepatic biliary drainage or endoscopic ultrasound-guided transhepatic drainage. When a hepatic-jejunal anastomotic stricture coexists, these methods may be particularly useful. However, biliary access can be challenging in patients without dilation of intrahepatic biliary ducts or in patients with ascites. In our cases, we could confirm the absence of judge hepatic-jejunal anastomotic strictures because the bile ducts were easily contrasted by cystography from the afferent loop. Thus, treatments should be selected depending on the patient's condition.

In conclusion, MS insertion using an overtube for afferent loop and Roux-limb obstruction from postoperative recurrence of biliary tract cancer under short DBE is safe and feasible. However, it is necessary to accumulate more cases to determine the true rates of adverse events and confirm the effectiveness of this approach in comparison with surgery and other treatments.

COMMENTS

Case characteristics

Two men in their sixties who underwent Roux-en-Y hepaticojejunostomy after presenting with cholangiocarcinoma and a fever (Case 1) and pancreaticoduodenectomy due to Vater's papilla cancer after presenting with fever and jaundice (Case 2) are reported here.

Clinical diagnosis

Case 1: Fever; Case 2: Fever and jaundice upon physical exam.

Differential diagnosis

Pseudocyst; ileus.

Laboratory diagnosis

Case 1: WBC, 9410/μL; C-reactive protein, 4.7 mg/dL; total bilirubin, 1.2 and 9.9 mg/dL; γ-glutamyltranspeptidase, 256 and 401 IU/L; aspartate aminotransferase, 38 and 273IU/L; and alanine aminotransferase,17 and 283 IU/L, for case 1 and case 2, respectively.

Imaging diagnosis

Computed tomography (CT) in case 1 revealed expansion at the site of hepatectomy in the reconstructed jejunum, mild expansion of intrahepatic bile ducts, and stenosis of reconstructed jejunum; in case 2, CT revealed ascites, dilation of the afferent loop, and a surrounding soft density.

Treatment

Metallic stent insertion with double-balloon endoscopy for malignant afferent loop and Roux-limb obstruction.

Related reports

Afferent loop and Roux-limb obstructions caused by postoperative recurrence of biliary tract cancer are rare and intractable.

Term explanation

Malignant afferent loop obstructions are rare adverse events due to the obstruction of the postoperative intestinal tract of Billroth II gastrectomy and pancreaticoduodenectomy.

Experiences and lessons

Metallic stent insertion using an overtube for afferent loop and Roux-limb obstruction caused by postoperative recurrence of biliary tract cancer under short double-balloon endoscopy is safe and feasible.

Peer-review

The technique is interesting and clinically relevant, and will be of interest to this journal's readership.

Abstract

Patients with indeterminate colitis (IC) are significantly younger at diagnosis with onset of symptoms before the age of 18 years with significant morbidity in the interim. The successful care of IC is based on microscopic visual predict precision of eventual ulcerative colitis (UC) or Crohn's colitis (CC) which is not offered in 15%-30% of inflammatory bowel disease (IBD) patients even after a combined state-of-the-art classification system of clinical, visual endoscopic, radiologic and histologic examination. These figures have not changed over the past 3 decades despite the introduction of newer diagnostic modalities. The patient outcomes after restorative proctocolectomy and ileal pouch-anal anastomosis may be painstaking if IC turns into CC. Our approach is aiming at developing a single sensitive and absolute accurate diagnostic test tool during the first clinic visit through endoscopic biopsy derived proteomic patterns. Matrix-assisted-laser desorption/ionization mass spectrometry (MS) and/or imaging MS technologies permit a histology-directed cellular test of endoscopy biopsy which identifies phenotype specific proteins, as biomarker that would assist clinicians more accurately delineate IC as being

either a UC or CC or a non-IBD condition. These novel studies are underway on larger cohorts and are highly innovative with significances in differentiating a UC from CC in patients with IC and could lend mechanistic insights into IBD pathogenesis.

Key words: Indeterminate; Ulcerative; Crohn's colitis; The colitides; Proteomics; Diagnostic accuracy

Core tip: This Editorial is introductory, dedicated to a novel and innovative study with clinical relevance regarding precision of indeterminate colitis (IC) into accurate diagnosis of either ulcerative colitis (UC) or Crohn's colitis (CC). To date, it is very difficult to predict the clinical course of IC, whether it will evolve into UC or CC. About 90% of IC is diagnosed at the time of colectomy for fulminant colitis and subsequent management critically depends on the correct eventual diagnosis. The outcome after colectomy and pouch anastomosis may be painstaking if IC turns into CC. The undergoing studies of proteomic analysis on colon biopsy specimens, if successful will permit delineate IC into UC or CC precision which could be of great help in decision making regarding treatment indication. Although the present data is convincing and support differentiated between UC and CC, this data requires validation and confirmation on a large scale by clinical studies. Hopefully, this editorial will stimulate research into this field to trying to overcome the diagnostic accuracy challenges in inflammatory bowel diseases.

Gastrointestinal endoscopy biopsy derived proteomic patterns predict indeterminate colitis into ulcerative colitis and Crohn's colitis. *World J Gastrointest Endosc* 2015; 7(7): 670-674 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/670.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.670

INTRODUCTION

In endoscopic medicine, predicting the phenotypic outcomes of "indeterminate colitis (IC)", given its unpredictable clinical presentation and disease course, is challenging[1,2]. Inadequate differentiated diagnoses of the two predominantly colonic inflammatory bowel diseases (IBD), ulcerative colitis (UC) and Crohn's colitis (CC), may lead to the inconclusive IC diagnosis even when a state-of-the-art classification system of combined clinical, endoscopic, radiologic and histologic tools[1,2] are used. Unless there is a unique and yet unclassified class of colitis, the field needs to develop supplemental molecular biomarker tools for precise and rapid distinction between UC and CC for patients that will otherwise be diagnosed with IC. Previous studies using mucosal biopsy[3,4] have been successful as prognostic indicators for IBD whether the colitis is in a quiescent or active state, but have not been able to distinguish UC from CC[3,4]. Patients with IC are significantly younger at diagnosis (M ± SEM, 9.53 ± 4.8 years)[5-8] with onset of symptoms before the age of 18 years[9-13]. IC shows an equal gender distribution[8,14,15]. In contrast, UC is predominant among males and the mean age at onset is 36-39 years[14-18]. These figures have not changed over the past 3 decades despite the introduction of newer diagnostic modalities[1,2,5,10,13,19]. Even after long-term surveillance, a substantial number of patients with IC still have an unchanged diagnosis[5,19,20], with significant patient suffering in the interim[5,19,20]. The continued presence of an IC diagnosis over a long period of time supports part of our hypothesis that IBD may represent a spectrum of diseases rather than just two entities, Crohn's disease (CD) and UC[21].

The need for IC classification into either UC or CC is important for proper care in patients suffering from IBD, with obvious therapeutic and prognostic implications[22]. Early and accurate diagnosis and sub-classification of UC and CC is therefore the cornerstone for personalized and evidence-based interventional care[23-25]. These two pathologies have differing therapeutic strategies and prognoses. Most patients with UC, or IC likely to develop UC[22], will require pouch surgery for resolution[26-30]. Pouch surgery is well-established[22] and restores gut continuity, defecation, deferral, and discrimination, but is only successful if the UC and/or IC likely to develop UC diagnosis is correct[31,32]. However, IC and UC are mistakenly diagnosed in patients with CC[1,33]. Current data show that 15% of IBD patients who undergo pouch surgery for presumed definitive UC (or IC likely to develop UC) subsequently are diagnosed with *de novo* CD in the ileal pouch[34,35]. Identifying patients with CC and positive outcomes after pouch surgery is a painstaking clinical experience[4,34,35]. Ileal pouch anal anastomosis is acceptable standard care for UC patients, and restorative proctocolectomy should be contraindicated for CC patients[4,36,37] .

Pouch complications are significantly higher in patients with CC (± 64%) and IC (± 43%) *vs* patients having UC (± 22%) ($P < 0.05$)[23,38,39]. This diagnostic dilemma holds potential morbidity from unnecessary and/or inappropriate surgery, and underscores the need for a research strategy focused on developing molecular biometrics to improve diagnosis of colitides at initial endoscopic biopsy[21,40-44]. De novo CD in the ileal pouch is the diagnosis most feared by IBD patients and doctors due to its intractable nature and associated complications which often necessitate excision of the pouch with a permanent end-ileostomy[45-49].

ADVANCES

Mass spectrometry (MS) and imaging mass spectrometry (IMS)[21] are non-invasive technologies that can measure individual molecules in complex endoscopic and surgical clinical specimens[40,41]. These analyses

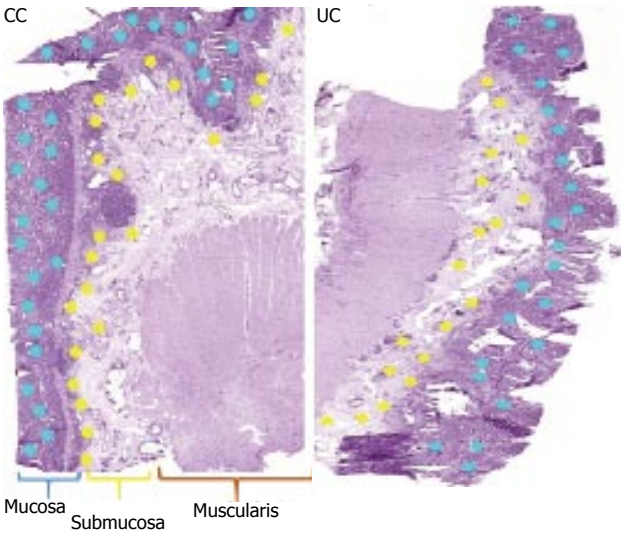

Figure 1 Illustrates histology-directed tissue compartment proteomics profiling using matrix-assisted-laser desorption/ionization mass spectrometry. Digital photomicrographs acquired form histology and matrix-assisted-laser desorption/ionization sections are used to identify and designate sites of interest for profiling. Using bioinformatics technology comparisons are performed in both the training and independent test set samples between inflamed mucosa and inflamed submucosa Crohn's colitis (CC) *vs* ulcerative colitis (UC). Tissue showing marked areas of pathological interest. Rings demonstrate matrix spots in mucosal (blue) and submucosal (yellow) layers (our unpublished data).

provide quantitative and qualitative data about cellular systems, and can differentiate diseased from normal tissue, and can identify diseases within the same organ[40,41,50]. These characteristics offer significant diagnostic and prognostic potential for clinical medicine and could supplement known clinicopathologic variables for delineating IC into UC or CC at a patient's first clinical visit. Due to the current alarming epidemiologic studies indicate that the incidence and prevalence of IBD is widening worldwide, especially in developing nations[9,21,51-60], established techniques like MS and IMS, which are affordable, non-invasive, easier, accurate and faster at screening for potential delineation of IBD, ought to be considered for clinical applications in IBD laboratories. The basic steps of the MS/IMS methodology of histology-directed proteomic patterns profiling are outlined in Figure 1.

Abstract

Cholangiocarcinoma (CCA) is a malignancy of the bile ducts that carries high morbidity and mortality. Patients with CCA typically present with obstructive jaundice, and associated complications of CCA include cholangitis and biliary sepsis. Endoscopic retrograde cholangiopancreatography (ERCP) is a valuable treatment modality for patients with CCA, as it enables internal drainage of blocked bile ducts and hepatic segments by using plastic or metal stents. While there remains debate as to if bilateral (or multi-segmental) hepatic drainage is required and/or superior to unilateral drainage, the underlying tenant of draining any persistently opacified bile ducts is paramount to good ERCP practice and good clinical outcomes. Endoscopic therapy for malignant biliary strictures from CCA has advanced to include ablative therapies *via* ERCP-directed photodynamic therapy (PDT) or radiofrequency ablation (RFA). While ERCP techniques cannot cure CCA, advancements in the field of ERCP have enabled us to improve upon the quality of life of patients with inoperable and incurable disease. ERCP-directed PDT has been used in lieu of brachytherapy to provide neoadjuvant local tumor control in patients with CCA who are awaiting liver transplantation. Lastly, mounting evidence suggests that palliative ERCP-directed PDT, and probably ERCP-directed RFA as well, offer a survival advantage to patients with this difficult-to-treat malignancy.

Key words: Endoscopic retrograde cholangiopancreatography; Cholangiocarcinoma; Stents; Self-expandable metal stents; Photodynamic therapy; Photodynamic therapy; Radiofrequency ablation; Radiofrequency ablation

Core tip: Endoscopic retrograde cholangiopancreatography (ERCP) is a valuable treatment modality for patients with cholangiocarcinoma (CCA), as it enables

luminal drainage of blocked bile ducts and hepatic segments by using plastic or metal stents. While there remains some debate as to if bilateral hepatic drainage is required and/or superior to unilateral drainage, the underlying tenant of draining any persistently opacified bile ducts is paramount to good ERCP practice. Although ERCP interventions cannot cure CCA, advancements in the field of ERCP, including ERCP-directed photodynamic therapy and radiofrequency ablation, likely confer a survival advantage and improve upon the quality of life of patients with incurable disease.

INTRODUCTION

Cholangiocarcinoma (CCA) is the second most common primary neoplasm of the liver[1]. It arises from malignant transformation of cholangiocytes, which are the epithelial cells that line the biliary tree. CCA may be classified based on location as intrahepatic, perihilar, or extrahepatic[1]. Perihilar lesions are further sub-classified depending on their proximal tumor extension according to the classification proposed by Bismuth[2]. Seventy percent of tumors present with bilateral hilar involvement - termed "Klatskin tumors" - and are unresectable cancers[2]. Although CCA is a rare malignancy with 3500 to 5000 cases diagnosed annually in the United States[3], mortality from this cancer is high due to a typically late presentation and limited curative therapies[3].

In patients with inoperable, incurable CCA, initial management usually involves drainage of malignant biliary obstruction and palliation of jaundice. Nevertheless, systemic or locoregional therapies do exist that offer the potential for tumor control, in part to mitigate the complications of further biliary obstruction. Chemotherapeutic agents and radiation therapies have been utilized to achieve this end, although their efficacy is limited, with partial response rates with chemotherapy demonstrated to be 35.9%, and with a stable disease rate of only 26.9%[4].

Over the past two to three decades, the management of CCA has evolved. While surgery remains a curative option for early disease, most cases of CCA are unresectable at the time of presentation. The typical presenting sign of CCA is jaundice. As such, decompressive biliary drainage techniques can help bridge symptomatic patients to surgery, and they can also be used for palliation by treating jaundice and pruritus and by reducing the risk of cholangitis. Various strategies have been employed for biliary drainage, including surgical drainage, percutaneous drainage, and endoscopic decompression *via* nasobiliary drainage or internal biliary stenting. Other mainly palliative modalities for treatment of CCA involve chemoradiation, transarterial chemoembolization, and ablative therapies such as brachytherapy, photodynamic therapy (PDT), and radiofrequency ablation (RFA), which can be applied intraoperatively, percutaneously, or endoscopically[5]. Herein, we will focus on endobiliary therapies for the treatment of CCA and its complications, and the majority of this review will pertain to interventions delivered *via* endoscopic retrograde cholangiopancreatography (ERCP).

BILIARY DECOMPRESSION

While surgical resection is the only treatment that offers curative intent to patients with CCA, the morbidity and mortality associated with liver resection is significantly higher in patients with obstructive jaundice than in patients with normal liver function[6]. Therefore, preoperative biliary drainage is routinely performed to reverse cholestatic liver dysfunction and reduce mortality after selective hepatectomy[7].

Historically, surgical bypass (hepaticojejunostomy or choledochojejunostomy) was the primary modality of biliary drainage prior to percutaneous and endoscopic advancements[8-11]. With advances in endoscopic therapy, particularly the development and refinement of ERCP, endoscopic decompression of obstructive jaundice due to malignant biliary stricturing from CCA should be considered the standard of care[12-16]. While adverse events are influenced by the clinical scenario, the risks associated with ERCP are well documented and uncommon. An American Society for Gastrointestinal Endoscopy guideline on "Complications of ERCP" reports a post-ERCP pancreatitis rate of about 3.5% (range 1.6%-15.7%), a rate of hemorrhage of 1.3%, and a perforation rate of 0.1%-0.6%[17]. Typically, the rate of post-ERCP cholangitis is 1% or less, but this risk does increase in situations of ERCP for drainage of malignant biliary obstruction[17].

In circumstances where biliary decompression is not possible or is incomplete by ERCP, percutaneous transhepatic biliary drainage (PTBD) can be an effective adjunctive therapy. However, PTBD is also associated with its own risks, including intra-procedural death in 1.7% of cases[18].

Many variables must be considered when endoscopic biliary drainage is pursued in patients with obstructive jaundice from CCA. Decisions include whether to use plastic stents (PS) *vs* self-expandable metal stents (SEMS) and whether to pursue unilateral *vs* bilateral biliary stenting.

UNILATERAL *VS* BILATERAL BILIARY DRAINAGE

In patients with Bismuth I perihilar cholangiocarcinoma,

which involves the extrahepatic bile duct but not the biliary confluence, a single stent that crosses the malignant stricture is usually adequate[12]. However, when considering patients with obstructive jaundice from more advanced CCAs that might involve the biliary confluence but not the second-order radicals (Bismuth Ⅱ), or for those that involve the right (Bismuth ⅢA), left (Bismuth ⅢB), or bilateral (Bismuth Ⅳ) hepatic ducts and higher-order branches, it has been suggested that drainage of as little as 25% of the liver can result in resolution of jaundice[19]. Thus, placement of a single stent into one lobe of the liver can result in sufficient biliary decompression in many cases. In some circumstances, segments of the liver that are inaccessible may be atrophied due to chronic involvement of tumor, making additional stenting unnecessary. However, in cases of Bismuth type II, Ⅲ, or Ⅳ CCA, the optimal location and number of stents remains controversial and has been addressed by a number of studies[12-16,20-31].

Deviere *et al*[12] demonstrated in 1988 that bilateral biliary stenting was associated with significantly improved survival and decreased development of cholangitis compared to unilateral stenting. However, in that study, contrast was injected into both lobes of the liver in all patients making the need for bilateral stenting more critical. In instances where one or more segments of the liver are injected with contrast, cholangitis may develop if adequate drainage is not achieved. This concept underscores an important point that - given the advancements in radiographic imaging - whenever possible, a thinly-sliced computed tomography (CT) scan performed on a multidetector scanner or a contrasted magnetic resonance imaging scan with magnetic resonance cholangiopancreatogram (MRCP) should be obtained prior to ERCP. High resolution cross-sectional imaging can identify areas of obstruction that can be selectively targeted for biliary decompression during ERCP, thereby avoiding over-opacification of the intrahepatic bile ducts[32,33].

In 1998, Chang *et al*[20] reviewed fluoroscopic images from ERCPs conducted for biliary decompression in 141 patients with hilar CCA. Those patients who had either a single lobe opacified and drained (unilateral stenting) or both lobes opacified and drained (bilateral stenting) had a significantly lower incidence of cholangitis and mortality compared with those patients who had both lobes of the liver opacified and only one side drained. These findings highlight that the decision to pursue unilateral *vs* bilateral stenting is greatly influenced by procedure-related issues, such as the extent of intrahepatic biliary opacification as well as the ease/difficulty of cannulating and subsequently draining various intrahepatic segments.

Other reports have suggested that drainage of more than 50% of the liver volume is associated with improved survival[34]. In a large retrospective review of 480 patients receiving endoscopic biliary drainage for hilar CCA, bilateral stenting (with either SEMS or PS) resulted in significantly longer overall stent patency compared with unilateral stenting [18 wk *vs* 17 wk for PS (P = 0.0004) and 27 wk *vs* 20 wk for SEMS (P < 0.0001)][26]. This finding had previously been reported in a smaller retrospective review of 46 consecutive patients undergoing palliative endoscopic biliary stent placement for malignant hilar obstruction. In a subgroup with hilar CCA, significantly greater overall stent patency was found in the group receiving bilateral stenting compared to the unilateral stenting group (P = 0.009)[27].

In 2001, De Palma *et al*[21] randomized patients in Italy with malignant hilar obstruction (about 57% from CCA) to unilateral or bilateral stenting for biliary decompression following a diagnostic cholangiogram. On intention-to-treat (ITT) analysis, patients who received unilateral 10-French (Fr) PS had significantly greater rates of successful stent insertion and drainage and also significantly lower rates of cholangitis (8.8% *vs* 16.6%, P = 0.013) compared to those who got bilateral PS. There were no significant differences between the two groups with respect to 30-d mortality, late complications, and median survival. It is important to note that successful stent insertion was significantly lower in the group randomized to bilateral PS (76.9%) as compared to the unilateral PS group (88.6%, P = 0.041). Bilateral stenting of complex hilar strictures from CCA is challenging and often requires significant device manipulation and repeated opacification of the biliary tree in order to access undrained hepatic segments using a guidewire. In fact, on per-protocol analysis (when only patients with successful unilateral and bilateral drainage were included) there was no difference in outcomes between these two groups, but this secondary analysis was underpowered to detect significant differences.

In considering these somewhat disparate data, it is probably best to be guided by the central tenet of endoscopic retrograde cholangiography, that drainage of any opacified large bile ducts or hepatic segments that do not drain spontaneously should be pursued. In a patient with complex perihilar stricturing, use of cross-sectional imaging to guide ERCP and limit contrast opacification can reduce the risk of cholangitis and other procedure-related complications. Planning an ERCP using cross-sectional imaging can also help one avoid opacifying atrophic segments that are less likely to be functional, which might also be more difficult to access and completely drain. When ERCP is performed using this type of a planned and deliberate approach, unilateral biliary stenting might be sufficient to relieve jaundice from a malignant hilar obstruction.

Lastly, effective treatment of patients with CCA requires multidisciplinary consultation. In patients with potentially resectable disease, the choice of which lobe or segments to drain may not be as simple as going after the largest volume of obstructed liver on cross-

sectional imaging. Indeed, presurgical biliary drainage of the lobe or segments of the liver that will remain after operative resection is key to avoiding atrophy of the liver remnant. If the bile ducts of the designated remnant liver are obstructed and not accessible by ERCP, drainage *via* PTBD should be pursued. In these situations, drainage of the portion of the liver targeted for resection might not be required, as atrophy of these segments is desired (and sometimes pursued by selective portal vein embolization) so as to cause hypertrophy of the future liver remnant, which reduces the risk of post-resection hepatic decompensation[35,36].

PLASTIC *VS* SELF-EXPANDABLE METAL STENTS

The issue of the most appropriate means of biliary decompression is further complicated by the decision to utilize either PS or SEMS. Plastic stents are smaller in caliber and tend to form biofilms, resulting in earlier obstruction than SEMS. On average, PS need to be exchanged at least every 3 mo, while SEMS may remain patent for 6 to 12 mo or longer. Raju *et al*[37] demonstrated median SEMS patency of 5.6 mo compared with 1.9 mo for PS, and they found SEMS to be more cost effective because of reduced need for re-intervention. The advantage of PS is that they are removable, and thus their use may be more attractive in patients with good functional status who might outlive a palliative SEMS. Metal stents are available in uncovered, partially-covered, or fully-covered versions. While fully-covered SEMS are potentially removable, their use across a perihilar stricture can be problematic as they can inadvertently obstruct other intersecting normal bile ducts due to their coating. Covered SEMS are also more prone to migration. Uncovered SEMS are less likely to migrate as tumor ingrowth keeps these stents in place, although tumor ingrowth can also lead to stent occlusion. In clinical practice, many interventional endoscopists tend to favor plastic biliary stenting in situations where the diagnosis remains in question, when surgery might still be possible, and in those patients who are likely to outlive the patency of permanent uncovered SEMS.

Multiple non-randomized and randomized trials have demonstrated greater patency with use of SEMS in patients with inoperable CCA, as compared to plastic stenting[13-16,23,25-30,38-40]. Peters *et al*[16] conducted a small prospective pilot study in 1997 to assess the efficacy of SEMS for palliation of jaundice in patients with malignant hilar strictures. Of the 17 patients included, 11 had CCA, and 9 demonstrated adequate drainage following SEMS placement as reflected by a significant decrease in bilirubin. The 2 patients who did not obtain relief from jaundice had extensive intrahepatic disease. Median stent patency was 12 mo with median survival of 10 mo. While these authors concluded that SEMS appeared to provide durable palliation for high-grade malignant biliary strictures, they cautioned against direct comparison with PS until a controlled trial comparing the two modalities had been completed.

In 2003, Kaassis *et al*[13] published a randomized study that found no significant survival difference in patients with malignant common bile duct strictures who underwent SEMS placement compared with patients who underwent PS placement. However, time to the first episode of biliary obstruction was significantly longer in the group receiving SEMS (P = 0.007). Metal stenting was also noted to be more cost-effective in patients without hepatic metastases, who had longer survival (5.3 mo *vs* 2.7 mo in patients with metastases). These authors recommended that plastic stenting was more appropriate in patients with advanced disease, signified by metastases, due to their shorter expected survival[13].

A large retrospective review of 480 patients who received endoscopic biliary drainage in the setting of hilar CCA over a 15-year period demonstrated greater functional success (defined by a decrease in bilirubin to less than 75% of pre-treatment level) with SEMS placement (97.9%) compared with PS placement (84.8%, P < 0.001)[26]. Furthermore, there were significantly greater rates of early complications (8.3% *vs* 2.0%) and late complications (56.4% *vs* 24.4%) in the group that received PS compared to the group that received SEMS. Interestingly, multivariate analysis using Poisson regression showed that SEMS placement (P < 0.01) and bilateral deployment (P < 0.01) were the only independent prognostic factors associated with stent patency[26].

In 2012, Sangchan *et al*[30] conducted an open-label randomized controlled trial in Thailand that compared PS to SEMS placement for unresectable hilar CCA. 180 patients underwent ERCP with randomization to unilateral placement of a 10-mm-wide SEMS *vs* a 7-Fr or 10-Fr PS into the hepatic duct with the largest area of obstruction based on pre-procedural CT or MRCP. On ITT analysis, the rate of successful drainage in the SEMS group was significantly greater than in the PS group (70.4% *vs* 46.3%, P = 0.011)[30]. Median survival time for the SEMS group (126 d) was also significantly longer compared with the PS group (49 d, P = 0.0021).

In 2013, a randomized controlled trial conducted in Japan compared SEMS to PS for drainage of malignant biliary strictures[15]. This study found the 6-month stent patency in the SEMS group was significantly greater (81%) compared with the PS group (20%, P = 0.0012). Kaplan-Meir analysis demonstrated a 50% patency rate of 359 d in the SEMS group as compared to 112 d in the PS group (P = 0.0002). Furthermore, the mean number of interventions for stent failure was significantly lower in the SEMS group (0.63 times/patient) compared to the PS group (1.80 times/patient, P = 0.0008). Lastly, the overall total cost for the treatment was significantly lower in the SEMS group than in the PS group (P = 0.0222).

Overall, these studies support the use of SEMS over

PS for long-term palliation of patients with malignant biliary obstruction, including from unresectable CCA. Typically, uncovered SEMS should be used for palliation when strictures are found across the biliary confluence, and these SEMS likely have even greater utility and cost-effectiveness when expected survival exceeds 3 mo, such as in those patients without metastatic disease. However, with the advent of ERCP-directed ablative therapies for unresectable CCA, a substantial proportion of patients might now expect to outlive even the patency of SEMS. In these patients, a strategy of repeated ERCPs for plastic stent revision and possibly repeated ERCP-directed ablations for locoregional tumor control is reasonable, particularly while they maintain good functional status and quality of life.

PERCUTANEOUS TRANSHEPATIC BILIARY DECOMPRESSION

Biliary decompression and stent placement for malignant biliary strictures can also be achieved by a percutaneous approach. In most centers, PTBD is performed by interventional radiologists. Decompression tubes may be inserted into dilated proximal biliary radicals to facilitate drainage of static bile above the level of obstruction. Alternatively, stenting across a malignant stricture can also be achieved by PTBD, which then allows for bile drainage internally into the duodenum. However, several studies have evaluated the use of PTBD with mixed results[14]. Complications associated with PTBD include vascular injury, risk for tumor seeding, and discomfort at the external drain site[28]. Additionally, PTBD has reported intraprocedural hemorrhage and sepsis rates of 2.5% and a death rate of 1.7%[18].

Hamy *et al*[23] evaluated 35 patients with malignant hilar obstruction (most had CCA) who received a palliative SEMS *via* a percutaneous-transhepatic route. They found a 97% rate of adequate biliary drainage with a median survival of 182 d and a 25% rate of recurrent jaundice after 180 d. These results were corroborated by a large retrospective multicenter study of 84 patients that compared the efficacy of percutaneous-transhepatic to endoscopic SEMS placement for initial malignant biliary decompression[28]. In this study, the rate of successful initial biliary decompression was higher in the percutaneous group (92.7%) as compared with the endoscopically-placed SEMS group (77.3%)[28]. However, overall stent patency and survival-once decompression was achieved-were similar between the groups, suggesting that a well-placed stent, irrespective of how it was placed, is the key to durable biliary decompression and improved survival in patients with malignant biliary obstruction.

Oftentimes, the decision to pursue biliary drainage *via* ERCP or PTBD is determined by clinical reasons, such as in patients with surgically altered gastroduodenal anatomy in whom PTBD might offer easier or more reliable access for therapeutic biliary interventions, or by local expertise. PTBD can be a valuable adjunctive therapy to drain obstructed bile ducts not accessible by ERCP, particularly in patients who might be surgical candidates and require drainage of the future liver remnant so as to prevent atrophy. In our experience, most patients favor endoscopic biliary drainage whenever possible, as it obviates the need for an external catheter for drainage or access. In general, if an experienced biliary endoscopist is available who can perform complex ERCP (as treatment of a hilar tumor is considered a level-3-complexity ERCP by American Society for Gastrointestinal Endoscopy guidelines[41]), we suggest attempting biliary decompression *via* ERCP. If adequate biliary drainage by ERCP is not achieved, then PTBD is an important adjunctive therapy in this patient population that should be pursued. Furthermore, once a PTBD track is mature (which typically requires 3-4 wk), a rendezvous-ERCP procedure can be performed to internalize biliary drainage of a previously inaccessible segment, after which the PTBD catheter can be removed.

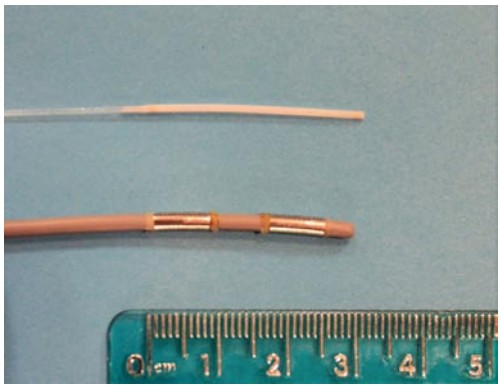

Figure 1 Endoscopic retrograde cholangiopancreatography-directed ablative therapies. Photodynamic therapy is applied *via* a laser fiber (above), whereas radiofrequency ablation is delivered using an 8-Fr catheter with two sets of bipolar rings (below).

ERCP-DIRECTED PHOTODYNAMIC THERAPY

PDT is a well-studied ablative therapy that induces tumor necrosis and apoptosis in treated portions of the biliary tree. The intravenous photosensitizer used in the United States is porfimer sodium (Photofrin, Pinnacle Biologics, Bannockburn, IL). While use of this drug for PDT in patients with CCA is done so off-label in the United States, Medicare and most private insurers in the United States do cover this procedure for palliation of unresectable CCA[42]. Porfimer sodium is typically administered intravenously, at 2 mg/kg, ideally 48 h (but possibly up to 72 h) before ERCP. At the time of ERCP, a 10-Fr bougie catheter (SBDC-10, Cook Medical, Bloomington, IL) or a choledochoscope (SpyGlass, Boston Scientific, Natick, MA) is advanced over a wire to

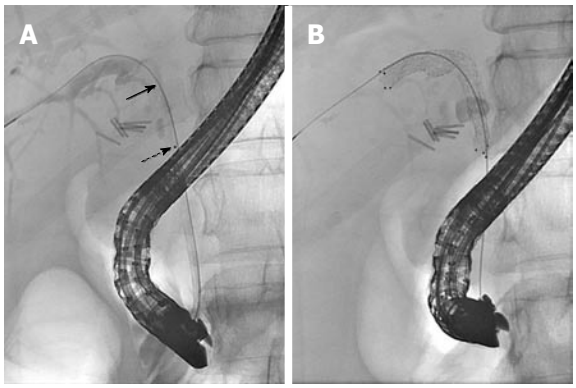

Figure 2 Endoscopic retrograde cholangiopancreatography-directed photodynamic therapy followed by unilateral metal stenting. A: Fluoroscopic view of a photodynamic therapy laser fiber delivered through a 10-Fr-bougie catheter during endoscopic retrograde cholangiopancreatography. The portion of the fiber that emits laser light is demarcated by the black dot (dashed arrow). The proximal-most tip of the fiber is not visible fluoroscopically (solid arrow) but is located near the biliary confluence; B: An 8 mm x 6 cm uncovered self-expandable metal stent was placed across a malignant stricture that involved the right hepatic duct and common hepatic duct.

the level of the malignant stricture and used to pass a laser fiber. This laser fiber (Figures 1 and 2) is then used to deliver activating light (at 630 nm for 750 s, with a light dose of 180 J/cm^2)[43]. When the photosensitizer is activated, oxygen free radicals are released that result in local tissue destruction. Since its first description for biliary tumor ablation in 1991[44], multiple studies have demonstrated that PDT can enable local tumor control and also can result in improved quality of life in this difficult-to-treat patient population[42,45-61]. Metal stent patency has also been shown to be significantly greater with PDT applied immediately prior to stent placement *vs* metal stent placement alone (median time of 244 d *vs* 177 d, respectively, $P = 0.002$)[49].

In 2003, Ortner *et al*[52] conducted a prospective, open-label, randomized, multicenter study of patients with unresectable CCA that compared PDT (using porfimer sodium) in addition to endoscopic or percutaneous stenting by using two 10-Fr endoprostheses *vs* stenting alone and demonstrated significant improvement in survival times (median 493 d *vs* 98 d, respectively, $P < 0.0001$)[52]. Improvement in cholestasis and quality of life indices were also reported. Another randomized controlled trial by Zoepf *et al*[60] in 2005 compared PDT (using Photosan-3, SeeLab, Wesselburenerkoog, Germany) and stenting *vs* stenting alone in patients with unresectable CCA. These investigators demonstrated significantly improved survival in the group that received PDT (21 mo) compared to the group that received only stents (7 mo, $P = 0.0109$). In this study, PDT was delivered *via* ERCP (transpapillary) or by percutaneous biliary access.

The survival benefit associated with PDT in patients with unresectable CCA has also been demonstrated by multiple heterogeneous cohort studies, which were mostly retrospective in nature[45,47,54,62,63]. In 2012, Leggett *et al*[50] conducted a meta-analysis that included six studies that contributed 170 patients with unresectable CCA who received PDT and biliary stenting *vs* 157 patients with CCA who underwent stenting alone. This meta-analysis found that PDT was associated with a statistically significant survival advantage (weighted mean difference of 265 d, $P = 0.01$) and significantly improved quality of life as reflected by improvement in Karnofsky score (weighted mean difference of 7.74, $P = 0.01$). While there appears to be sufficient data to support that at least one round of PDT offers a survival advantage to patients with incurable CCA, it is not clear if multiple rounds of PDT (done every few months) adds to the survival advantage[62]; nor is it clear if bilateral PDT is superior to unilateral PDT in the case of Bismuth IV tumors.

The merits of PDT are tempered somewhat by its potential side-effects. Although a study evaluating the safety and long-term efficacy of PDT using porfimer sodium reported no treatment-related mortality or grade-4 toxicity, complications including photosensitivity resulting in burns (Figure 3) and to a lesser extent bleeding, stenosis, and bile leak have been reported[46]. Cholangitis is usually the most commonly encountered problem that arises in patients with CCA who have undergone biliary intervention, and as expected cholangitis following PDT does occur. A major drawback with ERCP-directed PDT is the need for patients to avoid direct or indirect sunlight for 4-6 wk, which may significantly affect their quality of life. Efforts to limit light toxicity have also resulted in use of a newer photosensitizer meta-tetra(hydroxyphenyl)chlorin (Foscan, Biolitec AG, Jena, Germany) that has demonstrated efficacy in a small study while potentially removing the detrimental side-effects of prolonged skin photosensitivity[48]. Another major drawback of PDT is that the cost of a single-dose of porfimer sodium in a 75 kg patient is about USD $37208, which can be prohibitively high[43].

Nevertheless, PDT has several advantages including: (1) porfimer sodium preferentially accumulates in malignant cells, potentially reducing damage to non-malignant epithelium; and (2) laser light can refract through bile, which can transmit the PDT effect to malignant strictures that are not directly adjacent to (and might be inaccessible to) the laser fiber[43]. Because PDT is dependent on the transmittance of laser light, and does not require the laser fiber to directly make contact with tumor tissue, successful delivery of PDT through metal stents has been reported with appropriate adjustment of the light dose[64].

ERCP-DIRECTED RADIOFREQUENCY ABLATION

Percutaneously- and intraoperatively-directed RFA have been demonstrated by several studies to be efficacious for local tumor control in patients with

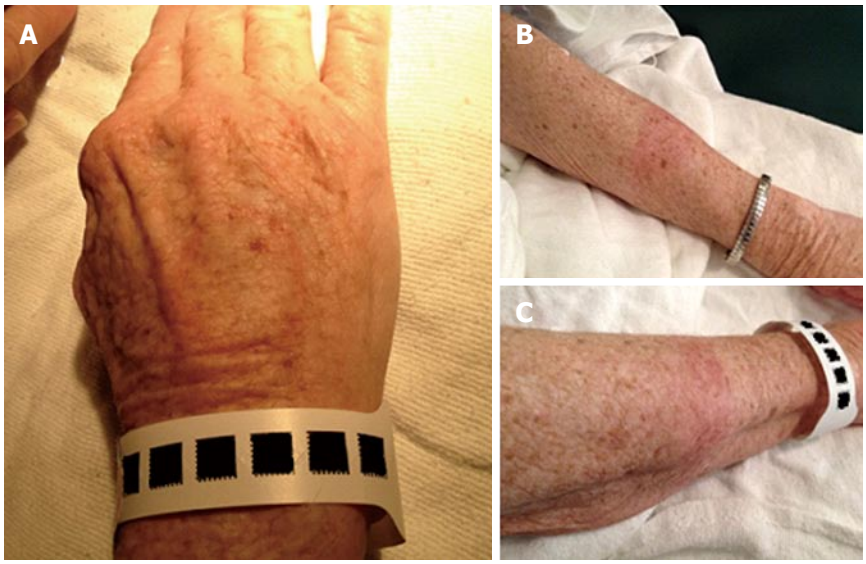

Figure 3 Photosensitivity following photodynamic therapy. A patient with unresectable cholangiocarcinoma was treated with photodynamic therapy. After 4 wk, a test dose of 10 min of exposure to direct sunlight on small areas of uncovered skin resulted in moderate burns on hands (A) and forearms (B, C). Two additional weeks of avoidance to even indirect sunlight was required.

inoperable CCA[65-70], including as an adjunct to surgery[71-73]. RFA has been used for local control of tumor recurrence following surgery in patients who may no longer be good operative candidates or for whom no other surgical intervention is possible[68,72], including those who have already undergone protocol liver transplantation for CCA[74]. However, complications following the percutaneous delivery of RFA are not trivial and have included gastrohepatic fistula[75], hemorrhage necessitating transarterial embolization[76], hepatic vein pseudoaneurysm[77], acute liver failure or abscess formation[78], and needle-tract seeding of tumor[79].

ERCP-directed RFA was developed to enable endoscopists to treat malignant biliary strictures *via* a mechanism of coagulative necrosis induced by thermal energy that is delivered *via* contact using a bipolar catheter[43]. One commercially available RFA catheter (Figure 1) is an 8-Fr device with two electrodes spaced 8 mm apart at the end of the catheter that can be passed over a guidewire (Habib EndoHPB; EMcision, London, United Kingdom)[80]. This device passed United States Food and Drug Administration 510[k] premarketing clearance in 2009. This RFA catheter can be passed through the accessory channel of a duodenoscope and into the bile duct (Figure 4). Fluoroscopic guidance is used to center the two sets of bipolar rings across a malignant stricture for RFA treatment (Figures 5 and 6).

In 2011, Steel *et al*[81] conducted a single-center open-label pilot study that demonstrated that ERCP-directed RFA could be performed safely and efficaciously in patients with malignant biliary strictures from unresectable pancreas cancer or CCA. In this initial study, all but one of 21 patients who had RFA followed by SEMS placement maintained stent patency at 30 d. One patient had asymptomatic biochemical pancreatitis, 2 patients required percutaneous gallbladder drainage, and 1 patient developed rigors. At 90-d follow-up, 3 patients had occluded biliary stents. Subsequently, in a retrospective series of 12 patients (9 with CCA) with malignant intraductal or perihilar biliary strictures, Tal *et al*[80] performed 19 successful RFA applications *via* ERCP followed by PS placement. These investigators used a setting of 8 W for treatment of intrahepatic and perihilar biliary strictures and 10 W for extrahepatic bile duct strictures using an ERBE electrosurgical generator (VIO 200D, ERBE Elektromedizin, Tübingen, Germany). However, biliary bleeding was observed at 4-6 wk in 3 patients (2 of whom died of hemorrhagic shock), and cholangitis developed in 4 patients, which was amenable to stent exchange. Finally, Figueroa-Barojas *et al*[82] reported on the use of ERCP-directed RFA in 25 patients with malignant biliary structures (11 patients had CCA). Procedures were performed using a RITA 1500X RF generator (Angiodynamics, Latham, NY) set at 7-10 W for a time period of 2 min. These investigators reported a resultant significant increase in mean bile duct diameter of 3.5 mm ($P < 0.0001$)[82]. In this series, 5 patients presented with pain after the procedure, one patient developed mild post-ERCP pancreatitis, and one patient developed cholecystitis following endobiliary RFA.

In 2014, Sharaiha *et al*[83] published a retrospective series of 66 patients with malignant biliary strictures (36 with CCA) who underwent either SEMS placement alone or RFA followed by SEMS placement. They reported 100% technical success in both groups. While these investigators found that rates of stent patency were similar between the two groups, on multivariate analysis, RFA was found to be an independent predictor of survival (HR = 0.29, 95%CI: 0.11-0.76, $P = 0.012$). Finally, RFA has been described as a means of treating tumor ingrowth of uncovered SEMS in the bile duct[84].

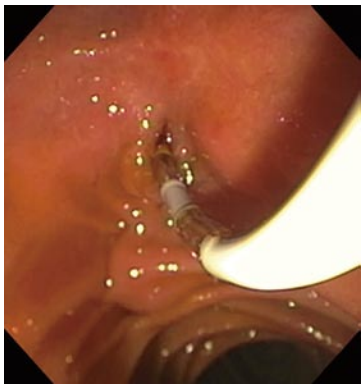

Figure 4 Endoscopic view of a radiofrequency ablation catheter being inserted into the bile duct by using a duodenoscope. A biliary sphincterotomy had been performed during a prior endoscopic retrograde cholangiopancreatography procedure in this patient with an unresectable cholangiocarcinoma to enable easier access to the bile duct. Note: this is not a depiction of radiofrequency ablation (RFA) actively being performed, as RFA is not typically applied with the bipolar coils exposed in the duodenal lumen, in order to avoid thermal injury to the duodenal wall.

Typically, the RFA catheter can be passed into a blocked stent and used under fluoroscopic guidance to ablate any tumor ingrowth, which is then removed by retrieval balloon sweep. This ablation may be followed by placement of an indwelling plastic stent or a second uncovered SEMS, in appropriate situations (Figure 6).

When compared to PDT, the advantages of endobiliary RFA include being able to provide ablative treatment without the patient having to come in 2 d in advance for infusion of a photosensitizer, easier delivery of the RFA catheter that can be done over a guidewire, and no requirement to avoid sunlight for several weeks to prevent photosensitivity. However, RFA requires direct contact with neoplastic tissue for ablation, thus it does not offer the "field effect" conferred by the laser light used in PDT, which can refract through bile to treat inaccessible blocked bile ducts.

In 2014, Strand *et al*[43] demonstrated comparable survival following ERCP-directed RFA *vs* ERCP-directed PDT. In this retrospective cohort study, 48 patients with unresectable CCA underwent RFA (n = 16) or PDT (n = 32) followed by plastic or metal biliary stenting. Overall median survival in both treatment groups was not statistically different (9.6 mo following RFA and 7.5 mo following PDT, P = 0.799). Furthermore, patients who underwent RFA had a lower mean number of plastic stents placed per month (0.45 *vs* 1.10, P = 0.001) but also had more episodes of stent occlusion (0.06 *vs* 0.02, P = 0.008) and cholangitis (0.13 *vs* 0.05, P = 0.008) per month, as compared to patients who received PDT.

In addition to the differing advantages and disadvantages of RFA *vs* PDT that were mentioned earlier, a major discriminating factor between these two ablative technologies is cost. Strand *et al*[43] noted that because both procedures required ERCP with sent exchange, the true cost differential is the difference between the cost of a dose of porfimer sodium (USD $37208) and the cost of the RFA catheter (USD $1295), which is $35913[43]. In the current environment of falling reimbursements and the need for cost-containment, this is a significant difference that favors ERCP-directed RFA.

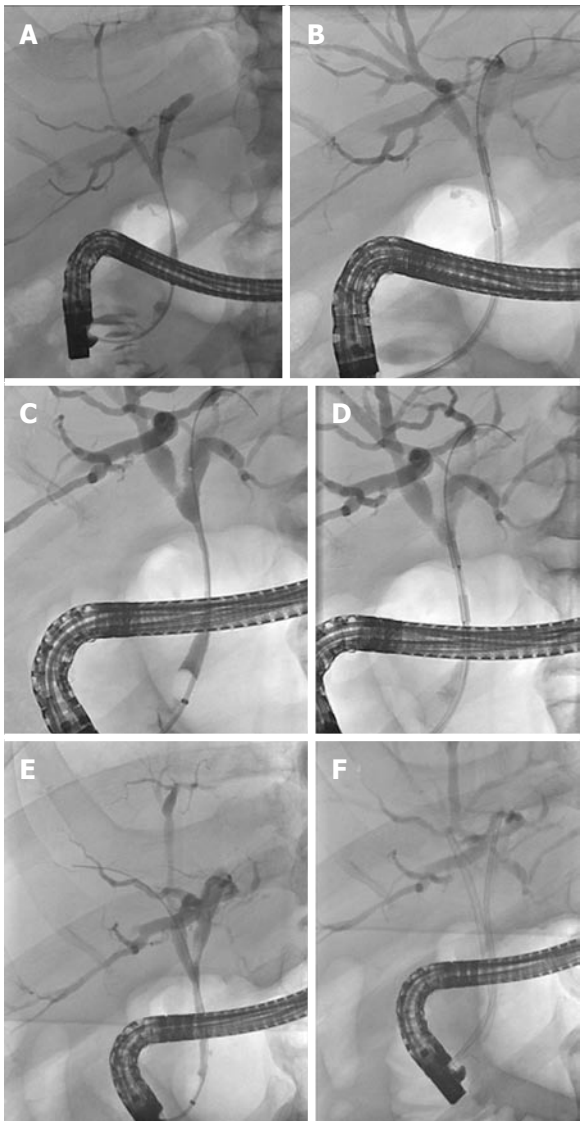

Figure 5 Effect of repeated endoscopic retrograde cholangiopancreatography-directed radiofrequency ablation on a malignant extrahepatic biliary stricture in a patient with unresectable cholangiocarcinoma. A long perihilar stricture is seen involving the extrahepatic duct (A) in a patient who had exploratory laparotomy that showed locally advanced and unresectable Bismuth I cholangiocarcinoma. A cholecystectomy had been performed at the time of laparotomy. Endoscopic retrograde cholangiopancreatography (ERCP)-directed radiofrequency ablation (RFA) was applied to this malignant stricture (B) followed by biliary stenting (not shown). Following two rounds of RFA done at about 3 mo intervals, a third ERCP showed moderate improvement in the stricture's diameter (C). Repeat ERCP-directed RFA was performed (D). After 4 rounds of RFA therapy, an ERCP 1 year later showed marked improvement of the extrahepatic bile duct with no high-grade stricture seen (E), and RFA was not repeated during this procedure. A 10-Fr plastic stent was placed into the right hepatic duct and a 7-Fr plastic stent was placed into the left hepatic duct for more durable biliary drainage (F), as this was an otherwise healthy patient with excellent functional status who would likely outlive metal stenting. While patients with Bismuth I cholangiocarcinoma often do well with a single extrahepatic biliary stent, this patient had previously had premature stent failure and cholangitis with a single plastic stent, thus two biliary stents were required.

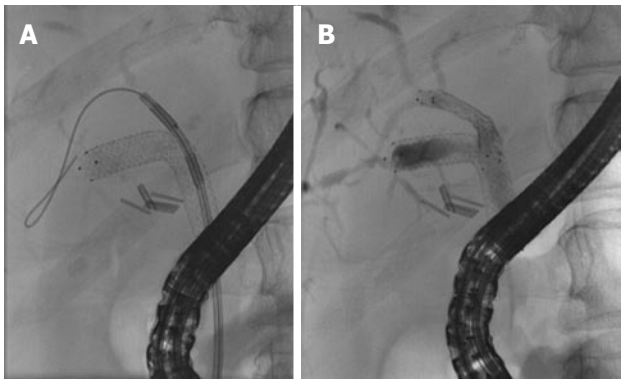

Figure 6 A patient with unresectable cholangiocarcinoma was previously treated with photodynamic therapy followed by placement of an uncovered metal stent (see Figure 2). For persistent symptomatic biliary obstruction due to undrained segments in the right liver, a wire was passed into the previously undrained segments which allowed for 6-Fr bougie dilation followed by 4-mm balloon dilation across the lattices of the existing large-cell uncovered self-expandable metal stent (SEMS) (not shown). After dilation, the 8-Fr radiofrequency ablation (RFA) catheter was deployed over the wire and through the SEMS, and RFA was applied to a malignant stricture that was obstructing drainage (A). Lastly an 8-mm uncovered SEMS was deployed through the previously placed 8-mm uncovered SEMS (B) enabling durable drainage of more of the right liver.

ERCP-DIRECTED NEOADJUVANT ABLATIVE THERAPY FOR CCA PRIOR TO LIVER TRANSPLANTATION

Experience with liver transplantation (LT) for unresectable CCA had previously been disappointing due to frequent cancer recurrence and poor 5-year survival rates[3]. To improve outcomes following LT for CCA, a protocol for neoadjuvant chemotherapy followed by LT was first developed at the University of Nebraska and then at the Mayo Clinic[3,85]. Patients who met the following criteria were included in this LT protocol: (1) perihilar location of suspected CCA; (2) a malignant-appearing stricture on cholangiography with malignant endoluminal brushing or biopsy, carbohydrate antigen 19-9 level > 100 U/mL (in the absence of cholangitis), mass on cross-sectional imaging, and/or polysomy on fluorescence *in situ* hybridization; (3) unresectable disease or disease arising in primary sclerosing cholangitis; (4) completion of neoadjuvant therapy before LT; and (5) medical suitability for LT[85]. Neoadjuvant therapy from the early "Mayo" protocol included administration of external beam radiation therapy (XBRT) and 5-fluorouracil, followed by brachytherapy[85-87]. Use of intraluminal brachytherapy and XBRT in patients with unresectable CCA has been reported for palliation of jaundice and as a treatment to temporarily obviate the need for biliary stenting[88,89]. Furthermore, a retrospective study by Darwish Murad *et al*[85] of 287 patients, 75% of whom received brachytherapy as part of neoadjuvant therapy prior to LT, demonstrated a 5-year ITT survival rate of 53% and post-transplant recurrence-free survival of 65%[85]. In this large series of patients, recurrence-free survival for patients who had received brachytherapy was similar to those who had not (HR = 1.05; 95%CI: 0.60-1.85)[85]. Other studies have also shown no mortality benefit from the addition of brachytherapy[90,91]. In an effort to mitigate side-effects associated with brachytherapy and the complexities associated with delivery of radioactive ribbons in the endoscopy or radiology suite, other endobiliary therapies for neoadjuvant locoregional CCA tumor control prior to LT have been adopted.

In particular, PDT, as mentioned previously, has been demonstrated to be a safe and potentially efficacious modality for locoregional control of perihilar CCA in palliative patients. In a proof-of-concept study performed at our institution, Cosgrove *et al*[42] reported on 4 patients with unresectable CCA who had undergone protocol-driven neoadjuvant chemoradiation followed by ERCP-directed PDT to provide endobiliary and local tumor control in patients who were awaiting LT[42]. Although the sample size of this study was small, none of the patients who received PDT had progressive locoregional disease or distant metastases during the pre-transplant period, and all patients underwent successful LT. ITT disease-free survival was 75% at a mean follow-up of 28.1 mo. Based on these data regarding PDT, as well as our comparable experience with RFA for patients with incurable CCA[43], our institution's protocol allows for the use of either PDT or RFA as an alternative to brachytherapy for locoregional tumor control in patients with inoperable CCA who are awaiting LT. Prospective trials to study these ERCP-directed neoadjuvant modalities for locoregional control in patients with CCA are indicated.

CONCLUSION

CCA is a malignancy with high morbidity and mortality due to its typically late presentation with obstructive jaundice, and its associated complications of cholangitis and biliary sepsis. ERCP is a valuable treatment modality for patients with CCA, as it enables internal luminal drainage of blocked bile ducts and hepatic segments by using plastic or metal stents. While there remains debate as to if bilateral (or multi-segmental) hepatic drainage is required and/or superior to unilateral drainage, the underlying tenant of draining any persistently opacified bile ducts is paramount to good ERCP practice and good clinical outcomes. Endoscopic therapy for malignant biliary strictures from CCA has advanced to include ablative therapies *via* ERCP-directed PDT or RFA. As chemoradiation is of limited efficacy in providing tumor control for this cancer, these endoscopic modalities, which offer the potential for locoregional control and hopefully more durable biliary drainage, are a much needed addition to our therapeutic endobiliary armamentarium. While ERCP techniques cannot cure CCA, advancements in the field of ERCP have enabled us to improve upon the quality of life of patients with incurable disease. ERCP-directed PDT has been used in lieu of brachytherapy to provide neoadjuvant local

tumor control in patients with CCA who are awaiting LT. Lastly, mounting evidence suggests that palliative ERCP-directed PDT, and probably ERCP-directed RFA as well, can offer a survival advantage to patients with this difficult-to-treat malignancy.

Abstract

The prognosis of rectal cancer (RC) is strictly related to both T and N stage of the disease at the time of diagnosis. RC staging is crucial for choosing the best multimodal therapy: patients with high risk locally advanced RC (LARC) undergo surgery after neoadjuvant chemotherapy and radiotherapy (NAT); those with low risk LARC are operated on after a preoperative short-course radiation therapy; finally, surgery alone is recommended only for early RC. Several imaging methods are used for staging patients with RC: computerized tomography, magnetic resonance imaging, positron emission tomography, and endoscopic ultrasound (EUS). EUS is highly accurate for the loco-regional staging of RC, since it is capable to evaluate precisely the mural infiltration of the tumor (T), especially in early RC. On the other hand, EUS is less accurate in restaging RC after NAT and before surgery. Finally, EUS is indicated for follow-up of patients operated on for RC, where there is a need for the surveillance of the anastomosis. The aim of this review is to highlight the impact of EUS on the management of patients with RC, evaluating its role in both preoperative staging and follow-up of patients after surgery.

Key words: Rectal cancer; Staging; Endoscopic ultrasonography; Accuracy; Therapeutic strategy

Core tip: In the era of tailored management of patients with rectal cancer (RC), endoscopic ultrasonography (EUS) has become crucial for the appropriate preoperative

staging of these patients. This review highlights the impact of EUS on the management of patients with RC, evaluating its role in both preoperative staging of RC and follow-up of patients after surgery. Finally, possible new application are discussed, on the basis of the technologic innovation and the evolution of the therapeutic strategies.

Role of endoscopic ultrasonography in the loco-regional staging of patients with rectal cancer. *World J Gastrointest Endosc* 2015; 7(7): 688-701 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/688.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.688

INTRODUCTION

Every year approximately 40000 patents are diagnosed with rectal cancer (RC), and the incidence of RC in the European Union is 15-25/100000 per year, with an estimated mortality of 4-10/100000 per year[1]. The prognosis of RC is strictly related to both T and N stage of the disease at the time of diagnosis[2]. This is traditionally staged according to local invasion depth (T stage), lymph node involvement (N stage), and presence of distant metastases (M stage) (Table 1)[3,4]. Staging RC is crucial for choosing the best multimodal therapy (Table 2)[2]: patients with high risk locally advanced RC (LARC) undergo surgery after neoadjuvant chemotherapy plus radiotherapy (NAT); those with low risk LARC are operated on after a preoperative short-course radiation therapy. The latter is used as a valid alternative to NAT in elderly patients, or for patients unfit for preoperative chemotherapy because of severe comorbidities. Finally, surgery alone is recommended only for early RC. Total mesorectal excision (TME) is the standard surgical approach, with or without sphincter preservation. Extended abdomino-perineal resection is performed in distal RC which requires sphincter demolition. Local excision is performed in small T1 cancers with favorable histology by means of trans anal endoscopic microsurgery (TEM) or trans anal minimally invasive surgery. Local excision is also performed in selected patients showing complete clinical response after NAT. Therefore, precise staging of patients has a pivotal role for the selection of different therapeutic options and team work among the members of the multidisciplinary team is mandatory to improve patients outcome[2].

Several imaging methods are used for staging patients with RC: computerized tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET) and endoscopic ultrasound (EUS)[1]. The latter has a high accuracy for loco-regional staging of RC, since it is capable to evaluate precisely the mural infiltration of the tumor (T), especially in the early RC.

Table 1 The 2010 AJCC staging system for primary rectal cancer

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*: Intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum
T4b	Tumor directly invades or is adherent to other organs or structures
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional nodal metastasis
N1	Metastasis in 1-3 regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in 2-3 regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or non-peritonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in 4 or more regional lymph nodes
N2a	Metastasis in 4-6 regional lymph nodes
N2b	Metastasis in 7 or more regional lymph nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site (*i.e.*, liver, lung, ovary, non-regional node)
M1b	Metastases in more than one organ/site or the peritoneum

On the other hand, EUS is less accurate in restaging RC after NAT and before surgery. Recently, EUS has been used in clinical trials where patients have been selected for less invasive therapies: polypectomy for T1 RC; TEM for T1/T2-N0 cancers, and NAT + TEM for T2N0 tumors. Finally, EUS is indicated for following-up patients operated on for RC, where there is a need for surveillance of the colorectal anastomosis, which is at risk for local recurrences[2,5-7].

This review evaluates the role of EUS in the loco-regional staging of patients with RC, analyzing both accuracy and limits of this imaging method, which is part of the multidisciplinary approach for patients with RC. In particular, the aim of the review is to highlight the impact of EUS on the management of patients with RC, evaluating its role in both preoperative staging and follow-up after surgery. Finally, possible new applications are discussed on the basis of the

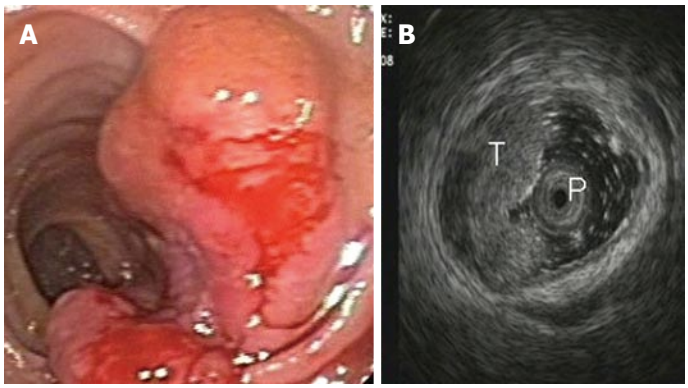

Figure 1 Stage T1 rectal cancer: (A) endoscopic and (B) ultrasonographic view. Endoscopic ultrasound with radial miniprobe (12 MHz), showing a small tumor located within the mucosa and superficial submucosal layers, and preservation of the outer layers of the rectal wall. T: Tumor; P: Radial probe.

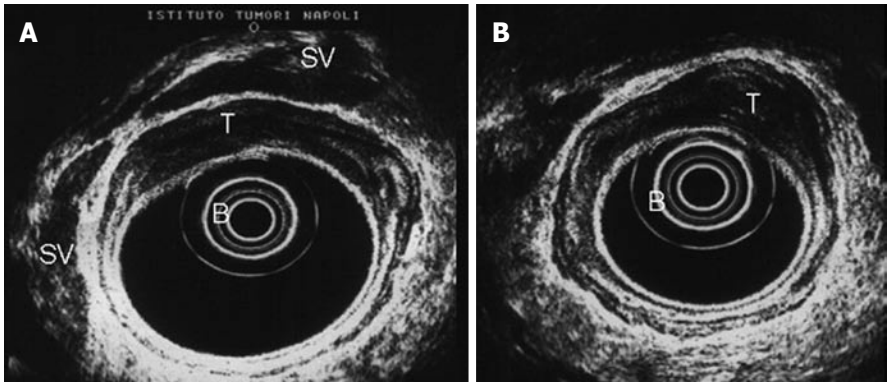

Figure 2 Stage T2 rectal cancer: Ultrasonographic view. The tumor infiltrated the entire wall, without invading the smooth outer margin of the muscularis propria (fourth layer). Endoscopic ultrasound with radial array transducer UM 20 (7.5-12 MHz). B: Ballon; T: Tumor; SV: Seminal vesicles.

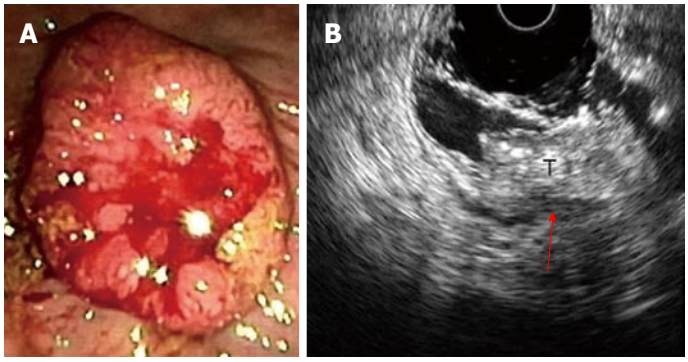

Figure 3 Stage T3 rectal cancer: (A) endoscopic and (B) ultrasonographic view. Endoscopic ultrasound with radial array transducer UM160 (5-20 MHz), showing increased wall thickness for the presence of a mass with inhomogeneous echogenicity, invading all the layers of the wall and minimal infiltration of the perirectal fat. T: Tumor; Red arrow: Infiltration of the perirectal fat.

technological innovation and the evolution of the therapeutic strategies[7-10] (Figure 1).

EUS Accuracy in staging rectal cancer T staging

At the time of EUS, RC usually appear as a hypoechoic mass, with loss of the normal echo-layers of the wall, which is inhomogeneous and irregular because of the fusion of the layers infiltrated by the tumor[5,9-11]. According to the infiltration depth, there are four different echoendoscopic T stages (uT) (Table 3, Figures 1-5). In patients with RC, EUS assesses the tumor penetration depth into the rectal wall, with an overall accuracy for T stage of about 84%, ranging from 63% to 96%, while the reported accuracy of CT and MRI are 65%-75% and 75%-85%, respectively (Table 4)[12-45]. In a systematic review of 31 articles published over a period of 20 years, Skandarajah *et al*[46] reported that EUS has an overall accuracy of 82% for T stage and it is useful for discriminating early superficial RC. In another review of 42 studies, which analyzed the accuracy of EUS in patients with RC, confirmed by pathological exam of the surgical specimen, Puli *et al*[47,48] concluded that EUS has a sensitivity of 81%-96% and a specificity of 91%-98%, showing a higher sensitivity for LARC (95%), compared with early cancer (88%). In a multicenter, prospective, study conducted in 384 hospitals in Germany over a 8-year period, Marusch *et al*[49] analyzed the diagnostic accuracy of rectal EUS in the clinical staging of 7000 patients with RC who had not received NAT. This allowed uT *vs* pT comparison, which showed a uT-pT correspondence of 65%. The latter was related to the hospital volume, with uT-pT correspondence of 63% for hospitals undertaking ≤10 EUS/year, 65% for those performing 11-30 EUS/year,

Table 3 T staging (uT) of rectal cancer at endoscopic ultrasound, according to the infiltration depth

uT1 = tumor invasion limited to the mucosa and the submucosa; this is further divided into T1m, if the tumor infiltrates the mucosa, with normal muscolaris mucosa, and T1sm, when there is submucosal invasion (Figures 1 and 7)
uT2 = tumor infiltration of the muscolaris propria, with the tumor mass extended through the first 4 layers of the rectal wall. The outer layer corresponding to the muscolaris propria is smooth, meaning that the tumor is still limited to the rectal wall (Figure 2)
uT3 = tumor invasion of the perirectal fat, with an irregular 4th layer, which means that the tumor has spread outside the rectal wall (Figures 3 and 4)
uT4 = tumor infiltration of adjacent structures and organs, which are strictly connected to the rectal hypoechoic mass (Figure 5)

From ref.[9].

and 73% for hospitals where more than 30 EUS/year were performed. Furthermore, the poorest uT-pT correspondence was found for T2 and T4 RC, with understaging occurring in 18% of cases and overstaging in 17% of patients[49]. These results were similar to those of a previous multicenter, prospective, study conducted by the same authors who reported that EUS had overall accuracy of 63% for T staging of RC. The diagnostic accuracy was 51% for pT1 RC, 58% for pT2 lesions, 73% for pT3 tumors, and 44% for pT4 cancers, with overstaging in 24% of cases and understaging in 13% of patients[33]. According to the results of both studies, EUS staging of RC in clinical practice does not have the same accuracy reported in the literature and the authors believe that EUS is a useful tool for guiding the therapeutic strategy of RC only when it is performed by experts[33,49]. Lower accuracy of EUS was also reported in a series of 545 patients with RC, where this method showed an overall accuracy of 69% for T stage and 64% for N stage[32]. A possible limitation of this study was the exclusion from the analysis of those patient who underwent NAT. This could have affected the accuracy of EUS for T stage, especially for T3 RC which is usually visualized the best at the time of EUS. Another pitfall of the study could be the different experience of the operators, which influenced the

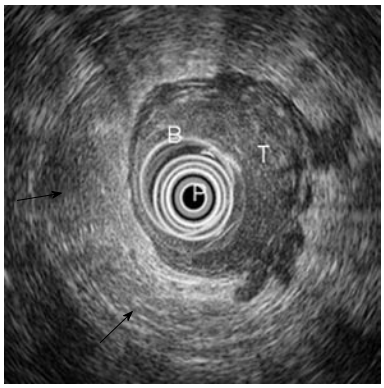

Figure 4 Stage T3 rectal cancer: Ultrasonographic view. Endoscopic ultrasound shows advanced cancer of the rectum with large hypoechoic and inhomogeneous thickening of the rectal wall, loss of the five-layered wall structure and deep infiltration of the perirectal fat. Endoscopic ultrasound with radial array transducer UM160 (5-20 MHz). B: Ballon; P: Transducer; T: Tumor; Black arrow: Perirectal fat.

accuracy of EUS, as highlighted by Marusch *et al*[33,49]. Indeed, Kauer *et al*[34] observed that there is a high inter-observer variability (61%-77%), according to the experience of the operator. These authors reported that EUS has an overall accuracy of 69% for T staging of RC, with T3 tumors better (86%) staged and T4 cancer the least (36%) accurately classified. Differentiating T1 from T2 was difficult in this retrospective series, where overstaging (19%) was much more frequent than understaging (12%)[34].

Superficial RC limited to the mucosa can be resected endoscopically. Whenever a trans anal resection is planned, it is recommended to perform a preoperative EUS staging of the tumor, as suggested by Kneist *et al*[50]. These authors evaluated the accuracy of EUS in 552 patients undergoing trans anal excision of RC and they reported that EUS has a sensitivity of 95% and a positive predictive value of 93% in staging early RC[50]. Similarly, Glancy *et al*[51] demonstrated that EUS has an overall accuracy of 95% in staging early superficial RC suitable for local treatment. This high accuracy rate was confirmed by Zorcolo *et al*[52], who reported that EUS allows a precise distinction between early and advanced RC, with sensitivity of 96%, specificity of 85%, and overall accuracy of 94%. The latter is lower in our personal series, where we reported that EUS has an accuracy rate of 81% in differentiating early (T1) from advanced RC (T2), with the same occurrence of overstaging and understaging (9%)[30]. Finally, a recent meta-analysis analyzed the results of 11 studies, which discussed the efficacy of preoperative EUS in staging patients with early RC: the sensitivity of EUS in diagnosing T0 was 97%, with a specificity of 96%[48]. These data support the conclusion that EUS accurately diagnoses T0 RC, helping physicians to choose endoscopic treatment for patients with early RC.

Several studies have shown that EUS accuracy for T stage is strictly related to the depth of infiltration and the accuracy is lower for T2 stage than for early

Table 5 Accuracy of endoscopic ultrasound for each single T stage

uTN stage compared with pTN stage; No previous neoadjuvant therapy (NAT).

(T1) or advanced (T3-4) RC (Table 5)[31,30,38,39,41]. These assumptions are supported by the results of another meta-analysis which examined 42 studies, with a total number of 5039 patients: the pooled sensitivity and specificity of EUS for T1 stage was 88% and 98%, respectively; for T2 stage, EUS had pooled sensitivity and specificity of 80% and 96%, respectively; for T3 stage, the pooled sensitivity and specificity of EUS were 96% and 91%, respectively; finally, for T4 stage, EUS had pooled sensitivity of 95% and specificity of 98%, respectively. The authors of this meta-analysis concluded that EUS should be the imaging method of choice for T staging of RC[47]. Despite the high accuracy that EUS has for T stage, this imaging method is not capable of differentiating peri-tumoral inflammation and edema from neoplastic infiltration. One of the mayor limits of EUS, is overstaging T2-T3 RC, with the risk of overtreatment[30,32,53-59]. In T3 stage cancer infiltrates the rectal wall up to the perirectal fat, with different penetration depth. The precise evaluation of the infiltration depth into the perirectal fat is an important prognostic factor for T3 RC. Harewood *et al*[56] demonstrated that T3 RC are not all equal, with minimally invasive disease carrying a more favorable prognosis. In a series of 42 patients with T3 RC, who underwent surgery without receiving NAT, EUS overstaged the minimally invasive (invasion < 2 mm beyond muscolaris propria at EUS) T3 cancer in 50% of cases, in comparison with advanced (invasion > 2 mm beyond muscolaris propria at EUS) T3 RC. These were overstaged only in 4% of cases. The reported EUS accuracy for differentiating T1/T2 and T3/T4 was 88%, with an overall accuracy of 76% for T stage and 63% for N stage. Since the overstaging rate of minimally invasive T3 RC was high, the authors recommend to exclude these patients from NAT, which should be used only for patients with advanced T3 RC[56]. These data highlight the importance of proper measurement of the infiltration depth of RC at EUS, because this information is crucial for establishing the prognosis and guiding the multimodal therapy. According to Esclapez *et al*[57], an ultrasonographic maximum tumor thickness cutoff point of 19 mm could be useful to classify patients preoperatively and select them for primary surgery or

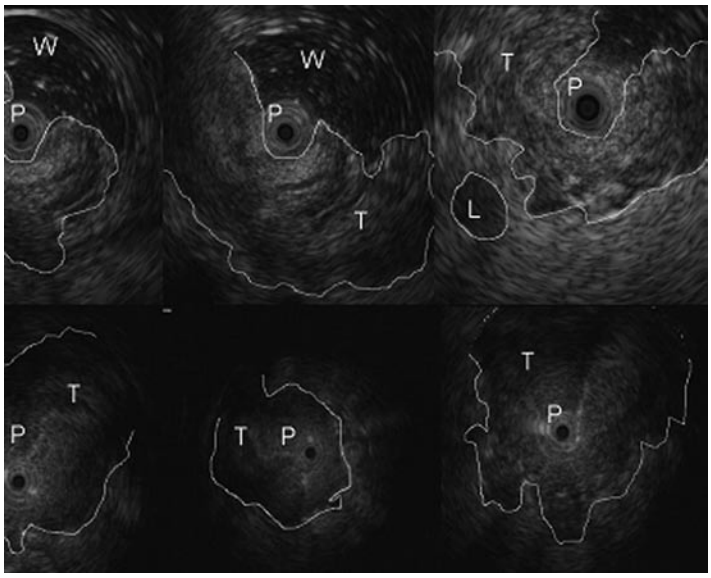

Figure 5 Stage T4 rectal cancer: Miniprobe ultrasonographic view. Endoscopic ultrasound with radial miniprobe (12 MHz) shows an advanced, stenotic rectal cancer with large hypoechoic and inhomogeneous thickening of the rectal wall, loss of the five-layered wall structure and invasion of adjacent organs. uN1 = 1-3 positive nodes
uN2 = More than 4 metastatic lymph nodes

From ref.[9].

NAT. Indeed, these authors showed that tumor thickness of more than 19 mm in uT3 RC was associated with a higher rate of postoperative recurrence[57].

In approximately 14% of RC there is a stricture that cannot be traversed by the echoendoscope, leading to inaccurate staging and potential errors because EUS evaluates only the distal portion of the cancer[5,50,51]. The presence of a stricture is a limitation for staging RC at EUS: this determines not only inaccurate T staging, but also incomplete N staging because perirectal lymph nodes cannot be examined. Moreover, a stricture often does not permit perpendicular position of the ultrasonographic beam and an adequate focal distance of the probe from the tumor leading to misstaging. All these pitfalls can lead to an incorrect staging of the tumor, which can then affect the therapeutic strategy[5]. Marone *et al*[60] reported that EUS has an overall accuracy of 83% in a series of 127 patients with RC, who underwent surgery without receiving NAT. When the T stages were analyzed separately, EUS showed an accuracy of 76% for T1, 72% for T2, 91% for T3 and 67% for T4 stages. Overall, EUS misstaged T in 16% of cases, with 11% of overstaging and 5% of understaging errors. The presence of a stricture lowered the accuracy rate of EUS for T stage from 93% to 56%; similarly the distance of RC from the anal verge affected the accuracy of EUS for T stage, which decreased from 92% for tumors located > 5 cm from the anal verge to 67% for cancer sites < 5 cm from the anus[60]. Therefore, the presence of a stricture and tumor distance of less than 5 cm from the anal verge are two factors limiting the accuracy of EUS in staging RC.

Recently, the capability of EUS in assessing MRF and predicting the circumferential resection margin (CRM) of RC has been evaluated by Granero-Castro *et al*[61]. In a series of 76 patients with mid-low RC, preoperative staging was performed by means of both MRI and EUS and the patients underwent surgery without receiving NAT. A comparison between preoperative (EUS and MRI) CRM status and pathologic examination after TME surgery was eventually made: overall accuracy of EUS and MRI in assessing CRM status was 84% and 92%, respectively, with similar negative predictive values (97%). When focusing on low RC, the overall accuracy of EUS increased to 87%, whereas MRI lowered its accuracy rate to 87%, with a negative predictive value of 96% for both imaging methods. These data suggest that EUS should be used together with MRI for predicting CRM involvement in low anterior RC.

N STAGING

EUS allows the assessment of perirectal lymph nodes for metastatic infiltration: these are metastatic when they appear as roundish or oval, homogeneous echo-poor nodules with a short axis of at least 5 mm (Figure 6)[5,7,9,10]. According to the number of metastatic lymph nodes, there are two different N (uN) echoendoscopic stages (Table 6).

The incidence of malignant metastatic lymph nodes in patients with RC is strictly related to T stage and varies from 6%-11% for T1, 10%-35% for T2 and 26%-65% for T4 RC[3,5,7,8]. Determination of lymph nodes involvement during EUS is difficult and less precise, with a variable accuracy of 63%-85% (Table 4)[12-45]. Kauer *et al*[34] reported that EUS has an overall accuracy of 68% in diagnosing metastatic lymph nodes associated to RC, with a sensitivity of 52% and a specificity of 82%. A recent meta-analysis of 35 published studies evaluated the accuracy of EUS in diagnosing metastatic lymph nodes of patients with RC[7]. EUS showed sensitivity of 73% and specificity of

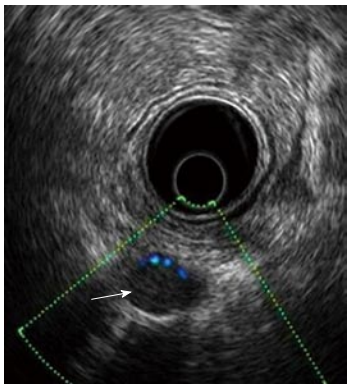

Figure 6 Perirectal metastatic lymph node: Ultrasonographic view. Endoscopic ultrasound with radial array transducer UM160 (5-20 MHz). White arrow: Perirectal metastatic lymph node.

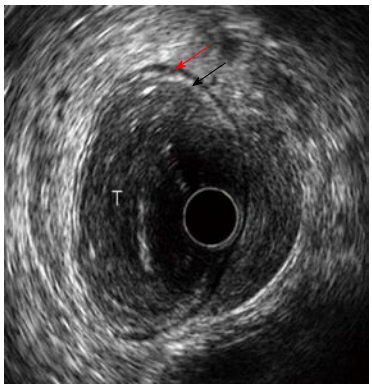

Figure 7 Stage T1 rectal cancer: miniprobe ultrasonographic view. Endoscopic ultrasound with radial miniprobe (12 MHz), showing a small tumor located within the mucosa and superficial submucosal layers, with preservation of the outer layers of the rectal wall. T: Tumor; Red arrow: Muscularis propria layer; Black arrow: Submucosa layer.

76% for N staging and the data analyzed supported the hypothesis that EUS is more accurate in excluding nodal invasion, rather than diagnosing it. Indeed, determination of nodal invasion is less accurate because of difficulty in discriminating between inflammatory and metastatic nodes, which leads to false positive diagnosis and possible overtreatment. The size of lymph nodes could be indicative of neoplastic invasion: nodes greater than 5 mm can be metastatic in 50%-70% of cases, whereas those smaller than 4 mm harbor malignancy in less than 20% of cases[16]. These data have been partly confirmed by Akasu *et al*[59], which observed that the incidence of nodal metastases is strictly related to the size of the lymph node in patients with RC: 9.5% for nodes less than 2 mm; 47% when the lymph node measures 3-5 mm and 87% for nodes larger than 6 mm. However, despite this correlation between size of the node and incidence of metastatic invasion, there are several reports of metastatic lymph nodes smaller than 5 mm in patients with RC, with an overall incidence of 18%[20,62-64]. There is a clear correlation between T stage of RC and risk of metastatic invasion of perirectal lymph nodes. The more advanced the RC, the higher the risk of metastatic lymph nodes: less than 5% with T1m and more than 80% with T3 RC[65,66]. The latter results were confirmed by Landmann *et al*[36], who reported that the accuracy of EUS for N staging decreases from 84% in pT3 RC to 48% in pT1 cancers. The low detection rate of metastatic lymph nodes in T1 RC is probably explained by the fact that in these cancers possible metastatic nodes are small, with a size variable from 0.3 to 3.3 mm. Therefore, EUS can misstage early RC where the presence of neoplastic invasion is possible even in small lymph nodes: this exposes a patient who undergoes local excision to pelvic recurrence because of misstaged early cancer. To avoid this, it was proposed to decrease the dimensional cut off of 5 mm to 3 mm, with increased sensitivity, but reduced specifity and overall accuracy for N staging at EUS. Indeed, with a 5 mm cut off, EUS has an overall accuracy of 89% for N stage in T1 RC, with sensitivity of 39% and specificity of 89%. On the other hand, reducing the cut off to 3 mm, EUS shows an increased (75%) sensitivity for N stage in T1 RC, with significantly reduced specificity (49%) and overall accuracy (53%)[31,36,45]. These data confirm that the size of the lymph node cannot be the only parameter to be used for assessing neoplastic nodal invasion in patients with RC[36,45,59,67].

EUS accuracy for N staging can be ameliorated associating other parameters to the dimensional criterion used for defining malignant lymph nodes. These ultrasound features include lymph node short axis size, echogenicity, shape, and border. Among them, those which better correlate with malignancy are: enlarged node ($\geqslant$ 1 cm in short axis), hypoechoic appearance, round shape, and smooth border[11]. The presence of two or more features is associated with EUS sensitivity of 77%, specificity of 29%, and accuracy of 54%. Three or more features give EUS a sensitivity of 68%, and a specificity of 52%, with an accuracy of 61%. Finally, with four or more features EUS shows sensitivity of 23%, specificity of 100% and accuracy of 61%. Simultaneous presence of all these features in a lymph node is related to 100% of positive predictive value, but this is a rare occurrence (less than 25% of cases)[65]. Despite all the efforts to find the right criteria, determination of lymph nodes involvement during EUS is less accurate and useful than T staging. The most important limitation is the difficulty in both discriminating between inflammatory and metastatic lymph nodes and recognizing small metastatic nodes. These limitations can be overcome by EUS-guided FNA, which allow sampling of the suspicious perirectal nodes, leading to correct N staging. However, even with EUS-guided FNA, the overall accuracy of EUS for N stage remains low, because distant metastatic lymph nodes are undetectable by EUS, since they are out of the scanning area. Indeed, incomplete evaluation of the iliac nodes is the most frequent cause of incorrect staging of patients with RC, leading to mistreatment in 6% of cases[16,45,62,63,66-70]. Recently, Kim *et al*[64] suggested that tridimensional EUS could obviate the low accuracy of

EUS for N staging. However, these results need to be confirmed.

PITFALLS IN STAGING RECTAL CANCER

Sometimes, EUS staging of RC can be incorrect and the cancer is misstaged because of overstaging rather than understaging. At EUS, hypoechoic fibrosis and/or inflammation cannot be differentiated by the hypoechoic mass of the tumor leading to overstaging. On the other hand, understaging occurs when the microscopic neoplastic invasion into the next layer is undetectable during EUS, especially when an entire layer is distended by the invading tumor which abuts into the adjacent layer, without showing clear infiltration. Moreover, a stricture which cannot be traversed limits the accuracy of EUS, while location, shape and size of the tumor can alter the direction of scanning and result in overstaging. Similarly, the T stage can influence the results of EUS staging, as in the case of T2 cancer for which EUS staging is less accurate. Finally, EUS is operator dependent and there is a substantial difference in accuracy between novice and experienced endoscopists, since the latter have learned over the time how to avoid technical problems, like oblique scans, overfilling of the balloon and inadequate water filling of the rectum[5].

MINIATURE ULTRASONIC PROBES

Dedicated echoendoscopes have some limitations due to the fact that combining endoscopy and ultrasonography in one instrument increases the diameter of such scopes (12-13 mm). Because of the large diameter, complete passage of severe strictures is often impossible. Furthermore, conventional EUS often requires a second examination, separate from the previous routine endoscopy. The miniature ultrasonic probes (diameters about 2 mm; frequencies 12-20-30 MHz) can be passed through the working channel of standard endoscopes to provide high frequency ultrasound images (Figures 1, 5 and 7). These miniprobes allow simultaneous endoscopic and ultrasonographic evaluation of the lesions, complete assessment of strictures that cannot be traversed by conventional echoendoscopes and accurate staging of superficial lesions[8]. The rarity of lymph node metastases in T1m or T1sm 1 RC supports the indication for endoscopic resection of these lesions, which require accurate preoperative staging. This has been performed by Harada *et al*[71], using a 15-MHz ultrasound miniprobe in 35 patients with submucosal invasive colorectal cancer. The accuracy of miniprobes was low (37%) in categorizing the different depth of submucosal invasion, while it was high (86%) in differentiating between mucosal/superficial submucosal infiltration (M and SM) and deep submucosal invasion (SM2, SM3, MP, and S)[71]. These data support the indication for ultrasonographic staging of early colorectal *via* miniprobes in order to plan endoscopic resection. In a prospective study of 131 consecutive patients with adenocarcinoma or broad-based polyps of colorectum, EUS accuracy for T staging with miniprobes was 96%, with 4% of overstaging and 2% of understaging[72]. The overall accuracy of N staging using miniature ultrasonographic probes was 87% (sensitivity 95%, specificity 71%, positive predictive value 87%, negative predictive value 88%). These data confirm that miniprobe ultrasonography has a high overall accuracy for both T and N staging of colorectal cancer and it may be useful for selecting patients fit for local resection. Finally, Gall *et al*[73] conducted a meta-analysis of ten studies with a total of 642 patients to evaluate the accuracy of miniprobe EUS in staging RC. The pooled sensitivity and specificity were respectively 91% and 98% for T1 cancers, 78% and 94% for T2 tumors, 97% and 90% for T3/T4 RC. Eight percent of T1/T2 cancers were upstaged to T3/T4 tumors and 5% of T3/T4 RC were downstaged. Finally, the pooled sensitivity and specificity for N staging were 63% and 82%, respectively. These data confirm that miniprobe EUS is highly effective for clinical staging of RC, allowing identification of those patients who may be suitable for nonsurgical treatments.

EUS-FNA for staging rectal cancer

According to a recent study, EUS-FNA is useful for assessing primary and metastatic rectal cancers. In this setting, EUS-FNA had sensitivity, specificity, positive and negative predictive values of 89%, 79%, 89% and 79% respectively. This technique improves staging of suspected nodal or distant metastases, but it is indicated only when cytologic results will change the therapeutic strategy[74,75]. This is the conclusion of Harewood *et al*[12], who reported that standard EUS modified therapeutic strategy of LARC in 25 patients, while only in 1 case EUS-guided FNA was crucial for choosing the correct therapy. According to Shami *et al*[76], EUS-guided FNA has a clinical impact of 19% on staging and subsequent management of patients with RC. In this cancer the incidence of lymph node metastases is strictly related to T stage, with a higher risk of nodal metastasis with more advanced T stages. Peritumoral lymph nodes are highly predictive of cancer invasion: the majority of perirectal nodes detected by EUS are metastatic in patients with RC. This is the explanation for the low clinical impact of EUS-guided FNA in staging patients with RC. Moreover, T3 RC is an indication for NAT, independently from N stage, which has no influence on the therapeutic strategy of patients with LARC[12,75]. EUS-guided FNA seems to offer the most potential for the management of T1-2 stage disease, where the presence of metastatic perirectal lymph nodes modifies the therapeutic strategy. Therefore, its use should be confined to this subgroup of patients[12,67,75,77]. This indication is confirmed by Levy and colleagues who evaluated the role of EUS guided FNA in N staging of 32 patients with RC and suspicious iliac lymph nodes[70]. In approximately 50% of cases, the sampled nodes were positive for neoplastic invasion and determined

a change in the therapeutic strategy. Of note, CT scan did not detect half of the lymph nodes which were malignant at EUS–guided FNA. These data support the need to properly investigate the iliac lymph nodes during staging of patients with RC.

EUS in comparison with CT and MRI for staging rectal cancer

In RC, EUS has been compared with digital examination, CT scan and MRI. EUS is superior to rectal digit examination, showing a higher accuracy (91%-92% *vs* 52%-60%). CT scan is unable to correctly define the single layers of the rectal wall and therefore is not indicated for T staging of RC, while it is crucial for diagnosing distant metastases[77]. EUS is more accurate than CT scan in loco-regional staging of RC, showing an accuracy rate of 87% for T stage and 62% for N stage, compared to that of CT scan (76% for T stage and 62% for N stage)[6,63,77]. Similarly, EUS was considered more precise (85% *vs* 77%) than MRI in determining the T stage of RC[77]. However, recent technology has allowed MRI to define the status of MRF and subsequently delineate the possible threatened CRM, making this imaging method crucial for loco-regional staging of RC[44]. A systematic review of 31 articles published over a 20-year period evaluated the role EUS and MRI in loco-regional staging of RC[46]. While EUS is more useful for staging early RC, with an overall accuracy of 82%, MRI is indicated for staging advanced disease, providing a better definition of both the mesorectum and the MRF. The latter is crucial for choosing the best therapeutic strategy. In another systematic review, Kwok *et al*[78] evaluated the role of CT scan, EUS and MRI in the preoperative staging of RC. In determining T stage, EUS was more accurate than CT scan and MRI. The latter, with the adjunct of an endorectal coil, has the same accuracy of EUS for T stage, while it is more precise in determining nodal metastases. Both EUS and MRI with an endorectal coil are limited by the presence of strictures when staging RC. An MRI with a pelvic phased-array coil is not invasive, has a high spatial resolution and appears to be a promising image method for loco-regional staging of RC[37,79]. Yimei *et al*[80] evaluated the reference value to surgeons of both EUS and MRI, reporting that EUS has higher sensitivity (P = 0.044) and specificity (P = 0.039) than MRI, showing elevated accuracy for early stage RC. This makes EUS staging crucial for the identification of those patients who are suitable for less invasive surgery. On the other hand, MRI is useful for the proper diagnosis of LARC which need to undergo multimodal treatment. MRI has been preferred to EUS because it is better tolerated, can be used in stenotic tumors and it can define the infiltration depth of MRF and assess the CRM. The latter is a crucial information for choosing the best therapeutic strategy. However, Cesmeli *et al*[81] point out that EUS is still important in the preoperative staging of early RC, because of its ability to delineate the different layer of the rectal wall, allowing the selection of those patients suitable for local excision. EUS can also improve N staging by performing FNA, whenever N stage can change the therapeutic strategy[81]. In a series of 49 patients, EUS and MRI showed similar accuracy (88%), in predicting pathologic CRM of low RC[82]. Therefore, EUS and MRI are complementary and should be both used for preoperative staging of patients with RC. The fact that staging accuracy is improved by combination of MRI and EUS is supported by the results of a recent study in which the authors compared feasibility and accuracy of both 1.5 Tesla MRI and three-dimensional (3D) EUS for staging patients with RC before and after preoperative chemotherapy[83]. The stage accuracy by MRI, 3D-EUS and the combination of MRI and 3D-EUS was 65%, 70% and 74%, respectively, before chemotherapy and 65%, 78% and 83%, respectively, after chemotherapy. The post chemotherapy staging by MRI alone was improved by a combination of MRI assessment of the lymph nodes and 3D-EUS assessment of the perirectal tissue penetration (P= 0.046). These results confirmed that staging accuracy is improved by combining MRI with EUS.

According to the data of the literature, EUS and MRI are superior for T- staging, while CT and PET/CT are the main stay for metastatic work-up. EUS is superior in staging early cancers and defining the infiltration of the anal sphincter, while MRI is excellent for staging T4 and clarifying both the MRF status and the infiltration of the elevator muscle; CT and EUS are complementary, rather than competitive in loco-regional and distant staging of RC[84-86]. Therefore, the best approach for RC is the combination of all different imaging methods, which are complementary: they should be utilized according to the clinical condition of the patient, the availability of each single test and the personal preference. Cost-benefit studies have demonstrated that the most cost-effective association of imaging methods is EUS plus CT scan[87].

Accuracy of eUS in staging locally advanced rectal cancer after chemoradiation

Loco-regional staging of RC after NAT is affected by local effects of the treatment which determines peritumoral inflammation, edema, necrosis, and fibrosis of the neoplastic tissue. This reduces the accuracy of EUS, leading to overstaging errors (Table 7)[88-90]. EUS staging of RC after NAT is inaccurate, as shown by Vanagunas and colleagues in a series of 82 patients with LARC[90]. After NAT, EUS correctly predicted complete response to chemoradiation in only 63% of cases and its overall accuracy for pathologic T-stage was 48%, with 14% of understaging and 38% of overstaging. These data suggest that EUS staging of RC after NAT is inaccurate, and its routine use for restaging patients should be discouraged. Similary, Marone *et al*[91] and Maor *et al*[92], demonstrated that EUS restaging of LARC after NAT has low accuracy. Both studies compared two groups of patients with LARC: one operated on without receiving NAT and another one who underwent surgery after NAT. The results of the studies were similar, showing

Table 7 Accuracy of endoscopic ultrasound in staging locally advanced rectal cancer after chemo-radiation

Ref.	Year	No.	T	Mistakes		N

uTN stage compared with pTN stage; Previous neoadjuvant therapy (NAT). Over: Overstaging; Under: Understaging.

that EUS restaging of LARC after NAT has low accuracy (60%-70%) and is able to predict a complete response in only 50% of cases. Further confirmation of this low accuracy came from a study where the authors compared sensitivity and specificity of EUS and MRI, in patients with LARC after NAT[93]. Both EUS and MRI had low accuracy (46% *vs* 44%) for T stage of LARC after NAT. Better accuracy of EUS restaging was reported by Radovanovic and colleagues who demonstrated that EUS has an accuracy of 75% for T stage after NAT, with 18% of overstaging and 7% of understaging[94]. The majority of overstaging occurred in patients with uT3 tumors, eventually found to have pT0-pT2 RC. EUS was able to correctly stage only one of the patients who had complete response after NAT. Despite the fact that EUS restaging accuracy for LARC was higher, the results of this study confirm that EUS is not useful after NAT.

EUS DIAGNOSIS OF LOCAL RECURRENCE IN PATIENTS OPERATED ON FOR RC

After surgery, local recurrence of LARC has an incidence of about 25%, which decreases to 10%, if NAT has been administered before surgery (10%). The risk of local recurrence is strictly related to T stage and it is higher for more advanced T stages, occurring mostly in the first two postoperative years[95-97]. Early identification of local recurrence and its immediate treatment could potentially improve patients survival. EUS has a high sensitivity, but low specificity in defining local recurrences. A limitation of EUS is its inability to clearly differentiate postoperative changes and benign lesions from cancer recurrence[95-97].

EUS-guided FNA increases the specificity of EUS (57% *vs* 97%). To date, there are no guidelines which define the role of EUS in the follow-up of patients operated on for RC, since there are no clear data that echoendoscopic follow-up and/or EUS-guided FNA influence patients survival after surgery for RC[95-97].

Future perspectives

The recent development of new technology for EUS generates novel applications for echoendoscopic diagnosis and staging of gastrointestinal tumors. Tridimensional EUS (3D-EUS) seems to improve the spatial visualization of RC allowing better evaluation of tumor resectability[98]. 3D-EUS is more accurate than 2D-EUS and CT scan in T staging of RC, for which the three imaging methods have an accuracy of 78%, 69% and 57%, respectively[64]. 3D-EUS visualization of the outer margin of the rectal wall is well related to neoplastic infiltration and metastatic nodal invasion diagnosed by pathological examination of the surgical specimen. Some data suggest that 3D-EUS allows correct visualization of MRF, which was not well delineated by 2D-EUS. Proper measurements of the tumoral area before and after NAT could be a useful criterion for evaluating the response of RC to NAT[98-100].

Elastography is a new technique which has been recently added to the armamentarium of EUS and allows measurement of tissue elasticity useful to differentiate normal from tumoral tissue. Preliminary data have shown that simultaneous elastography during EUS improves its accuracy for T staging of RC[98]. Finally, EUS with contrast medium administration (contrast harmonic EUS or CH-EUS) and simultaneous Doppler visualization allows the study of tumoral vascularization and irroration. These data are useful for the evaluation of both tumoral response to NAT and efficacy of anti-angiogenic treatments, because this combination of techniques shows accurately those changes in the vascular pattern of RC which reflect its response to therapy. Miyata *et al*[101] evaluated the micro-vascularization of lymph nodes by means of CH-EUS in order to differentiate benign from malignant nodes: sensitivity, specificity, and accuracy of CH-EUS for malignant lesions were 95%, 97%, and 97%, respectively. These data show that CH-EUS is accurate in detecting minimal changes of tumoral vascularization in lymph nodes which harbor neoplastic invasion. This information could address the correct use of FNA-guided EUS, whenever it is needed[101,102]. To date, there are still little data on the clinical application of simultaneous use of these new methods together with standard EUS. Therefore, further clinical trials are needed for the evaluation of indication, accuracy, clinical impact and limitation of CH-EUS and Doppler-EUS.

CONCLUSION

Prognosis of patients with RC is strictly dependent from the stage of the disease at the time of diagnosis. Multidisciplinary approach to patients with RC is the standard of care in order to reduce local recurrences and improve survival outcomes. A strong cooperation among members of a multidisciplinary team is mandatory to improve patients outcomes, because the latter are strictly dependent from the chosen therapeutic strategy. This is the results of an accurate loco-regional staging, especially if metastatic disease has been excluded. CT scan, MRI, PET are the imaging method used for staging RC and give information on both loco-regional and distant disease. In the last decades, EUS has been

used in combination with these imaging methods for staging RC in order to better define both the T stage and the involvement of loco-regional lymph nodes. EUS has significant clinical impact on patients with RC, allowing to identify those who are candidate for local excision and/or direct surgery, without receiving NAT. LARC is well defined by EUS, even if the identification of both MRF and possible threatened CRM is more precisely obtained by MRI. The latter lacks accuracy for mid - low anterior RC, which could be better staged by EUS, as recent data suggested. Therefore, EUS and MRI are complementary and they should be used simultaneously, with a significant increase of the overall accuracy for the T stage of RC. EUS is superior in identifying early cancers and infiltration of anal sphincter, while MRI is excellent in recognizing T4, in relationship to MRF infiltration of the elevator muscle. While EUS and MRI are superior for T- staging, CT and PET/CT are the main stay for metastatic work-up.

Restaging after NAT is mandatory for establishing a correct prognosis of patients with RC and choosing the most effective treatment. This should be tailored according to the results of NAT, whose experimental drugs can be tested in clinical trials and evaluated by means of restaging RC. The latter is not performed by means of EUS because this imaging method has low accuracy in restaging RC, due to the difficulty in differentiating inflammation and tissue fibrosis from actual residual cancer.

EUS has low sensitivity, but high specificity in diagnosing local recurrences in patients operated on for RC, because it is unable to differentiate perianastomotic surgical changes from recurrent cancer. In this case, EUS-guided FNA increases specificity, but its use in clinical practice has not been standardized. Probably, high resolution images and guided FNA are the best combination for improving EUS accuracy in naive and recurrent RC.

Technological improvements, like elastography, contrast medium administration, high ultrasonographic frequencies and 3D, will certainly improve EUS accuracy and broaden its clinic use; however there is a need for further studies which should confirm the potential of these new technologies.

In conclusion, accurate EUS staging is crucial for the best treatment of each single patient with RC and especially LARC, because patients can be understaged or overstaged, with subsequent mistreatments.

Abstract

Perforations, leaks and fistula involving gastrointestinal (GI) tract are increasing encountered in clinical practice. There is a changing paradigm for their management with surgical approach being replaced by conservative approach including endoscopic therapy. Clips (through the scope and over the scope) and covered stent are front runners for endotherapy for GI leaks and fistula. Over the scope clips introduced recently, can treat larger defects compared to through the scope clips. Covered stents are suited for larger defects and those associated with luminal narrowing. However cervical esophagus, gastro-esophageal junction, stomach and right colonic lesions may be better for clip therapy rather than stenting. Recent developments in this field include use of endovac therapy which consists of a sponge with suction device, biodegradable stent, use of fibrin glue and some endo-suturing device. Conservative therapy with no surgical or endoscopic intervention, may be suitable for a small subset of patients. An algorithm based on location, size of defect, associated stricture, infection and available expertise needs to be developed to reduce the mortality and morbidity of this difficult clinical problem.

Key words: Fistula; Leak; Perforation; Post operative; Endoscopy; Endoscopic; Surgery; Stent; Suture; Endoclip; Clip

Core tip: Gastrointestinal (GI) leaks and fistula are increasingly recognized in our day to day practice. While these patients were earlier managed by surgical interventions, more and more such patients are now considered for endoscopic therapy. Endotherapy for GI leaks include endoclips (through the scope and over the scope), covered stents, fibrin glue, suture devices and more recently introduced endoscopic vacuum therapy using bioactive sponge. Since the experience with these modalities is limited, there are hardly any clear guidelines to treat these difficult patients. This review article deals with endotherapy of GI leaks and fistula and presents an updated experience as well some guidance to select appropriate modality.

INTRODUCTION

Gastrointestinal (GI) leaks and fistula constitute disruption of GI wall. GI leaks and fistula can be either spontaneous due to GI pathology or may be iatrogenic. There seems to be increase in prevalence of GI leaks and this seems primarily due to increasing complexity of GI surgery and endoscopic interventions. There is a changing paradigm in management strategy of GI leaks and fistula. While majority of these complicated patients were managed by surgery 15-20 years back, non-operative treatment including endoscopy presently constitute the primary modality of therapy[1]. There is evidence to suggest that this changing paradigm in form of endoscopic therapy is associated with improved outcome and shortened length of hospital stay[1]. This review deals with endoscopic techniques and their present status in the management of GI leaks and fistula.

Management of pancreatic and bile ductal leaks is however, not discussed.

DEFINITION AND ETIOLOGY

Perforation, fistula and leaks are terms, which are often used interchangeably. However in strict terms, they are somewhat different. Perforation refers to acute full thickness defect in GI tract. Leaks are defined as disruption of surgical anastomosis resulting in a fluid collection[2]. The term fistula usually means an abnormal communication between two epithelialized surfaces[2]. Table 1 enumerates the causes of GI leaks and fistula[3-17], while Table 2 distinguishes the underlying etiology for leaks and fistula. Table 3 details the endoscopic procedures associated with increased risk of perforation[18].

Table 1 Etiology of gastrointestinal leaks and fistula

Diagnostic endoscopy including endoscopic ultrasound
Dilation: bougie, balloon, achalasia
Polypectomy/EMR/ESD
Foreign body
Endoscopic variceal therapy including ligation
POEM
Anastomotic dehiscence
Boerhaave's syndrome
Diverticulitis
Laser
PEG
Endoscopic sphincterotomy
Biliary stent migration
Ampullectomy
Appendicular abscess
Empyema

EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; POEM: Peroral endoscopic myotomy; PEG: Percutaneous endoscopic gastrotomy.

Table 2 Causes of leaks and fistula

Leaks	Fistula
Iatrogenic (60%)	Malignant (50%)
Endoscopy	Benign
EVL	Stents
Dilatation	Tuberculosis
ESD/EMR	Crohn's
POEM	Iatrogenic
Spontaneous	Trauma
Boerhaave's	Surgical
Foreign body	AIDS
Surgical	
Trauma	

EVL: Endoscopic variceal ligation; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; POEM: Peroral endoscopic myotomy; AIDS: Acquired immune deficiency syndrome.

TOOLS AND TECHNIQUES

The two options for managing GI leaks and fistula include surgery and endotherapy. The choice between two is decided by size of disruption, location and accessibility of lesion, presence of contamination, time of diagnosis and availability of expertise. Whatever be the choiced option for repairing the disruption, the management needs to include bowel rest, institution of appropriate antibiotics, drainage of associated collection, pneumoperitoneum, pneumothorax and maintenance of nutrition. Proton pump inhibitors are instituted, if leaks are located in upper GI tract. As highlighted in a recently published Position Statement of European Society of Gastrointestinal Endoscopy, it is important to have a systematic approach for diagnosis and treatment of GI perforations[18]. Endoscopist must record details of findings, attending physician must evaluate the clinical profile, necessary investigations which may include a CT scan and a blood picture should be carried out, a decision should then be taken whether to perform endotherapy or surgery and finally post endotherapy monitoring must be done to evaluate success or failure of the endotherapy[18]. Table 4 lists the endoscopic modalities, which can be used for closure of GI leaks and fistula. Of these, endoclips and covered stents are the two modalities, which are most commonly used and have most consistent results.

Endoclips

Endoclips, which are more frequently used for arresting GI hemorrhage can also be used for closing the GI wall disruptions and work like surgical sutures or staples[3,4,19]. First report of endoclipping for closure of GI perforation came from Germany[20]. This report discussed successful endotherapy of a perforation after endoscopic removal of gastric leiomyoma[20]. Endoclips can either be through the scope (TTS) clips, where clip applicator with loaded clip is introduced through the biopsy channel of the endoscope or recently available over the scope (OTS) clips, which are mounted over the scope tip like variceal band ligator device and released by a similar technique. TTS clips (Figure 1) are available in various designs and sizes: Quick clip

Table 3 Endoscopic procedures in different parts of gastrointestinal tract associated with increased risk of iatrogenic perforation

Esophagus and stomach	
Dilatation	ESD
EMR	Foreign body removal
POEM	EVL
Small bowel	
Altered anatomy	DBE in altered anatomy
Dilatation in Crohn's	ESD
Dilatation of GJ stricture after gastric bypass	
Colon	
EMR	Balloon dilatation
ESD	Old age, co-morbidity
Inexperience	Inflammatory colonic disease

ESD: Endoscopic submucosal dissection; EMR: Endoscopic mucosal resection; POEM: Peroral endoscopic myotomy; EVL: Endoscopic variceal ligation; DBE: Double-balloon; GJ: Gastrojejunostomy.

Closure
Endoclips
Suture
Sealant: Fibrin, cyanoacrylate
Diversion
Covered stents

(Olympus, America Inc., Center Valley PA, United States), Resolution clip (Boston Scientific Inc., Natick, United States) and Instinct clip (Cook Medical Inc.; Bloomington, IN, United States). Some of these are rotatable and re-openable, making them convenient to appropriately align the disrupted tissue. Figure 2 shows an esophageal tear treated by TTS clips.

OTS clips (Figure 3) from Ovesco Endoscopy GmbH (Tuebingen, Germany) are nitinol, super elastic, biocompatible clips with teeth designed in the shape of a bear trap and can produce a full thickness closure. OTS clips are available in various shapes and sizes and selection of a particular size depends upon the size of the defect. For larger defect, one can use accessories like anchor and twin grasper, which can pull the defective mucosa into the OTS cylinder or reduce the gap of the defect respectively (Figure 3). One should carefully avoid capturing twin grasper or anchor while releasing the clip. Figure 4 illustrates the use of OTS clips in a patient with two defects in gastric wall located diagonally opposite one another following a Whipple's surgery. Two OTS clips were placed with the help of anchor and twin grasper through a double channel endoscope. Follow-up CT scan confirmed the complete closure of defects.

In general, it is believed that OTS clips cover a larger defect and one OTS clip can be compared with results obtained with 5 TTS clips. In large defects, such as after Endoscopic Submucosal Dissection (ESD), multiple TTS clips can be used to fix an endoloop at the margin of the defect and then pulling the loop and closing it can obliterate the defect. There are case reports of OTS clips

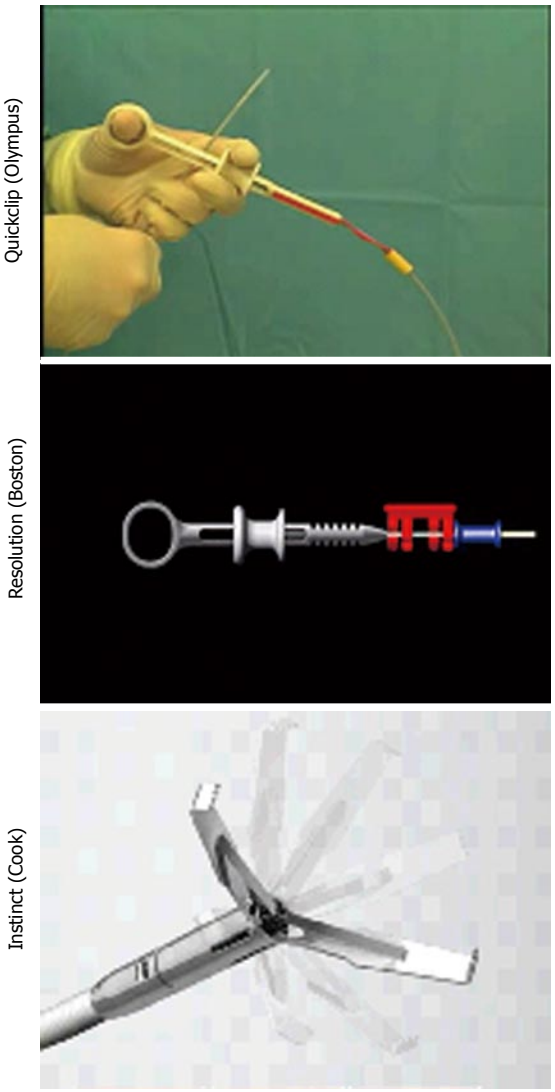

Figure 1 Through the scope clips.

Figure 2 Endo clips (Through the scope) used to close an esophageal defect due to Boerhaave's syndrome.

applied under laparoscopic control in order to achieve greater success[21].

Both TTS and OTS clips have been used to close fistula and leaks located in esophagus, stomach as

Figure 3 Over the scope clips (ovesco) (A) clip, (B) clip mounted on the endoscope, (C) anchor, (D) twin grasper.

well as colon[20,22-30]. While most of these studies involve small number of patients, large series have reported results of clips to close leaks following ESD and endoscopic mucosal resection (EMR)[23,31]. Minami *et al*[23], in a series of 117 patients with gastric leak following EMR, demonstrated a success rate of 98.3% with TTS clips. Interestingly, they found a similar recovery rate for patients with perforation treated by clips and non perforated patients[23]. Of the 39 patients with perforations following ESD reported by Jeon *et al*[32] managed by endoclip, there was no failure. Overall success rate is higher for esophagus and stomach and somewhat moderate for colonic leaks. Voermans *et al*[22] reported their experience of OTS clips in 36 patients with iatrogenic perforations (esophageal: 5, gastric: 6, duodenal: 12, colonic: 13). Overall success rate of OTS clips was 89% with only one patient having endotherapy related complications. A large muti-center retrospective study by Chavez *et al*[33] involved 188 patients with GI leaks and fistula treated with OTS clips. 27 patients were lost during follow-up. Of the remaining patients, OTS was used as primary treatment in 97 patients and as rescue therapy in 64 patients. The success rate was 75% in first group and 47% in second group. Overall success rate was 64% (103 out of 161 patients). The result was better for perforation (95%) and leaks (80%), compared to fistula (45%).

In general clips are preferred over stents, if the leak is located in proximal esophagus or in distal most esophagus as well as for stomach and right colon[34]. While TTS clips are effective for leaks smaller than 10 mm[35], OTS clips are preferred if defect is larger than 20-30 mm. Prior ablation at edges of defect to make it raw, may help in clip placement[36]. While closing a large leak, it may be worthwhile to attempt to include adjacent omental patch within the clip, akin to surgical practice[37]. Because of possibility of leakage of air during the procedure, it may be a good idea to use CO_2 insufflation during endotherapy of leaks and fistula[18]. In order to get best results, it is important to apply endoclips early after detection of leaks and perforations[35]. There is no reported risk of peritoneal dissemination or tumor recurrence after endoclips used for perforations following ESD or EMR performed for early cancers[38,39].

Luminal stenting

A large variety of stents are available to close luminal defects (Figure 5). These stents are covered (at least partially), so as to seal the defect and avoid contamination of the disrupted area. Mostly these stents are self - expanding metallic stent except for a single design of plastic stent (Polyflex, Boston). Fully covered stents, because of their ease at removability, are generally preferred particularly in the setting of benign disease. Figure 6 shows a patient with leak following gastrojejunostomy done for distal duodenal obstruction. One of the major issues with use of covered stent for closing of the GI defects is the risk of migration in absence of any obstructive pathology. This can be reduced by using large sized stents (Mega stents by Niti or Danis stent by Ella Figure 7), modified stents designs with extra covering in the shaft of stent (Figure 8) or by anchoring the stent by using endoclips or externalised threads (Figure 9)[40].

Stents have been used mostly in esophagus, duodenum and colon. Van Boeckel *et al*[41] reported the

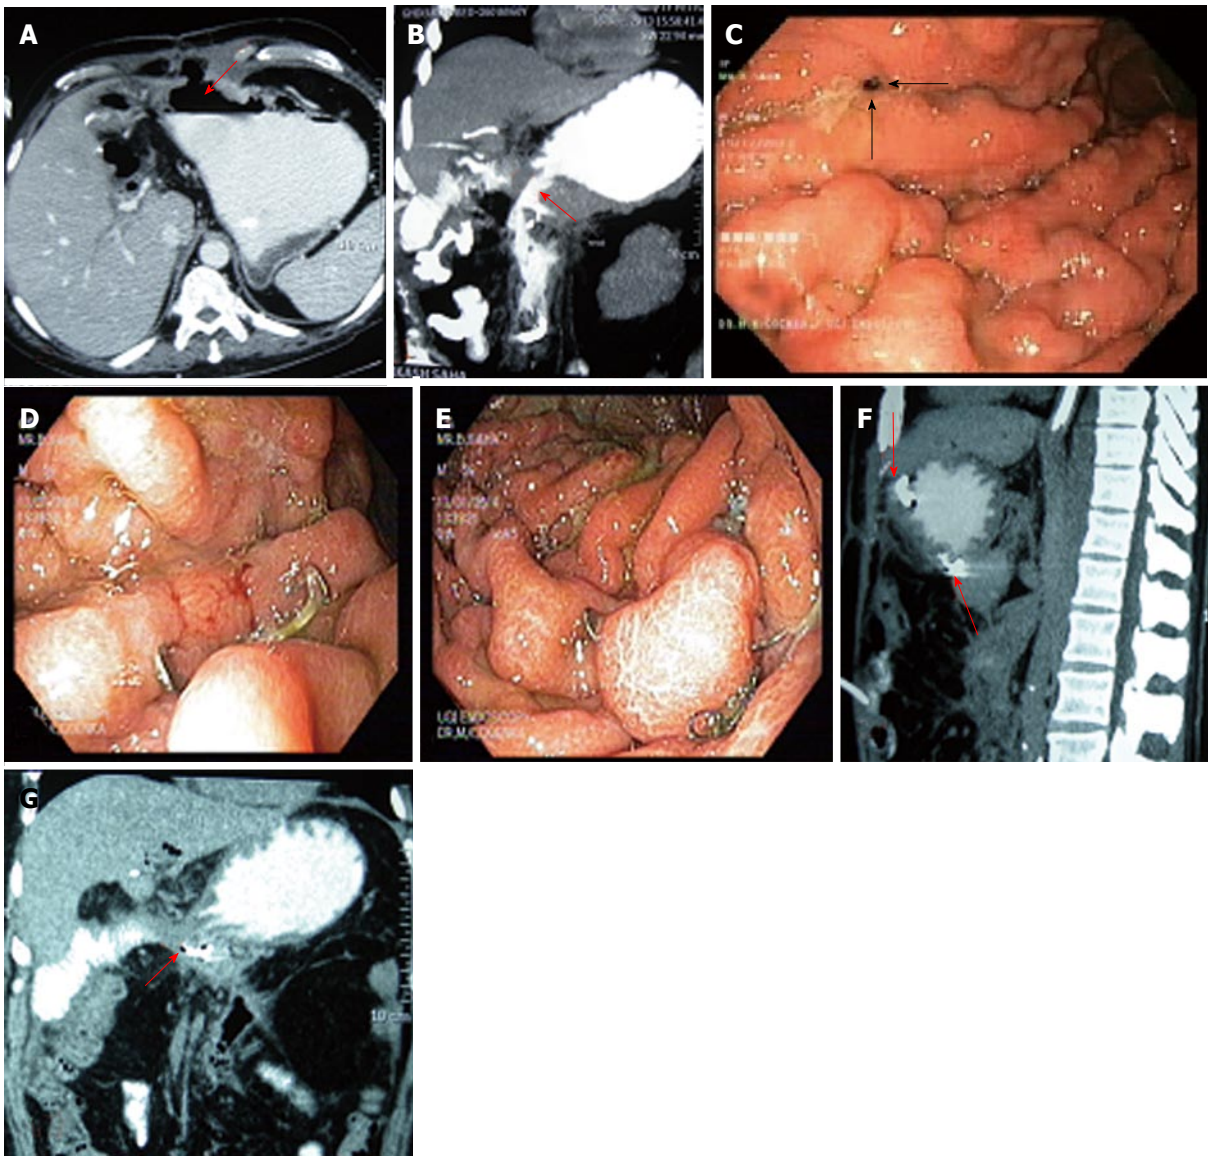

Figure 4 Dual gastric leak following Whipple's Surgery treated by over the scope clips. A and B: Anterior and posterior defects (arrows); C: Endoscopic view showing leak on anterior gastric wall (arrows); D and E: The OTS clips placed on anterior and posterior defects respectively; F and G: Follow-up CT scan showing the clips (arrows) with demonstration of closure of leaks. OTS: Over the scope.

results of 25 studies with luminal stent for iatrogenic esophageal leaks. In the cumulative data involving 267 patients, they reported a clinical success of 85% for closure of leak with no difference between plastic stent, fully covered or partially covered metal stents (84%, 85% and 86% respectively P = 0.097). Overall complication rate was 34%. Migration rate was somewhat higher for plastic stents compared to fully covered and partially covered stents (31% *vs* 26% *vs* 12% respectively). There was however, no difference in other complications such as tumor in-growth or over-growth. Freeman *et al*[42] recently reported that factors associated with failure of leak closure with stent placement include leak at cervical esophagus and esophagogastric junction, injury greater than 6 cm and additional distal leak. Tables 5 and 6 gives details of results of case series with endotherapy in esophageal and gastric iatrogenic perforation respectively[22-24,39,43-56]. As shown most of the series with gastric perforation have used clips, while both clips and stents have been used for esophageal perforation.

Bariatric surgery is not uncommonly complicated by leaks and fistula. In a retrospective study, over a period of 6 years involving 1499 bariatric surgery, Spyropoulos *et al*[57] reported a 2% incidence of luminal leak. Leaks were noted in sleeve itself, at staple line or at anastomosis site (gastrojejunostomy or enteroenteral). Of the 30 patients with leak, stents were used in 9, while surgery was performed in 3 patients and conservative approach was followed in 18 patients. Another recent study by EI Mourad *et al*[58] reported success of stent to close leaks following bariatric surgery in 41 out of 47 patients. Mega stents with a diameter of 30 mm are best suited for these indications.

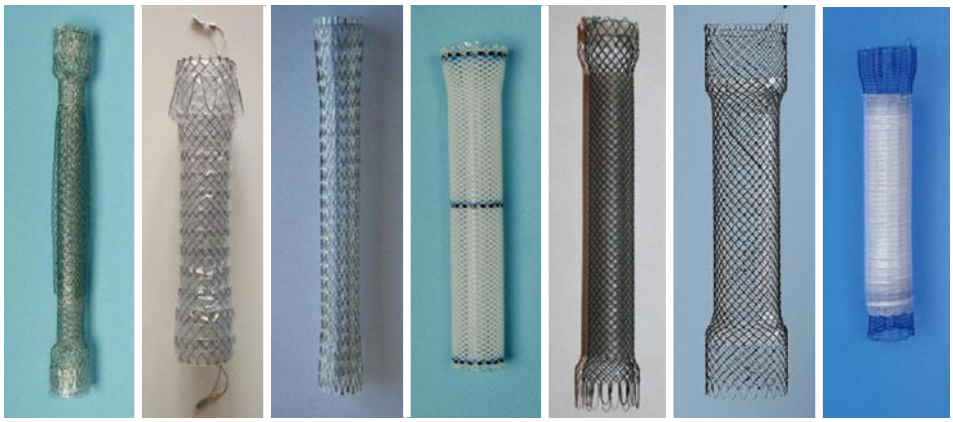

Figure 5 Stents for gastrointestinal leaks/fistula.

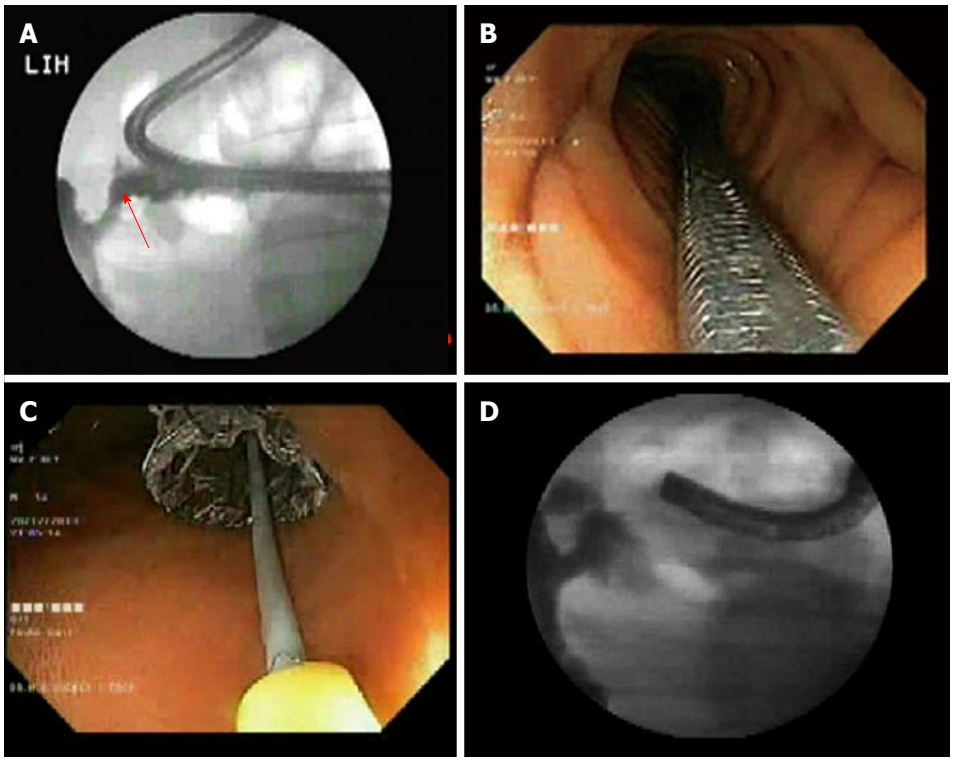

Figure 6 Leak after duodeno-jejunostomy managed by luminal stenting. A: Contrast introduced through the surgical drain site shows the leak (arrow); B: Stent being deployed; C: Fully deployed covered stent; D: Contrast through the surgical drain shows the closure of the leak.

Suturing and sealants

While suturing and use of sealants have been used to close GI leaks and fistula, results are mixed and experience is limited. Some of the suturing devices include EndoCinch suturing device (C.R. Bard, Inc, Boston, Mass, United States) Sefestitch (Safestitch, Medical Inc, Miami, Florida), Medical Power System (Power Medical Interventions, Longtrome, Pennsylvania), ESD Flexible Endoscopic Suturing devices by Wilson-Cook Medical (Winston- Salem, North Carolina) and Eagle Claw (Olympus Corporation, Tokyo, Japan)[59]. All these devices are either being still investigated or have not stood the test of time. Apollo Overstitch system (Figure 10) introduced recently, has been shown to have encouraging results[60,61]. This device is front-loaded onto a double - channel endoscope and allows continuous or interrupted stitches to be made with a cinching device. The merits of this approved device include the ability to reload the device inside the body eliminating the need to remove it between stitches as well as predictability of tissue needle penetration due to it being not suction based. Moreover, the device allows one endoscopic channel to be free to allow passage of grasping forcep for better tissue apposition[61].

Sealants which have been used to obliterate GI leaks and fistula include Cyanoacryate and Fibrin glue[62,63].

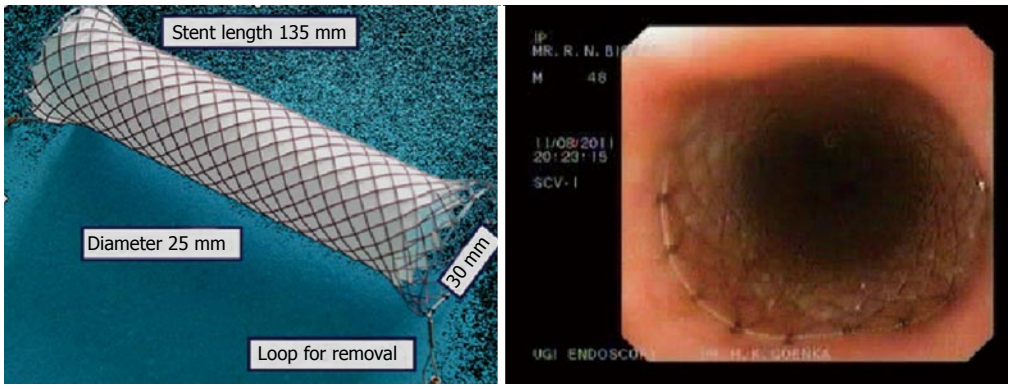

Figure 7 Danis stent.

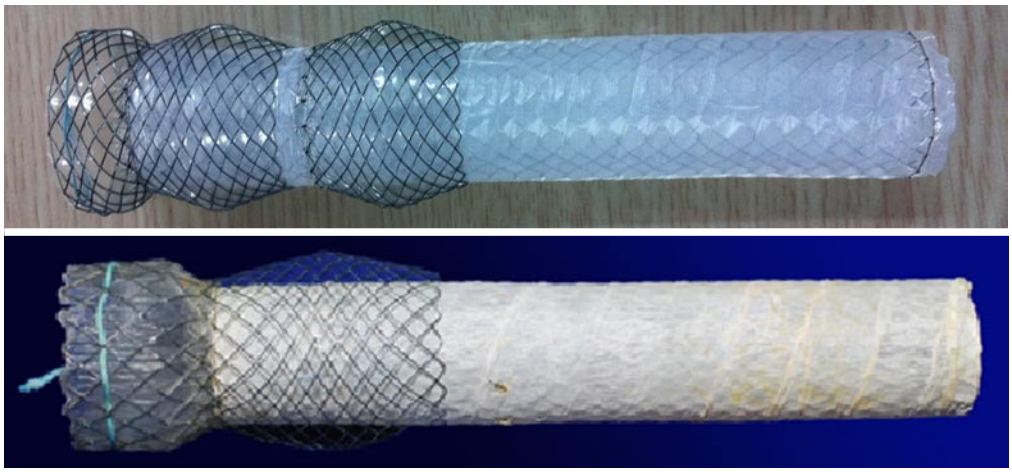

Figure 8 Modified stent design to prevent stent migration.

In a study by Rábago *et al*[62], 15 patients with post operative GI fistula were treated with Fibrin glue (combination of thrombin with fibrinogen). Complete sealing was obtained in 86.6% with a mean 2.5 sessions (range: 1 to 5) and a mean healing time of 16 d (range 5-40 d). Cyanoacrylate has been successfully used to close an esophagojejunal anastomotic leak after failed conservative therapy[63].

LIMITATIONS AND COMPLICATIONS

While endotherapy is exciting and results are encouraging, it has limitations in situations such as large perforation, difficult endoscopic position, fibrosis at the edge of the defect, evidence of abscess or fecal contamination *etc*[64]. Additional procedures or surgical alternatives should be considered in these circumstances. It is important to identify patients with failed clip closure as surgery should be promptly instituted in these patients in order to avoid sepsis and its consequences[65]. Monitoring should therefore be done by clinical profile and repeated blood counts. While endotherapy is safe if performed judiciously, complications such as perforation and bleeding are known. In particular, one must be careful while introducing endoscopes loaded with OTS clips, since the bigger insertion diameter can lead to iatrogenic perforations[22].

RECENT DEVELOPMENTS

Some of the recent techniques used to close GI leaks and fistula include Endovac therapy, Plugs and grafts, Biodegradable stents and Cardiac septal occluder. Endoscopic vacuum assisted closure sponge or Endovac therapy has been used in setting of leaks associated with infections (Figure 11)[66-69]. Ahrens *et al*[68] reported 5 patients with post esophageal surgery anastomotic leaks treated by endovac therapy. Polyurethane sponges with a drainage tube fixed to it allowing continuous suction was positioned endoscopically in the wound cavity and sponge was changed at regular interval. All 5 patients had closure of leak after a median of 9 sponge changes, median duration of drainage being 28 d. Two patients did require bougie dilatation for esophageal stenosis and one of them had fatal outcome due to aortoanastomotic fistula after dilatation. Loske *et al*[67] reported success in 13 out of 14 patients with esophageal leak treated by Endovac therapy with sponge being placed in the esophageal lumen (intraluminal method) or in the extraluminal

wound cavity (intracavitary method). Similar technique has also been used for colonic anastomotic leaks with success in 28 out of 29 patients.

Plugs and grafts used include Vicryl plug and Surgisis. Surgisis soft tissue graft (Cook Biotech Inc, West Latayette, Ind) is an acellular bioactive prosthetic biomatrix produced from sheep intestinal submucosa[70]. In contrast to synthetic prosthetic material which has inherent risk of foreign body reaction, sepsis and secondary fistula formation, surgisis has been shown

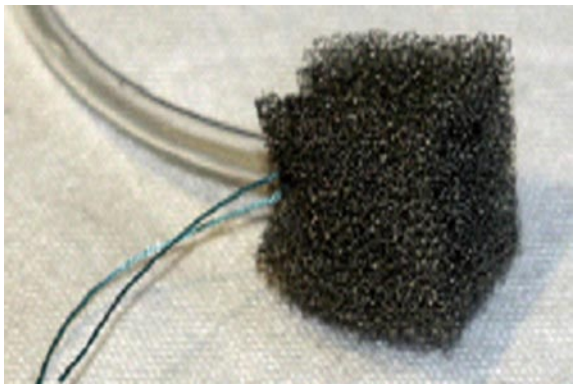

Figure 11 Endoscopic vacuum-assisted closure sponge (Endovac Therapy).

to be safe in contaminated tissues. It has been used successfully to treat complicated infected fistula after surgical resections including bariatric surgeries[71-73]. Vicryl mesh in combination with fibrin glue (covering the mesh as well as injected into the submucosa at the edge of the defect) used by Böhm *et al*[74] has also shown success in 13 out of 15 patients with leaks or fistula in upper GI tract following surgery for cancer. One to four sessions were used for this purpose.

Biodegradable stents have been used in a small series of 5 patients with esophageal leaks[75]. Four out of these 5 patients responded, inspite of 3 stents migrating during follow up. Cardiac septal occluder (Amplatzer Occluder, AGA Medical Corp, Plymouth, MN) used for cardiac septal defects have been used successfully by Repici *et al*[76] to close esophago - tracheal fistula. More data is however, required with these modalities before they are included in routine clinical practice.

CONSERVATIVE TREATMENT

While majority of patient with GI wall disruptions are candidates for either surgery or endotherapy, a small selected group of patients with iatrogenic perforation can be managed by conservative approach[18]. This subset includes stable patients who have perforations in cervical esophagus or a small number of patients with gastric or duodenal perforation, which are diagnosed late (> 12 h), are asymptomatic, have no signs of peritonitis and do not show free fluid or contrast extravasation at CT scan[18]. Somatostatin and its analogue octreotide, which decrease intestinal secretions, have also been used to improve the results of this conservative approach both in adults as well as children[77-79]. However, their role has been primarily considered for post-operative dehiscence, particularly after pancreatic surgery[78,79].

In conclusion, leaks and fistula involving GI tract are increasingly encountered in our routine practice. In a small select group of patients, there is a scope for conservative treatment of perforation and leaks. However, majority of patients are treated by surgery or endoscopic therapy. Techniques such as Endoclips (TTS and OTS) and covered metal stents have made endotherapy a preferred method to treat GI leaks and fistula. In general small leaks (< 10 mm) can be managed by traditional TTS clips, larger leaks require covered stents or OTS clips. Leaks and fistula associated with luminal strictures should be managed by luminal stenting. Recent developments with use of Endovac, Plugs and Graft and Biodegradable stents are encouraging. In particular, use of Endovac in the setting of sepsis seems promising. In view of multiple endoscopic modalities available with us, an algorithm based on location, size and associated features need to be developed to use these techniques judiciously.

Abstract

The current evidence in favor of the laparoendoscopic rendezvous is promising and demonstrates the main advantages of this technique in regard to shorter hospital stay and selective cannulation of the common bile duct (CBD), avoiding thus the inadvertent cannulation of the pancreatic duct. In addition, in the rendezvous technique the contrast medium is not injected retrogradely as during the traditional endoscopic retrograde cholangiopancreatography (ERCP), when the medium accidentally could be injected under pressure into the pancreatic duct. The RV technique minimizes that risk. Both these main advantages of the RV technique over the classic ERCP, are related with a significant lower incidence of hyperamylasemia and post-ERCP pancreatitis, compared with the traditional two stage procedure. Choledocholithiasis is present in 10% to 15% of patients undergoing cholecystectomy. To date, the ideal management of CBD stones remains controversial. Prospective randomized trials have shown that laparoscopic management of the CBD stones, as a single stage procedure, is the most efficient and cost effective method of treatment. Laparoendoscopic rendezvous has been proposed as an alternative single stage approach. Several studies have shown the effective use of this technique in the treatment of CBD stones by improving patient compliance and clinical results including shorter hospital stay, higher success rate and less cost. The current evidence about the use of this technique presented in this review article is promising and demonstrates the main advantages of the procedure.

Key words: Common bile duct stones; Laparoendoscopic rendezvous; Endoscopic retrograde cholangiopancreatography; Cholecysto-choledocholithiasis; Laparoscopic cholecystectomy

Core tip: This is a review article for the laparoendoscopic rendezvous technique - a promising single stage procedure in the treatment of patients with cholecysto-

choledocholithiasis. In this article we highlight the main advantages of the procedure compared to the traditional two stage approach [preoperative endoscopic retrograde cholangiopancreatography (ERCP) followed by laparoscopic cholecystectomy]. These advantages include the selective cannulation of the common bile duct and the avoidance of high pressure injection of the contrast medium into the pancreatic duct. Both factors are directly related with the pathogenesis of post-ERCP pancreatitis. The current evidence demonstrated in this paper is in favor of the laparoendoscopic rendezvous, however, this technique is still not widely accepted.

Baloyiannis I, Tzovaras G. Current status of laparoendoscopic rendezvous in the treatment of cholelithiasis with concomitant choledocholithiasis. *World J Gastrointest Endosc* 2015; 7(7): 714-719 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/714.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.714

INTRODUCTION

Choledocholithiasis is present in 10%-15% between patients undergoing cholecystectomy. The overall incidence of unsuspected common bile duct (CBD) stones is approximately 4%[1,2]. Once discovered, CBD stones should be removed in order to prevent several complications, such as acute pancreatitis, jaundice and acute ascending cholangitis and hepatic abscess. The obvious aim in the treatment of patients with choledocholithiasis is to achieve ductal clearance with the less number of interventions and least morbidity[3].

Over the past few decades, there have been significant improvements in both the diagnosis and treatment of patients with gallstone disease and CBD stones. Before the introduction of laparoscopic cholecystectomy, patients with cCBD stones underwent CBD exploration by open surgery. Although a high success rate of CBD clearance was achieved, the significant morbidity and mortality of a major abdominal surgery remained. Since then, many alternative treatment modalities have been developed. Especially, the introduction and evolution of endoscopic retrograde cholangiopancreatography with endoscopic sphincterotomy, which gradually became the gold standard for the treatment of biliary duct stones[1,4].

Nowadays, laparoscopic cholecystectomy (LC) is the treatment of choice for patients with symptomatic cholelithiasis. The introduction of LC as a minimal invasive procedure, has also changed the therapeutic strategies for the management of choledocholithiasis. To preserve the minimal invasive concept of management, a number of options have been proposed, including two and single step management. Thus, the therapeutic approaches today vary, depending on availability experience and expertise and include open or laparoscopic CBD exploration, various combinations of LC and endoscopic retrograde cholangiopancreatography (ERCP) and combined laparo-endosopic procedures[5].

Due to this wide variation of treatment options the ideal management of cholelithiasis and concomitant choledocholitthiasis remains controversial. In the open surgery era, prospective studies compared the use of ERCP and endoscopic sphincterotomy (ES) before open cholecystectomy to open cholecystectomy with surgical exploration of the CBD. In these trials, a shorter hospital stay for patients underwent preoperative ES was reported, as well as, lower mortality and morbidity rates in patients over 60 years of age after ES[6,7]. In the era of LC, the combination of preoperative ERCP and LC is considered the treatment of choice for concomitant cholecysto-choledocholithiasis and remains the most frequently applied strategy at most hospital centers[8].

LAPAROSCOPIC CBD EXPLORATION

Since its introduction, ERCP has mainly been used preoperatively for the diagnosis of choledocholithiasis. However, a high incidence of negative ERCPs was recorded, raising the fear of major complications in patients who do not actually need the procedure. In addition to morbidity many patients were dissatisfied because of the need to have two procedures, an endoscopic for the clearance of CBD and a laparoscopic one for the removal of gallbladder. Thus, there was a desire from many surgeons to provide a single stage approach for the treatment of choledocholithiasis[4,9]. The evolution of laparoscopic surgery stimulated the application of laparoscopic approach for the management of CBD stones. Skilled laparoscopic surgeons proposed LCBD exploration as an effective alternative for the treatment of choledocholithiasis.

Prospective randomized trials comparing LCBD exploration with two stage procedures, have shown that laparoscopic management of the CBD stones, as a single stage procedure, is associated with equivalent success rate and patient morbidity but shorter hospital stay and lower cost[10,11].

Two, recently published meta-analyses, included studies comparing one stage vs two stage management of CBD stones. One stage procedures included LC and LCBDE or intraoperative ERCP, while two stage procedures included LC preceded of followed by ERCP. These meta-analyses showed that both clinical practices have similar clinical outcomes[12,13]. Two studies in the meta-analysis published by Alexakis *et al*[12] reported cost analysis. Both found a significantly higher costs for the two stage management.

Laparoscopic CBD exploration is a logical extension of LC. However it has not gained popularity amongst the surgical community. LCBDE, either through the transcystic route or through choledochotomy, is a technically demanding procedure and requires clinical experience in the open technique and advanced laparoscopic skills[2,10]. Thus, it has remained a procedure for experienced and/or enthusiastic laparo-

scopic surgeons. Apparently, scientific data from centers of excellence cannot not always be extrapolated into everyday clinical practice.

LAPAROENDOSCOPIC RENDEZVOUS FOR THE TREATMENT OF CHOLEDOCHOLITHIASIS

Despite the evidence from prospective randomized trials suggesting the superiority of the so-called one-stage management of cholecysto-choledocholithiasis in regards to the hospital stay and cost effectiveness, two-stage techniques, mainly preoperative ERCP followed by LC, are currently being used by most clinicians in their daily practice[10,11].

ERCP is associated with a failure rate to cannulate the ampula of Vater ranging from 4%-18% of cases while post ERCP pancreatitis is a major complication which can follow inadvertent pancreatic cannulation and contrast injection[14-16]. The laparoendoscopic rendezvous (LERV) procedure, which is a single stage combined laparoscopic and endoscopic approach to CBD stone treatment, represents an effective alternative to the sequential treatment which, in addition, minimizes the risk of inadvertent pancreatic duct cannulation and subsequently the risk of pancreatitis. Several studies during the past decades have shown the effectiveness of this technique as a single stage procedure in the treatment of CBD stones by improving patient compliance and leading to shorter hospital stay, higher success rate and lower cost. However, organization and technical problems have not facilitated the diffusion of this method[5,9,17,18].

The combined laparoendoscopic treatment was first described by Deslandres *et al*[19] in 1993. However, the method didn't encountered wide interest immediately. After the years, many authors used this approach in their practice. In 2009, La Greca *et al*[20] published the first review of original papers and case reports including a total number of some 800 patients, describing the results and comparing the LERV treatment with the other two main available treatment options. The overall effectiveness of the LERV technique was 92.3%. The duration of the endoscopic part of the procedure ranged from 8 to 82 min (mean 35 min), while the time of the whole LERV procedure was 40 to 360 min with a mean time of 104 min. The conversion rate to open surgery was 4.7%. The overall mortality and morbidity rates were 0.37% and 5.1% respectively. The mean hospital stay of patients treated with the LERV procedure was 3.9 d (range from 2 to 51 d)[20].

The advantages of the LERV approach were outlined by most authors of the reviewed studies. The most important suggested advantages compared with the LCBD exploration, which represents the single stage management rival, were the reduced operation time and lower technical difficulties. On the other hand, the main clinical advantages in comparison with the more popular two stage treatment (ERCP followed by LC) is the lower incidence of complications (especially pancreatitis), the higher success rate and the reduced hospital stay[20].

LAPAROENDOSCOPIC RENDEZVOUS AND POST-ERCP PANCREATITIS

The incidence of the post-ERCP pancreatitis ranges between 1% to 14%[21,22]. Multiple cannulation attempts have been described as an iatrogenic risk factor for post-ERCP pancreatitis. One of the most important technical factors in the concept of the LERV technique is that it facilitates the endoscopic procedure by the insertion of a guide-wire through the cystic duct and CBD into the duodenum ensuring thus elective CBD cannulation and avoiding the inadvertent cannulation of the pancreatic duct. This technical advantage provided by laparoendoscopic RV is of paramount importance, especially in cases with anatomical variations and difficult papilla cannulation[1,8].

Another important mechanical factor related to the pathogenesis of post-ERCP pancreatitis is the volume and high pressure of contrast medium injected by the endoscopist inadvertently into the pancreatic duct, during canulation of the papilla of Vater. Using the LERV technique the contrast medium is injected by the surgeon through the cystic duct avoiding thus the direct injection into the pancreatic duct[15,16].

In a recent study, LERV has been compared with standard ERCP at the same stage after the completion of LC. In this prospective randomized trial no case of post-ERCP pancreatitis was reported in either arm. However, during standard ERCP the risk of inadvertent pancreatic duct cannulation still exists, since selective cannulation of the bile duct is not ensured by the insertion of the guide-wire, as in the case of LERV[23].

Two CRTs in which LERV compared with the traditional two stage procedure reported lower serum amylase levels in patients treated with the LERV technique[8,24]. A statistically significant higher medium amylase value recorded by Tzovaras *et al*[24] in their study for the group of patients who underwent therapeutic ERCP followed by LC. La Greca *et al*[25] recorded a statistically significant reduction in serum amylase levels, in patients treated with rendezvous technique compared to ERCP/ES treatment. The authors concluded that the effectiveness and safety of the RV technique is mostly depended on the antegrade injection of the contrast medium by the surgeon through the cystic duct[25].

A statistically significant lower incidence of acute post-ERCP pancreatitis was recorded in two controlled randomized trials comparing the laparoendoscopic technique with the traditional two stage treatment[1,26]. All three meta-analyses, published to date confirmed the statistical significance of the lower post-ERCP pancreatitis rates in favor of the LERV technique[27-29]. The assessment of the overall ERCP/ES related complications in two of three meta-analyses, also confirmed

a statistically significant difference favoring the RV approach. However, when these complications were separately assessed in a subgroup analysis, no differences were found in the incidences of bleeding, perforation, cholangitis, cholecystitis and gastric ulcer.

EFFECTIVENESS OF THE LAPAROENDOSCOPIC RENDEZVOUS TECHNIQUE

It has been demonstrated that the LERV technique is an attractive option for the treatment of patients with CBD stones. It offers an advantage in selective cannulation of the CBD especially in cases of difficult papilla cannulation and where ERCP has already failed to provide a reliable therapeutic solution.

Tzovaras *et al*[30] used the LERV technique for the treatment of 22 patients who had at least one failed attempt of ERCP because of the presence of anatomic variations, mainly papillary diverticula or deemed unable to cooperate for a classic ERCP. Selective CBD cannulation achieved in all but two in whom the guidewire could not advance through cystic duct, however, the procedure completed using the classic retrograde way of ERCP intraoperatively[30].

In their controlled randomized study, Morino *et al*[8], proceeded with the rendezvous technique in 9 patients, initially randomized to the two stage approach, in whom ERCP failed to be performed. The treatment completed successfully in 8 patients using the laparo-endoscopic approach, indicating the use of the LERV technique as a safe and relatively easy way to cannulate selectively the CBD in patients in whom ERCP has failed[8].

La Greca *et al*[20] reported a higher overall effectiveness of the LERV technique regarding the CBD clearance compared to either preoperative ERCP or laparoscopic CBD exploration[20]. In controlled randomized trials comparing the LERV technique with the two stage treatment, the success rates of CBD stones clearance were similar for both treatment approaches[1,8,24,26]. However, as reported by Wang *et al*[29] in their meta-analysis, the success rate of CBD cannulation was significant higher for the rendezvous technique than the sequential treatment (RR = 2.54, 95 %CI: 1.23-5.26; $P = 0.01$)[29].

LAPAROENDOSCOPIC RENDEZVOUS TECHNIQUE AND TOTAL HOSPITAL STAY

Obviously, the laparoendosopic rendezvous as a single stage procedure is related with shorter hospital stay, comparing with the traditional two stage treatment. Four RCTs recorded statistically significant reduced hospital stay for patients treated with the LERV technique, comparing with the two stage approach[1,8,24,26]. Two meta-analyses confirmed the total hospital stay was significantly shorter with the RV technique compared with the sequential treatment[27,29]. This is mainly because a minimum of 24-48 h waiting period is required to ensure that no post-ERCP complication has occurred, before proceeding to LC in the two stage approach. It is difficult if not impossible this time interval to be reduced and this is a clear disadvantage of the two stage approach.

DISCUSSION

The LERV technique is a combined surgical and endoscopic procedure and it has been proposed as an alternative, single stage approach, for the treatment of patients with cholecysto-choledocholithiasis. This technique, did not reach wide acceptance immediately, because it requires the availability of surgical and endoscopic teams in the operating room. La Greca *et al*[20] presented the main disadvantage of the LERV technique to be logistics and organizational problems for an operation requiring the presence of two teams. Lella *et al*[1] considered this technique even more difficult to perform in the emergency setting. However, Tzovaras *et al*[24] concluded that the LERV could be effective and safe even in the urgent setting, including emergency cases in their study[24]. Obviously, in the era of minimal invasive surgery, any possible logistic problems should be resolved making the LERV technique available in the treatment of cholecysto-choledocholithiasis and its complications improving clinical results and patient's discomfort.

In comparing the laparoendoscopic approach with the sequential treatment, it should be mentioned that this technique ensures elective CBD cannulation, avoiding thus the inadvertent cannulation of the pancreatic duct. In addition, in the LERV technique the contrast medium is not injected retrogradely as during the traditional ERCP, when the medium accidentally could be injected under pressure into the pancreatic duct. The LERV technique minimizes that risk. Both these main advantages of the LERV technique over the classic ERCP, are related with a significant lower incidence of hyperamylasemia and post-ERCP pancreatitis, compared with the traditional two stage procedure[27-29].

The CBD clearance rate is an important outcome for the treatment of patients with CBD stones, leading in reduction of conversion rates to open surgery, which is associated with higher morbidity. The LERV technique is associated with at least equally high rates regarding overall CBD clearance compared to the traditional two stage approach, although it is associated with significantly higher success rate of CBD cannulation and lower number of procedures required for complete clearance. This technical advantage could be applied in clinical practice, especially in difficult papilla cannulation making it much easier for the endoscopist.

LERV is related with an additional operating time of approximately 30-45 min to be performed compared with the single laparoscopic cholecystectomy stage of

the sequential treatment. However, it saves more or less similar time in the endoscopic suite, where ERCP is performed as a separate procedure in a sedated but usually not anesthetized patient. Moreover, the extra time which represents the additional time needed for the performance of cholangiography and insertion/advancement of the guide wire into the duodenum would be balanced in case that intraoperative cholangiography is routinely used during LC[24].

Despite the aforementioned advantages of LERV there is some concern about the distention due to insufflation of the stomach and small intestine during the endoscopic part of the procedure. The use of a special bowel desufflator to decrease bowel distention or a laparoscopic small bowel clump placement across the first loop of jejunum, have been proposed to overcome this problem. It has been also suggested to perform as much as possible dissection of the gallbladder during the laparoscopic part before the beginning of the endoscopic part of the procedure[8,24].

Laparoendoscopic rendezvous is an attractive alternative for the treatment of patients with cholecysto-choledocholithiasis. The current evidence in favor of the LERV is promising and demonstrates the main advantages in regard to shorter hospital stay and selective cannulation of the CBD. The concept of the RV technique contributes in avoiding the main mechanisms of iatrogenic pancreatic damage, leading in lower incidence of post-ERCP pancreatitis. LERV requires basic laparoscopic equipment and skills; The only additional laparoscopic skill is the ability to perform an intraoperative cholangiogram, however, at an extra cost of increased operating time[24]. Despite the general improvement of skills in the last years, LERV is still considered as the least invasive approach for the treatment of cholecysto-choledocholithiasis[31]. However, the availability of the LERV nowadays is limited in most hospital centers, where the choice of the best approach for the treatment of patients with CBD stones is based on the institutional availability and expertise of their surgical and endoscopy teams. It seems that the lack of cooperation between the two teams, still does not facilitate the diffusion of the LERV procedure.

Abstract

Although uncommon, sporadic nonampullary duodenal adenomas have a growing detection due to the widespread of endoscopy. Endoscopic therapy is being increasingly used for these lesions, since surgery, considered the standard treatment, carries significant morbidity and mortality. However, the knowledge about its risks and benefits is limited, which contributes to the current absence of standardized recommendations. This review aims to discuss the efficacy and safety of endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) in the treatment of these lesions. A literature review was performed, using the Pubmed database with the query: "(duodenum or duodenal) (endoscopy or endoscopic) adenoma resection", in the human species and in English. Of the 189 retrieved articles, and after reading their abstracts, 19 were selected due to their scientific interest. The analysis of their references, led to the inclusion of 23 more articles for their relevance in this subject. The increased use of EMR in the duodenum has shown good results with complete resection rates exceeding 80% and low complication risk (delayed bleeding in less than 12% of the procedures). Although rarely used in the duodenum, ESD achieves close to 100% complete resection rates, but is associated with perforation and bleeding risk in up to one third of the cases. Even though literature is insufficient to draw definitive conclusions, studies suggest that EMR and ESD are valid options for the treatment of nonampullary adenomas. Thus, strategies to improve these techniques, and consequently increase the effectiveness and safety of the resection of these lesions, should be developed.

Key words: Polyps; Duodenum; Adenoma; Resection; Endoscopy

Core tip: Widespread use of endoscopy leads to increase detection of sporadic nonampullary duodenal adenomas. Due to significant morbidity and mortality of surgical treatment in this setting, endoscopic treatment with endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD), has been progressively used for the resection of these lesions. This extensive and detailed review discusses the efficacy and safety of EMR and ESD in this context. We conclude that EMR and ESD are valid options for the treatment of sporadic nonampullary duodenal adenomas. Strategies to improve these techniques, and consequently increase their effectiveness and safety should be developed.

INTRODUCTION

We searched Medline (PubMed) for all published manuscript up to 2014. The search terms used were "(duodenum OR duodenal) (endoscopy OR endoscopic) adenoma resection". The search was restricted to English language and was extended by carefully reviewing the bibliographies of the pertinent manuscripts on this subject. Of the 189 retrieved articles, and after reading their abstracts, 19 were selected due to their scientific interest. The analysis of their references, led to the inclusion of 23 more articles for their relevance in this subject.

Duodenal adenomatous polyps are a rare disease in the general population, reported as incidental findings in up to 0.1%-0.34% of the patients undergoing upper gastrointestinal endoscopy[1,2]. The evolution and widespread of this exam contributed to the increase in smaller sized polyps early diagnosis[3-5]. Adenomas are the histologic subtype that constitutes the majority of the duodenal lesions that need resection[2,6]. For this reason, they must be distinguished from non-adenomatous polyps, namely the ones that originate in the mucosa (gastric metaplasia) or submucosa (carcinoid tumors, leiomyomas, lipomas, inflammatory fibroid polyps and gastrointestinal stromal tumors), hamartomatous polyps (Brunner glands hyperplasia and Peutz-Jegher polyps, among others), and metastatic polyps[1,5,6]. One of the goals of the treatment, common to all duodenal adenomas, is the elimination of the tumoral progression risk, which correlates with the size of the lesion and is similar to that of colorectal adenomas[6,7].

These lesions are classified, according to its location, in ampullary (if they involve the duodenal bulb major - ampulla of Vater - or minor) or not ampullary. In both circumstances, they may occur as part of a genetic syndrome associated with the development of polyps, as the Familial Adenomatous Polyposis, or sporadically[8,9].

Sporadic nonampullary adenomatous polyps have similar incidence in both sexes and are mostly diagnosed accidentally between the sixth and eighth decades of life[5,6]. Typically, these lesions are solitary, with sessile or flat morphology, more than 10 mm, located in the second portion of the duodenum and asymptomatic[9-14]. However, depending on their size, location and histological characteristics, they can cause dyspepsia, abdominal pain, bleeding and bowel obstruction[5].

The traditional therapeutic approach for duodenal polyps is local surgical excision or radical surgery, respectively characterized by high rates of recurrence and significant morbidity and mortality[15,16]. In 1973, Haubrich described the first endoscopic excision of a duodenal adenoma, which, since then, has been pointed out by several publications as a safe and effective alternative to surgery[3,4,10,11,17-19]. In a retrospective analysis of 62 patients with duodenal nonampullary polyps, the morbidity of the surgical therapy was significantly superior to the one of the endoscopic resection (33% *vs* 2%)[20].

The use of endoscopic techniques in the duodenum is still controversial, since it represents a diagnostic and technical challenge[3,6]. The duodenum has several peculiarities that make the endoscopic resection complications risk higher than the one described elsewhere in the gastrointestinal tract[21]. Indeed, its narrow lumen and retroperitoneal fixation hampers the maintenance of an adequate vision field during the procedure[22]. On the other hand, this organ has the thinnest wall of the digestive tract and shows a thick fibrous submucosa, even in a non-pathological situation, which can limit the protrusion of the mucosa achieved by the submucosal saline injection[22].

The scientific evidence of the risks and benefits of the endoscopic treatment and its long-term outcomes in the resection of nonampullary polyps, both sporadic and associated with genetic syndromes, is limited[23,24]. This reality contributes, along with the fact that this type of lesions is infrequent and has a natural history and clinical importance that is not fully understood, to the absence of a specific set of criteria for clinical guidance[5,24,25]. Consequently, the therapeutic strategies are usually considered taking into account the patient's condition, the characteristics of the lesion and the experience of who performs the endoscopic technique[5,7,24].

In 2010, a review published by the National Institute of Clinical Excellence highlighted the lack of published material that addressed this topic[23]. Although the number of clinical trials has increased since then, the best treatment of nonampullary adenomas remains

subject of discussion[9]. The purpose of this work is to review the scientific literature regarding endoscopic resection of sporadic duodenal nonampullary adenomatous polyps, highlighting the benefits and drawbacks of EMR and ESD based on the analysis of different outcomes obtained with their practice.

INITIAL ASSESSMENT

Before endoscopic resection, it is essential to characterize the size of the polyp, duodenal folds and lumen extension involvement[6]. It should be ensured that it doesn't involve the ampulla of Vater (which would imply a different diagnostic and therapeutic approach) with a side-viewing endoscope or with endoscopic ultrasound[5,6,25].

The endoscopic appearance of duodenal adenomas cannot always distinguish them safely from non-adenomatous polyps and thus, all lesions considered suspicious should be biopsied[25]. It is also important to determine the resectability of the lesion and detect any signs that suggest submucosal invasion, and that influence the treatment, such as tumors with depression (IIc in the Paris Classification), type Ⅴ pit pattern classification described by Kudo, presence of bleeding, induration, ulceration or irregularities on the surface of the polyp and non-lifting sign after submucosal saline injection[5,6,26,27].

The exact role of endoscopic ultrasound in the evaluation of nonampullary adenomas remains uncertain[24]. When it's impossible to establish the relationship of the polyp with the pancreaticobiliary tree with a forward and side-viewing endoscopy, endoscopic ultrasound is an alternative technique, obviating the need of an endoscopic retrograde cholangiopancreatography[5]. Some researchers advocate its use in the evaluation of the depth of duodenal polyps larger than 20 mm[7,24]. However, according to Al-Kawas, the routinely use of endoscopic ultrasound, apart from not bringing great benefit, would have a considerable cost[7].

Newer techniques such as magnification endoscopy, endoscopy with narrowbanding imaging or chromoendoscopy (with a non absorbable dye such as indigo carmine) allow better delineation of the margins of the lesion and can be used in the initial evaluation of duodenal adenomas, potentially reducing incomplete resection rates[6,21]. Although there is little information regarding the use of magnification chromoendoscopy in the duodenum, this technique showed a reduction of local neoplastic recurrence from 8.7% to 0.5% when associated with EMR of flat colonic lesions bigger than 2 cm[28]. Shinoda *et al*[29] found that magnification endoscopy with narrowbanding imaging or indigo carmine is more accurate than endoscopic ultrasound in the evaluation of the gastric and oesophageal mucosal cancer depth. Future research will be essential for the determination of these techniques' role in the duodenum[13].

EMR

This technique was developed to remove sessile or flat tumors that are confined to the superficial layers (mucosa and submucosa) of the GI tract wall. Classically, it's used for *en bloc* or piecemeal resection, if the diameter is less or more than 2 cm, respectively[30]. The lesion is initially elevated by the injection of a saline substance into the submucosa that causes its protrusion into the duodenal lumen. Depending on the size of the polyp, the volume of injected solution can vary between 5 and 50 mL, and it may be necessary to repeat this procedure if the cushion created by the injected fluid dissipates before the resection is complete[30]. There are several solutions currently available, but isotonic saline (0.9% NaCl) is the most frequently used[30]. However, scientific evidence suggests that hypertonic solutions originate a better and longer-lasting elevation[6,31]. This procedure allows the isolation of the mucosa involved, facilitating its resection with an endoscopic snare, and reduces the risk of thermal and mechanical injury of the deepest layers. The non-lifting sign enables the identification of polyps that are likely to have submucosal invasion, and that don't usually have an indication for endoscopic treatment[6,19,31]. The inclusion of adrenaline in the injected solution reduces the haemorrhagic risk and provides better visibility[6]. As a diagnostic tool, and differently from ablative therapy, it holds an important role in obtaining samples for histological analysis[31]. When compared to snare or forceps polypectomy, EMR allows resection of a larger area, as well as access to deeper levels, through the excision of the medium or deep submucosal layer[31]. It thus facilitates histological assessment of the entire lesion and thereby identifies foci of malignancy that cannot be included in the surface sample obtained by forceps or snare biopsy[18] (Figure 1).

Efficacy

The predominantly retrospective published clinical trials report an EMR complete resection rate of nonampullary adenomas of 79%-100%[4,10-14,18,19,32,33]. In the studies that indicate the type of resection, it appears that in 64% of the cases it was possible to remove the polyp *en bloc*, having the remaining been excised with piecemeal resection[4,10,12,13,18,32-35]. The latter is more frequent in lesions larger than 20 mm, hardly removed safely *en bloc*, and seems to be associated with higher rates of recurrence and residual lesion[13,18,19,33]. The execution of the technique is a critical factor in minimizing these potential risks[19].

Kedia *et al*[12] studied the relationship between the adenomatous polyp size, the extent of duodenal lumen involved, and the efficacy of EMR. He concluded that although there is a significant association between the proportion of duodenal lumen involved and complete endoscopic resection, the same doesn't happen between the latter and the size of the lesion. The complete resection rate achieved in tumors involving less than

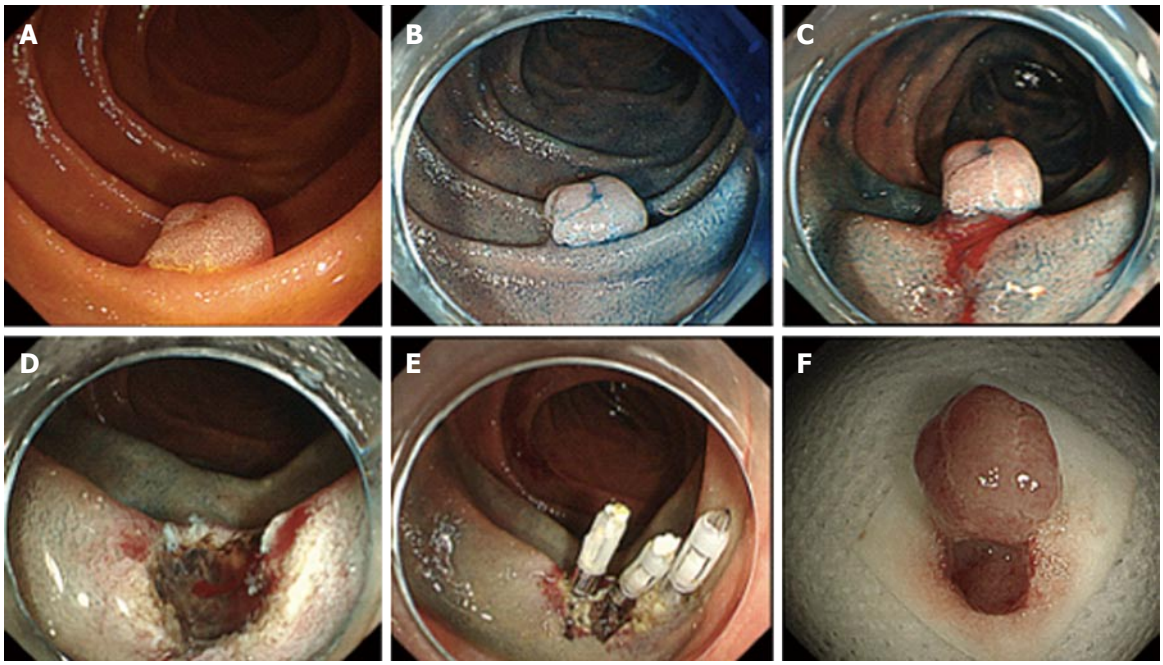

Figure 1 Endoscopic resection of a sporadic neoplastic lesion in the duodenum using endoscopic mucosal resection technique. A: Sessile lesion in the descending duodenum seen with white light (type 0 - Isp of the Paris classifi-cation); B: Same lesion after chromoendoscopy with indigo carmine; C: Same lesion after subepithelial injection of diluted adrenalin; D: Resected area after endoscopic mucosal resection; E: Closure of the resected area with clips; F: Lesion resected *en bloc*. Histology revealed a well-differentiated tubular adenocarcinoma limited to the mucosa, with 7 mm × 8 mm, without lymphatic or vascular invasion.

one quarter of the luminal circumference was 94.7%, compared to 45.5% in those involving one quarter to half of the circumference. In lesions where more than half of the luminal circumference was involved no lesion was resected successfully. Thus, this author suggests that the strongest clinical predictor of a successful polyp excision is the luminal extension that it involves. The American Society for Gastrointestinal Endoscopy (ASGE) guidelines indicate that surgery should be considered in adenomas involving more than 33% of the circumference of the lumen[24].

In the studies that report the number of sessions required to achieve complete resection, 80% of the cases it was possible with one session, 17% with two sessions and only 3% in three sessions[6]. In all situations, the purpose of who performs the EMR should be to remove the entire polyp in one session, without compromise of security[21]. Areas with residual adenoma and fibrosis are more difficult to resect during subsequent interventions, which are associated with increased risk of complications[6,9,21].

The recurrence rate varies widely between 0% and 36%, and all described recurrent lesions were treated with polypectomy snare or ablative therapy[6,9,13,18,19,36]. This high rate reinforces the need of a detailed resection of all adenomatous tissue, possibly with use of adjuvant therapy, and a rigorous follow-up period, especially in larger adenomas or with piecemeal resection[6,12,19].

Safety

Bleeding, which is associated with duodenal abundant vascularization, occurs during EMR (immediate bleeding) in 9% of procedures[6]. As there is no standardized definition of immediate haemorrhage, it's hard to know whether the reported cases were clinically significant or had comparable gravity. However, Lepilliez *et al*[18] does not consider it a true complication, since it can often be controlled by application of endoscopic clips, using ablative therapy or adrenaline injection adrenaline. None of the described cases needed blood transfusion[3,4,6,10,11,18,19].

Late bleeding rate ranges from 0 to 12%[1,4,10,12,13,18,19,33]. A recent study, that included 50 nonampullary adenomas, showed that the risk of delayed haemorrhage is significantly higher in lesions which diameter was bigger than 30 mm[35]. In all cases, bleeding occurred within the first 48 h after resection and was mostly approached conservatively or with endoscopic mono or bipolar electrocautery, epinephrine injection, haemostatic clips or a combination of these[1,4,10,12,13,18,19,33].

The proceeding method regarding the presence of visible non-bleeding vessels and the closure of the resected area as a preventive measure of late haemorrhage, are questions that don't gather a consensus answer[35]. Kim *et al*[13] defends that primary closure with clips is preferable to ablative therapy, since it does not increase the risk of tissue injury. Although closure of primary defects smaller than 2 cm is usually possible, it will probably be unnecessary, except in cases where there is potential risk of late bleeding[35]. On the other hand, areas bigger than 2 cm cannot be safely closed because of the difficulty in opposing margins of the defect[13,18,35]. In the study of Lépilliez *et al*[18], the difference found between late haemorrhage rate of the

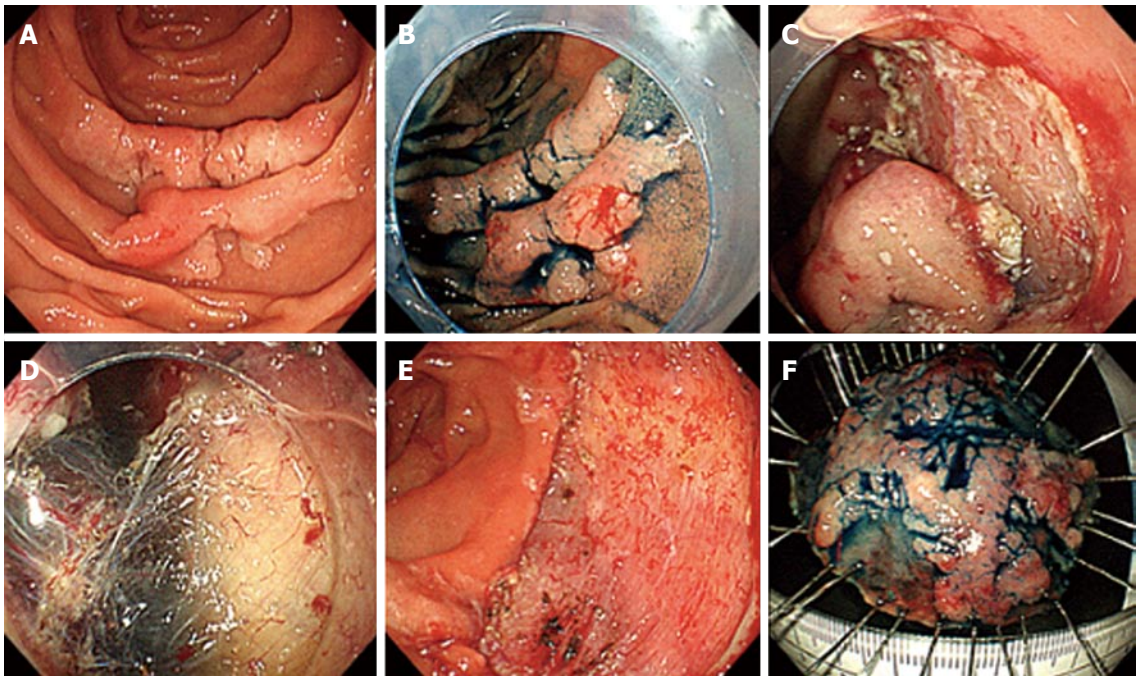

Figure 2 Endoscopic resection of a sporadic neoplastic lesion in the duode-num using endoscopic submucosal dissection technique. A: Flat lesion in the descending duodenum seen with white light (type 0-IIa of the Paris classi-fication); B: Same lesion after chromoendoscopy with indigo carmine; C: Partial dissection with endoscopic submucosal dissection; D: Dissection plan where the submucosal layer and the partially dissected lesion can be seen; E: Dissected area; F: *En bloc* dissected lesion. Histology revealed a well-differentiated adenocarcinoma limited to the mucosa, 40 mm × 32 mm, without lymphatic or vascular invasion.

cases that had haemorrhagic prevention systematically done (with ablative therapy or clips) or bleeding treatment was required during the procedure, and cases that didn't have bleeding prevention or immediate haemorrhage occurred, was statistically significant. In the first group, consisting of 14 patients, there was no late haemorrhage, while in the second 5 bleedings occurred in 23 patients (22%).

EMR has a perforation risk of the duodenal wall of 0.6%[6,35]. Registered perforations were managed with endoscopy or surgery conversion[18,35]. Resection limited to the adenomas that lifted after the submucosal injection may be a way of preventing this complication[36].

ESD

This technique is widely used for *en bloc* resection of gastrointestinal lesions[5]. Despite its growing use in the stomach, colon and oesophagus, its use in the duodenum is less frequent[37]. This fact is probably due to its retroperitoneal fixation, thin wall and narrow lumen, which make the intervention at this location technically difficult[14,29]. The low prevalence of duodenal lesions may be one of reasons that can explain the ESD long learning curve in the duodenum[14]. The published studies that performed this technique are few and include a small number of patients with short follow-up periods[14,29,33,38,39].

ESD is generally performed in several stages. After marking the margins of the lesion, by electrocauterization, and lifting it by submucosal injection, a circumferential incision is made in this layer, and the lesion is dissected from the underlying layers by using dissection knives[30] (Figure 2).

Efficacy

Complete resection rate of sporadic adenomatous nonampullary polyps by ESD ranges from 86% to 100%[14,22,29,33,38,39]. No recurrence was described[14,22,33,38,39]. The choice of ESD instead of piecemeal EMR may be a way of reducing the recurrence associated with this last technique[13].

In a study by Honda *et al*[14], in which 15 non ampullary adenomas were resected by endoscopy (9 by ESD and the rest by EMR), found that the average diameter of the lesions removed by ESD was 24 mm (the largest lesion had 39 mm), and that those removed by EMR had an average size of 8 mm. The mean time of the interventions was also registered. ESD and EMR procedures took respectively 85 and 16 min in average. The inclusion of larger and more challenging lesions, as well as duodenal more difficult haemostasis in duodenum, are possible explanations given by the author for the time consumed by ESD.

Obtaining en bloc resection with negative margins is a well-known ESD advantage[40]. According to Endo *et al*[33], ESD should be the procedure of choice for lesions larger than 10 mm, and when it is desirable to obtain en bloc resection (including lesions whose biopsy or magnification endoscopy are suggestive of carcinoma). In their study, all adenomas larger than 10 mm resected by EMR revealed positive margins. All adenomas resected by ESD had negative margins (the

biggest lesion diameter was 30 mm).

Safety

In three clinical trials, ESD was associated with a bleeding rate between 8% and 22%[14,22,41]. All cases were managed with endoscopic haemostatic clips, without requiring blood transfusion. The reported duodenal perforation rate is 31%[14,22,33,38,39]. This percentage is higher than the one obtained in the oesophagus, stomach and colon, and is associated to the anatomical peculiarities of the duodenum[22]. Duodenal perforation may have a difficult approach and contribute to increased morbidity and mortality of the patient, hospitalization period and health care costs[40].

Late perforation is a very serious complication that, according to a retrospective study published in 2013, is significantly associated with the endoscopic technique that was used and the location of the lesion[41]. In this study, that included lesions resected by EMR or ESD, all late perforations occurred after ESD or piecemeal EMR, which according to the authors, may be due to electrocautery overloading. It was also found that all perforations were distal to the ampulla of Vater, which seems to happen because of the proteolysis or chemical irritation caused by exposure of the duodenal wall to the pancreatic juice and bile enzymes, which can be decreased with the administration of protease inhibitors[14,39]. Given that there are several factors that may be associated with perforations, it is difficult to clarify which ones are more likely to relate to their origin[22]. Jung suggests that ESD is itself a perforation risk factor and, therefore, it should be performed only in selected patients[39]. The most appropriate prophylactic intervention and approach to late perforation in the duodenum have not been established yet[41].

FOLLOW-UP

The guidelines published by the ASGE emphasize that all patients who have undergone endoscopic resection of a sporadic duodenal adenoma should be considered for a follow-up program for the detection and treatment of any recurrence[24]. However, because of the lack of information, formal recommendations regarding surveillance intervals have not been defined. These should be applied on a patient-basis adjusted on the characteristics of the polyp, adequacy of the initial resection, eventual occurrence of complications and comorbidities of the patient[22]. According to a review article, most authors recommended a follow-up endoscopy 3-6 mo after resection, followed by surveillance endoscopies each 6 to 12 mo[6].

CONCLUSION

Analysis of the literature on this topic reveals a reduced number of reviews and studies, that generally include a small sample of patients and short follow-up periods, which hinders drawing consistent conclusions about the endoscopic resection long-term effectiveness of sporadic nonampullary adenomas[13,19,26,34]. Some of the results obtained in clinical trials exhibit considerable variability, which doesn't have a clear justification, but may be associated, for example, to inconsistencies in outcome definitions by different authors, as well as the length of the follow-up period[7]. Moreover, most studies have a retrospective character, which can introduce selection bias and underestimate the complication rate[34].

Although most of the analysed studies and endoscopic techniques mentioned in this review were predominantly developed in Asian countries, it is important to note that this reality may not reflect the Western context[6]. After comparing these two populations, Min *et al*[34] states that Western studies show a lower complete resection rate, and suggests that this discrepancy can be clarified by the smaller sized lesions included in Asian studies, since the diagnosis of smaller adenomas has increased in these countries due to gastric cancer screening programs and subsequent widespread of the endoscopy[12,18,19,34]. Local recurrence rates are higher in Western countries, which again may be explained not only by the difference in the lesions size, but also by the follow-up period after resection, that seems to be shorter in Asia (6-29 mo *vs* 13-71 mo)[34]. Authors, however, rarely address this divergence.

EMR is an alternative to surgery in patients with less invasive superficial duodenal adenomas, entailing shorter hospital in-stay, lower costs, and providing a reasonable complication rate that can usually be controlled by endoscopy[13]. Resection is most likely to be complete in adenomas involving less than half of the luminal circumference[12]. It requires a tight monitoring period, especially after big adenomas or piecemeal resection, so that early detection and treatment of residual or recurrent lesions is possible[6,13]. ESD, although potentially providing en bloc resection with negative margins, has higher haemorrhagic and perforation risks in the duodenum when compared to EMR[9]. Therefore, when choosing the appropriate endoscopic technique, the risks of the procedure must be balanced against its benefits[40].

Although the scientific evidence level in this area is limited, the results obtained in these last years are encouraging. However, prospective studies with larger samples and extended follow-up periods will be necessary. Future development of techniques and tools that contribute to the prevention and early detection of recurrence, and increase the efficacy and safety of endoscopic resection in the duodenum, will be essential for a better therapeutic approach to these patients.

Abstract

AIM: To assess the feasibility and safety of liquid nitrogen spray cryoablation at the duodenal papilla in a porcine model.

METHODS: This prospective study protocol was approved by the University of Florida Institutional Animal Care and Use Committee. Six pigs underwent liquid nitrogen spray cryotherapy at the duodenal papilla. Freeze time of 20-s was applied per cycle (4 cycles/session). Survival animals (n = 4) were monitored for adverse events. Hemoglobin, white blood count, liver tests, and lipase were obtained at baseline and post-treatment. EGD was performed on day#7 to evaluate the papilla and for histology. All animals were euthanized and necropsy was performed at the end of the one-week survival period. Feasibility was defined as successful placement of the decompression tube in the duodenum, followed by delivery of spray cryotherapy to the duodenal papilla. Safety was determined by monitoring post-treatment blood tests and clinical course. Treatment effect was defined as endoscopic and histologic changes after cryotherapy. This was established by comparing endoscopic and histologic findings from mucosal biopsies prior to cryotherapy and on post-operative day (POD)#7. Full-thickness specimen was obtained post-mortem to assess depth of injury.

RESULTS: Spray cryotherapy was feasible and successfully performed in all 6/6 (100%) animals. Cryospray with liquid nitrogen (four 20-s freeze-thaw cycles) at the duodenal papilla resulted in white frost formation at and around the target region. The mean procedural

time was 54.5 min (range 50-58 min). All six animals studied had stable blood pressure, heart rate, and pulse oximetry measurements during the procedure. There were no significant intra-procedural adverse events. There were no significant differences in hemoglobin, white cell count, liver tests or lipase from baseline to post-cryotherapy. Survival animals were monitored daily post-operatively without any clinical ill effects from the cryotherapy. There was no bleeding, infection, or perforation on necropsy. Endoscopic on POD#7 showed edema and ulceration at the duodenal papilla. On histology, there was loss of crypt architecture with moderate to severe necrosis and acute mixed inflammatory infiltration in each specimen following cryotherapy. The extent of cryogen-induced tissue necrosis (depth of injury) was limited to the mucosa on full-thickness specimen evaluation.

CONCLUSION: Endoscopic liquid nitrogen spray cryotherapy is feasible and safe for ablation at the duodenal papilla in a porcine model.

Key words: Liquid-nitrogen cryotherapy; Cryoablation; Duodenal adenoma; Ampullectomy; Papillectomy

Core tip: With advances in therapeutic endoscopy, endoscopic resection is commonly performed for the management of ampullary adenomas. However, endoscopic papillectomy can still carry significant morbidity, especially in elderly patients with comorbidities. Hence, less invasive effective endoscopic ablative modalities would be desirable. In this study, we demonstrate that endoscopic liquid nitrogen spray cryotherapy is feasible and safe for ablation at the duodenal papilla in a porcine model. These preliminary findings suggest a potential role of cryotherapy as an adjunct endoscopic treatment for residual/recurrent ampullary lesions or as a primary modality in patients who are not optimal candidates for surgery or endoscopic resection.

Yang D, Reinhard MK, Wagh MS. Feasibility and safety of endoscopic cryoablation at the duodenal papilla: Porcine model. *World J Gastrointest Endosc* 2015; 7(7): 728-735 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/728.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.728

INTRODUCTION

Ampullary adenomas are dysplastic glandular lesions that arise from the major duodenal papilla. These lesions can occur sporadically or arise in the context of genetic syndromes such as familial adenomatous polyposis. If not removed, ampullary adenomas can potentially undergo malignant transformation to ampullary cancer with a reported incidence from 25% to 85%[1-3]. Based on this risk, these lesions have been treated historically with pancreatoduodenectomy, a highly invasive surgical intervention associated with high morbidity and mortality[4,5]. With advances in therapeutic endoscopy, there has been a shift towards endoscopic resection, with consideration of surgery only for locally advanced lesions. While endoscopic approaches for the treatment of ampullary adenomas are less invasive than surgery, adverse events associated with endoscopic papillectomy still carry a reported morbidity and mortality rate of 23% and 0.4% respectively[6]. Hence a less invasive modality for endoscopic ablation of ampullary lesions would be helpful, especially in elderly asymptomatic patients with comorbidities.

There has been a growing interest in endoscopic mucosal ablative techniques for the management of different gastrointestinal pathologies, ranging from adenomatous lesions, dysplasia and/or intramucosal carcinoma, to bleeding mucosal lesions in the GI tract[7]. Currently, the role of endoscopic ablative techniques (argon plasma coagulation, laser therapy, monopolar o bipolar coagulation) for ampullary adenomas is limited to destruction of residual or recurrent adenomatous tissue following resection[8].

Cryotherapy is a mucosal ablative technique that employs non-contact delivery of either low-pressure liquid nitrogen or compressed carbon dioxide (CO_2) gas for tissue destruction.

There are currently two commercially available endoscopic cryotherapy systems for the gastrointestinal tract. One device delivers low-pressure liquid nitrogen (at -196 ℃) (CryosprayAblation, CSA Medical Inc, Baltimore, MD) whereas the other system is based on the Joule-Thompson effect, in which highly compressed CO_2 gas produces cooling upon rapid expansion and decrease in pressure (Polar Wand; GI Supply, Camp Hill, PA)[9]. Most of the current clinical experience with endoscopic cryotherapy as a mucosal ablative technique is primarily related to the data on ablation of Barrett's esophagus, where this method has been shown to be efficacious and well tolerated[10]. The use of cryotherapy in other extra-esophageal sites, besides treatment of bleeding in the stomach and colon[11], has been limited to some degree by the concern of gas expansion and high risk of barotrauma and perforation in other regions of the GI tract. We recently reported preliminary data suggesting that liquid nitrogen cryotherapy is a safe technique even in patients with altered post-surgical gastric anatomy when appropriate measures are taken for cryogen gas decompression[12]. The aim of our study was to investigate the feasibility and safety of endoscopic liquid nitrogen spray cryotherapy at the duodenal papilla in a porcine model.

MATERIALS AND METHODS

Study

This prospective study protocol was approved by the

University of Florida Institutional Animal Care and Use Committee. Six female pigs (sus) weighing 80-100 lbs were obtained from the University of Florida Swine Unit. The aim of this study was to prospectively assess the feasibility and safety of endoscopic liquid nitrogen spray cryotherapy at the duodenal papilla in a porcine model.

Animal care and use

The animal protocol in this study was designed to minimize pain or discomfort to the animals. Pigs were housed and maintained in the University of Florida Animal Care Services unit. The animals were acclimatized to laboratory conditions (23 ℃, 12h/12h light/dark, 50% humidity, *ad libitum* access to food and water) for 7-10 d prior to experimentation. All animals were euthanized by barbiturate overdose (intravenous injection, 150 mg/kg pentobarbital sodium) for necropsy.

Outcomes and definitions

Primary outcomes: (1) feasibility was assessed by the technical success of cryotherapy in this porcine model. Technical success was defined as successful placement of the cryotherapy decompression tube past the papilla in the second portion of the duodenum, followed by delivery of liquid nitrogen spray to the duodenal papilla; and (2) safety was determined by monitoring peri-procedural blood tests and clinical course. Endoscopic adverse events were defined based on previously established criteria[13] and post-operative signs of distress, behavior changes, and/or loss of appetite. Elevation of liver tests and lipase post-cryotherapy to more than 3 times the upper limit of normal was considered abnormal.

Secondary outcome: Treatment effect was defined as endoscopic and histologic changes after cryotherapy. This was established by comparing endoscopic and histological findings from mucosal biopsies prior to cryotherapy and on post-operative day (POD)#7. The degree of intestinal injury was graded as previously described by Park *et al*[14]. Full-thickness specimen was obtained post-mortem to assess depth of injury.

Endoscopes and accessories

A single-channel gastroduodenoscope (GIF-140 Olympus Medical Systems, Tokyo, Japan) was used for the study. A pediatric colonoscope (PCF-140, Olympus Medical Systems, Tokyo, Japan) was used as needed, to overcome the J-shaped porcine gastric anatomy in order to have adequate length of the scope available to access the distal duodenum. Endoscopic biopsy forceps (Boston-Scientific, Natick, MA) were used for endoscopic tissue acquisition.

Cryotherapy

Liquid nitrogen spray cryotherapy (CryoSpray Ablation system, CSA Medical Inc, Baltimore, MD) was used for the study. This cryotherapy system, consists of (1) a console with a liquid nitrogen holding tank and a foot pedal for the release of low-pressure (3 to 6 psi) liquid nitrogen (temperature -196 ℃); (2) a 7-French cryocatheter, which is inserted through the working channel of an endoscope; and (3) a modified orogastric cryode compression tube (CDT) placed alongside the endoscope prior to starting cryotherapy. This special decompression tube has two channels, one for passive venting and another for active suction, attached to a separate suction machine to evacuate the rapidly expanding evaporated cryogenic gas during the procedure.

Freeze time was defined as the time interval from the visualization of white frost (ice formation) along the entire surface of the papilla until the cryospray was stopped. Procedure time was defined as the time from endoscope insertion to withdrawal.

Pre-operative care and anesthesia

Animals were not fed for 24 h prior to the procedure. Animals were pre-anesthesized with intramuscular (IM) injection of 4 mg/kg Telazol, ketamine 2 mg/kg, xylazine 2 mg/kg, and atropine (0.04 mg/kg) or glycopyrrolate (0.001 mg/kg). Induction was performed with isoflurane 3%-5% *via* mask delivered with a precision vaporizer prior to intubation. General endotracheal anesthesia was administered with Isoflurane 1%-3.5%. An intravenous (IV) line was placed in the marginal ear vein. Pigs were intubated and placed on mechanical ventilation.

Blood tests

In survival studies, blood specimens to evaluate hemoglobin (Hb), white blood count (WBC), liver tests (AST, ALT, alkaline phosphatase and bilirubin), and lipase were obtained prior to endoscopic treatment (day 0) and post cryotherapy (day 1 and on day 7).

Endoscopic procedure

The intended treatment site (duodenal papilla) was identified by endoscopic visualization. The pediatric colonoscope (Olympus Medical Systems, Tokyo, Japan) was introduced past the second portion of the duodenum and a 0.035 inch, 350 cm length guide-wire (Jagwire, Boston Scientific, Natick, MA) was placed. The endoscope was exchanged over the guidewire and the CDT was placed distal to the papilla. Adequate positioning of the CDT (tip of tube past the papilla in the second portion of the duodenum) was confirmed by re-inserting the endoscope, and the guide-wire was removed. The CDT was connected to active high suction controlled by a foot pedal during cryotherapy.

For survival animals, two peri-ampullary endoscopic biopsies were obtained as baseline prior to initial cryotherapy. The cryocatheter was introduced through the accessory channel of the endoscope and oriented to directly target the duodenal papilla. The freeze time was established as the period from ice formation along the entire surface of the papilla until the cryospray was stopped. The liquid nitrogen dosimetry of 4 cycles of 20-s freeze time was based on published dosing from previous animal studies[15,16]. There was complete

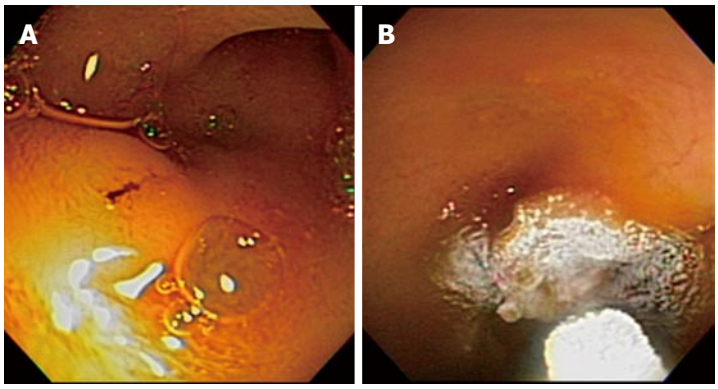

Figure 1 Endoscopic view of porcine duodenal papilla. A: Normal porcine duodenal papilla prior to treatment; B: Frost formation at the porcine duodenal papilla following liquid nitrogen cryotherapy.

thawing of ice between freeze cycles. Expanding liquid nitrogen gas was continuously suctioned via the CDT and through the endoscope between freeze cycles. Continuous monitoring for abdominal distention was performed by anesthesia personnel during the procedure.

Post-operative care, follow up and necropsy

The first two animals were used exclusively to evaluate the feasibility of liquid nitrogen cryotherapy at the duodenal papilla, and thus, were not survived. The animals were euthanized upon completion of the endoscopy, and necropsy performed. At necropsy, the peritoneal cavity and cryotherapy site was visually inspected for perforation, bleeding or damage to surrounding structures.

In survival experiments, pigs were extubated and recovered from general anesthesia. The pigs were monitored daily for any post-treatment adverse events, based on signs of distress, behavior changes, and/or loss of appetite. Oral feedings with standard chow were started the same day after recovering from anesthesia (day 0). Blood specimens were obtained at baseline (day 0), post-cryotherapy day 1 and day 7. Endoscopy was repeated on day 7 after cryotherapy to assess treatment effect at the duodenal papilla and biopsies were obtained at the cryotherapy site. At the end of the procedure, animals were euthanized and necropsy performed to rule out intra-abdominal adverse events associated with cryotherapy, such as transmural injury, bleeding, bowel perforation or abscess formation. Full-thickness duodenal specimen was obtained for histologic examination from one of the survival animals following necropsy.

Histologic examination

Biopsy specimens from all survival animals were obtained at the cryotherapy site on day 7 to assess the degree of intestinal injury. To evaluate the depth of the treatment effect, a full-thickness specimen containing the duodenal papilla was harvested from one of the survival animals following necropsy. All specimens were fixed in 10% neutral buffered formalin for at least 48 h, embedded in paraffin and stained with standard hematoxylin and eosin. The degree and depth of intestinal injury was graded by a single experienced pathologist as previously described in the text.

Statistical analysis

Summary data was expressed as the mean ± SD, and range. One-way analysis of variance (analysis of numerical data) was performed (GraphPad Prism version 6.00 for Windows, GraphPad Software, San Diego California, United States). The statistical methods of this study were reviewed by [Name, division, organization].

RESULTS

Endoscopic liquid nitrogen spray cryotherapy was performed at the duodenal papilla in 6 animals (2 non-survival and 4 survival studies).

Feasibility and safety of liquid nitrogen spray cryotherapy at the duodenal papilla

The duodenal papilla was identified in all 6 cases. The distal end of the CDT was successfully placed past the papilla into the second portion of the duodenum (Figure 1A) in all 6 animals. Cryospray with liquid nitrogen at the duodenal papilla resulted in white frost formation at and around the target region (Figure 1B). Four 20-s freeze-thaw cycles were applied with thawing between each session. Technical success was initially confirmed in the two non-survival animals and also subsequently achieved in all four survival swine studies (6/6; 100%). The mean procedural time was 54.5 min (range 50-58 min). All six animals studied had stable blood pressure, heart rate and pulse oximetry measurements during the procedure and there were no intra-procedural adverse events.

In survival studies, all 4 animals were recovered from general anesthesia and transferred to their housing facility, where they resumed regular feeding the same day of the procedure. The swine were monitored daily without any clinical ill effects from the cryotherapy (no change in activity, feeding habits and bowel and bladder elimination functions). There were no significant changes in Hb, WBC, liver tests or lipase on day 1 and 7 following cryoablation when compared to baseline (Table 1). There was no evidence of bleeding, infection (abscess), or bowel perforation on necropsy in any of

Table 1 Laboratory findings from survival animals (n = 4) at baseline (prior to liquid nitrogen cryospray application), on post-cryotherapy day #1 and #7

Lab	Mean (range)			*P* value
	Baseline	Day 1	Day 7	
Hemogloobin, g/dL	11.2 (10.2-12.3)	11.8 (11.1-12.3)	11 (9.9-11.6)	0.36
White blood count, K/μL	16.6 (12.9-17.4)	19.8 (14.1-22)	17.4 (15-21.9)	0.53
Alkaline phosphatase, U/L	98.8 (90-112)	102 (93-112)	84.5 (72-100)	0.15
Alanine transaminase, U/L	44.3 (32-52)	57.5 (47-80)	53.5 (45-57)	0.25
Aspartate transaminase, U/L	22.8 (16-31)	117.3 (24-385)	22.3 (17-29)	0.37
Total bilirubin, mg/dL	0.2 (0.1-0.3)	0.2 (0.1-0.2)	0.1 (0.1-0.2)	0.53
Lipase, U/L	5.5 (4-8)	9.3 (6-11)	4.8 (2-9)	0.06

Table 2 Histology findings

Swine	Baseline[1]		Day 7[2]	
	Crypt architecture	Inflammation	Crypt Architecture	Inflammation
1	Normal	None	Moderate necrosis	Moderate
2	Normal	None	Moderate necrosis and extensive debris	Moderate to severe
3	Normal	None	Severe necrosis and moderate debris	Severe with dense fibrosis
4	Normal	None	Moderate necrosis and extensive debris	Moderate

the animals.

Liquid nitrogen cryotherapy effects on the duodenal papilla

At 7 days after cryotherapy, survival animals underwent a follow up endoscopy for evaluation of treatment effect on the duodenal papilla. Edema, erythema and ulceration of the papilla were seen on endoscopy (Figure 2). Mucosal biopsies from the papilla were obtained and compared to baseline. The histologic findings of each animal are summarized in Table 2. There was loss of crypt architecture with moderate to severe necrosis and acute mixed inflammatory infiltration in each specimen obtained from the duodenal papilla on day 7 following cryotherapy. The extent of cryogen-induced tissue necrosis (depth of injury) was limited to the mucosa, with the application of four 20-s freeze-thaw cycles of liquid nitrogen (Figure 3).

DISCUSSION

Endoscopic papillectomy has been increasingly used for the treatment of ampullary adenomas and early cancers. While this approach is less invasive than surgery, it is still associated with significant risks and is mainly performed by experienced endoscopists. As such, alternative endoscopic ablative therapies would be helpful, especially for the treatment of elderly asymptomatic patients with multiple comorbidities.

Endoscopic cryotherapy has been primarily used for the management of dysplastic Barrett's esophagus and early esophageal cancer. The clinical application of this mucosal ablative technique in extra-esophageal gastrointestinal tract has been limited by the potential risk of perforation from barotrauma. When liquid nitrogen is delivered to the lumen, it undergoes phase transformation into a gaseous state as energy is delivered to the target tissue[16]. If not evacuated properly, the rapidly expanding nitrogen gas can be a risk for gastrointestinal perforation. Previous reports have evaluated the feasibility of liquid nitrogen cryotherapy in the stomach[17]; however, its application in the small intestine has not been evaluated.

The present study demonstrates the feasibility and safety of endoscopic liquid nitrogen spray cryotherapy at the duodenal papilla in a porcine model. The commercially available CDT could be successfully placed, with the tip of the tube in the second portion of the duodenum in all 6 animals in this study. This step was crucial as it allowed for adequate suction of the nitrogen gas during cryospray application at the duodenal papilla. There were no apparent adverse effects associated with the cryotherapy based on daily post-treatment monitoring, lab data and necropsy 7 d following treatment. There was no evidence of changes in hemoglobin, WBC, liver tests or lipase from ablation at the duodenal papilla.

Our study validated cryogen treatment effect at the duodenal papilla on endoscopy and histology 7 d following treatment. The dosimetry of 4 cycles of 20-s freeze in this study was based on previous reports in animal studies as well as the commonly applied dosimetry for liquid nitrogen spray cryotherapy used in the treatment of BE with high-grade dysplasia or adenocarcinoma[18-20]. Endoscopic appearance of lesions at the duodenal papilla on day 7 ranged from mild erythema and edema to superficial erosions. These results are similar to the endoscopic findings reported by Johnston *et al*[15] in swine esophagus on day 7 following liquid nitrogen cryospray application.

Figure 2 Endoscopic view of duodenal papilla 7 d following liquid nitrogen cryospray application.

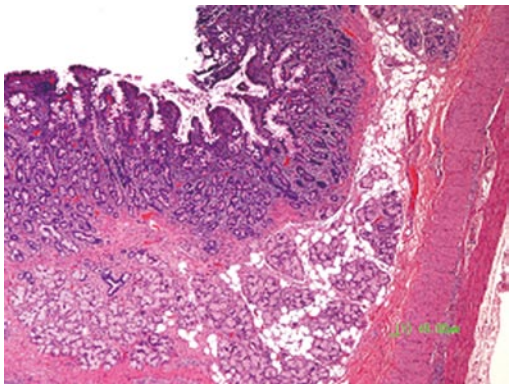

Figure 3 High-power microscopic view (HE x 40) of porcine duodenal papilla 7 d after application of a liquid nitrogen cryospray dose of 20 secfor 4 freeze-thaw cycles. There is severe blunting and loss of villar tips, infiltration of fibrous tissue and influx of mixed inflammatory cells into the lamina propria and loss of crypt architecture extending through the mucosa. The submucosa and muscularis propria are intact.

Our results demonstrate the effect of cryospray on histology based on the mucosal biopsies from the duodenal papilla on day 7. Histology on day 7 (4/4 animals) revealed loss or blunting of villous tissue and tips, crypt architectural distortion with necrosis and debris, and a mixed moderate to severe inflammatory infiltrate. This is a marked change from the normal histology obtained at baseline from the duodenal papilla and confirms treatment effect from the liquid nitrogen cryospray. We also demonstrate from a full-thickness specimen that the depth of injury was reserved to the mucosa, with inflammation and necrosis limited to the lamina propria and intact submucosa and muscularis propria. Previous animal studies have demonstrated dose-dependent injury to the esophagus, with necrosis involving the submucosa and even transmural damage with short exposures (15-30 s)[15,21]. In contrast, Shin and colleagues revealed that average grades of injury in the stomach across various doses were lower when compared with the esophagus[7]. We can speculate that the depth of tissue injury at the duodenal papilla from 4 cycles of 20-s of freeze time followed by thawing was associated with less injury compared to other studies because of differences in anatomical location in the gastrointestinal tract and mode of delivery (liquid nitrogen *vs* carbon dioxide). Further studies are needed to evaluate the relationship of cryogen dosimetry and depth of tissue injury in the small bowel.

We acknowledge the limitations of this study. First, our experiments were performed in a porcine model. While this animal model has been commonly used for experimental endoscopic studies, there are some important differences between human and porcine GI tract anatomy. The distal common bile duct and pancreatic duct in swine are not confluent at the duodenal papilla in pigs. In fact, while the biliary orifice is situated proximally in the duodenum at the papilla the pancreatic duct orifice is located separately several centimeters distal to the site of the biliary orifice. Since the primary aim of this pilot study was to evaluate the feasibility and safety of cryoablation at the duodenal papilla, we did not investigate treatment effect at the separate pancreatic duct orifice. This anatomical difference theoretically confers a decreased risk for pancreatic adverse events, including pancreatitis, when the duodenal papilla or biliary tract is manipulated in the porcine model. Thus, while there were no significant changes in serum lipase levels in our study to suggest pancreatitis following cryotherapy, we cannot definitively assess for this adverse event. Future studies are needed to evaluate the treatment effect and safety of cryotherapy at the pancreatic orifice. For this same reason, a pancreatic stent was also not placed after cryotherapy at the biliary orifice/papilla in this study, though this would need to be placed in human patients as is routinely done after endoscopic ampullectomy.

Second, as opposed to a side-viewing endoscope that is used in humans for endoscopy therapy at the papilla, a forward viewing endoscope (or pediatric colonoscope to overcome the J-shaped porcine gastric anatomy) was used to advance to the distal duodenum for adequate placement of the cryotherapy decompression tube. This technical hurdle may not be an issue with the human anatomy. Interestingly, the side-viewer may pose another challenge not encountered with the forward viewing endoscope used in this study. Use of the elevator of the side-viewing duodenoscope may theoretically kink the cryo catheter and not allow cryotherapy. However, the recently available, second generation of the cryotherapy device (truFreeze G2 spray cryotherapy device, CSA Medical Inc, Baltimore, MD) has a stainless steel reinforced catheter that enables 180 degree retroflexion and this upgrade may overcome the potential problem with the elevator. Additional studies in humans would be needed to evaluate the technical feasibility of placing the decompression tube side-by-side with a duodenoscope and performing cryotherapy with use of the elevator.

Third, in the absence of an animal model for ampullary lesions, cryotherapy was performed on normal porcine tissue. Thus, the extent of cryogen-induced effects may differ in humans with pathology (adenoma/carcinoma) at the duodenal papilla. Furthermore, our

study was limited to small numbers of animals and findings on depth of injury need to be confirmed in larger human protocols. Lastly, the study follow-up was relatively short (7 d); therefore, long term cryo ablative effects at the duodenal papilla were not evaluated.

Despite these shortcomings, our feasibility data shows that there were no adverse events from cryotherapy at the papilla. Specifically, there was no evidence of GI tract perforation, bleeding, cholangitis or bile duct injury despite directly spraying liquid nitrogen (that transforms to gaseous state with major increase in volume) at the open biliary orifice and therefore up the bile duct. Hence it appears that cryotherapy may be a viable option for treating ampullary lesions but further studies are needed to examine optimal dosimetry, effects on the pancreas and ablation of actual neoplastic tissue.

Our preliminary findings suggest that endoscopic liquid nitrogen cryotherapy at the porcine duodenal papilla is both feasible and safe. This data may serve as starting point for assessing the potential role of cryotherapy as an adjunct endoscopic treatment for residual/recurrent ampullary lesions or as a primary modality in patients who are not optimal candidates for surgery or endoscopic resection. Further studies are needed to determine the relationship between dosimetry and tissue injury at the duodenal papilla, with specific testing for effects on the pancreatic duct.

COMMENTS

Background

There is a growing interest in endoscopic mucosal ablative techniques for the management of different gastrointestinal pathologies, ranging from adenomatous lesions, dysplasia and/or intramucosal carcinoma. The role of endoscopic ablative techniques for the management of ampullary adenomas has not been fully elucidated.

Research frontiers

Cryotherapy is an emerging endoscopic mucosal ablative technique. Most of the current clinical experience with endoscopic cryotherapy is primarily related to data on ablation of Barrett's esophagus. The use of cryotherapy in other extra-esophageal sites has been limited to some degree by the concern of gas expansion and high risk of barotrauma and perforation in other regions of the GI tract.

Innovations and breakthroughs

The authors had previously reported preliminary data suggesting that liquid nitrogen cryotherapy is a safe technique even in patients with altered post-surgical gastric anatomy when appropriate measures are taken for cryogen gas decompression. This is the first study that has evaluated the feasibility and safety of endoscopic liquid nitrogen spray cryotherapy at the duodenal papilla in a porcine model.

Applications

This study demonstrates that spray cryotherapy was feasible and successfully performed in all animals. Survival animals thrived without adverse events. Follow-up evaluation one week post-treatment confirmed cryotherapy-induced tissue necrosis limited to the mucosa. These preliminary findings suggest a potential role for cyrotherapy as a primary or adjunct modality for patients who are not optimal candidates for surgery/endoscopic resection or in those with residual/recurrent disease.

Terminology

Endoscopic cryotherapy: mucosal ablative technique that employs non-contact deliver of either low-pressure liquid nitrogen or compressed carbon dioxide gas for tissue destruction. Technical success was defined as the successful placement of the cryotherapy decompression tube past the papilla followed by the delivery of liquid nitrogen spray to the target. Treatment effect was defined as endoscopic and histologic changes after cryotherapy. Freeze time was defined as the time interval from the visualization of white frost (ice formation) along the entire surface of the papilla until the cryospray was stopped.

Peer-review

Well designed, elegant animal study. The primary aim of the study was to assess the safety of a new therapeutic modality. The first acquired data proved the feasibility and safety during the short term follow-up period. The data are important and could be used in human studies.

Abstract

AIM: To investigate the safety profile of acquiring additional intestinal biopsies for research purposes in children undergoing a medically indicated colonoscopy.

METHODS: A retrospective review of 122 pediatric patients who underwent colonoscopy over a 9 mo time period was completed. 38/122 participants consented to a research study in which 4 additional biopsies were obtained, in addition to routine biopsies. The outcomes after colonoscopy were measured in the research participants, and compared to 84 control participants who did not consent for the study. Groups were compared with regard to number of biopsies obtained, underlying diagnosis, and both serious and minor adverse outcomes. Data was collected including: age, gender, race, indication, diagnosis, number of biopsies obtained per case and post procedure adverse events. Medical records were reviewed and a questionnaire was completed by each of the ten gastroenterologists who performed procedures during the study. Physicians were asked about individual patient outcomes to ensure that all adverse events, such as perforation, excessive bleeding, infection, and minor gastrointestinal outcomes, were captured and included.

RESULTS: The research group had more biopsies obtained (mean = 13.58 ± 4.21) compared to controls (mean = 9.33 ± 4.40), $P \leqslant 0.0001$, however there was no difference in adverse events. Serious outcomes, defined as perforation, bleeding and infection, did not occur, in either group. As such, the relationship between serious adverse events and number of biopsies obtained was not determined. Minor gastrointestinal outcomes, such as abdominal pain, diarrhea or vomiting, were reported in 21 patients (8 research participants and 13 control participants) however the incidence of minor gastrointestinal outcomes between the two groups did not vary significantly, $P = 0.45$. Additionally, the mean

number of biopsies obtained in patients who had a minor outcome (mean = 12.1 ± 0.77), compared to those with no adverse outcome (mean = 10.34 ± 0.5), revealed no statistical difference between the groups (P = 0.12), suggesting that number of biopsies is not associated with incidence of minor adverse events.

CONCLUSION: Patients participating in research requiring acquisition of additional biopsies for research purposes alone, are not at an increased risk of adverse outcomes.

Key words: Pediatric colonoscopy; Outcomes; Research; Safety; Intestinal biopsy

Core tip: Acquiring biopsies for research purposes during a colonoscopy may facilitate translational research in the field of gastroenterology. However, the safety profile of acquiring research biopsies has not been established. Our study is the first to conclude that acquiring additional biopsies for research during a colonoscopy does not pose additional risk to the pediatric patient. This manuscript may serve as a reference to researchers applying for IRB approval in biological specimen studies. Additionally, our study is additive to the body of literature on outcomes after pediatric colonoscopy, in that minor gastrointestinal symptoms were the only reported adverse event after colonoscopy.

Mait-Kaufman J, Kahn S, Tomer G. Obtaining research biopsies during pediatric colonoscopy: Safety and adverse events. *World J Gastrointest Endosc* 2015; 7(7): 736-740 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/736.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.736

INTRODUCTION

Colonoscopy with biopsies is a common procedure in children for the evaluation and diagnosis of gastrointestinal disease. Serious complications, such as perforation and bleeding are routinely discussed during the consent process, however, these events are rare[1-3]. Several adult studies have sought to measure the incidence of adverse outcomes during routine procedures[2,4,5], and this data has largely been applied to the pediatric population[6]. In adults, colorectal perforation is presumed to occur in 0.09% of the general population[7,8], while it remains unclear as to whether patients with pre-existing inflammatory bowel disease (IBD) are at an increased risk for serious outcomes, such as perforation[7,9,10]. The incidence of bleeding after colonoscopy is thought to occur infrequently during routine procedures[8].

There is limited data on serious adverse events in children, such as bleeding. Although one study found that 38.6% (34/86) of all reported complications were related to gastrointestinal bleeding, bleeding was not defined[3]. Other pediatric studies did not include bleeding in their outcome analysis[6]. Infection, similarly regarded as a serious and uncommon outcome after colonoscopy, has not been widely studied in pediatrics[11]. Likewise, minor post-procedure gastrointestinal symptoms, such as bloating and abdominal pain, are not well described in the pediatric literature[12].

The current pediatric studies are limited in number and do not quantify the number of routine biopsies obtained per procedure which may be a risk factor for adverse events. Additionally, these studies have not addressed whether obtaining additional biopsies solely for research purposes imposes additional risk to the patient. To our knowledge, this issue has not been addressed in the pediatric or adult literature. It is critical to establish the safety profile of collecting additional biopsies for research during routine procedures, so that investigators seeking institutional review board (IRB) approval are able to proceed with important research questions. The absence of this risk assessment may explain why studies involving the collection of pediatric biological specimens are difficult to pursue. Such IRB protocols pose a challenge to both author and reviewer, in that the lack of prior safety data serves as an obstacle for IRB approval. To address this gap, we performed a retrospective review for all children undergoing routine medically indicated colonoscopies and measured adverse events. Thirty-one percent of the participants had previously consented for a research study involving the acquisition of four additional intestinal biopsies designated for research purposes. By comparing adverse events in the research study participants to patients who did not consent, the controls, we established that acquiring additional biopsies for research alone is safe.

MATERIALS AND METHODS

We performed a retrospective review of all pediatric patients undergoing a medically indicated routine colonoscopy from June 5, 2013-March 5, 2014. Anesthesia was provided by pediatric anesthesiologists.

Patients who had previously provided written and oral consent for a biological specimens study were identified (n = 38); these participants consented to have four additional intestinal biopsies taken for research purposes alone. This research-consented cohort was then compared to non-study participants (n = 84), who had only routine biopsies obtained during the procedure.

Data was collected including: age, gender, race, indication, diagnosis, number of biopsies obtained per case and post procedure adverse events. Post-procedure adverse events were defined as events occurring within one week of the procedure. Medical records were reviewed for patient phone calls, general practitioner and gastroenterology clinic appointments, emergency department visits and hospital admissions within one week post-procedure. For those patients who were admitted to the hospital prior to their colonoscopy, the

inpatient record was reviewed.

We administered a questionnaire to the ten gastroenterologists who performed procedures during the aforementioned time period regarding individual patient outcomes to ensure that all adverse events, such as perforation, excessive bleeding, infection, and minor gastrointestinal outcomes, were captured and included. This study was approved by the Office of the Human Research Protection Program, Institutional Review Board at Albert Einstein College of Medicine, Bronx, NY.

Statistical analysis

Differences in participant demographics between groups were compared using analysis of variance or t tests for continuous variables and χ^2 or Fisher's exact tests for categorical variables. All analyses were performed using GraphPad Prism version 6 (San Diego, CA). All tests for significance were two-sided, and a value of $P < 0.05$ was considered significant.

RESULTS

A total of 122 colonoscopies were performed during the study period: 38 patients consented to have additional biopsies obtained for research during the medically indicated procedure, compared to 84 non-research related cases. One thousand two hundred and ninety biopsies were obtained, including 136 intestinal biopsies for research alone. The average number of biopsies obtained per case was significantly higher in the research cohort, 13.6 compared to 9.3 in the control group, (P < 0.0001) (Table 1). Participant demographics are detailed in Table 1. Of note, statistical differences in race and age were observed in the research compared to the control groups, P = 0.04 and P = 0.05, respectively. One patient (2.6%), age 0-5, participated in the research study, compared to 16 (19%) who underwent routine colonoscopy alone (P = 0.05). No statistical difference in gender distribution was observed when comparing research to control participants.

The research cohort consisted of 38 patients, 17/38 (44.7%) of whom had IBD, compared to 21/84 (25%) of the patients in the control group (P = 0.03) (Table 1). IBD diagnosis type, such as Crohn's disease (CD) or ulcerative colitis (UC), did not vary significantly between the two groups, P = 0.23.

There were no cases of perforation, infection or hemorrhage in the research or the control group. Given that no serious outcomes occurred in our cohort, the relationship between number of biopsies and serious adverse events was not measured. Minor gastrointestinal outcomes, however, did occur in 8/38 research participants, and 13/84 control participants (Table 2). The incidence of minor gastrointestinal outcomes was not statistically different when comparing the research and control groups, P = 0.45, although the research group had significantly more biopsies obtained per procedure, P < 0.0001. Additionally, the mean number of biopsies obtained in patients who had a minor outcome (mean = 12.1 ± 0.77), compared to those with no adverse outcome (mean = 10.34 ± 0.5), revealed no statistical difference between the groups

Table 3 Indications for colonoscopy

Indication (%)	Research (n = 38)	Control (n = 84)	P value[1]
Abdominal pain	50	50	1
Diarrhea	44.7	36.9	0.41
Rectal bleeding	36.8	34.5	0.8
Weight loss	44.7	20.2	0.01
Loss of appetite	34.2	10.7	0.002
Constipation	18.4	15.5	0.68
Vomiting	15.8	14.3	0.83
Fatigue	23.7	3.57	0.001
Fever	7.89	3.57	0.31
Joint pain	10.5	1.19	0.02
Rash	5.26	0	0.03

[1]All P values calculated to a significance level of 0.05.

(P = 0.12), suggesting that number of biopsies is not associated with incidence of minor adverse events.

When comparing mechanism of reporting and management of adverse minor events no statistical differences were noted when comparing research participants to controls. Likewise, gastrointestinal symptoms reported as minor events were similar between the two groups.

Overall, during this time period, 38 children with IBD underwent colonoscopy: 47.4% (18/38) of this group were newly diagnosed patients, 11 with CD, 6 with UC, and 1 with indeterminate colitis, while 52.6% (20/38) had been previously diagnosed with IBD. Minor outcomes occurred in 21% (8/38) of patients with IBD. The incidence of minor adverse events in IBD versus non-IBD patients, did not vary significantly between the two groups, P = 0.45.

The most common indication for colonoscopy was abdominal pain, occurring in 50% of patients, while diarrhea was the second most common indication (Table 3). Weight loss, loss of appetite, fatigue, joint pain and rash occurred more often in the research group, P = 0.01, P = 0.002, P = 0.001, P = 0.02, and P = 0.03, respectively.

DISCUSSION

To our knowledge, no studies to date have evaluated the safety profile of taking additional intestinal biopsies for research purposes. Obtaining intestinal biopsies for research may facilitate investigations that will further our understanding of pediatric gastrointestinal illnesses. Our study shows that participation in research during a medically indicated colonoscopy does not place the patient at an increased risk for bleeding, perforation, infection, or minor gastrointestinal outcomes, which is in line with prior pediatric studies, as complications during routine colonoscopy are rare[3,6,7,9,11,13], and can be applied to studies involving biological specimens.

Adverse events after pediatric colonoscopy, particularly in regard to IBD, have not been well studied, as subjects with pre-existing disease are often excluded from the cohort[6]. Our data suggests that patients with IBD are not at increased risk for perforation or bleeding, which refutes prior findings[10]. A larger percentage of IBD patients (8/38, 21%) sustained minor adverse outcomes compared to non-IBD patients (13/84, 15.5%), however this difference was not found to be statistically significant. Our findings support a prior study by Tam *et al*[9] that evaluated pain indices in children with IBD, pre and post procedure, and found that patients with functional bowel disease report more pain, compared to children with IBD[9].

Interestingly, our research-consented cohort consisted of a larger percentage of IBD patients, 44.7% compared to 23.8% in the control group. From this, we may conclude that parental concern is greater in children more likely to have IBD, which may explain a greater willingness to participate in studies or to benefit from research. Alternatively, selection bias may impact the recruitment of children most likely to have IBD. In this study, however, all children undergoing colonoscopy during the aforementioned time period were asked to participate.

Given that serious adverse events did not occur in our cohort, we were unable to correlate number of biopsies obtained with incidence of serious adverse events. However, we did observe that of the patients who reported minor gastrointestinal outcomes, most (71.4%) reported the same symptom with which they presented for colonoscopy. Therefore, minor gastrointestinal events occurring after a procedure may be secondary to the primary gastrointestinal complaint, rather than the procedure. In regard to the consent process and clinical practice, clinicians may reassure parents that minor symptoms after a procedure are most commonly related to underlying symptoms on presentation, and not to the colonoscopy itself.

There are few studies in the current pediatric literature that discuss minor adverse outcomes after colonoscopy. Our study found that 17.2% of our population reported minor symptoms after colonoscopy, which is consistent with prior data, for example, Steiner *et al*[12] found that post-procedure symptoms occur in 14%-17% of patients; sore throat, diarrhea and excessive gas occurred in 6% of patients, while abdominal pain occurred in 3%[12]. In our study 1.6% of participants were admitted post procedure for observation, while Steiner et al. admitted 1.1% patients, suggesting that the general concern level regarding minor symptoms is low. Of the 17 patients who reported symptoms, 1 was under the age of 5, suggesting either that minor symptoms are more common in older children, or that underreporting is at play in younger age groups. On a similar note, only 1 patient between the ages 0-5 participated in the research study, compared to 16 children in the control group under the age of 5, suggesting that parents of very young children are less likely to consent for studies requiring the collection of biological specimens. In one study, children 0-5 years of age were the most likely group to have a complication, $P \leqslant 0.001$[3]; this supports the notion that very young

patients may have an increased risk for complications after colonoscopy and that children over the age of 5 may be more suitable candidates for research studies involving acquisition of additional biopsies.

The limitations of our retrospective study include small sample size, limited duration of the study, and selection bias, as underlying gastrointestinal symptoms may have affected study outcome. Additional studies with larger groups of pediatric patients undergoing colonoscopy for medical reasons, while participating in research, are warranted in order to further attest that no additional risk is imposed to the patient. This will allow researchers to pursue questions that will enhance our current knowledge of chronic gastrointestinal problems in children, specifically IBD.

COMMENTS

Background

Colonoscopy with biopsies is a common procedure in children for the evaluation and diagnosis of gastrointestinal disease. There is limited data on serious adverse events in children, such as bleeding, infection and perforation. Likewise, minor post-procedure gastrointestinal symptoms, such as vomiting and abdominal pain, are not well described in the pediatric literature. Current pediatric studies have not addressed whether obtaining additional biopsies solely for research purposes imposes additional risk to the patient. It is critical to establish the safety profile of collecting additional biopsies for research during routine procedures, so that investigators may proceed with studies involving biological specimens. The lack of safety data may explain why studies involving the collection of pediatric biological specimens are difficult to pursue.

Research frontiers

Institutional review board (IRB) protocols involving biological specimen collection pose a challenge to both author and reviewer, in that the lack of prior safety data serves as an obstacle for IRB approval. In order to address key research questions using translational research methods, safety data must be available for reference.

Innovations and breakthroughs

To date, the incidence of adverse events occurring when collecting additional biopsies for research during medically indicated colonoscopies has not been addressed in the pediatric or adult literature.

Applications

The study results suggest that acquiring additional biopsies for research during medically indicated colonoscopies is safe.

Terminology

Serious adverse events after colonoscopy include bleeding, perforation and infection. Minor events after colonoscopy include abdominal pain, diarrhea and vomiting.

Peer-review

This is a small retrospective study in which the authors assessed the safety profile of acquiring additional intestinal biopsies for research purposes during medically indicated colonoscopies. The results indicate that it is safe to acquire such biopsies in children for the purposes of facilitating translational research. The publication of this study may serve as a reference for researchers seeking IRB approval in biological specimen studies, and suggests the need for larger studies in the future.

Abstract

AIM: To identify the features of early signet ring cell gastric carcinoma using magnification endoscopy with narrow band imaging (NBI).

METHODS: A retrospective review was conducted of 12 cases of early signet ring cell gastric carcinoma who underwent treatment in a single institution between January 2009 and April 2013. All patients had magnification endoscopy with NBI and indigo carmine contrast to closely examine the mucosal architecture, including the microvasculature and arrangement of gastric pits. Histologic examination of the final endoscopic submucosal dissection or gastrectomy specimen was performed and compared with the endoscopic findings to identify patterns specific to signet ring cell carcinoma.

RESULTS: Twelve patients with early signet ring cell gastric carcinoma were identified; 75% were male, and average age was 61 years. Most of the lesions were stage T1a (83%), while the remainder were T1b (17%). The mean lesion size was 1.4 cm^2. On standard endoscopy, all 12 patients had a pale, flat lesion without any evidence of mucosal abnormality such as ulceration, elevation, or depression. On magnification endoscopy

with NBI, all of the patients had irregularities in the glands and microvasculature consistent with early gastric cancer. In addition, all 12 patients exhibited the "stretch sign", an elongation or expansion of the architectural structure. Histologic examination of the resected specimens demonstrated an expanded and edematous mucosal layer infiltrated with tumor cells.

CONCLUSION: The "stretch sign" appears to be specific for signet ring cell carcinoma and may aid in the early diagnosis and treatment of this aggressive pathology.

Key words: Signet ring cells; Early gastric cancer; Magnification endoscopy; Narrow band imaging; Stretch sign; Endoscopic submucosal dissection

Core tip: With aggressive screening, gastric cancer can be detected in the early stages, leading to the possibility of successful minimally invasive treatments, such as endoscopic submucosal dissection. A rare type of gastric cancer, signet ring cell carcinoma, has aggressive biological features, but patients treated in the early stages may actually fare better than those with adenocarcinoma. Here we present findings specific for signet ring cell carcinoma that can be identified on magnification endoscopy, potentially securing a diagnosis in the early stages of the disease without the need to rely on random biopsies.

Endoscopic features of early-stage signet-ring-cell carcinoma of the stomach. *World J Gastrointest Endosc* 2015; 7(7): 741-746 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i7/741.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i7.741

INTRODUCTION

Gastric cancer can be detected in the early stages by aggressively screening asymptomatic patients. In Japan, where such rigorous screening is conducted, half of gastric cancers are now diagnosed in the early stages of the disease[1]. Early detection affords the opportunity for less invasive treatment options, such as endoscopic submucosal dissection (ESD). However, signet ring cell carcinoma, an unfavorable subtype of gastric cancer that may require more aggressive treatment, has been reported in up to 29% of gastric cancer patients in the United States[2] and over 10% in Japan[3]. If treated early, signet ring cell carcinoma has a better prognosis than other subtypes; however, advanced signet ring cell carcinoma has a prognosis that is even worse than undifferentiated adenocarcinoma[4]. Early diagnosis of signet ring cell carcinoma is therefore critical to guide optimal treatment, but the typical presentation during conventional endoscopy is a pale, flat lesion that can easily be missed even by experienced endoscopists.

Advanced endoscopy using a magnifying endoscope and narrow band imaging (NBI) technology may play an important role. Previous studies have reported fine mucosal patterns of gastric pits and microvasculature that can be identified and classified using magnification endoscopy with NBI[5-7], and that it is possible to predict the depth of invasion of early gastric carcinomas prior to histologic assessment[8,9]. We postulate that magnification endoscopy and NBI can be further applied to the early detection of signet ring cell carcinoma.

The purpose of this study was to review our experience with magnification endoscopy with NBI in 12 cases of early signet cell gastric carcinoma, and to identify specific endoscopic patterns that may predict the final pathologic diagnosis.

MATERIALS AND METHODS

Patient selection

A retrospective chart review was performed to identify patients who underwent endoscopic and/or surgical intervention for signet ring cell gastric carcinoma in a single institution (Showa University Northern Yokohama Hospital). We identified 12 cases of signet ring cell gastric carcinoma during the study period from January 2009 to April 2013.

Magnification endoscopy

Diagnostic procedures were performed following the ingestion of 5 cc of viscous 2% lidocaine and administration of light intravenous sedation. Magnification endoscopy was performed in a single center utilizing high-resolution magnifying upper endoscopes (Olympus Evis Lucera Spectrum, GIF-H260Z, Tokyo, Japan) with 10.8 mm diameter tips and color charge-coupled-device (CCD) optical lenses with a 140 degree field of view. A distal attachment with 3 mm depth (MB-162, Olympus, Tokyo, Japan) was utilized as described by Yao *et al*[10], and images were recorded with NBI both before and after administration of 0.3% indigo carmine dye. Endoscopic images were reviewed by expert endoscopists and assessed for irregularity of the gastric pits and/or microvasculature.

Histopathology

Histologic examination of the final specimen following ESD or laparoscopic-assisted partial or total gastrectomy was performed by pathologists specializing in gastrointestinal pathology, and lesions were classified according to the Japanese classification system[11]. Pathologists did not have access to the endoscopic findings.

Table 1 Demographic data and tumor characteristics of 12 patients with signet ring cell early gastric carcinoma

No.	Age	Sex	Location of tumor	Size (mm)	Depth	Operation	F/U (mo)
1	64	F	Lower body/posterior	10 × 9	T1a	ESD	54
2	77	M	Pyloric/lesser curve	5 × 4	T1a	ESD	45

Biostatistics

The data presented are a qualitative analysis of a single cohort. No statistical tests were performed.

RESULTS

Patient demographics and clinical outcomes

Patient demographic data are summarized in Table 1. Of the 12 patients with signet ring type early gastric cancer, mean age was 61.3 (range 39-87), and 75% were male; the lesions had a maximum dimension of 1.3 cm on average (range 0.5-2.2 cm) with a mean area of 1.4 cm^2 (range 0.2-4.2 cm^2); 83% of lesions were T1a, and 17% were T1b. ESD was performed in 83% of cases; laparoscopic-assisted distal gastrectomy or laparoscopic-assisted total gastrectomy was performed in the remaining 17% due to pre-operative suspicion of lymph node metastases. There was 100% disease-free survival at a median follow-up of 2.5 years.

Endoscopic findings

On standard white light endoscopy, all 12 patients with signet ring early gastric cancer had pale, flat lesions without gross mucosal abnormality such as ulceration, elevation, or depression. On magnification endoscopy, each of the patients had irregularities in the glands and microvasculature, consistent with early gastric cancer; however, in addition, the architecture appeared to be expanded or elongated, as if it had been "stretched", within a portion of the lesion for all 12 patients (Figures 1 and 2).

Pathologic correlation

On histologic examination, patients with signet ring early gastric cancer demonstrated an expanded and edematous mucosal layer infiltrated with tumor cells

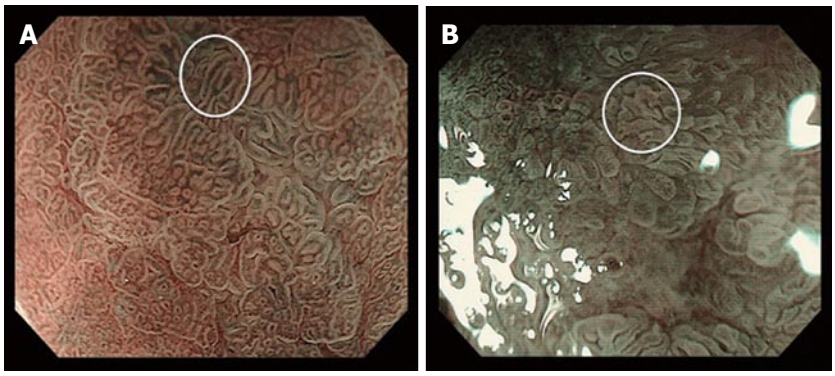

Figure 2 Magnification endoscopy of the stomach: (A) normal polygonal architecture (bottom left, underlying "a") and a signet ring cell gastric carcinoma demonstrating an elongated or "stretched" gastric gland (white circle); (B) a non-signet ring cell adenocarcinoma demonstrating irregular (non-polygonal) but non-elongated glands (white circle).

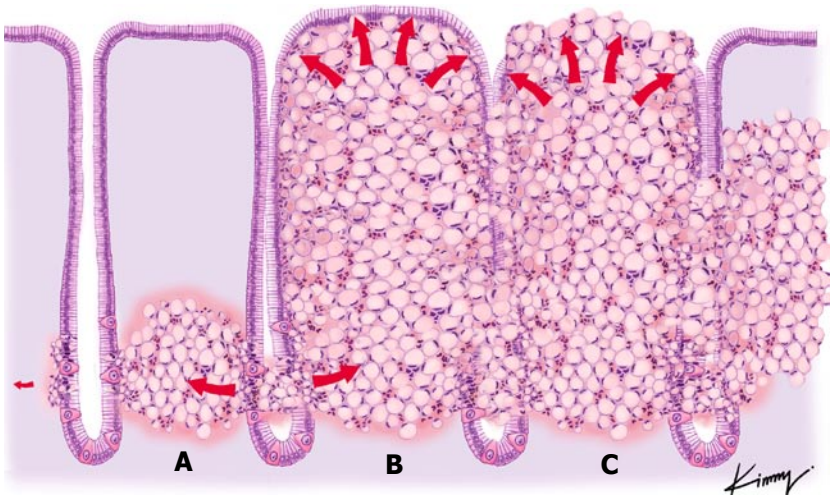

Figure 3 Theoretical view of the pathophysiology of signet ring cell differentiation: (A) tumor cells originating in the neck of the gland and spreading to the submucosal space; (B) an increasing number of tumor cells being packed together, resulting in a barrel shape; and (C) the previously non-exposed tumor becoming exposed through necrosis and formation of an ulcer.

Figure 4 Microscopic view of a signet ring cell gastric carcinoma, demonstrating: (1) normal appearing gastric mucosa (left); and (2) signet ring cells (black dashed circle) causing distortion of the gastric glands (right), consistent with the endoscopic finding of the "stretch sign."

(Figure 1).

DISCUSSION

In all 12 cases of signet ring-type early gastric cancer in our institution, we identified the "stretch" sign - elongation of the architecture of the submucosa. Anecdotally, we do not note any architectural elongation in our non-signet ring early gastric cancer patients.

All 12 of our signet ring early gastric cancer patients underwent either endoscopic or surgical resection and are doing well at 2.5 years median follow-up; however; the optimal treatment for this subgroup of patients has not yet been determined. The current Japanese guidelines recommend ESD for non-ulcerated pT1a undifferentiated gastric cancer with tumor size $\leqslant$ 2 cm, but while some studies have shown only a 4% rate of lymph node metastases for tumors limited to the mucosa (as compared with 92% for tumors with submucosal spread)[12].

In an animal study, signet ring cells originated from the lamina propria at the level of the gland neck and spread through the mucosal[13]. We postulate that this proliferation of signet ring cells along the lamina propria results in clusters of tumor cells, causing the "stretched" appearance of the gastric pits and microvasculature that we observe on magnification endoscopy (Figures 3 and 4).

Our study is limited by its retrospective design and the small numbers associated with the relative rarity of early stage signet ring cell gastric cancer.

Additional studies are needed to further identify unique microendoscopic features of signet ring cell gastric cancer and to more accurately determine the sensitivity and specificity of the "stretch sign". Given that ESD is still considered an investigational treatment in the presence of signet ring cells due to the more aggressive biology and unfavorable prognosis[11,14], the presence of the "stretch sign" may help to identify patients with signet ring cells and perhaps guide more aggressive treatment, such as wider margins during ESD or earlier progression to formal surgical resection.

In conclusion, we found that signet ring cell carcinoma can be identified by the expansion or "stretching" of the gastric pits and microvasculature. This may allow for the diagnosis of signet ring cell carcinoma in the early stages using magnification endoscopy, reducing the impact of sampling error if random biopsies are taken, and perhaps guiding more aggressive treatment.

The authors would like to thank Chananya Hokieti ("Kimmy") for her help with the illustrations.

COMMENTS

Background

Gastric cancers are aggressive tumors of the stomach that are often asymptomatic in the early stages. By the time patients develop symptoms, the tumors are often advanced and may be incurable. Aggressive screening regimens have been introduced in countries with a high prevalence of gastric cancer, such as Japan, leading to more gastric cancers being diagnosed in the early stages.

Research frontiers

Signet ring cell carcinoma, a rare subtype of gastric cancer, is unique in its biology and progression. Compared to "standard" adenocarcinoma, patients with early stage signet ring cell carcinomas have a better prognosis; meanwhile, patients with later stage signet ring cell carcinomas have a much worse prognosis than those with adenocarcinoma. Identifying and treating signet ring cell carcinoma in its early stages is therefore critical.

Innovations and breakthroughs

Early gastric cancers can be examined with magnification endoscopes using a narrow band imaging to reveal the architecture of the most superficial layers of the stomach, the mucosa and submucosa. This reveals the shapes of the gastric glands and the organization of the tiny submucosal blood vessels. In this study the authors present 12 patients with signet ring cell carcinoma; all of the patients have unique changes to the architecture of the glands and blood vessels (specifically, "stretching") that the authors have only seen when signet ring cells are present.

Applications

Use of the "stretch sign" during magnification endoscopy can potentially be used to identify patients who have signet ring cell carcinoma, allowing their prognosis and treatment to be tailored to the more aggressive biology of their cancer.

Terminology

Magnification endoscopes are upper endoscopes with a special tip and image processing equipment that can zoom in to see the organization of groups of cells. Narrow band imaging uses a small range of light (rather than the full "white light" spectrum) to highlight borders between normal and abnormal areas of the stomach. The "stretch sign" is the authors' term for elongation or "stretching" of the usual architecture of the gastric glands and the tiny submucosal vessels.

Peer-review

It is a concise and easy to read paper which brings a new progress in the field of early gastric cancer diagnosis.

Abstract

AIM: To review results of endoscopic treatment for anastomotic biliary strictures after orthotopic liver transplantation (OLT) during an 8-year period.

METHODS: This is a retrospective review of all endoscopic retrograde cholangiopancreatographys (ERCPs) performed between May 2006 and June 2014 in deceased OLT recipients with anastomotic stricture at a tertiary care hospital. Patients were divided into 2 groups, according to the type of stent used (multiple plastic or covered self-expandable metal stents), which was chose on a case-by-case basis and their characteristics. The primary outcome was anastomotic stricture resolution rate determined if there was no more than a minimum waist at cholangiography and a 10 mm balloon could easily pass through the anastomosis with no need for further intervention after final stent removal. Secondary outcomes were technical success

rate, number or ERCPs required per patient, number of stents placed, stent indwelling, stricture recurrence rate and therapy for recurrent anastomotic biliary stricture (AS). Stricture recurrence was defined as clinical laboratorial and/or imaging evidence of obstruction at the anastomosis level, after it was considered completely treated, requiring subsequent interventional procedure.

RESULTS: A total of 195 post-OLT patients were assessed for eligibility. One hundred and sixty-four (164) patients were diagnosed with anastomotic biliary stricture. ERCP was successfully performed in 157/164 (95.7%) patients with AS, that were treated with either multiple plastic (n = 109) or metallic billiary stents (n = 48). Mean treatment duration, number of procedures and stents required were lower in the metal stent group. Acute pancreatitis was the most common procedure related complication, occurring in 17.1% in the covered self-expandable metal stents (cSEMS) and 4.1% in the multiple plastic stent (MPS) group. Migration was the most frequent stent related complication, observed in 4.3% and 5.5% (cSEMS and MPS respectively). Stricture resolution was achieved in 86.8% in the cSEMS group and in 91% in MPS group. Stricture recurrence after a median follow up of 20 mo was observed in 10 (30.3%) patients in the cSEMS and 7 (7.7%) in the plastic stent group, a statistically significant difference (P = 0.0017). Successful stricture resolution after secondary treatment was achieved in 66.6% and 62.5% of patients respectively in the cSEMS and plastic stents groups.

CONCLUSION: Multiple plastic stents are currently the first treatment option for AS in patients with duct-to-duct anastomosis. cSEMS was associated with increased pancreatitis risk and higher recurrence rate.

Key words: Biliary stricture; Benign; Liver transplant; Endoscopic retrograde cholangiopancreatographys; Endoscopic treatment; Plastic stent; Self-expandable metal stent

Core tip: Endoscopic treatment is effective and safe in the management of post liver transplant biliary complications, mainly for anastomotic strictures. Progressive dilation and multiple plastic stenting have been demonstrated as the best endoscopic therapeutic modality with high success rates and low recurrence. Fully covered stent-expandable metal stents may be an option for endoscopic therapy potentially reducing the number and procedures lowering the costs, however their complication rate needs to be further evaluated.

INTRODUCTION

Biliary complications have been considered for a long time the "Achilles' heel" of orthotopic liver transplantation (OLT), due to its elevated incidence, need for long-term therapy and major impact on graft survival and quality of life. Despite the advances in surgical techniques, organ selection, preservation and immunosuppression, the biliary tract remains the most common site for postoperative complications[1-4].

The incidence of biliary complications varies from 6% up to 40% of patients and includes strictures, leakages, stones, casts, sludge and sphincter of Oddi dysfunction[1-5].

Among the risk factors enrolled in the development of biliary complications the most important are: type of liver transplant procedure, reconstruction technique, organ preservation, technical factors during surgery, reperfusion injury, infection, prolonged cold and warm ischemia, hepatic artery thrombosis or stenosis, chronic rejection, ABO incompatibility, underlying disease, donation after cardiac death and older age donor[2-4,6-8].

Diagnosis of biliary complications after liver transplantation is challenging. Patients usually present asymptomatic elevations of bilirubin, alkaline phosphatase, gamma-glutamyl transferase and/or liver enzymes. Non-specific symptoms such as anorexia, fever, pruritus, jaundice and rarely pain (due to immunosuppression and hepatic denervation) can be observed.

The evaluation should start with an abdominal ultrasound (US) with Doppler of hepatic vessels. If hepatic artery thrombosis or stenosis is suspected, angiography should be indicated for specific treatment (Figure 1). If bile duct dilation, stones and/or leakage are identified by US the patient should be referred to therapeutic endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous trans-hepatic cholangiography (PTC)[7,9-13]. In case of normal abdominal US, a liver biopsy should be performed to exclude rejection. Finally, in patients with normal US and rejection ruled out by liver histology, a magnetic resonance cholangiopancreatography (MRCP) should precede more invasive procedures (Figure 1)[14]. Those patients who have a stricture or leakage confirmed by MRCP will be referred to therapeutic ERCP or PTC according to the type of biliary reconstruction.

Concerning management, although surgical repair used to be the standard treatment in the past, non-operative therapy of biliary complications has become the first line option in the last two decades[3,6]. Endoscopic approach is well established as the preferred therapeutic modality for patients with duct-to-duct anastomosis[15].

This paper will summarize the results of endoscopic treatment for anastomotic biliary strictures after

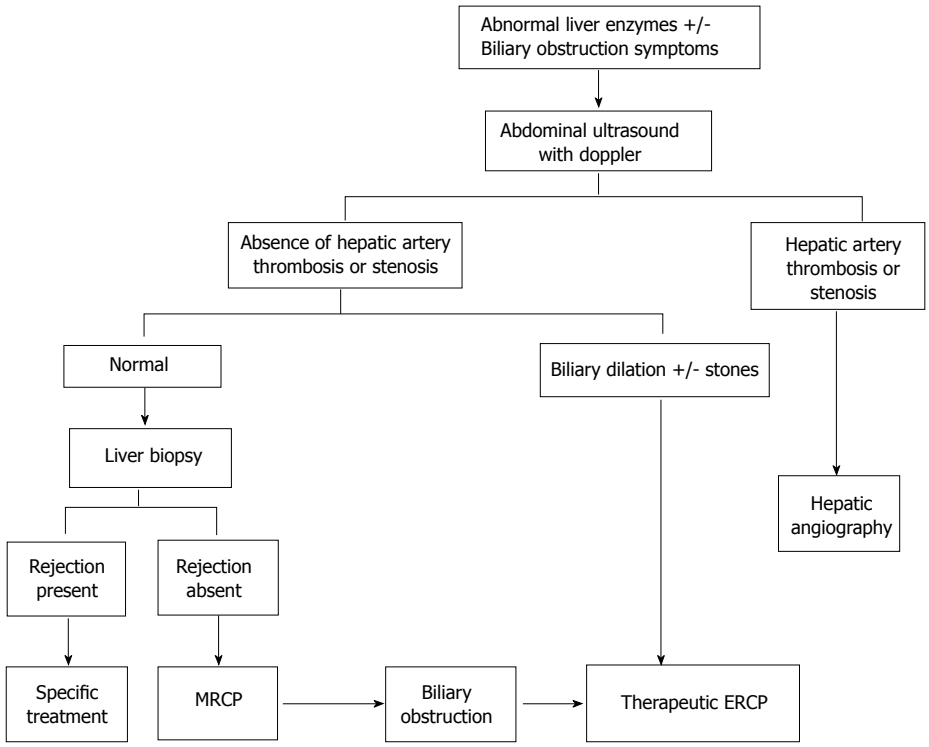

Figure 1 Algorithm for evaluation of suspected biliary obstruction after orthotopic liver transplantation in patients with duct-to-duct reconstruction. MRCP: Magnetic resonance cholangiopancreatography; ERCP: Endoscopic retrograde cholangiopancreatographys.

deceased OLT in a tertiary center during an 8-year period and review the literature with future therapy considerations.

MATERIALS AND METHODS

Hospital Israelita Albert Einstein, São Paulo, Brazil, is a tertiary care hospital where around 120 liver transplantations are carried out annually. The study was reviewed and approved by the Hospital Israelita Albert Einstein Institutional Review Board. We retrospectively evaluated all ERCPs performed between May 2006 and June 2014 in deceased orthotopic liver transplant recipients with duct-to-duct anastomosis and suspected biliary complications. This paper reports our overall experience in such patients. All study participants, or their legal guardian, provided informed written consent prior to study enrollment. Procedures were performed under monitored care anesthesia.

Anastomotic biliary stricture (AS) was defined as a dominant short narrowing at the anastomotic site. Patients with AS were individually treated according to standardized protocols either with multiple plastic or single metal stents.

Briefly, plastic stents were initially placed after sphincterotomy and stricture balloon dilation. ERCP was repeated at 3-mo intervals for stent exchange, following a progressive balloon dilation and increasing number of stents protocol at each session, until 12 mo of therapy.

Covered self-expandable metal stents (cSEMS) were deployed with or without sphincterotomy and removed after a 3-mo period if a partially covered metal stent-expandable metal stents (PCSEMS) was used or after 6 mo in case of a fully covered stent-expandable metal stents (FCSEMS). In our early experience, biliary SEMS were placed without sphincterotomy, which we started to perform after recognizing a high rate of pancreatitis in these patients. PCSEMS were also used in our early experience, when fully covered SEMS were not available in Brazil.

Complications after ERCP (pancreatitis, cholangitis, hemorrhage, perforation) were defined by established criteria[16].

Initial technical success was the ability to obtain a cholangiogram and accomplish stent placement at ERCP alone or with a trans-hepatic *rendezvous* procedure. The investigators determined successful stricture resolution if there was no more than a minimum waist at cholangiography and a 10 mm balloon could easily pass through the anastomosis with no need for further intervention after final stent removal. All patients were followed at the institution transplant clinic through a combination of routine laboratory testing and clinical examination protocol. Stricture recurrence was defined as the return of clinical symptoms and/or elevated liver function tests with imaging evidence of obstruction at the anastomosis level causing biliary flow impairment requiring a subsequent interventional procedure in a patient previously considered successfully treated.

The primary outcome was anastomotic stricture resolution rate. Secondary outcomes were technical success rate, number or ERCPs required per patient,

Table 1 Summary of patients characteristics

number of stents placed, stent indwelling, follow-up duration, stricture recurrence rate and therapy for recurrent AS.

Descriptive statistics were used to summarize data. Data was reported as the mean, standard deviation and range. Recurrence data was analyzed by the Kaplan-Meier method. Statistical data analysis was performed by the author (Martins FP) and reviewed by Hospital Israelita Albert Einstein Statistics Department.

RESULTS

A total of 195 post-OLT patients were referred to our Endoscopy Unit with a suspected biliary complication between May 2006 and June 2014. One hundred and sixty-four (164) patients were diagnosed with anastomotic biliary stricture (Figure 2).

Patients were divided into 2 groups, according to the type of stent used (multiple plastic or covered self-expandable metal stents), which was chosen on a case-by-case basis (Table 1). Both groups were similar concerning gender, age, time from OLT to anastomotic stricture and associated biliary or hepatic artery lesions.

Among the 164 patients with confirmed post-OLT anastomotic biliary stricture, initial technical success was obtained in 157 (95.7%); 109 individuals being treated with plastic stents and 48 with cSEMS (16 PCSEMS and 32 FCSEMS). Percutaneous trans-hepatic cholangiography was required in 11 (7.0%) patients to achieve access due to high-grade stricture or sharp angulation at the anastomosis. After percutaneous approach cSEMS were used in 7 and plastic stents in 4 cases.

Seven patients failed initial ERCP: 3 were referred to surgery (hepatic-jejunal anastomosis), 2 received external trans-hepatic biliary drainage, one was referred to re-transplantation and one died due to multiple organ failure after an episode of severe acute pancreatitis.

cSEMS: Covered self-expandable metal stents; ERCP: Endoscopic retrograde cholangiopancreatographys.

A total of 341 ERCPs were performed. Ten patients in the cSEMS group and 9 in the plastic stent group still have the stents in place and were excluded from analysis. Mean treatment duration, number of procedures and stents required were lower in the metal stent group (Table 2).

Acute pancreatitis was the most common procedure related complication, occurring in 17.1% in the cSEMS and 4.1% in the plastic stent group (Table 2). Other 4 patients (5.7%) presented abdominal pain without pancreatitis, requiring hospital admission to receive intravenous analgesics. Among stent related complications, migration was the most frequent, observed in 4.3% and 5.5% of patients with metal and plastic stents respectively.

There was one death (0.3%) related to severe acute pancreatitis in one patient who was also a technical failure.

There was no lost of follow-up until the primary outcome. Stricture resolution was achieved in 86.8% in the cSEMS group (Figure 3) and in 91% in the multiple plastic stents group (Figure 4). There were 5 failures in the cSEMS group, two of them presented spontaneous distal stent migration (Figure 5).

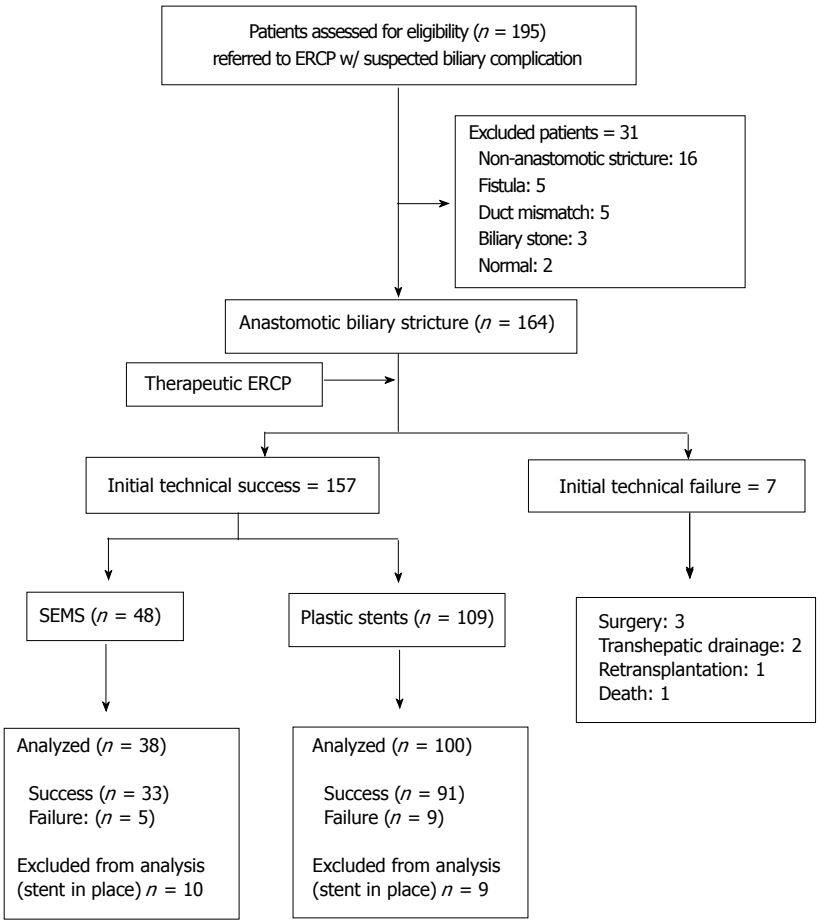

Figure 2 Flow chart of patients in the study. ERCP: Endoscopic retrograde cholangiopancreatographys; SEMS: Stent-expandable metal stents.

Table 3 Summary of the patients outcomes *n* (%)

Failure	6 (37.5)	1 (6.7)
In treatment	0 (0.0)	3 (20.0)
Lost of follow-up	0 (0.0)	1 (6.7)

cSEMS: Covered self-expandable metal stents.

Late stricture recurrence was observed in 10 (30.3%) patients in the cSEMS and 7 (7.7%) in the plastic stent group (Table 3). A Kaplan-Meier analysis (Figure 6) disclosed a statistically significant difference in the recurrence rate between both groups ($P = 0.0017$).

In the cSEMS group, 8 patients received re-treatment with multiple plastic stents, 2 received another cSEMS, 4 were referred to surgery and 1 lost of follow-up. In the multiple plastic stents group, secondary treatment consisted of cSEMS in 9 patients, multiple plastic stents in 4, surgery in 2 and PTC in 1 (choice of treatment in patients who failed initial treatment was decided by the referring physician). The results are summarized in Table 3.

DISCUSSION

Bile duct strictures after OLT are the most common biliary complication and have been classified according to their location into anastomotic strictures and non-anastomotic. They will be discussed separately in this paper as they differ in pathogenesis, presentation, natural history and response to treatment.

Anastomotic strictures present as a thin, short, localized and isolated narrowing in the area of biliary anastomosis as a result of fibrotic healing arising from ischemia at the end of both the donor and recipient bile duct[4,6,17]. They occur in 5% to 15% of patients after deceased OLT and 19% to 32% after living donor liver transplantation (LDLT)[3,4,6,18,19]. Early presentation

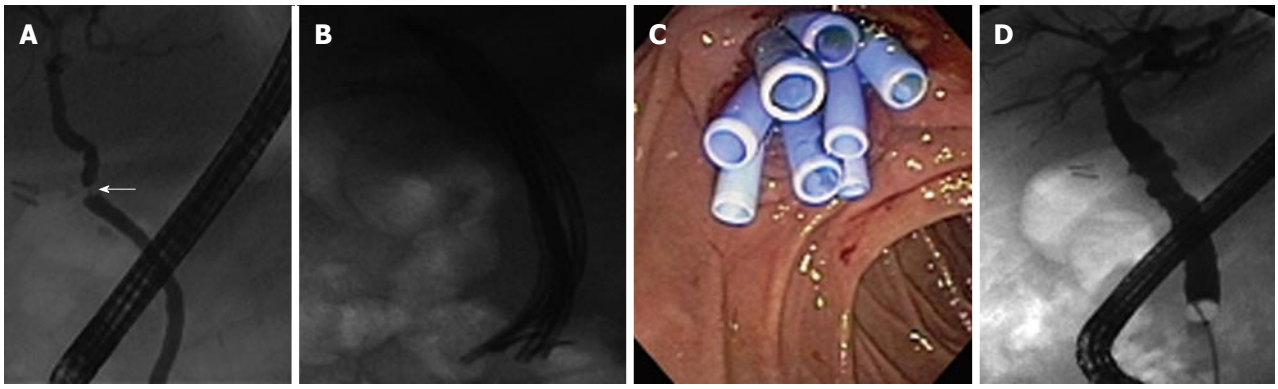

Figure 3 Patient with post-orthotopic liver transplantation anastomotic stricture from index endoscopic retrograde cholangiopancreatographys. A: Retrograde cholangiogram demonstrating post-OLT anastomotic stricture (arrow); B: Patient was treated with progressive multiple plastic stents; C: Patient was treated with progressive multiple plastic stents; D: Final cholangiogram revealing complete stricture resolution. OLT: Orthotopic liver transplantation.

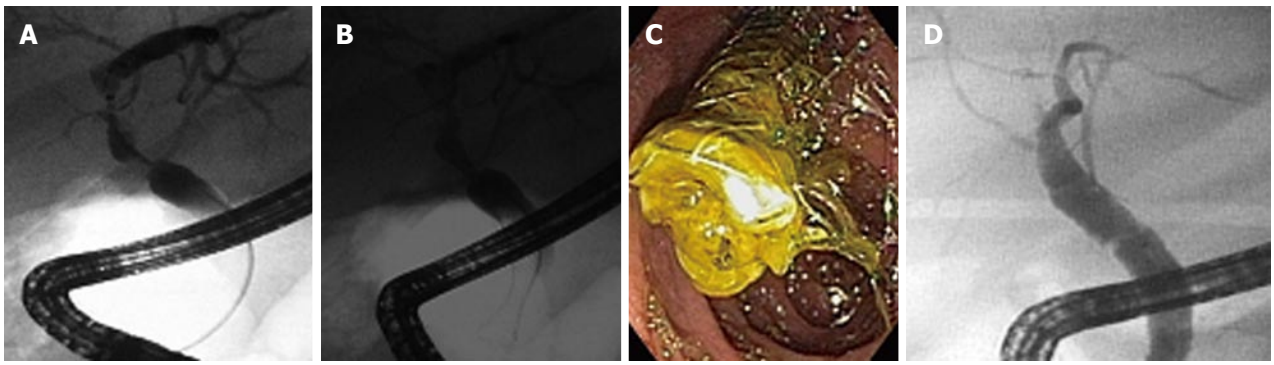

Figure 4 Patient with post-orthotopic liver transplantation anastomotic stricture. OLT: Orthotopic liver transplantation; FCSEMS: Fully covered stent-expandable metal stents.

Figure 5 Recurrent anastomotic stricture after fully covered stent-expandable metal stents distal migration.

(within 12 wk) of anastomotic strictures have been related to technical issues, such as, small caliber of bile ducts, mismatch in size between donor and recipient ducts, inappropriate surgical techniques including suture material, tension at the anastomosis and excessive use of electrocautery[20]. The presence of bile leak has been reported as an independent risk factor for the development of AS; the underlying process may be related to the inflammation and subsequent fibrosis as a local effect caused by the bile itself or it may be a marker of poor vascularity in those patients in whom the leak is not originated from the cystic stump[8,21]. Late strictures are mainly due to vascular insufficiency, ischemia and problems with healing and fibrosis[12,22].

The majority of anastomotic stricture develops within the first year after OLT. In our series, the mean time between OLT and biliary stricture presentation was about 7 mo. Patients usually present asymptomatic or may have non-specific symptoms with abnormalities in liver function chemistries. Clinical suspicious must be confirmed by imaging diagnostic tools and patients are then referred to treatment, accordingly to the algorithm presented above.

There has been a transition over the past two decades in the primary management of benign biliary strictures from surgery to minimally invasive *via* ERCP. Endoscopic therapy presents a lower complication rate and shorter hospital stay when compared to surgery, not compromising the option of operation in case of failure[23,24]. Percutaneous therapy is still considered a second line option for patients with duct-to-duct anastomosis, though reserved to failed endoscopic

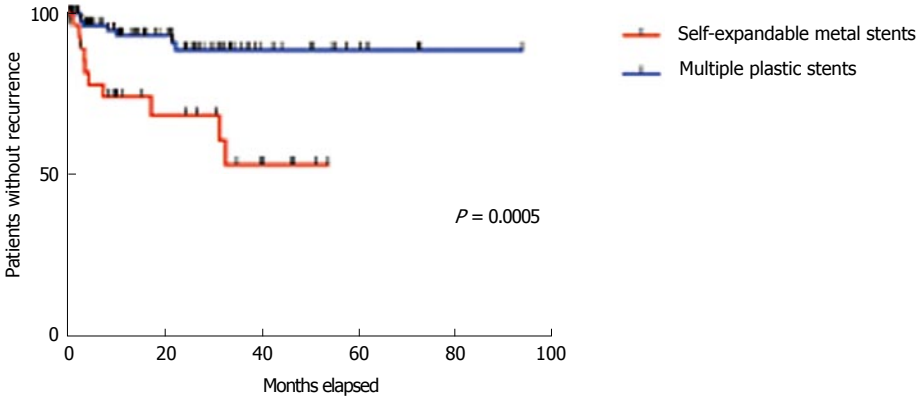

Figure 6 Stricture recurrence after resolution.

access to the anastomotic stricture, and patients with hepaticojejunostomy or choledochojejunostomy reconstruction. Currently surgical revision is confined for patients who have failed endoscopic and percutaneous therapy with re-transplantation being the final option.

Most patients with anastomotic stricture require multiple endoscopic interventions at 3-mo intervals for 12 to 24 mo with balloon dilation and long-term stenting[4,6,7,19,25-29]. The rational for multiple biliary stents placement through the stricture is to maintain the maximal expansion in luminal diameter achieved during balloon dilation, possibly promoting the re-modelation of bile ducts over the stents and preventing duct narrowing when stents are still in place[27,30]. In addition, the use of multiple stents may reduce complications related to stent occlusion, such as obstructive jaundice and cholangitis by adding biliary drainage through interstent channels[27,30,31].

A recent systematic review showed that stricture resolution rates were 78.3% for stent indwelling of less than 12 mo, compared with 97% for those longer than 1 year. The corresponding recurrence rates were 14.2% and 1.5% respectively[32].

In our center, we adopted an aggressive multiple plastic prophylactic stent exchange protocol over 1 year period, achieving a stricture resolution rate of 91%, which compares favorably with literature results. Recurrence rate after a mean follow-up of approximately 2 years is as low as 7.7%, reinforcing the benefits of extending the treatment up to 1 year.

A recent multivariate regression analysis was published assessing the outcome of endoscopic treatment of biliary complications after OLT[5]. Patients who received a graft from living donor or from a donor after cardiac death and those who had a reoperation for a non-biliary indication within the first month after liver transplantation were less likely to respond to endoscopic therapy[5]. Another factor apparently associated to stricture recurrence is the presence of a biliary leakage at initial ERCP[33]. On the other hand, early onset strictures seem to respond better and this finding may be related to the fact that those with late-onset are likely to be more fibrotic and therefore tighter and more resistant to therapy[8,27,33,34]. However, in case of recurrence, patients appear to respond well to repeated endoscopic treatment[8,27,30,35].

The major drawbacks of endoscopic treatment with balloon dilation and multiple plastic stents placement are the need of multiple procedures. Partially or fully covered SEMS were introduced on the market and became a very appealing option for benign biliary strictures due to their removability[36-49].

Post OLT biliary strictures offer an anatomical advantage for the placement of SEMS, which is the presence of the graft duct, permitting enough space above the stenosis to accommodate the metal stent distant from the hepatic confluence. Kahaleh *et al*[44] have been pioneer in the use of SEMS for benign biliary strictures of different etiology. Firstly, by describing metallic stent removability[44] and afterwards testing partially and fully covered SEMS in different clinical and technical settings[42,43,50-52].

Temporary placement of FCSEMS in patients with post-OLT anastomotic strictures refractory to conventional endoscopic therapy reached 87.5% to 100% initial success rate with a 4.5% to 7.4% recurrence. The major drawback of FCSEMS use was migration; occurring in 27.2% to 37.5%, even though with no clinical consequences[36,40,46].

In a systematic review that included 21 studies, multiple plastic stents were compared with metal stents in post liver transplant anastomotic stricture. There was significant heterogeneity in stent protocols, types of SEMS used, the use of balloon dilation or plastic stents before SEMS placement, primary outcome and stent free follow-up. There were no randomized controlled trials or non-randomized studies comparing these two modalities. Two hundred patients treated with SEMS were analyzed and stricture resolution rate was 80% to 94% when stent indwelling was longer than 3 mo, very similar to a 94% to 100% rate seen with multiple plastic stent for at least 12 mo. Moreover SEMS were used as a second line therapy for refractory strictures in 125 of these patients, what can be considered a

selection bias for more difficult strictures. The main problem with SEMS was stent migration, occurring in 16% of cases[32]. The rate of stricture resolution is lower in patients with FCSEMS migration[32,46,48].

In our study, we analyzed 38 post OLT patients with anastomotic stricture treated with cSEMS as a first line approach, reaching a stricture resolution of 86.8% after a mean stent indwelling of 124.2 d. Although the initial success was comparable with the currently standard multiple plastic stent treatment, there was a 30.3% recurrence rate after a mean of 310 d. We wonder if this higher recurrence rate was due to the shorter stent indwelling or the smaller final diameter of a 10 mm (30 French) cSEMS compared with the maximum number of plastic stents (up to 90 French per ERCP session) achieved in the other group.

We presented a mid-term evaluation of our randomized controlled trial comparing cSEMS with multiple plastic stents at DDW 2013. Although success rate was similar between groups, mean treatment duration and number of procedures required were statistically lower in cSEMS group ($P < 0.001$ for both comparisons). Moreover in our prospective trial, the mean total diameter for plastic stent group was 59 French (range 20 to 104.5 French)[47].

In summary, temporary placement of FCSEMS has been demonstrated effective and safe in the treatment of post OLT anastomotic strictures and should be considered for patients with refractory strictures[36,40,42,43,49]. On the basis of the current data, FCSEMS may allow anastomotic biliary stricture resolution with fewer procedure sessions possibly reducing treatment global cost, with the initial high price of a SEMS being compensated by the reduction in the number of ERCPs and the total number of plastic stents used during the 12-mo treatment period[53].

Questions remain about the optimal stenting interval and ideal metal stent. Concerning the first question, FCSEMS may be left in place for longer periods than partially covered ones, but prospective randomized studies with long-term follow-up are necessary to confirm this concept. The pursue for the ideal SEMS is still ongoing, it should be fully covered with an inert and resistant coating and have no fins, which seem to be associated to significant tissue reaction.

Concerning complications rate, in our study, the rate of post procedure acute pancreatitis in the plastic stent group was 4.1%, which compares favorably with the literature reports[54,55]. However, the rate of pancreatitis in the cSEMS group was 17.1%, which is exceedingly high even for a high-risk population.

Biliary sphincterotomy is usually not performed before SEMS placement in malignant biliary obstructions and therefore in the first 16 cases in our study cSEMS were deployed without one. The high incidence of acute pancreatitis (50% in the first 16 cases) came to our attention raising a debate over the impact of the sphincterotomy preceding metal stent deployment in a benign biliary stricture. Moreover, the severity of the event after cSEMS placement without sphincterotomy was also alarming, since 1 case was severe, 5 moderate and 2 mild.

The main hypothesis was that placing a trans-papillary metal stent in a native papilla without prior sphincterotomy was the main reason for the high rate of post procedure pancreatitis. Differently from patients with malignant obstruction that probably have already pancreatic parenchymal atrophy secondary to insidious pancreatic distal obstruction and therefore do not present acute pancreatitis after trans-papillary SEMS[56] Currently in our practice, all cSMES are placed after a biliary sphincterotomy in the post-OLT anastomotic stricture what drastically decreased acute pancreatitis rate to 12.5% (4/32) and all events were mild.

Although advances in surgical technique, organ preservation and selection have been made, biliary complications remain a significant source of morbidity in post liver transplant patients. Endoscopic treatment is already established as standard first line therapy. Progressive balloon dilation and multiple plastic stenting have been considered the first treatment option for biliary stricture in patients with duct-to-duct anastomosis. Our study shows encouraging results regarding placement of biliary cSEMS as the therapeutic endoscopic choice aiming to reduce the number of procedures and thus have a positive impact in cost, morbidity and quality of life of these patients, however their complication rate needs to be further evaluated.

COMMENTS

Background

Biliary complications have been considered for a long time the technical "Achiles heel" of orthotopic liver transplantation (OLT), with biliary strictures incidence up to 40% of patients. The standard strategy for post OLT biliary strictures in patients with duct-to-duct anastomosis has been balloon dilation followed by insertion of multiple plastic stents. Recently, covered self-expandable metal stents (cSEMS) has been increasingly used in the management of benign biliary strictures.

Research frontiers

The major drawback of conventional endoscopic treatment with multiple plastic stents placement is the need of multiple procedures. cSEMS have removability previously demonstrated in published studies and longer patency. In the area of benign biliary lesions, the current research hotspot is to evaluate the effectiveness and adverse events related to cSEMS.

Innovations and breakthroughs

Current evidence does not suggest a clear advantage of SEMS use over multiple plastic sten. In the study although success rates were similar, mean treatment duration and number of procedures required were statistically lower in cSEMS group. On the basis of the current data, fully covered stent- EMS may allow anastomotic biliary stricture resolution with fewer procedure sessions possibly reducing treatment global cost, with the initial high price of a SEMS being compensated by the reduction in the number of endoscopic retrograde cholangiopancreatographys and the total number of plastic stents used during the 12-mo treatment period.

Applications

Conventional endoscopic treatment with progressive balloon dilation and multiple plastic stenting has been considered the first option for post-OLT biliary stricture for decades. The study shows encouraging results regarding placement of biliary cSEMS as the therapeutic endoscopic choice aiming to reduce the number of procedures and thus have a positive impact in cost, morbidity and quality of life of these patients, however the complication rate

needs to be further evaluated.

Terminology

Anastomotic biliary strictures in the post-OLT scenario present as a short narrowing at the area of choledochal anastomosis. Endoscopic therapy can be performed by standardized protocols either with multiple plastic or single metal stents. Multiple plastic stents are placed after sphincterotomy and stricture balloon dilation, exchanged at 3-mo interval, until 12 mo of therapy. cSEMS are deployed at the index procedure and removed after approximately 6 mo.

Peer-review

This is a good descriptive study in which the authors analyzed the effectiveness and safety of endoscopic therapy in the management of post-OLT anastomotic biliary stricture. The results are interesting and suggest that cSEMS is a potential therapeutic option to multiple plastic stents that could be used for reducing the number of procedures and overall costs.

Abstract

Full thickness gastrointestinal defects such as perforations, leaks, and fistulae are a relatively common result of many of the endoscopic and surgical procedures performed in modern health care. As the number of these procedures increases, so too will the number of resultant defects. Historically, these were all treated by open surgical means with the associated morbidity and mortality. With the recent advent of advanced endoscopic techniques, these defects can be treated definitively while avoiding an open surgical procedure. Here we explore the various techniques and tools that are currently available for the treatment of gastrointestinal defects including through the scope clips, endoscopic suturing devices, over the scope clips, sealants, endoluminal stents, endoscopic suction devices, and fistula plugs. As fistulae represent the most recalcitrant of defects, we focus this editorial on a multimodal approach of treatment. This includes optimization of nutrition, treatment of infection, ablation of tracts, removal of foreign bodies, and treatment of distal obstructions. We believe that by addressing all of these factors at the time of attempted closure, the patient is optimized and has the best chance at long-term closure. However, even with all of these factors addressed, failure does occur and in those cases, endoscopic therapies may still play a role in that they allow the patient to avoid a definitive surgical therapy for a time while nutrition is optimized, and infections are addressed.

Key words: Perforation; Fistula; Anastomotic leak; Over the scope clips; Overstitch; Stent; Endoscopic

Core tip: Endoscopic methods are replacing surgical options as the first line therapy for a wide array of gastrointestinal tract defects. Here we will review the available endoscopic modalities, their appropriate applications and their respective success rates. The fusion of standard surgical principles with flexible, intra-luminal modalities is likely to be the key to the successful endoscopic management of these challenging clinical problems.

Winder JS, Pauli EM. Comprehensive management of full-thickness luminal defects: The next frontier of gastrointestinal endoscopy. *World J Gastrointest Endosc* 2015; 7(8): 758-768 Available from: URL: http://www.wjgnet.com/1948-5190/full/v7/i8/758.htm DOI: http://dx.doi.org/10.4253/wjge.v7.i8.758

INTRODUCTION

Whether in the form acute perforations, acute or sub-acute anastomotic leaks or chronic fistulae, full-thickness gastrointestinal (GI) tract defects remain a challenging and highly morbid healthcare problem. According to the Center for Disease Control (CDC) over 6 million abdominal procedures (including upper and lower endoscopies) were performed in the United States in 2010[1]. As the number of abdominal procedures performed annually in the United States increases, the number of full thickness GI defects that occur as a result will also increase. Historically, full-thickness luminal defects mandated surgical exploration (with its associated high rates of morbidity and mortality)[2,3]. Recent advancements in the comprehensive endoscopic management of GI defects have yielded encouraging results.

In centers of expertise, endoscopic methods have begun to replace surgical options as the first line therapy for a wide array of GI tract defects[4-6]. Here we will review the available endoscopic modalities, their appropriate applications and their respective success rates. The fusion of standard surgical principles with flexible, intra-luminal modalities is likely to be the key to the successful endoscopic management of these challenging clinical problems. Much like polyp resection, gastrostomy tube insertion and GI bleeding, we believe that surgery for full-thickness luminal defects will shortly be relegated only to patients who fail endoscopic therapy in the majority of cases[7].

SCOPE OF THE PROBLEM

GI tract defects include perforations, anastomotic leaks and fistulae and occur with numerous disease states as well as following a wide array of endoscopic, surgical and radiologic procedures. They vary greatly in their presentation and in their associated morbidity and mortality; an acute esophageal perforation from an endoscope and a persistent gastro-cutaneous fistula following gastrostomy tube removal are clearly different clinical entities. Yet until recently, these processes were thought of similar when endoscopic modalities were considered. As the volume of cases within which endoscopic closure could be attempted increases, it becomes increasingly clear that a spectrum of endoscopic therapies is necessary.

Technical limitations are not the only hurdle to overcome in the complete endoscopic management of these conditions. Many surgeons are unaware of or unwilling to permit (and/or not able to perform themselves) the application of novel therapies to patients who have perforations, leaks or fistulae. Many endoscopists with the skill and expertise to manage full thickness perforations do not have access to the patients presenting with these problems (unless they are the result of an iatrogenic endoscopic injury). There is therefore a disconnect between those individuals with the knowledge and skill to manage full thickness perforations and those who are evaluating and caring for the patients. The volume of this patient population is not inconsequential. The spectrum of diseases to which endoscopic methods could be applied includes:

Esophageal

The incidence of acute perforations during esophagogastroduodenoscopy (EGD) is approximately 0.03%[8,9]. One series of 217, 507 EGD procedures had a perforation rate of 0.033% with the esophagus being injured most commonly (51%)[9]. That same series showed a mortality rate of 17% despite intervention. The CDC reported that the total number of upper endoscopies performed in the United States in 2010 (including both diagnostic and therapeutic) was 1.1 million[1]. With an average perforation rate of 0.03%, this would equal 330 perforations.

Anastomotic leaks after esophagectomy ranges from 8%-10%[10,11]. Furthermore, patients with esophageal leaks after surgical resection have an increased mortality rate ranging from 18%-35% compared to patients undergoing similar procedures without leaks[10,12-14].

Gastric

Postoperative gastric leaks range from 1.7%-2.5% after Roux-en-Y gastric bypass (RYGB) and 1.5%-7% after sleeve gastrectomy[5,15-17]. The mortality rate for patients who develop leak ranges from 0.6%-14%[18,19]. The American Society for Metabolic and Bariatric Surgery reported that the number of bariatric surgeries performed in the United States is steadily rising with 158000 cases in 2011 and 179000 cases in 2013.

Iatrogenic gastric perforations during upper endoscopy are rare, but it is the site of injury in 3% of all iatrogenic injuries during both diagnostic and therapeutic EGD[9].

Gastrogastric fistulae occur in patients who underwent Roux-en-Y gastric bypass and develop a fistulous connection between the gastric pouch and the native bypassed stomach that is left *in-situ*. In one series of 1292 patients who underwent Roux-en-Y gastric bypass, 1.2% developed gastrogastric fistulae[20].

Gastrocutaneous (GC) fistulae represent an abnormal connection between the stomach and the skin. GC fistulae can occur at the site of percutaneous endoscopic gastrostomy (PEG) tubes, which are subsequently removed. In the vast majority of cases, these fistulous tracts close spontaneously after the PEG tube is removed. However, in 1.1% of cases these fistulae persist[21,22]. Approximately 216000 PEG tubes

are placed each year[21].

Duodenal and small bowel

Worldwide, peptic ulcer disease affects 4 million people annually[23]. Between 2%-14% of those ulcers will perforate with mortality ranging from 10%-40%[24,25]. In the setting of acute perforation during upper endoscopy, the duodenum is the location of perforation in 32% of cases[9].

Enterocutaneous (EC) fistulae, or tracts from the small bowel to the skin, are a devastating complication of abdominal surgery with mortality rates approaching 20%[26]. Patients with EC fistulae suffer from malnutrition, dehydration, skin excoriation, infection and sepsis. Although the largest percentage of EC fistulae are in patients with Crohn's disease, other inflammatory processes, malignancy, abdominal surgery, trauma, and radiation are all well-known causes[27].

Colon

The incidence of acute colonic perforations during screening colonoscopies ranges from 0.07% to 0.082%[15,28]. These numbers are similar for both screening and therapeutic colonoscopies. In 2010 there were roughly 500000 colonoscopies performed in the United States which would mean that there were approximately 400 perforations[1].

Fistula formation from the colon to other structures or to the skin is most commonly due to diverticular disease, but may also occur in patients after surgical intervention. In one review from the Cleveland Clinic of all patients treated for diverticular disease from 1960 to 1986, 20.4% had internal fistulae with colovesicular fistulae being the most common (65%)[29]. In one series examining colocutaneous fistulae, 88 of 93 patients (94.6%) were following surgery[30].

The incidence of leaks after colorectal resection and anastomosis ranges from 2.6%-26.2%[31]. Many patients who develop an anastomotic leak and require reoperation ultimately receive a permanent stoma[32,33]. Historically, the majority of these cases were treated surgically with the associated morbidity and difficulty of caring for these patients who are often in extremis. The advent of multiple endoscopic techniques and modalities has provided a safe and effective alternative to open surgical management of these complex problems[34].

Other conditions

There are a myriad of other types and combinations of GI tract leaks that are potentially addressable endoscopically including those related to cancer, radiation therapy, urologic procedures and radiologic interventions. Radiation therapy to the abdomen for other reasons can result in abdominal pathology including perforation and fistulae in up to 5% of patients[35]. In one review of fluoroscopically placed intraperitoneal chemotherapy catheters 6 of 750 patients (0.8%) experienced bowel perforation at the time of catheter placement[36].

When one considers the total volume of patients who present with a full thickness GI tract defect, it becomes clear that endoscopic therapies have the ability to change the way we think about managing a wide array of complex disease states.

AVAILABLE ENDOSCOPIC THERAPIES IN THE ACUTE OR CHRONIC SETTING AND THEIR OUTCOMES

The majority of the published literature describing the success of endoscopic management of GI defects consists of small case series and retrospective reviews. To date, there have been no randomized trials to evaluate the efficacy of endoscopic management versus traditional surgical management. The small reported successes of endoscopic management compared to the increased morbidity and mortality associated with surgical management of these disease processes are pushing the use of endoscopic therapies forward and expanding their scope of application. Larger, randomized trials need to be performed to further establish the following endoscopic therapies as both effective and superior to open surgical techniques.

It should be emphasized that the chronicity of the defect has implications about its etiology. Csendes *et al*[37] defined defects appearing 1-4 d as acute, 5-9 d as intermediate, and 10 or more days as late. Leaks presenting less than 2 d from the procedure likely represent a technical error such as stapler misfire or tissue injury while leaks presenting 5-7 d after the procedure more often represent ischemia[38].

Acute GI perforations are those that are identified at the time of injury or immediately afterwards by the sequelae that most commonly accompany perforations including fever, tachycardia, elevated white blood cell count, abdominal pain, peritonitis, systemic inflammatory response syndrome, and sepsis[39]. Early diagnosis and treatment of the defect is essential for improved patient outcomes[37].

Chronic defects are evidenced by contained fluid collections, or established fistulae to the skin or other tubular structures. The success of endoscopic therapies in the setting of longstanding leaks and fistulae has been more limited with fistulae being particularly difficult to manage[40-43]. Our experience has been similar to what has previously been reported. Since 2012 we have endoscopically managed 14 patients with GI fistulae and 6 patients with leaks and achieved a long-term closure rate of 64% and 100% respectively[44]. We believe there are multiple factors affecting the outcome in more chronic GI defects that we will explore in more detail later.

Through the scope clips

Endoscopic clips that are passed through the endoscopic working channel and are deployed within the lumen of the GI tract were initially designed for hemostasis and endoluminal marking (Figure 1). They are also

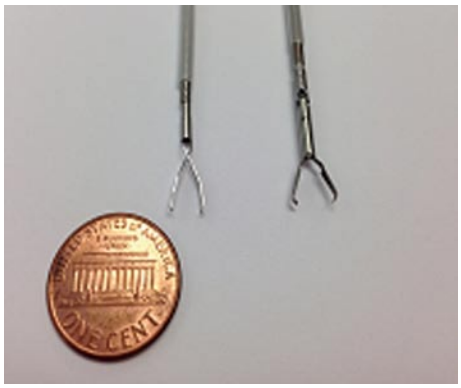

Figure 1 Examples of through the scope clips prior to deployment. Left: QuickClip 2 (Olympus Medical Systems Co., Tokyo, Japan); Right: Resolution Clip (Boston Scientific, Marlborough, MA).

referred to as through the scope clips (TTSC), hemoclips and endoclips. In the late 1990's, reports emerged describing their use as a method to close gastric and colonic perforations[45,46]. Although effective at closing smaller defects, the ability to close larger defects is quite poor due to the small size of the clips, the low grasping force that they generate and the inability to grasp deeper tissues[45]. They are more effective at closing surgically incised tissue with straight regular edges, as opposed to tissue that was bluntly perforated with irregular, striated or gaping edges. Their effectiveness at closing surgically incised mucosal edges has been well documented in the areas of submucosal dissection and POEM (Figure 2)[47-50].

TTSC have been shown to be successful in closing iatrogenic defects in the GI tract with clinical success rates ranging from 59%-83%[51,52]. It is felt that the limitation to their success is their small size, small closing force and mucosa-only tissue apposition, although in the right setting such as small defects that are not gaping, they can be quite effective.

These two factors about endoclip use have introduced bias into the initial clinical experience with acute GI tract perforations. Many acute defects are successfully closed with readily available endoscopic equipment and therefore escape the preview of surgical consultation. Larger defects are more likely to be unsuccessfully managed with TTSC clips and therefore surgeons receive a biased view of the true success rate of the most commonly applied endoscopic therapy.

Endoscopic suturing devices

The endoscopic suturing platform (Overstitch, Apollo Endosurgery, Austin, TX) is a disposable device that is attached to the end of a therapeutic double channel endoscope (Figure 3). It allows for placement of full-thickness absorbable or non-absorbable sutures. The device can be used multiple times without the need to remove the scope from the patient. The sutures can also be applied in a running or interrupted fashion (including simple and figure-of-8 sutures). Since its introduction, it has been successfully used in the closure of GI fistulae, acute perforations and at sites of endoscopic resection[53,54].

Endoscopic suturing devices have been found to provide safe and effective suturing. In one human *in-vivo* study, the Overstitch device was found to place sutures consistently at a subserosal depth in the colon without full thickness penetration or injury to adjacent structures[55]. It has been used successfully in the closure of staple-line leaks after sleeve gastrectomy, anchoring stents to help prevent migration, and closing gastrogastric fistulae[6,54,56,57]. However, the long-term success has been mixed with one study of 95 patients with gastrogastric fistulae achieving a 35% long-term closure rate[58].

Stents

The use of stents as a diversion method in full thickness GI defects is a non-FDA approved use that has been widely accepted by surgeons and endoscopists alike as a method for defect management. Stent deployment at the site of the defect helps by allowing diversion of enteric contents away from the defect. Multiple types of stent have been studied including metallic (partially or completely covered), plastic (covered, expandable), and biodegradable (Figure 4). Stent placement often permits continued enteral nutrition and can be used in cases of larger defect (> 1.5 cm)[59-61]. Although stents have been successful at treating GI defects, they are prone to migration in as much as 20%-30% of cases and require frequent observation with radiographic monitoring[61,62]. This has been addressed with techniques using TTSC and endoscopic suturing devices to anchor the stent in place. Stents also do not create a complete seal within the GI tract and, although variable in its amount, leak around stents is a near universal finding. Percutaneous placement of enteric stents have also been effective in patients with high-output EC fistulas by decreasing the output of the fistula, improving wound care, TPN requirements, and oral diet tolerance[63].

There is a large body of evidence supporting the use of stents in the treatment of GI defects. A recent meta-analysis of 7 studies of stent placement for acute leak after bariatric surgery showed a radiographically confirmed closure rate after stent removal of 87.8% (95%CI: 79.4%-94.2%)[64]. That same analysis showed a migration rate of 16.9% and only 9% of patients undergoing reoperation. Some authors advocate for clip placement to anchor the stents to help prevent migration. One study used 2 to 4 endoscopic clips to anchor the stent in 23 of 44 consecutive patients and found that stent migration occurred in 13% of patients with clips and 34% of patients without[65].

Sealants

Tissue adhesives and hemostatic agents, including fibrin sealant, have been used with varying degrees of success in the management of GI track defects. Fibrin sealant is composed of fibrinogen and thrombin, which are combined to make an acellular clot at the site of

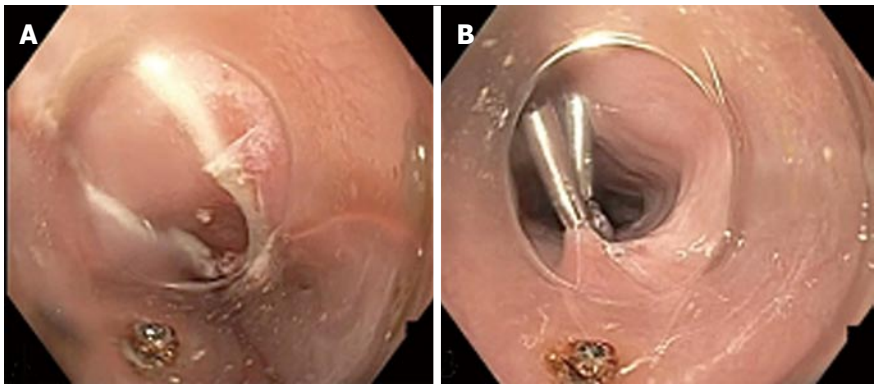

Figure 2 Endoscopic view of mucosotomy during peroral endoscopic myotomy. A: Esophageal mucosal defect after completion of peroral endoscopic myotomy; B: Defect closed with sequentially placed through the scope clips.

application. In one report fibrin glue was injected into the submucosa of a tracheoesophageal fistula causing a wheal and subsequent occlusion of the fistula in a pediatric patient[66]. In another series of 15 patients with persistent fistulae after conservative treatment, fibrin glue was used to occlude the fistula opening and resulted in long-term closure in 86.6% of patients after a mean of 2.5 sessions[67]. Tissue adhesives and sealants will likely be utilized primarily as an adjunct therapy to the definitive closure of leaks with an alternative method (such as a clip or suturing device).

Fistula plugs

SurgiSIS AFP plugs (Cook Biotech, West Lafayette, IN) were developed for the use in anal fistulae and have been used successfully in the treatment of GC fistulae after bariatric surgery[68]. Porcine small intestinal submucosa (SIS) is a bioprosthetic collagen material used in many settings including hernia repair, dressings for venous stasis ulcers, and anal fistulae. One group used SurgiSIS strips to endoscopically occlude GI fistulae in 25 patients with an 80% long-term closure rate[69].

Vacuum-assisted devices

Vacuum-assisted sponge closure has been used in the setting of esophageal and colorectal defects. Porous sponge foam is cut to be just smaller than the defect and sutured to the end of a nasogastric feeding tube (Figure 5). This is then grasped with endoscopic graspers and introduced into the defect. The nasogastric tube is then placed on continuous external suction. This suction minimizes secretions escaping through the defect while increasing blood flow to the area. Furthermore, the sponge induces granulation of the surrounding tissue and promotes healing[70]. Sponges need to be changed every 2-3 d. Small defects with adjacent fluid collections that aren't septated are more amenable to this therapy.

Vacuum-assisted sponge devices have been used successfully in small esophageal defects. In one series of five patients with fluid collections related to a leak at an esophageal anastomosis, all 5 patients resolved their leak with vacuum-assisted sponge therapy. The median length of therapy was 28 d with 9 sponge changes. Two of the patients developed stenosis at the anastomosis and one suffered from a fatal hemorrhage after a dilation procedure revealed an aortoanastomotic fistula[70].

Managing leaks with endoscopically placed tubes

Other strategies for managing leaks from the GI tract

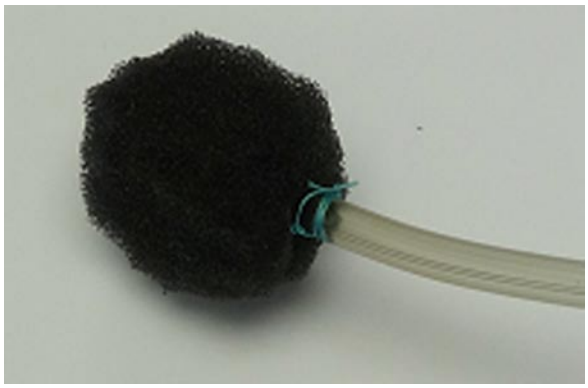

Figure 5 Vacuum-assisted closure device constructed of porous sponge and sutured to a nasogastric feeding tube.

Figure 6 Examples of the over the scope clips (Ovesco Endoscopy, Tubingen, Germany).

without repairing the defect include using the hole for other therapeutic modalities. Such "tube ostomy" formation is a standard surgical maneuver for difficult perforations in retroperitoneal organs like the colon and duodenum. In patients who presented with an acutely dislodged PEG tube and a leaking gastrotomy, the defect can be used to enter the abdominal cavity endoscopically, and replace the tube correctly, a so called "PEG rescue"[71]. We recently published a similar technique in a patient with a dislodged esophagostomy tube. By passing a wire from the cutaneous opening at the skin, securing this wire in the esophagus endoscopically, and drawing the wire out through the patients mouth, a new esophagostomy tube could be placed without any further surgical intervention[72]. Both of these examples illustrate the ability of the endoscopist to use established techniques to endoscopically manage what would traditionally be managed surgically.

Over the scope clips

Over the scope clips (OTSC) (Ovesco Endoscopy, Tubingen, Germany and Padlock, Aponos Medical, Kingston, NH) have gained popularity for the closure of GI track defects. Their ease of use, large capacity caps and short learning curve are the factors responsible for their surge in use.

Ovesco OTSC are made of elastic, biocompatible nitinol and are capable of full thickness closure of defects measuring 2 cm in diameter[73] (Figure 6). Two devices are available to use in conjunction with the OTSC to aid in apposition of the tissues prior to firing: a twin-grasper and a 3-pronged tissue anchor. Either device can be passed through the working channel and is used to secure the edges of the defect and draw them up into the cap prior to deployment of the OTSC. Because of the larger size of OTSC compared to TTSC they are able to close larger defects and take full-thickness bites of the tissue. They also provide a larger closure force due to their design. The Padlock device consists of a nitinol ring and a clear applicator cap that is placed on the end of the endoscope (Figure 7). Once deployed, the ring provides 360-degree tissue compression and approximation.

OTSC has been reported in many case series to be successful in closing acute perforations, leaks, and fistulae with long-term success rates ranging from 71%-100%[74-78]. A recent multi-centered international review examined 188 patients with acute perforations, leaks, and fistulae who were treated with OTSC and found that long-term closure rates were achieved in 90%, 73.3% and 42.9% respectively[79]. Since 2012 we have endoscopically treated 20 patients with the OTSC (6 with leaks and 14 with fistulae) resulting in a 100% and 64% closure rate respectively[44].

FACTORS LEADING TO SUCCESSFUL OUTCOMES

There are multiple factors that influence the ultimate closure rate in any endoscopic therapy, but common themes emerge in the literature in regards to closure rates. Defect size, that is the size of the luminal defect, not the length of the leak or fistula outside the GI tract, seems to play a role with smaller defects being easier to close than larger ones[58]. This is likely due to the technically difficult closure that larger defects present. Also, even though OTSC has been shown to close larger defects measuring up to 3 cm, in *ex-vivo* studies the bursting pressures have been much lower in repairs of larger defects compared to smaller ones[80]. Using the right tool for the type and location of the defect is crucial. Time from perforation to attempted closure certainly plays a role, with longer times being less successful[40-43]. Accurately measuring and appreciated the size of the defect and ensuring closure fluoroscopically at the time of attempted closure also play a role. Furthermore, the type of defect remains important, with acute perforations being more successfully closed than leaks or more chronic fistulae[41].

RECOMMENDATIONS FOR ENDOSCOPIC CLOSURE

When there is clinical suspicion for acute GI perforation, leak, or fistulae, at an area of the GI tract that is reachable by endoscopic means, we recommend prompt

Figure 7 Example of the Padlock over the scope clips (Aponos Medical, Kingston, NH).

Figure 8 Endoscopic removal of suture foreign body at the opening of a rectal stump fistula.

endoscopic evaluation and treatment. The absolute contraindication to endoscopic therapy is evidence of peritonitis on abdominal exam[73]. Prompt endoscopic intervention provides two major benefits: Firstly, the endoscopist is able to provide a direct evaluation of the location and extent of the defect, and secondly, they are able to provide timely therapeutic attempts at closure for those lesions that are appropriate for endoscopic management.

The method of closure in acute full thickness GI defects will be dictated by three factors: the location, the size, and the operator's proficiency and familiarity with each therapy. Smaller defects may be amenable to TTSC, while larger ones may require one or more deployments of the OTSC. Very proximal perforations may not be amenable to stenting due to the foreign-body sensation that many patients experience with proximal stenting that approaches the upper esophageal sphincter. In many cases of initial failure, multiple attempts with various modalities are often required to ultimately obtain long-term closure[81]. We previously described the use of laparoscopy and endoscopic stent placement for management of leaks following bariatric surgery, but have since moved to definitive endoscopic closure of all leaks with endoscopic suturing or over the scope clips[5]. We now reserve stent use for leaks not amenable to or that have failed previous attempts at definitive closure.

We do not recommend any one type of endoscopic therapy for any specific location in the GI tract. Rather, we recommend that the endoscopist become familiar with all treatment modalities so as to use whichever method he/she deems appropriate based on clinical judgment. We reemphasize that often these defects require multiple attempts with varying modalities to achieve long-term closure, thus familiarity with all types of endoscopic therapies is strongly encouraged.

Because endoscopic closure of fistulae has routinely achieved the lowest long-term success rates, we recommend adopting traditional surgical fistula management techniques jointly with endoscopic attempts at closure[82-85]. Addressing the factors described by the classic acronym FRIENDS (foreign bodies, radiation, infection/inflammation, epithelialization, neoplasm, distal obstruction, and steroids) in the setting of fistula management is imperative to long-term success. It has been our experience that by addressing these issues on a case-by-case basis, we have achieved somewhat higher closure rates in patients with long-term fistulae. Since 2012 we have endoscopically treated 14 patients with GI fistulae with the OTSC resulting in a 64% closure rate[44].

Foreign bodies at the endoluminal opening of any fistula will contribute to its persistence by the foreign body reaction that they perpetuate. We routinely remove any suture, indigestible food matter, or other foreign bodies present within fistulous tract (Figures 8 and 9). Furthermore, once external drains have effectively treated the fluid collection for which they were placed, they should be removed in conjunction with the endoscopic treatment of the fistulous opening.

Infection must be treated with adequate source control in the form of external drainage for infected fluid collections and organism-specific antibiotic coverage. If the patient displays hemodynamic instability or sepsis due to uncontrolled infection, surgical intervention may be warranted as endoscopic management is typically reserved for the more stable patient.

Inflammation at the site of the fistulous opening is a commonly sited factor for failed closure. It is felt that closure rates are lower due to the difficulty in achieving adequate tissue apposition due to the fibrotic and inflamed edges that are present at the fistula opening[86]. Cauterization of the margins of chronic fistulae has been advocated to facilitate subsequent closure with the OTSC[87]. We routinely ablate the margins prior to clip placement in all chronic fistulae.

Epithelialization of the fistula tract can be addressed by both mechanical and ablative techniques. We frequently use argon plasma coagulation to ablate the epithelialized surface of the fistula tract to help prevent recurrence (Figure 10)[88]. Other authors have described mechanical debridement with biopsy forceps or brushes to disrupt the epithelial lining that may be present with more chronic tracts.

Distal obstruction or stenosis may precipitate the

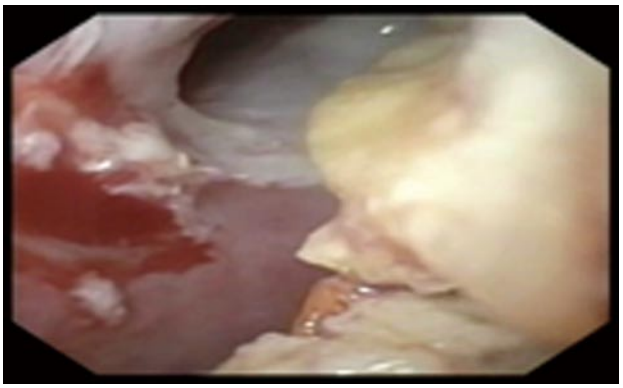

Figure 9 Undigested food within an esophago-cutaneous fistula tract.

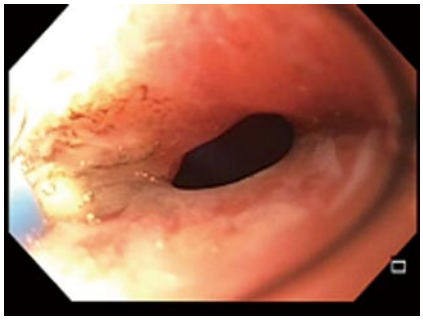

Figure 10 Circumferential argon plasma coagulation catheter ablating epithelialized fistula tract.

failure or breakdown of more proximal anastomoses or staple-lines[89]. When distal stenosis is discovered, this must be addressed concomitantly with any attempt to close proximal fistulae. Stenosis may be adequately treated with serial endoscopic dilations, though more recalcitrant strictures may require stenting (Figure 11)[90].

For the patient who is receiving steroid therapy for unrelated processes, coordination with the provider managing their steroids may provide a window where the steroid load can either be lessened or withheld for a period while endoscopic treatment is attempted. This may not be possible in all cases, but should be addressed on a case-by-case basis.

Maintaining adequate nutrition in these patients is imperative to promote healing. We recommend early enteral feeding in all cases possible. This may be achieved by obtaining feeding tube access distal to the site of the fistula such as a nasojejunal tube, or a percutaneous endoscopic jejunostomy tube. If this is not feasible, total parenteral nutrition may be initiated and continued until enteral feeding is tolerated.

In patients with acute perforations, endoscopic management alone may be sufficient for long-term success. In patients with chronic GI fistulae, all aspects of a patient's care must be optimized in order to achieve long-term success. Similar to the treatment of a patient with acute GI hemorrhage, multimodality endoscopic therapies may be required for more complex or chronic

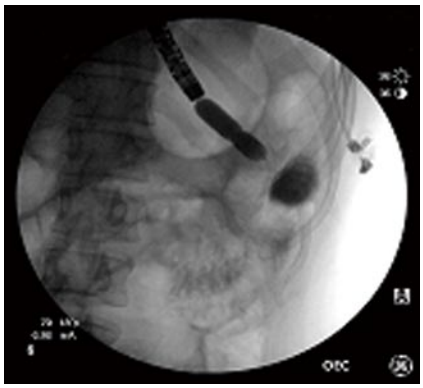

Figure 11 Endoscopic balloon-dilation of a stenotic gastrojejunostomy with adjacent jejunoanastomotic fistula.

GI tract perforation. A large gastro-gastric fistula after RYGB, for example, may require suture foreign body removal, argon plasma ablation of the epithelialized track, endoscopic suture closure of the largest portions of the defect, over the scope clip application to smaller portions and endoscopic dilation of a simultaneous gastro-jejunal anastomotic ulcer. Failure to address all of these issues will likely result in short term endoscopic failure.

Unfortunately, there will be patients who ultimately fail endoscopic therapy and will require surgical intervention. However, even in these patients, early endoscopic management can lessen the symptoms of high-output fistulae, enable patients to leave the hospital if even for a brief period, allow time for nutritional status to be improved, infections to be treated, and time for more in-depth operative planning that would otherwise not be available in the emergent setting.

CONCLUSION

There has been a great deal of advancement in the field of endoscopic treatment of full thickness GI defects with high rates of long-term closure. TTSCs, endoscopic suturing devices, stents, sealants, fistula plugs, vacuum-assisted devices, and OTSC have all been shown to be effective modalities. The treatment of acute perforations is generally more effective than the treatment of chronic fistulae. Because of this, we recommend a marriage of endoscopic therapies with classic fistula management to give the patient the best chance at long-term closure. Ultimately, even in the case of failure, endoscopic therapy can "buy time" for patient optimization prior to definitive surgical management.

Abstract

The rising use of nonanesthesiologist-administered sedation for gastrointestinal endoscopy has clinical significances. Most endoscopic patients require some forms of sedation and/or anesthesia. The goals of this sedation are to guard the patient's safety, minimize physical discomfort, to control behavior and to diminish psychological responses. Generally, moderate sedation for these procedures has been offered by the non-anesthesiologist by using benzodiazepines and/or opioids. Anesthesiologists and non-anesthesiologist personnel will need to work together for these challenges and for safety of the patients. The sedation training courses including clinical skills and knowledge are necessary for the registered nurses to facilitate the patient safety and the successful procedure. However, appropriate patient selection and preparation, adequate monitoring and regular training will ensure that the use of nurse-administered sedation is a feasible and safe technique for gastrointestinal endoscopic procedures.

Key words: Registered nurse; Sedation; Gastrointestinal endoscopy; Safety; Complication

Core tip: The registered nurse-administered sedation for gastrointestinal endoscopy (GIE) procedures has clinical consequences. Generally, moderate (conscious) sedation for these procedures has been offered by the registered nurses by using benzodiazepines and/or opioids. Sedation training courses including clinical skills and knowledge are necessary for the registered nurses to facilitate the patient safety and the successful procedure. However, appropriate patient selection and preparation, adequate monitoring and regular training as well as anesthesiologist consultation in high risk cases and procedures will ensure the use of sedation by registered nurses is a safe and effective technique in GIE procedure.

INTRODUCTION

Currently, gastrointestinal endoscopy (GIE) procedure is usually performed for diagnosis and treatment of gastrointestinal abnormalities. The need for sedation is depended on the patient physical status, degree of endoscopic difficulty and type of endoscopy, duration of procedure and physicians' preferences. The best methods for sedation during these GIE procedures are still controversial[1]. Endoscopic sedation can be administered by the trained nurse. However, the nurse administering sedation must be skilled to manage the oversedated patients[2,3]. The aim of the report is to present the current knowledge and the clinical application for routine clinical practice concerning the registered nurse-administered sedation for GIE procedures.

DEFINITIONS

Several guidelines created by the American Society of Anesthesiologists (ASA)[4] and the American Academy of Pediatrics[5] created the guidelines and definitions of procedural sedation.

Minimal (mild) sedation
