World J Gastrointest Endosc 2016 January 10; 8(1): 1-29

Editorial Board

2014-2017

The *World Journal of Gastrointestinal Endoscopy* Editorial Board consists of 330 members, representing a team of worldwide experts in gastrointestinal endoscopy. They are from 40 countries, including Australia (3), Austria (3), Brazil (6), Canada (3), China (62), Croatia (1), Czech Republic (1), Denmark (1), Ecuador (1), Egypt (3), France (1), Germany (8), Greece (10), Hungary (2), India (11), Indonesia (1), Iran (6), Iraq (1), Ireland (2), Israel (1), Italy (37), Japan (43), Lebanon (1), Lithuania (1), Malaysia (1), Mexico (4), Netherlands (1), Norway (2), Poland (4), Portugal (5), Romania (1), Singapore (3), Slovenia (2), South Korea (19), Spain (9), Thailand (2), Turkey (11), United Arab Emirates (1), United Kingdom (14), and United States (43).

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Yong-Liang Zhu, PhD, Assistant Professor, Second Affiliated Hospital of College of Medicine, Zhejiang University, Hangzhou 310009, Zhejiang Province, China

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Thomson Reuters Web of Science Emerging Sources Citation Index, PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Confocal laser endomicroscopy permits *in-vivo* microscopy evaluation during endoscopy procedures. It can be used in all the parts of the gastrointestinal tract and includes: Esophagus, stomach, small bowel, colon, biliary tract through and endoscopic retrograde

cholangiopancreatography and pancreas through needles during endoscopic ultrasound procedures. Many researches demonstrated a high correlation of results between confocal laser endomicroscopy and histopathology in the diagnosis of gastrointestinal lesions; with accuracy in about 86% to 96%. Moreover, in spite that histopathology remains the gold-standard technique for final diagnosis of any diseases; a considerable number of misdiagnosis rate could be present due to many factors such as interpretation mistakes, biopsy site inaccuracy, or number of biopsies. Theoretically; with the diagnostic accuracy rates of confocal laser endomicroscopy could help in a daily practice to improve diagnosis and treatment management of the patients. However, it is still not routinely used in the clinical practice due to many factors such as cost of the procedure, lack of codification and reimbursement in some countries, absence of standard of care indications, availability, physician image-interpretation training, medico-legal problems, and the role of the pathologist. These limitations are relative, and solutions could be found based on new researches focused to solve these barriers.

Key words: Confocal laser endomicroscopy; *In-vivo* microscopy; Barret esophagus; Gastrointestinal cancer; Confocal laser endomicroscopy probe

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Confocal laser endomicroscopy (CLE) permits *in-vivo* microscopy evaluation during endoscopy procedures. It can be used in all the parts of the gastrointestinal tract with accuracy in about 86% to 96%. In spite of its high accuracy as well as several clinical applications, CLE is still not used in routine clinical practice. This could be correlated to many factors such as: cost of the procedure, lack of codification and reimbursement in some countries, absence of standard of care indications, availability, physician image-interpretation training, medico-legal problems, and the role of the pathologist. However, these limitations are relative, and solutions could be found

based on new research leading to increased consensus overcoming present barriers.

Robles-Medranda C. Confocal endomicroscopy: Is it time to move on? *World J Gastrointest Endosc* 2016; 8(1): 1-3 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i1/1.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i1.1>

INTRODUCTION

Confocal laser endomicroscopy (CLE) is an advanced endoscopic imaging modality that provides histology-like images at 1000-fold magnification for *in-vivo* microscopy evaluation^[1]. Since the first publication about the use of CLE in the gastrointestinal tract, ten years have passed^[2].

The technology was initially developed for an endoscope-integrated CLE system (e-CLE) (EC3870K, Pentax Medical, Japan) with specific applications to upper and lower endoscopy, and a few years later for a probe-based CLE system (p-CLE) (Cellvizio, Mauna Kea Technologies, France)^[1,2].

Nowadays only p-CLE is commercially available, with the advantage that it can be used in other parts of gastrointestinal tract as in bilio-pancreatic diseases through endoscopic retrograde cholangiopancreatography and endoscopic ultrasound.

Several studies have demonstrated a high correlation of results between CLE and histopathology in gastrointestinal lesions^[1,2]. In fact, CLE has overcome some of the limitations found in endoscopy (macroscopy) and histopathology (microscopy), thus improving patient management.

In spite of its high accuracy and several clinical applications, CLE is still not routinely used in the clinical practice due to many barriers.

CLINICAL EVIDENCE AND APPLICATIONS

It has been demonstrated that white light endoscopy is not accurate for predicting histological inflammation or other alterations such as nonspecific erythema, nodularity, erosions, etc.^[3].

Moreover, the limits between neoplastic and inflammatory areas are very narrow/unclear due to the coexistence of these processes together.

When using CLE during endoscopy we can clearly understand why the correlation between standard videoendoscopy and histopathology is not higher than 70% in most cases^[4].

Many studies evidence an accuracy of 81.5% using p-CLE for the diagnosis of dysplasia in Barrett esophagus^[5].

In gastric diseases, CLE has had an accuracy of 94%-96% for diagnosis of malignancy when compared directly with histological biopsies^[6]; and 88% for pre-malignant conditions such as intestinal metaplasia^[7].

In colon conditions, CLE has had an accuracy of 82%

for predicting polyp histology *in-vivo*, increasing to 94% if used in combination with digital chromoendoscopy with narrow band imaging during procedures^[8]. Moreover, in inflammatory bowel diseases (IBDs), various studies have examined the role of CLE in surveillance of IBD patients, assessing the extent of disease, targeting biopsies, earlier detection of dysplasia, assessment of mucosal healing, and defining treatment protocols^[9,10].

Recently, new applications in the biliary tract and for diagnosing subtypes of pancreatic cysts have been studied showing a mean accuracy of 85% for diagnosis of neoplastic and non-neoplastic lesions^[11,12].

IS IT TIME TO MOVE ON?

In spite of its high accuracy as well as several clinical applications, CLE is still not used in routine clinical practice. This could be correlated to many factors such as: cost of the procedure, lack of codification and reimbursement in some countries, absence of standard of care indications, availability, physician image-interpretation training, medico-legal problems, and the role of the pathologist.

However, these limitations are relative, and solutions could be found based on new research leading to increased consensus overcoming present barriers. Examples of this could be: cost-effective studies and analysis, meta-analysis, learning curve studies, etc.

A recent study performed at our institution demonstrated the benefit of using CLE in cases of "diagnostic doubts", causing changes in diagnostic and therapeutic approach in 40% of cases, in the performance of target biopsies in 100% of cases (17/17) and making other diagnostic or therapeutic methods unnecessary in all cases^[13].

In this regard, a patient with Barrett esophagus and dysplasia at histopathology but without dysplasia criteria at high definition with chromoendoscopy could have diagnosis benefits using CLE. Other examples are: patients with biliary tract stenosis of unknown origin where citobrush did not evidence neoplasia, and the difficult management during follow-up repetitions. In both cases, need of newer tests and examinations, biopsies, etc., will be unnecessary, reducing the cost management of these patients.

One of the biggest problems when using CLE, is that histopathology remains the gold-standard technique for final diagnosis of diseases. However, histopathology could have a 20% to 30% misdiagnosis rate due to many factors such as interpretation mistakes, biopsy site inaccuracy, or number of biopsies^[4].

Another suggestion would be to use CLE in cases where other investigative procedures have shown an absence of malignancy as a method of confirmation of the negative results. This would eliminate many of the medical and cost-related problems mentioned above. The rationale for this is based on the fact that 9 out of 10 biopsies are benign and that the accuracy of CLE to confirm non-neoplastic lesions is higher than its

accuracy for confirming positive neo-plastic results.

FUTURE PERSPECTIVES

New studies focused on solving the relative barriers in using CLE are currently necessary. The results obtained during the last ten years validate the use of CLE in clinical practice, and the first step to doing this could be dealing with patients with diagnostic uncertainties. This could improve and solve many unclear diagnoses as well as improve therapeutic decisions and/or follow-up procedures in this kind of patient.

Abstract

Effective colorectal cancer screening relies on reliable colonoscopy findings which are themselves dependent on adequate bowel cleansing. Research has consistently demonstrated that inadequate bowel preparation adversely affects the adenoma detection rate and leads gastroenterologists to recommend earlier follow up than is consistent with published guidelines. Poor preparation affects as many as 30% of colonoscopies and contributes to an increased cost of colonoscopies. Patient tolerability is strongly affected by the preparation chosen and manner in which it is administered. Poor tolerability is, in turn, associated with lower quality bowel preparations. Recently, several new developments in both agents being used for bowel preparation and in the timing of administration have brought endoscopists closer to achieving the goal of effective, reliable, safe, and tolerable regimens. Historically, large volume preparations given in a single dose were administered to patients in order to achieve adequate bowel cleansing. These were poorly tolerated, and the unpleasant taste of and significant side effects produced by these large volume regimens contributed significantly to patients' inability to reliably complete the preparation and to a reluctance to repeat the procedure. Smaller volumes, including preparations that are administered as tablets to be consumed with water, given as split doses have significantly improved both the patient experience and efficacy, and an appreciation of the importance of the preparation to colonoscopy interval have produced additional cleansing.

Key words: Bowel preparation; Colonoscopy; Adenoma detection rate; MiraLAX; Polyethylene glycol; Sodium picosulfate; Oral sulfate solution

Core tip: Improvements in efficacy and tolerability of

bowel preparation include new formulations that are more tolerable to patients without sacrificing efficacy or safety, and a better understanding of the ideal timing of bowel preparation administration.

Harrison NM, Hjelkrem MC. Bowel cleansing before colonoscopy: Balancing efficacy, safety, cost and patient tolerance. *World J Gastrointest Endosc* 2016; 8(1): 4-12 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i1/4.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i1.4>

INTRODUCTION

Many patients describe the bowel preparation prior to colonoscopy as the most unpleasant part of the whole procedure and the biggest deterrent to repeating it. Unfortunately, in addition to being the most loathed aspect, the bowel preparation is one of the most critical components of effective screening for colon cancer. The ideal bowel preparation, though this has not yet been developed, is one that is safe, highly effective and reliable, convenient, and tolerable enough that patients are not deterred from repeating the procedure.

Inadequate bowel preparations lead to lower adenoma detection rates and more frequent follow up intervals than would otherwise be recommended by guidelines based on colonoscopy findings. The European Panel of Appropriateness of Gastrointestinal Endoscopy found that polyp detection was related to the quality of bowel cleansing^[1]. Relative to a low quality preparation, a high quality or intermediate quality preparation produced a 1.46 and 1.73 odds ratio (OR) of polyp detection^[1]. Sherer *et al*^[2] found a lower detection rate of advanced histology in the setting of poor preparation, though the number of polyps 6-9 mm detected was not different. In studies that have looked at early repeat colonoscopy following a suboptimal preparation, the quality of preparation is strongly associated with incidence of missed polyps and adenomas^[3-5]. Lebwahl *et al*^[3] found a 42% overall miss rate after inadequate bowel prep with a 47% miss rate for adenomas less than 10 mm and 27% miss rate for adenomas greater or equal to 10 mm. Hong *et al*^[4] found that the adenoma detection rate decreased as the quality of bowel prep decreased with a precipitous drop off seen as the quality decreased from fair to poor. Ultimately, the adenoma detection rate was associated with patient tolerability with an OR of 0.39 in the setting of poorly tolerated preparations^[6].

The evidence for the benefit of bowel preparation prior to colorectal surgery is less convincing. While it remains the overwhelming practice of surgeons to prescribe a mechanical bowel preparation, studies have not convincingly showed that it reduces the incidence of mortality, skin and soft tissue infections, or peritonitis as compared to no preparation^[7]. Recent studies have supported the use of oral and parenteral antibiotics prior

to procedure. As with the preparation for endoscopy, there is no clear superiority of one regimen over another.

Poor preparation is not an uncommon occurrence. Rates of inadequate bowel preparation are estimated to be as high as 30.2% with as many as 10% being so poor as to preclude any further evaluation^[8]. Due to the increased risk of missed polyps and decreased efficacy of screening in the face of a poor bowel prep, research has found that, in patients with a poor bowel prep, gastroenterologists are less likely to adhere to recommended screening intervals and more frequently recommend closer follow up than would otherwise be appropriate based on intra-procedure findings^[9-11]. Shortened follow up intervals translate into increased screening costs, estimated to be as much as a 12% to 22% increase, and greater inconvenience to patients^[12].

A 4 L preparation of polyethylene glycol (PEG) has been considered the gold standard in terms of prep efficacy but is reviled by patients due to its poor taste and discomfort associated with the larger volumes. Alternate formulations have been developed, but these have had other drawbacks in terms of safety, tolerability, or efficacy. Recently, new options have received Food and Drug Administration (FDA) approval and these may offer improved tolerability without sacrificing efficacy (Table 1).

POLYETHELENE GLYCOL

Four liters PEG-ELS (electrolyte lavage solution) administered in split doses is considered by most to be the standard against which all other bowel preparations are judged^[13]. A systemic review and meta-analysis by Enestvedt *et al*^[13] found an OR of 3.46 that a split dose 4 L PEG-ELS preparation would produce a good or excellent bowel preparation compared with other methods. The pooled analysis did not reveal any other significant differences in performance measures such as overall experience or willingness of patients to repeat the procedure, or in side effects such as nausea.

Nonetheless, many studies conclude that patients prefer lower volume preparations to the full 4 L PEG. Often preceded by a stimulant laxative such as bisacodyl or magnesium citrate, 2 L PEG preparations have been found to achieve equivalent levels of bowel cleansing with enhanced patient experience^[14-19]. A 1994 study comparing single dose preparations of 4 L PEG-ELS with 2 L PEG-ELS preceded by bisacodyl found comparable cleansing^[14]. The subjects in the 2 L PEG-ELS group rated the preparation more tolerable and more patients were able to complete the preparation than in the 4 L group (93% vs 66%). Sharma *et al*^[15] found similar results in a trial comparing 4 L PEG-ELS with 2 L PEG-ELS with bisacodyl or magnesium citrate. The quality of preparation was rated better with 2 L PEG-ELS with bisacodyl or magnesium citrate than with 4 L PEG-ELS (8.1 vs 7.8 vs 7.3). This was coupled with lower procedure times and higher patient

satisfaction scores. Of 24 subjects who had a previous bowel prep with 4 L PEG-ELS, 88% of those in the 2 L PEG-ELS plus magnesium citrate and 56% of those in the 2 L PEG-ELS plus bisacodyl preferred the low volume preparation. A follow up study by the same group found small, likely clinically insignificant serum electrolyte changes following low dose PEG-ELS with stimulant laxatives^[20]. A low volume PEG plus ascorbic acid in comparison with 4 L PEG-ELS produced an equivalent number of adequate bowel preps (94.6% vs 90%), was better tolerated and produced fewer adverse events (80.2% vs 89.9%)^[21]. Similar results have been obtained in other studies though some have shown that cleansing in the right colon was superior with the 4 L PEG preparation^[22,23].

The relative efficacy of the 2 L PEG preparations is undiminished when it is administered as a split dose^[24,25]. A 2013 study of 2 L PEG-citrate plus bisacodyl and simethicone found that successful preps were achieved in 92.8% vs 92.1% of patients using the 2 L PEG and 4 L PEG respectively^[24]. A higher percentage of excellent right colon preps were observed in the 4 L PEG group. The 2 L PEG prep was better tolerated (31.6% reporting symptoms vs 45.2%) and more patients expressed willingness to repeat the same procedure in the future (90.6% vs 77%). Similar results were obtained using split dose 2 L PEG-ascorbic acid alone^[25]. There was no significant difference in the quality of bowel prep or number of patients achieving an adequate bowel prep in 2 L vs 4 L groups (7.0 ± 2.1 vs 7.1 ± 2.0 and 73.2% vs 76.3%)^[25]. The low volume preparation was rated significantly more tolerable with 14.3% of subjects reporting difficulty in taking the preparation vs 30.7% with the 4 L PEG preparation^[25].

MIRALAX

Though it has not been FDA approved for the purpose, MiraLAX (Bayer Healthcare, Leverkusen, Germany)

has come into widespread use as a bowel prep agent in spite of equivocal evidence supporting its efficacy as compared to FDA approved alternatives due to the convenience of using an over the counter product and superior palatability. A recent survey of practicing gastroenterologists found that one third regularly recommend some sort of MiraLAX based bowel prep to their patients with rates as high as 50% in suburban practices and a positive correlation between the number of colonoscopies performed and the likelihood of recommending a MiraLAX based bowel prep^[26]. MiraLAX based bowel preps, typically 238 mg of MiraLAX in 64oz of Gatorade, has generally, though not universally, been found to be more tolerable to patients^[27-30].

The data regarding the cleansing achieved with MiraLAX is more mixed. McKenna *et al.*^[30] found that single dose MiraLAX was non-inferior compared to 4 L of PEG-ELS, both taken the night before procedure. Both MiraLAX and PEG-ELS produced equivalent BBPS (7.0 vs 7.2) and had similar percentages of patients achieving adequate bowl preps (BBPS ≥ 6, 81.3% vs 84.3%). The authors found no difference in time to cecal intubation or withdrawal time. MiraLAX was preferred by study subjects. Similar results were obtained in a study by Samarasena *et al.*^[28] comparing split dose MiraLAX with split dose PEG-ELS. Again, no significant difference in BBPS (8.01 vs 8.33) was observed and the MiraLAX based prep was given significantly better ratings in terms of taste and tolerability with 96.8% vs 75% of subjects willing to repeat the prep in the future. A comparison of MiraLAX in Gatorade plus bisacodyl with 4 L PEG-ELS found superior results overall (93.3% vs 89.3% with excellent/good cleansing) and equivalent results when the analysis was limited to only ASA class 1 patients of which there were more in the 4 L PEG-ELS group^[31]. The authors noted that the increased rate of adequate preparations derived primarily from more frequent good and less frequent fair preparations.

Other researchers have found inferior bowel prep

with MiraLAX based regimens compared with PEG-ELS. Hjelkrem *et al.*^[27] compared split doses of 4 L PEG-ELS with MiraLAX (alone and with either bisacodyl or lubiprostone) and demonstrated inferior preps with all of the MiraLAX based preps (Ottawa score of 5.1 vs 6.9, 6.3, and 6.8). Cleansing was adequate with all preps, but there was a higher incidence of excellent preps in the Golytely arm (49% vs 15%, 20%, and 19%). No difference in adenoma detection rates was observed. A lower rate of excellent prep and overall inferior BBPS was also observed by Enesvedt *et al.*^[29] when comparing MiraLAX with 4 L PEG-ELS. PEG-ELS produced a mean BBPS of 9% and 70% of preps were rated excellent which was superior to a mean BBPS of 8% and 55% of preps rated excellent for MiraLAX. A follow up study by Enesvedt *et al.*^[32] comparing MiraLAX with PEG-ELS showed that, in addition to less frequently achieving a BBPS greater than or equal to 7, MiraLAX was associated with a lower adenoma detection rate (16.1% vs 26.2% with PEG-ELS).

There have been concerns about the safety of MiraLAX for bowel preparation after reports of severe hyponatremia^[33]. Unlike the electrolyte solutions used for prescription bowel preps, the sports drink (typically Gatorade) is not osmotically balanced and is relatively hypotonic. Two randomized controlled trials have since demonstrated comparable safety with standard 4 L PEG preparations^[28,30]. Neither trial detected a clinically or statistically significant difference in serum electrolytes. Though, the study populations were relatively small and may not detect very infrequent adverse events, it is reassuring that not even a trend toward greater electrolyte abnormalities was observed.

SODIUM PHOSPHATE

Sodium phosphate (NaP) is an osmotic laxative that was initially prescribed as a more tolerable alternative to whole gut lavage with PEG preparations. It was widely used and well tolerated by patients as a much smaller volume of fluid was required for successful prep; however, concerns about safety and confounding mucosal changes have limited the use of this agent more recently. Because of concerns of significant electrolyte disturbances and even acute renal failure, the use of sodium phosphate preps is not recommended in multiple populations including patients over the age of 55, patients taking certain medications such as angiotensin converting enzyme inhibitors (ACEi), and those with pre-existing renal disease, heart failure, and liver disease. Sodium phosphate carries a black box warning regarding the risk of acute phosphate nephropathy.

In comparison to single dose 4 L PEG-ELS, NaP produced equivalent to superior bowel cleansing with improved patient tolerability^[34-38]. The greater tolerability of NaP as compared to PEG preparation has been nearly universal^[35-38]. Subjects, including 37 who had been prepped with PEG for prior colonoscopy, rated NaP easier

to complete and less uncomfortable^[35].

Unfortunately, in spite of its superior tolerability, NaP is not without significant adverse side effects^[39]. Hyperphosphatemia following NaP has been well documented in patients with both normal and impaired renal function and has been associated with hypocalcemia. Cases of acute phosphate nephropathy have largely occurred in patients with pre-existing renal disease, but have also occurred in setting of dehydration in patients with otherwise normal renal function^[40]. NaP is thought to cause renal injury by precipitating nephrocalcinosis^[39,40]. The risk of adverse events is increased patients taking ACEi or angiotensin receptor blockers and who are of advanced age^[39]. Additional suspected risk factors include existing renal disease, female gender, volume depletion, and abnormal bowel motility^[39].

NaP has also been reported to cause mucosal inflammation and ulcerations that give the appearance of inflammatory bowel disease. A randomized control trial compared patients receiving PEG-ELS with NaP and found an association between NaP use and the presence of nonspecific aphthoid like mucosal lesions^[41]. Lesions were present in 24.5% of subjects receiving NaP vs 2.3% of those receiving PEG. Though pathological evaluation of the lesions was not consistent with IBD, the authors reported that they were endoscopically similar to those seen in Crohn's disease. This association was substantiated in a larger observational trial of 730 patients who were administered a NaP bowel prep and followed for 3 years after the procedure^[42]. In this study, only 3.3% of patients exposed to NaP demonstrated mucosal lesions on endoscopy, but these lesions were of the type seen in anti-inflammatory drug induced injury and in IBD. As a result of these observations, NaP is not recommended in patients undergoing colonoscopy to evaluate for suspected IBD^[41,42].

ORAL SULFATE SOLUTION

Sulfate is a poorly absorbed anion that does not cause significant fluid or electrolyte shifts^[43,44]. In comparison with sodium phosphate, sodium sulfate produced more liquid stool and, unlike phosphate, did not increase the propensity for calcium to precipitate in renal tubules^[43]. Oral sulfate solution (OSS) is available in two formulations: SuPrep (two doses of sodium, phosphate, and magnesium sulfate; Braintree Laboratories, Braintree, MA) and Suclear (one dose of sodium, phosphate, and magnesium sulfate followed by a second dose of PEG 3350 in 2 L of water; Braintree Laboratories, Braintree, MA).

A 2009 study by Di Palma *et al.*^[44] demonstrated equivalent bowel cleansing with OSS and 2 L PEG-ELS given as single and split doses. Split dosing was superior to single dose for both preparations (82.4% and 80.3% vs 97.2% and 95.6% for OSS and PEG-ELS respectively). OSS was associated with a higher frequency of excellent preparations in the split dose arm

(63.3% vs 52.5%). A subsequent study by this group comparing split dose OSS (SuPrep) with single dose 4 L sulfate free PEG-ELS found a significantly higher rate of adequate and excellent preparations in the OSS group (98.4% vs 89.6% and 71.4% vs 34.4%)^[45]. OSS also resulted in less residual stool in the right colon. There were small changes in serum electrolytes with OSS which the authors reported as clinically insignificant. A third study by this group compared split dose OSS plus PEG-ELS (Suclear) with split dose 2 L PEG-ELS and OSS plus PEG-ELS given the night before procedure with 10 mg bisacodyl followed by 2 L PEG-ELS^[46]. The split dose administration produced equivalent rates of successful prep (93.5% in both arms). Single dose OSS with PEG-ELS was non-inferior to PEG-ELS given with bisacodyl (89.8% vs 83.5%) and associated with significantly more excellent preparations (47.7% vs 35.6%). In both arms of the study, OSS plus PEG-ELS was associated with a higher incidence of side effects (vomiting in the split dose arm and overall discomfort in single dose arm.) The authors looked specifically at the efficacy in the elderly (age ≥ 65) and found that the split dose OSS with PEG-ELS produced more successful preparations (93% vs 86%) in this population. Patients with pre-existing comorbidities (cardiac or renal disease, diabetes, and hypertension) had similar rates of adverse events with both preps.

SODIUM PICOSULFATE

Sodium picosulfate (PMC) is a stimulant laxative given in combination with an osmotic laxative component such as magnesium citrate or magnesium oxide and citric acid which combine to form magnesium citrate. PMC has been used extensively in Canada and Europe for the past 20 years, but was only recently approved for use as a bowel preparative agent in the United States. The formulation available in the United States, Prepik (Ferring Pharmaceuticals, Parsippany, NJ), is given as a split dose. Like sodium phosphate, this is a hyperosmolar preparation may not be suitable for patients with heart failure, renal insufficiency, end stage liver disease, or baseline electrolyte abnormalities. There have been reports of clinically significant hyponatremia following PMC bowel preparations and a retrospective cohort study by Weir *et al.*^[47] confirmed that use of PMC in patients older than 65 years was associated with an increased risk of 30 d hospitalization for hyponatremia, but not with increased risk of acute neurological symptoms or mortality.

Katz *et al.*^[48] compared PMC, given as single and split doses, with single dose 2 L PEG and bisacodyl administered the day before. Single dose PMC compared favorably with single dose PEG producing successful cleansing in 83.0% vs 79.7% or patients and comparable cleansing seen throughout all segments of the colon. Adverse events were similar between the two groups, and patient acceptability was significantly greater in the PMC arm. With split dose administration,

PMC performed significantly better than single dose 2 L PEG with bisacodyl^[49]. Good or excellent Aronchick scores were more frequent in the PMC arm in both the overall colon (84.2% vs 74.4%) and in the individual segments. Again, PMC was rated more tolerable than 2 L PEG. Similar results were observed by Kojecy *et al.*^[50] in a comparison of PMC and 4 L PEG in single and split doses. Split dose regimens were preferable regardless of the agent. Single dose PMC produced a higher percentage of acceptable preps compared to PEG (82.6% vs 73%). There was no significant difference in the number of subjects with adequate prep among the remaining study arms; split dose PMC (81.6%), single dose PMC (82.6%), and split dose PEG (87.3%). Both PMC based regimens were rated more tolerable than either PEG based prep. Single dose PEG was most associated with nausea and bloating. Single dose PMC had the least abdominal pain reported, but split dose PMC had the highest association with incontinence. There was a slight preference for the single dose PMC preparation among older subjects and for the split preparation in younger subjects. These findings have been replicated in other studies with PMC achieving similar percentages of adequate bowel cleansing compared with PEG while being significantly preferred by study subjects^[51,52]. Another study evaluated PMC alone versus in combination with PEG found little additional benefit with PEG^[53]. Only in the right colon was there a significant difference in Ottawa bowel prep scores between the PMC alone and PMC plus 2 L PEG groups (1.34 ± 1.022 vs 1.11 ± 0.97). As in other studies, the PMC alone regimen was preferred by patients (89% vs 72.3%) and had less associated nausea.

There has been only one study directly comparing PMC with OSS^[54]. Rex *et al.*^[54] found a higher rate of successful and excellent preparations with OSS in comparison with PMC (94.7% vs 85.7% and 54% vs 26%). Unlike the OSS arm, there were 4 patients in the PMC arm who required additional preparation before the procedure could be attempted and 9 patients in whom the cecum was not reached. There was no significant difference in the polyp detection rate (50.9% vs 42.9%), adenoma detection rate (26.0% vs 23.8%), or flat lesion detection rate (9.5% vs 4.8%), and no difference in the procedure duration (mean 16.5 min vs 16.6 min). There was no difference in adverse events in the two arms and, though nausea was generally mild in both arms, subjects taking PMC reported better scores for nausea (Table 2).

TIMING OF PREP

Regardless of the preparation used, the quality of preparation has proven higher with split dose vs day before administration. This has been demonstrated most clearly with PEG based preparations. A 2005 study compared 4 L PEG preparations given as a single dose with dietary restrictions on the evening before the procedure or as a split dose without dietary restrictions

Table 2 Advantages and disadvantages of available bowel preparations

Prep	Advantages	Disadvantages
4 L PEG	Effective Safe in most populations	Poor taste Very high volumes Poorly tolerated by patients
2 L PEG	Effective Safe in most populations	Poor taste High volumes High cost
MiraLAX	Well tolerated by patients Available over the counter Existing studies indicate it is safe	Not as effective as prescription PEG preparations Rare reports of hyponatremia
Sodium phosphate	Available as oral tab	Inappropriate for use in patients with renal disease, volume depletion, heart or liver failure, or who are taking ACEi or NSAIDs
Sodium picosulfate	Well tolerated by patients	Risk of acute phosphate nephropathy and subsequent chronic kidney disease Cost
OSS	Well tolerated by patients Small volumes to be ingested	Not as effective as PEG or OSS Inappropriate for patients with heart failure, renal insufficiency, end stage liver disease, or baseline electrolyte abnormalities
	Pleasant taste Well tolerated by patients Highly effective Available as oral tab	High cost High cost Not as well studied

PEG: Preparation of polyethylene glycol; ACEi: Angiotensin converting enzyme inhibitors; NSAIDs: Nonsteroidal anti-inflammatory drugs; OSS: Oral sulfate solution.

and found that, even without dietary restrictions, the split dose preparation produced significantly better preps^[55]. A randomized control trial of evening before vs split dose PEG preparations that included both high and low volume preparations found that, regardless of the volume of preparation, split dose administration produced significantly more successful preps (75.2% vs 43.0%) and a lower rate of aborted procedures (6.9% vs 21.2%)^[56]. A pre-post study by the Veteran's Health Administration assessed efficacy and acceptance of split dose bowel preps in an elderly populations with multiple co-morbidities and found that the split dose preparations were better tolerated by patients and produced superior results^[57]. Both right and left colon preparations were improved with split dose administration (excellent/good preps achieved in 81.4% vs 63% and 85.9% vs 71.6% respectively)^[57].

These results were validated in 2 meta-analyses^[58,59]. Kilgore *et al*^[58] included 5 trials in an analysis which found split dose PEG produced an OR of 3.7 of a satisfactory bowel preparation as well as improved patient tolerability. Martel *et al*^[59] obtained similar results in an analysis of 47 trials. In this study which included split dose preparations of PEG, NaP, and PMC, the OR of a successful prep with split vs evening before preparation was 2.51. Subjects reported greater willingness to repeat the split dose preparation.

Concerns have been raised about the risk of peri-procedural aspiration with split dose regimens. In 2010, Huffman *et al*^[60] examined 712 patients with EGD of which 254 had received split dose bowel preps for concurrent colonoscopy. While the residual gastric volume was higher in patients who received the split dose preparation as compared with patients scheduled

for EGD only (19.7 mL vs 14.6 mL), there was no difference between when compared with patients who received day before preparation (20.2 mL) and the 5 mL difference is unlikely to be clinically significant^[60].

Recent studies have shed light on the reason for the improved cleansing seen with split dose preparations and highlighted the importance of a short duration between the completion of a bowel prep and the start of the colonoscopy^[61-64]. A prospective analysis of colonoscopy start times and the time of the last dose of bowel prep showed an inverse relationship between the degree of cleansing and the length of this interval^[64]. Subsequent studies have reinforced this finding and clarified the ideal time interval between bowel prep and colonoscopy. Eun *et al*^[62] compared intervals of more and less than 7 h and of more and less than 4 h and found that, in each case, superior cleansing was seen with the shorter interval. A 3 to 5 h interval produced the best cleansing throughout the colon in a prospective study by Seo *et al*^[61], though the association was not as high as with the amount of PEG ingested (OR 1.85 for prep to colonoscopy time vs 4.34 for quantity of PEG ingested).

Following from these findings, researchers have looked at the feasibility of preparations completed entirely on the morning of the planned procedure^[65-67]. Varughese *et al*^[65] compared morning only preparation with preparation completed entirely the evening prior and, consistent with the finding that the interval between preparation and procedure is a determinant of the quality of preparation, found that morning only preparation is superior to evening before preparation. Matro *et al*^[66] compared morning only to split dose administration of PEG-ELS and found equivalent cleansing and adenoma detection with improved tolerability in the morning only

group. Similar findings were obtained by Longcroft-Wheaton *et al*^[67] in comparing morning only to split dose sodium picosulfate.

CONCLUSION

Effective, safe, and reliable options for bowel preparation are becoming increasingly available though the most tolerable options remain the most costly. Improved efficacy has also been achieved with alterations in the dosing schedule, namely split dose administration and a better understanding of the optimal interval between preparation and the colonoscopy. These adjustments have proven more tolerable as well as more effective. The consensus of the major Gastrointestinal Societies is that the choice of agent should be tailored to the individual patient, but that a split dose regimen can be recommended in all cases^[68,69]. Additional research is needed to develop tools to assist providers in choosing an optimal regimen for their patients as factors such as age and comorbid conditions may affect the efficacy and safety of a particular agent. The optimal choice of bowel preparation must be guided by the circumstances of the individual patient undergoing procedure; however, low volume PEG preparations would appear to come closest to being the ideal preparatory agent in that it is effective, generally well tolerated, has an excellent safety record in a population of patients with a range of comorbid conditions, and is relatively inexpensive. Ongoing studies are evaluating the impact of interventions such as improved pre-procedure patient education and smart phone based applications that remind patients of when to take their prep are showing promise with regard to improved patient tolerability and adherence and may offer a path toward both patient and endoscopist satisfaction.

Abstract

With advances in endoscopic technologies, endoscopic clips have been used widely and successfully in the treatment of various types of oesophageal perforations, anastomosis leakages and fistulas. Our aim was to summarize the experience with two types of clips: The

through-the-scope (TTS) clip and the over-the-scope clip (OTSC). We summarized the results of oesophageal perforation closure with endoscopic clips. We processed the data from 38 articles and 127 patients using PubMed search. Based on evidence thus far, it can be stated that both clips can be used in the treatment of early (< 24 h), iatrogenic, spontaneous oesophageal perforations in the case of limited injury or contamination. TTS clips are efficacious in the treatment of 10 mm lesions, while bigger (< 20 mm) lesions can be treated successfully with OTSC clips, whose effectiveness is similar to that of surgical treatment. However, the clinical success rate is significantly lower in the case of fistulas and in the treatment of anastomosis insufficiency. Tough prospective randomized multicentre trials, which produce the largest amount of evidence, are still missing. Based on experience so far, endoscopic clips represent a possible therapeutic alternative to surgery in the treatment of oesophageal perforations under well-defined conditions.

Key words: Oesophageal perforation; Endoscopic clipping; Upper gastrointestinal perforation; Endoscopy; Over-the-scope clip

INTRODUCTION

Despite remarkable advances in surgery and intensive care, oesophageal perforation is still a life-threatening condition^[1,2]. It is iatrogenic (caused by a device) in a majority of cases; perforation caused by a foreign body or trauma and spontaneous perforation are less frequent. Several well-known factors influence its course: location and cause of perforation, time from diagnosis until care, co-morbidities of the oesophagus, general condition of the patient and selected treatment^[3,4]. In addition to oesophageal perforation, suture insufficiency of the oesophagus and other oesophageal fistulas also pose serious therapeutic challenges nowadays.

With the development of endoscopic technology during the last two decades, endoscopic clips and self-expanding stents have been used successfully and ever more widely in the treatment of oesophageal perforations/fistulas of various origins^[5,6]. Oesophageal injury was first closed endoscopically with the placement of clips in 1995; the injury had occurred as a consequence of pneumatic dilatation in a patient with achalasia^[7]. Since then, this method has been used for oesophageal perforations of various aetiologies, including Boerhaave syndrome^[8-11]. To date, the method has been successful, especially in the treatment of small (< 2 cm) injuries. The following review article describes indications of endoscopy and endoscopic clips in the treatment of oesophageal perforation.

DISCUSSION

Aetiology of oesophageal perforation

Various causes of perforation or rupture of the oesophagus are well-known: iatrogenic, foreign body, postmictic (spontaneous, Boerhaave syndrome) trauma, tumour and surrounding inflammation. Iatrogenic injuries are still the most common cause; the second most common is spontaneous oesophageal rupture. These two types represent more than two-thirds of the perforations based on a number of publications from different countries^[12,13]. Suture insufficiency in the oesophagus (oesophageal/gastric resections and other sutures) and fistulas of various aetiologies fall into a separate group. In recent decades, the appearance and more widespread use of new therapeutic endoscopic methods have significantly increased the incidence of iatrogenic oesophageal perforations. It can be well determined which endoscopic

interventions confer increased risk of perforation: (1) dilatation of the oesophagus (balloon/bougie); (2) endoscopic resections [endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD)]; and (3) removal of a foreign body. Dilatation of the oesophagus is almost as old as endoscopy; however, this method is still not without risks. The risk of perforation is greatest in the case of balloon dilatation (especially due to achalasia), with an approximate 2% overall cumulative rate, which can be reduced if endoscopic guidance is provided and if a balloon with a small (30 mm) diameter is used at the beginning of the intervention^[14-16]. The risk of perforation in the dilatation treatment of peptic and other benign strictures is significantly lower with the use of a guide wire and a bougie (0.18%); however, in the case of malignant strictures, the risk of injury is increased again (0.48%)^[17]. In the case of endoscopic resections (EMR and ESD), the risk of perforation is similar to that of balloon dilatation (2%-3%)^[10,18].

Diagnosis of oesophageal perforation

A bidirectional chest X-ray is usually taken in addition to an oesophagogram with water-soluble contrast material to confirm perforation. The oesophagogram is the most common test procedure, but there are a number of false negative results (10%)^[19]. Nowadays, abdominal and thoracic CT examinations are also routine^[20]. The sensitivity of the CT examination is especially important in detecting a small amount of mediastinal/pleural air and/or fluid^[21,22]. If the examination is combined with an oesophagogram, the exact location of extravasation can be determined more precisely. An endoscopic examination^[23] may likewise be helpful in the diagnosis. Endoscopy is not only important in setting up the diagnosis, but also in confirming previously unknown accompanying co-morbidities of the oesophagus (such as tumour and stricture), which may significantly modify the treatment strategy. Endoscopy also offers an immediate treatment option (if the conditions are suitable), and it may also be helpful intraoperatively during surgical intervention (in checking whether the sutures are intact, in inserting a nasogastric/jejunal probe, etc.)^[23]. The diagnosis of a perforation is especially important in the case of an endoscopic intervention (EMS, ESD, balloon dilatation, etc.), which also determines therapy and prognosis^[24].

TREATMENT OF OESOPHAGEAL PERFORATION: GENERAL CONSIDERATIONS

Essential elements in the treatment of oesophageal perforation include resolving the source of the infection, operative or non-operative closure of the defect, and thoracic and mediastinal debridement. Important parts of therapy are controlling sepsis, intensive monitoring, targeted antibiotic/antimycotic treatment, fluid therapy

and strengthening the immune system of the body with enteral nutrition.

Several obvious factors determine treatment strategy and prognosis: (1) time of the diagnosis (delay); (2) localization of the perforation; (3) severity and size of the perforation; (4) presence of septic complications, physiologic reserves of the patient and existing co-morbidity of the oesophagus; and (5) the experience of the professionals providing care.

Primary closure of the oesophagus is successful in more than 90% of cases if the defect is closed within 24 h and there were no co-morbidities in the oesophagus (tumour, stricture, *etc.*)^[25,26]. In this phase, tissues are not oedematic and are easy to suture/close; in addition, there is no active bacterial infection in the thoracic cavity and/or mediastinum. If the perforation occurred more than 24 h beforehand, the prognosis is significantly reduced due to rapidly developing septic complications and less successful surgical/conservative treatment^[12,27].

It is well-known that thoracic transmural injuries of the oesophagus have the worst prognosis due to rapidly developing mediastinitis and sepsis, followed by injury of the abdominal segment, while perforation in the cervical segment has the best prognosis.

Intramural injuries usually respond well to conservative treatment. Transmural and transpleural injuries represent the worst defects. Treatment strategy is also essentially influenced by the size of the defect. These factors are especially important in using the endoscopic technique (see below).

General stress tolerance of the patient, existing co-morbidities and severe septic condition are known to worsen the prognosis^[12,27]. Existing co-morbidities of the oesophagus are especially important in selecting a treatment option, but may also influence the prognosis significantly (such as tumorous perforation).

Today, it is only possible to manage oesophageal perforations with multidisciplinary co-operation. The role of a surgeon experienced in the treatment of perforations and that of a gastroenterologist familiar with new innovative endoscopic techniques are decisive. Treatment has to be administered individually with an understanding of the general principles involved.

TREATMENT OPTIONS FOR OESOPHAGEAL PERFORATION

Endoscopic procedures representing a minimal or significantly lower burden are more widely used not only in the diagnosis of oesophageal perforation, but also in its treatment. A number of publications, especially case histories, demonstrate the successful use of endoscopic clips and self-expanding stents in the treatment of oesophageal injuries^[5,28]. The applicability of endoscopic methods has also been confirmed in experimental animal models (endoscopic clipping vs suturing vs thoracoscopic repair)^[29]. Endoscopic clipping basically results in the immediate resolution of the oesophageal defect, while

various types of stents aid in resolving extravasation from the oesophagus (diversion of enteral contents) and provide further slow healing of the injury. Stent implantation is mainly used in the treatment of large (> 2.5-3 cm) injuries of the middle and lower third segments of the oesophagus, and is especially suitable for the treatment of tumorous perforations where dysphagia is also resolved. Several types of stents are known, such as self-expanding plastic stents and fully and partially covered, self-expanding metal stents. In the case of injuries of the gastro-oesophageal junction, a partially covered stent is recommended with the smallest migration tendency if there is no oesophageal stricture^[30]. The success of the procedure also depends on early application. Any delay in endoscopic treatment significantly reduces the chances of healing of the oesophageal perforation, as is the case with other treatment options^[5]. According to the latest systematic review, the overall technical and clinical success rates of oesophageal stent placement in patient groups were 91% and 81%, respectively, and mortality was also acceptably low at 13%^[31]. One of the most common complications of stent implantation is stent migration, which occurs in 20.8% of cases; this percentage is lower (11%) in the case of metal stents and higher for plastic stents (27%)^[31]. However, stent migration may be reduced significantly with clips (proximal clip fixation^[32]).

Vacuum-assisted technology

A method providing permanent continuous suction/drainage, is used in a number of areas with high efficacy, such as in the treatment of open abdomen, chronic wounds and suture insufficiency (rectum and oesophagus)^[33]. The procedure is suitable for the treatment of chronic fistulas, particularly well-defined peri-oesophageal abscesses. It can also be used for intrathoracic oesophagus anastomosis insufficiency. It may be used to stimulate the formation of granulation tissue; therefore, the duration of prolonged secondary wound healing is decreased significantly^[34-36]. Due to excessive granulation tissue formation, oesophageal stenosis can occur later within a 6%-40% range, but with an incidence of 15% in most cases^[37]. Due to severe mediastinal/intrathoracic infection, the mortality rate is also naturally high (0%-20%) with this method^[37].

ENDOSCOPIC CLIPS

Endoscopic clips have been used in the treatment of oesophageal perforation for 20 years; however, the number of publications on their use has only increased during the last few years. Generally, experience is available with two types of clip: the through-the-scope (TTS) clip and the over-the-scope clip (OTSC). TTS clips were developed for haemostasis and the treatment of mucosal ruptures. However, they may only be used in treating small (< 10 mm) injuries due to their limited (< 11 mm) wingspan.

The wingspan of the OTSC (OVESCO Endoscopy,

Tübingen, Germany) is not significantly larger (11-14 mm), but the system also features a special applicator cap^[38]. The entire thickness of the tissue may be pulled into the cap by suction and/or with graspers, and the tissue may be united with special clamps (a bear claw). Experience shows that this innovative clipping device made of biocompatible nitinol also provides stronger closure of large (1-2 cm) defects^[39]. Nowadays, several types of clips are available (blunt/atraumatic and pointed-teeth/traumatic). There is also a special "anchor" which aids in the closure of fibrotic fistulas. It only takes an experienced endoscopic professional a few minutes to close a defect^[40]. One iatrogenic oesophageal injury has been reported with the use of this device when an endoscopic OTSC was inserted^[40]; the injury may have been caused by the 2 mm rim of the plastic cap. However, experience shows that the device can be used safely, and the complication rate is around 1%^[40,41].

CLOSURE OF OESOPHAGEAL PERFORATION WITH ENDOSCOPIC CLIPS

Tables 1 and 2 summarize the results of the PubMed (Medline) search.

We used the following key words: Oesophageal perforation, gastrointestinal perforation, endoscopic clip (ping) and OTSC (latest search date: 15 March 2015). We processed the data from 38 articles and 127 patients. We placed causes of perforation into three categories in the table: Perforation was defined as an acute iatrogenic or spontaneous defect, leak as an insufficiency/disruption of a surgical anastomosis, and fistula as a chronic residual inflammatory communication between the oesophagus, with a mediastinal or pleural space or tracheobronchial tract under the skin.

Statistical analysis: Categorical data were analyzed using χ^2 and Fisher's exact test [SPSS version 15.0 (© 2007 SPSS Inc.)].

Most publications are case reports or retrospective analyses with heterogeneous indications. The number of publications significantly increased after the first clinical use of the OTSC clip in 2007, first in Europe and then in the United States and other countries as well. Neither randomized nor comparative (TTS vs OTSC) studies have been conducted with the use of clips. One prospective European multicentre study and two retrospective North American multicentre studies have been published on the use of OTSC clips in the treatment of GI perforations^[40-42]. Unfortunately, salient information is missing from numerous articles, and generally there are no reports on the follow-up period at all.

Based on the results, it can be concluded that both clips are suitable for the treatment and early management (< 24 h) of iatrogenic, spontaneous oesophageal perforation in the case of limited injury and contamination.

TTS clips are successfully used for injuries of an average of 10 mm, while OTSC clips may also be successful in the treatment of larger injuries. More clips may also be used to close a defect, and various clips may be combined^[40,43]; in addition, closure with a clip may be repeated^[44]. In accordance with the latest recommendations from the European Society of Gastrointestinal Endoscopy^[30], clips may only be used in the treatment of an injury in the case of safe care, in stable patients, with a clear oesophagus, limited mediastinal contamination and limited injury (intramural/transmural). Certain immediately diagnosed iatrogenic perforations meet this criterion system in particular. If the amount of mediastinal and/or pleural fluid is more significant, mediastinal and/or pleural space drainage/VATS treatment usually cannot be avoided. The treatment algorithm is summarized in Figure 1.

PERFORATIONS

Based on our analysis (Tables 1 and 2), clips were used early (immediate diagnosis, < 24 h), especially in the case of minimally contaminated iatrogenic injuries or spontaneous ruptures, and the success of healing was similar to that of surgical treatment [TTS 88.8% (24/27); OTSC 92.86% (26/28)]. Although TTS and OTSC clips were used for injuries of varying sizes, their success rates did not diverge significantly (88.8% vs 92.85%, $P > 0.12$). Of further interest, clips were used with a similar success rate for the far smaller number of perforations of > 24 h which are only associated with a well-defined mediastinal inflammation/abscess [TTS 100% (8/8) vs OTSC 83.3% (5/6)]. Transoesophageal lavage of the process or even vacuum therapy may be of great aid in resolving the abscessing mediastinal process^[45].

In selected cases of Boerhaave syndrome, closing the oesophageal injury with endoscopic clips might also be successful. TTS clips were used in two cases. In one patient, a minimal transmural oesophageal injury was diagnosed (a little air in the mediastinum), only the mucosal injury was partially closed with endoscopy, and conservative treatment was administered^[46]. In another patient, a 5-7 mm transpleural injury was closed with 3 TTS clips, and additional thoracic drainage and enteral nutrition were administered^[47]. In three additional cases, OTSC clips were used successfully to close a spontaneous transmural injury^[43,48,49]. In the two matured (> 24 h) perforations, additional VATS therapy was necessary. Similarly, only limited cases have been reported on the treatment of injuries caused by foreign bodies^[50,51].

Broad-spectrum antibiotic therapy and suspension of oral nutrition are required in addition to successful early endoscopic care. In the majority of cases, complication-free healing can be expected with careful indication. However, close monitoring of the patient and additional therapy such as mediastinal/pleural drainage or even

surgical treatment, if necessary, are also essential.

FISTULAS/CHRONIC INJURIES

Fistulizing chronic injuries and treating anastomosis insufficiencies represent a separate group. Experience shows that OTSC clips have provided relatively secure closure so far, but the success rate in acute cases [OTSC 57.7% (15/26) vs TTS 100% (4/4) ($P < 0.05$) for fistulas; OTSC 77.7% (12/18) vs TTS 54.5% (6/11) ($P < 0.05$) for leaks] differed significantly in the groups.

Closure is technically often unfeasible, especially in the case of fibrotizing, scarred fistulas and a severely inflamed environment^[52]. Most problems stem from insufficiency of the oesophageal anastomosis diagnosed in the early postoperative state. These cases are usually subacute, the tissues are extremely fragile, often ischaemic, and therefore the tendency to heal is already decreased^[53]. The success rate for the closure of chronic

fistulas is also reduced by previous radiation therapy. If a TTS clip is used, argon plasma coagulation and other mechanical freshening up (with a cytology brush) may aid in stabilizing the clip. These extra manoeuvres may only increase tissue oedema and the success of clip deployment when OTSC clips are used^[41,52]. There are only a few case reports on successful closure of a chronic spontaneous oesophageal rupture and a consequently developed fistula with endoscopic clips^[9,11].

Endoscopic vacuum therapy may be helpful in reducing the inflammatory cavity and closing the remaining fistula with good localization in the case of chronic injuries and mediastinal/pleural inflammation^[37,45]. Following initial stent placement and removal in the treatment of an early, well-defined injury, a cavity marked by chronic inflammation may remain, one which may not be resolved with primary clipping alone. In these cases, EVT and/or surgical treatment (VATS) represent the primary therapeutic procedure^[34-36,45].

Table 2 Published literature reporting over-the-scope clip closure of oesophageal perforations

Ref.	Cause	Size/mm	Time to treatment (< 24 h <)	Im/Tm/Tp	Method	Nr	Clinical success	Additional treatment	Hospital stay /d	Follow-up
Pohl <i>et al</i> ^[67]	Leak (1)	< 0	> 24	Tp	OTSC	1	1/1(100%)	No	30	ND

Im: Intramural; Tm: Transmural; Tp: Transperal; ND: Non determined; VATS: Video assisted thoracoscopy.

Very few articles report long-term follow-up data. The biggest and most detailed report is a North American study which evaluated gastrointestinal defects in 188 patients treated with OTSC. Success was achieved in 60.2% of the patients in a median follow-up of 146 d. The long-term rate for clinically successful closure of perforations (90%) and leaks (73.3%) was significantly higher than that of fistulas (42.9%). The study also showed significantly greater long-term success when OTSCs were used in primary therapy.

On the whole, it is clear that closure with clips shows the best results in the treatment of early injuries, and the success rate for clinical recovery approaches the result for surgical treatment.

Other uses of clips

Endoscopic clips may also be used with endoloop. The

method was first used for endoscopic mucosal resection to resolve large defects^[54]. Later, it was successful in the treatment of Mallory-Weis syndrome^[55] and in closing oesophageal fistulas^[56]. Due to the limited number of these articles, no conclusions can be drawn about their efficacy.

CONCLUSION

A number of case reports and case series reports have been published on the successful outcome of clip closure of endoscopic perforations, but high-evidence, case-controlled, multicentre studies are still missing. This method can only be used under very strict conditions (Figure 1). The introduction of OTSC clips significantly increases the size of treatable lesions (from 1 to 2-3 cm). However, this technique is only used in a limited

Figure 1 Algorithm for the management of oesophageal perforations.

number of centres. It is important to point out that both conventional TTS and the new OTSC methods are both safe. But a learning curve period and experience will both be necessary in their usage, including the selection of patients suitable for clip treatment. Multidisciplinary teams (surgeon, endoscopy specialist and intensive care therapist) are further important conditions in the successful treatment of oesophageal perforations. Surgical treatment still constitutes the primary therapy in oesophageal perforation. Based on the results so far, we can state that endoscopic closure of early, well-defined oesophageal perforations represents a therapeutic alternative to surgical treatment.

Abstract

Despite the advances of medical, endoscopic and

radiological therapy over recent years the mortality rates of acute variceal haemorrhage are still 16%-20% and the medium term outcome has not improved in the last 25 years. Early transjugular intrahepatic portosystemic shunt has proved to be an effective therapy for selected groups of patients with a high risk of re-bleeding and moderate liver disease. However, there is an unmet need for a therapy that can be applied in patients with a high risk of re-bleeding and advanced liver disease either as definitive therapy or as a bridge to permanent therapy. Self-expanding metal stents can be placed without the need for endoscopic or fluoroscopic control and, once in place, will provide effective haemostasis and allow a route for oral fluids and nutrition. They can remain in place whilst liver function recovers and secondary prophylaxis is initiated. We review the results of 6 case series including a total of 83 patients and the first randomised controlled trial of self-expanding metal stents *vs* balloon tamponade (BT) in the management of refractory variceal haemorrhage. We report that self-expanding metal stents provide effective haemostasis and perform better than BT in refractory bleeding, where they are associated with fewer complications. Whilst the most effective place for self-expanding metal stents in the management algorithm needs to be determined by further randomised controlled trials, currently they provide an effective alternative to BT in selected patients.

Core tip: Failure to control bleeding in high-risk patients with variceal haemorrhage is still common, and not all patients are suitable for transjugular intrahepatic portosystemic shunts. Self-expanding metal stents can be placed without the need for endoscopic or fluoroscopic control and, once in place, provide effective haemostasis and allow a route for oral fluids and nutrition. They

can remain in place whilst liver function recovers and secondary prophylaxis is initiated or whilst definitive therapy is provided. Self-expanding metal stents provide effective haemostasis and perform better than balloon tamponade in refractory bleeding, where they are associated with fewer complications.

Hogan BJ, O'Beirne JP. Role of self-expanding metal stents in the management of variceal haemorrhage: Hype or hope? *World J Gastrointest Endosc* 2016; 8(1): 23-29 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i1/23.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i1.23>

INTRODUCTION

Acute variceal bleeding represents a devastating decompensating episode and occurs at a rate of 4% per year in patients with cirrhosis, increasing to 15% per year in those with medium or large varices^[1].

Outcomes from a single episode of variceal bleeding have improved significantly in recent years. Better endoscopic therapy exists in the form of endoscopic variceal ligation and tissue adhesive glue^[2,3] and more effective pharmacotherapy including potent vasoactive drugs^[4,5] and prophylactic antibiotics^[6]. However, the mortality rates of 16%-20% are still significant and medium term outcome has not improved in the last 25 years^[7-10].

Failure to control bleeding, as defined by the Baveno V criteria, is estimated at approximately 17% in the modern era^[11]. Traditional factors associated with failure to control bleeding at 5 d and mortality at one month were active bleeding at endoscopy, severity of liver disease and an hepatic venous pressure gradient of > 20 mmHg^[12,13]. More recently the model for end-stage liver disease (MELD) score has been shown to be useful in predicting outcome, with a MELD score < 11 being associated with < 5% mortality and a MELD score > 19 with > 20% mortality^[14].

CURRENT OPTIONS FOR FAILURE OF STANDARD THERAPY

Failure to control bleeding requires salvage therapy such as balloon tamponade (BT) or insertion of transjugular intrahepatic portosystemic shunts (TIPS). These methods are effective at control of bleeding, but have important limitations. BT is a temporary therapy which most experts suggest can be used for a maximum duration of 24 h as a bridge to more definitive therapy^[15]. The success of BT in controlling haemorrhage is reported to be between 88%-91% in the first 24 h^[16]. BT is associated with the risks of oesophageal tear, mucosal ischaemia and aspiration pneumonia. TIPS carries a risk of worsening liver function and encephalopathy and is associated with a 30 d mortality of 30% when used as a

rescue therapy^[17]. In addition TIPS is not readily available in many centres that manage upper gastrointestinal haemorrhage.

The importance of early haemostasis was demonstrated in a randomised controlled trial of early TIPS insertion. Participants were randomised to either TIPS insertion within 72 h or standard medical therapy, which could include rescue TIPS. It demonstrated a reduction in uncontrolled bleeding or re-bleeding in the early TIPS group (3% vs 45%), a reduction in average intensive care unit stay (3.6 d vs 8.6 d) and a significant reduction in 1 year mortality (14% vs 39%, $P = 0.001$)^[18]. Patients over 75 years of age, those with a Childs Pugh score > 13 and those with advanced hepatocellular carcinoma were excluded from this study. Similar results have been shown using early TIPS in high-risk patients selected for a hepatic venous pressure gradient > 20 mmHg^[19].

Attempts to replicate these results outside of clinical trials have been encouraging, but show that patient selection is vital and TIPS can be associated with significant complications. A United Kingdom centre began implementing an early TIPS protocol in 2010 for high-risk patients with acute variceal haemorrhage (Childs Pugh C or Childs Pugh B with active bleeding at endoscopy). The median time to TIPS was 12 h and the same exclusion criteria as reported in the above early TIPS study applied. Overall 30-d mortality was 8.6% and at 6 mo it was 14.7%. The re-bleeding rate was 11.4% and all re-bleeding occurred within the first 7 d^[20]. A series from France proved similar efficacy with regards to haemostasis, with failure to control bleeding in 1/23 (4%). However, in this series there was a significant deterioration in liver function in 10/23 with 5 patients dying and 5 requiring transplantation. In addition 5/23 patients developed acute heart failure and 3 of these required mechanical ventilation^[21].

Based on this data it would seem reasonable to promote TIPS as an initial treatment for high-risk patients with portal hypertensive bleeding. However, TIPS requires specialist equipment and expertise, and the logistics of providing this to all high-risk patients would be difficult for many healthcare systems internationally. There is, therefore, a need for a treatment which can be applied easily and effectively to patients at high risk of re-bleeding that could reduce early re-bleeding and promote a bridge to effective secondary prophylaxis or TIPS.

SELF-EXPANDING MESH-METAL STENT FOR VARICEAL HAEMORRHAGE

The SX-ELLA Danis stent (Ella CS, Hradec Kralove, Czech Republic) is a removable, covered, self-expanding mesh-metal stent (SEMS) that was designed for the emergency treatment of oesophageal variceal bleeding. It is 135 mm long and 25 mm in diameter giving it the ability to tamponade bleeding varices in the distal oesophagus. It is supplied with a unique insertion

system, where by a gastric balloon is inflated to anchor the distal end of the stent at the gastro-oesophageal junction when traction is applied. The Danis stent can be deployed without direct endoscopic or fluoroscopic guidance, and its' position should be confirmed by chest radiograph after insertion. Stents can be left in place for up to 14 d and can be removed endoscopically using the accompanying stent removal device. The stent provides immediate haemostasis and prevents re-bleeding for the time it is *in situ*. This allows recovery of liver function, consideration of definitive therapy and institution of secondary prophylaxis in addition to maintaining an oral route for fluids and nutrition. SEMs have also be useful in the management of BT related oesophageal rupture and for broncho-oesophageal fistula.

CURRENT EVIDENCE FOR SEMS

To date there have been 4 large case series, with ≥ 10 patients, a number of smaller case series and reports and one randomised controlled trial assessing the safety and efficacy of SEMs in the control of variceal haemorrhage^[22-24].

The first series was reported by Hubmann *et al*^[25] in 20 patients with Child-Pugh B or C cirrhosis and massive ongoing bleeding. Two patients received Choo stents (140 mm \times 18 mm) and three patients received a Boubela-Danis stent (95 mm \times 20 mm). The next 15 patients received the purpose designed SX-ELLA Danis stent as described above. The first five were placed *via* an endoscopic guide wire and fluoroscopic control, the remainder were placed using the insertion device without a guide-wire or fluoroscopy. The stents were able to successfully control haemorrhage in all cases with no reported re-bleeding during 30 d of follow-up. In one case there was mild ulceration in the distal oesophagus after removal, no other complications were reported. Following stent extraction at a median of 5 d (1-14 d), 18 patients went on to have a definitive procedure to prevent re-bleeding (TIPS, azygoportal disconnection, liver transplant, radiological embolization or endoscopic intervention (variceal ligation or sclerotherapy)). Mortality was 10% within 30 d (one at day three from hepatic failure and one at day five from multi-organ failure) and 20% at 60 d (Figure 1).

The same group of investigators published a further series of the SX-ELLA Danis stent including 15 patients previously described, with an additional 19 patients all of whom had failure to control bleeding following standard endoscopic techniques^[26]. Haemostasis was achieved in all 34 cases using the SX-ELLA Danis stent without complications. All stents were deployed successfully, for a mean of 6 d (range 1-14 d). There were a total of 7 instances of stent migration, which was attributed to low stent position at insertion. Mortality was 26.5% at 30 d and 29.4% at 60 d and there was no re-bleeding reported during follow-up.

A tertiary United Kingdom centre reported SEMs use in 10 patients with on-going variceal bleeding

despite standard endoscopic therapy^[27]. Two patients had the added complication of BT induced oesophageal rupture. Stents were successfully deployed in 9 cases, in once case the gastric balloon failed to inflate and the procedure was abandoned. Nine/ten patients had active bleeding at the time of endoscopy and haemostasis was achieved in 7/9 (78%). The patients with continued haemorrhage were subsequently shown to be bleeding from gastric varices. The mortality rate at 6 wk was 50%.

Fierz *et al*^[28] described a combined case series of 9 patients from Swiss Hospitals. They reported a total of 9 bleeding episodes in 7 cirrhotic patients (two patients had two separate bleeds). In three cases SEMs was used as first line endoscopic therapy, and in the remaining 6 cases there had been inadequate control of haemorrhage with band ligation or sclerotherapy. The majority of patients were Child-Pugh class C and the mean MELD score was 34. All stents were placed with endoscopic assistance and two cases of distal stent migration were noticed, no other complications were reported. Control of haemorrhage was achieved in all cases, except one where the stent was not deployed correctly. The reported 6 wk mortality rate of 78% is high and reflects the severity of underlying liver disease in this cohort^[28].

Zakaria *et al*^[29] have reported a series of 16 patients where SEMs was used for the primary therapy of variceal haemorrhage. Patients with hepatitis C related cirrhosis and evidence of on-going bleeding from varices, cherry red spots, or fresh blood in the oesophagus or stomach received a stent for between 2 and 4 d. Successful control of haemorrhage with the SEMs was reported in 14/16 patients. Of the two treatment failures one was caused by the rupture of the gastric balloon and sclerotherapy was applied to the varix and in the second the SEMs failed to control bleeding from a GOV-1 varix which required cyanoacrylate glue.

The results of the first randomised controlled trial comparing SEMs to BT were published in abstract form in 2013^[30]. This was a multicentre trial of 8 hospitals in Spain.

The study included consenting adult patients with cirrhosis and acute variceal bleeding (as defined by the Baveno II consensus) who met either of the following inclusion criteria: (1) Failure to control bleeding (as defined by Baveno IV criteria) despite pharmacological (somatostatin 3 or 6 mg/12 h *iv* or terlipressin, 2 mg/4 h *iv*) AND endoscopic therapy (oesophageal banding ligation preferably or sclerotherapy); and (2) Massive bleeding, uncontrolled despite pharmacological therapy started at any moment, with no need of previous endoscopic therapy. Uncontrolled bleeding was defined as an upper digestive bleeding in which no hemodynamic stability (systolic arterial pressure > 70 mmHg and heart rate < 100 bpm) could be achieved.

The exclusion criteria were oesophageal rupture; oesophageal, gastric or upper respiratory tract tumor; oesophageal stenosis; recent oesophageal surgery;

Figure 1 The Danis Stent with delivery system. A: The SX-ELLA Danis stent is supplied preloaded in an insertion device that has a 26F diameter and is 60 cm long; B: A balloon at the distal end of the insertion device (shown partially inflated) allows anchoring of the distal end of the stent at the cardia during deployment; C: The fully deployed stent is 135 mm long and 25 mm wide.

previous oesophageal tamponade to treat the index bleed; a big hiatal hernia precluding the correct placement of the oesophageal device; known hepatocellular carcinoma surpassing Milan criteria and terminal disease.

Twenty-eight patients were randomized to BT ($n = 15$) or SEMS (SX-Ella Danis; $n = 13$).

Both groups were matched for the aetiology and severity of liver disease, presence of active bleeding at endoscopy and for the initial therapy received. SEMS were placed without endoscopic or fluoroscopic guidance, but under sedation, and their position confirmed by chest radiograph. Stents remained *in situ* for a maximum of 7 d and during that time patients could undergo a TIPS. The median time to TIPS was reported as 3.5 (0-7) d in the SEMS group and 0.8 (0-1) d in the BT group. The number of patients who underwent successful TIPS placement was not reported. Unfortunately, due to difficulties with participant recruitment the study was under powered. The initial power calculation suggested that 23 patients would be required in each group (Table 1).

One patient in the SEMS group received a BT due to technical difficulties deploying the stent, however the analysis was performed using an intention to treat basis. Haemostasis was achieved in 77% of the SEMS group and 43% of the BT group ($P = 0.1$). The incidence of serious adverse events was lower in the SEMS group, particularly the incidence of aspiration pneumonia 2/13 vs 8/15 in the BT group. Survival at 15 d was 61% and

47% in the SEMS and BT groups respectively ($P = 0.4$).

LIMITATIONS OF SEMS IN VARICEAL HAEMORRHAGE

There have been reports of minor oesophageal ulceration several case series describing SEMS placement. However, this resolved spontaneously on removal of the stent and neither mortality nor oesophageal perforation have been observed.

Stent migration is the main issue encountered after deployment and, if occurs, impedes effective haemostasis. If adequate traction is not applied to the delivery device at the time of stent deployment, migration is more likely to occur.

There have been a number of reports of failed deployment due to balloon rupture. The insertion device is designed with a safety feature where by the balloon will rupture if more than 100 mL of air is insufflated. This is designed to prevent the complication of an over distended balloon causing an oesophageal tear, should it have been misplaced in the oesophagus (rather than the stomach) prior to inflation. Rupture of the balloon can be avoided if only 100 mL of air is insufflated.

In one case report a patient developed respiratory failure 6 d following successful control of bleeding using an SX-ELLA Danis stent^[22]. Bronchoscopy revealed narrowing of the bronchus due to external compression from the proximal portion of the stent. The stent was

Table 1 Summary of case series reporting self-expanding mesh-metal stent use in the control of oesophageal variceal haemorrhage

Ref.	Stent used	n	Indications/severity of liver disease	Length of Insertion (d)	Initial Haemostasis with SEMS	Mortality (d)	Complications/notes

Zakaria <i>et al</i> ^[29] , 2013	SX-ELLA Danis	16	Primary therapy in acute variceal bleed CP A 13%/B 50%/C 37%	2-4	94%	25%	Uncontrolled bleeding from GOV-1 varix after insertion in 1 patient Failure to place stent in 1 patients

¹20 patients included in this trial were also included in the first trial by Hubmann *et al*^[25]; ²Dechene *et al*^[22] previously reported 1 patient from this series in 2009. FTCB: Failure to control bleeding; BT: Balloon tamponade; EBL: Endoscopic band ligation; CP: Child-Pugh score; MELD: Model for end-stage liver disease score; GOV-1: Gastro-oesophageal varices type 1.

removed and bronchial obstruction resolved. In this case varices were secondary to hilar cholangiocarcinoma and the patient died from liver failure 7 d after the stent was removed.

CONCLUSION

Despite the recent advances in treatment of variceal bleeding there are still significant rates of treatment failure and mortality and there is still considerable variation in patient outcomes.

Current guidelines for the management of variceal haemorrhage suggest that a TIPS should be considered for high risk cases and in patients with bleeding refractory to standard medical and endoscopic therapies^[15,31]. However, TIPS is not suitable for all patients and the complications of liver failure and hepatic encephalopathy limit the use of TIPS in some patients. There is, therefore, an unmet need where standard endoscopic therapy is ineffective and TIPS is not a suitable treatment.

SEMS are very effective in the control of oesophageal variceal haemorrhage, and in all of the series reported to date the only "stent failures" have either been where the stent was not deployed correctly or

where the bleeding was from concomitant gastric varices. The mortality rates reported in the case series are very variable, and the main determinant is whether they are used as definitive therapy, or as a bridge to another therapy, mortality being improved with the latter.

It is not yet clear whether SEMS have a defined place in the algorithm for the management of variceal haemorrhage. The data from Escorsell *et al*^[30] has not confirmed that SEMS perform better than BT in refractory bleeding, but there was a trend towards fewer complications and more effective haemostasis. This has led to a recommendation from the BAVENO VI committee for SEMS to be considered as an alternative to BT in their most recent consensus report^[15]. Further data from randomised controlled trials are required to guide clinicians in their use of these devices, however they are an attractive alternative to BT and may be an effective bridge to definitive therapy.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Lucian Negreanu, MD, PhD, Assistant Pharmacist, Assistant Professor, Doctor, Head, Internal Medicine II Department, Internal Medicine II Gastroenterology, University Hospital Bucharest, 050098 Bucharest, Romania

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Achalasia is a motility disorder of the esophagus

characterized by dysphagia, regurgitation of undigested food, chest pain, weight loss and respiratory symptoms. The most common form of achalasia is the idiopathic one. Diagnosis largely relies upon endoscopy, barium swallow study, and high resolution esophageal manometry (HRM). Barium swallow and manometry after treatment are also good predictors of success of treatment as it is the residue symptomatology. Short term improvement in the symptomatology of achalasia can be achieved with medical therapy with calcium channel blockers or endoscopic botulin toxin injection. Even though few patients can be cured with only one treatment and repeat procedure might be needed, long term relief from dysphagia can be obtained in about 90% of cases with either surgical interventions such as laparoscopic Heller myotomy or with endoscopic techniques such pneumatic dilatation or, more recently, with per-oral endoscopic myotomy. Age, sex, and manometric type by HRM are also predictors of responsiveness to treatment. Older patients, females and type II achalasia are better after treatment compared to younger patients, males and type III achalasia. Self-expandable metallic stents are an alternative in patients non responding to conventional therapies.

Key words: Achalasia; High resolution manometry subtypes; Eckardt score; Per-oral endoscopic myotomy; Pneumatic dilatation; Botulin toxin; Myotomy

INTRODUCTION

Achalasia is a motility disorder of the esophagus characterized by dysphagia, regurgitation of undigested food, chest pain, weight loss and respiratory symptoms^[1,2].

Achalasia is a relatively rare condition with incidence ranging from 0.3 to 1.63 cases per 100000 people per year in adults^[3-6]. There seems to be no difference in sex and racial distribution. Incidence rates of this pathology seems to be rising, it remains unclear if this reflects a true rise in the incidence or an improved diagnosis^[3,6,7-16].

Most studies found the median age at the diagnosis to be over 50 years^[3,4,17] whereas other authors have suggested a bimodal distribution of incidence by age with peaks around 30 and 60 years of age^[7-9].

Although the etiology remains unknown, it has been established that achalasia results from the disappearance of the myenteric neurons leading to loss of peristalsis and failure of relaxation of the lower esophageal sphincter, particularly during swallowing^[18].

Antibodies against myenteric neurons have been found in serum samples obtained from patients affected with achalasia^[19-21]. Genetic^[22-27], autoimmune^[28,29], and viral^[30-33] conditions may play a role in the development of the condition.

Since symptoms of achalasia are not specific, the diagnosis of the disease can be delayed for as long as 5 years^[34,35]. Dysphagia for solids and liquids occurs in > 90% of patients affected with achalasia, other symptoms include weight loss (35%-91%), food regurgitation (76%-91%), respiratory complications such as chest pain (25%-64%) and heartburn (18%-52%) nocturnal cough (30%) and aspiration (8%)^[1,36-38].

In a patient presenting with dysphagia, it is mandatory to rule out malignancies but also pseudoachalasia or any other anatomical lesions with radiology or endoscopy. Old age, weight loss and rapidly progressing dysphagia are particularly suspected for pseudo-achalasia and thus should be investigated by the mean of and endoscopic ultrasound or computer tomography (CT)-scan^[39,40]. These imaging techniques will reveal thickening of the esophageal wall, mass or lesions.

However, both endoscopy and radiology only identify about half of patients with achalasia, especially in early

stage. Endoscopy may reveal a dilated esophagus with retained food and a difficult access to gastric cavity due to increased resistance of the gastro-esophageal junction in advanced stages of the disease.

In addition, a timed barium swallow esophagram (TBA) can be done to assess emptying of the esophagus; the height of the barium column 5 min after the ingestion is a measure of emptying^[41,42] (Figure 1). A TBA has proven itself useful also in the post-operative assessment of the disease.

Manometry is the mainstay of the assessment in achalasia both before and after treatment. Manometric features of achalasia are absence of peristalsis, incomplete relaxation of LOS on deglutition (residual pressure > 10 mmHg) with increased resting tone of LOS and, sometimes, increased intra-esophageal pressure^[2].

High resolution manometry (HRM) is now regarded as the gold standard for the diagnosis of achalasia^[43,44], this diagnostic technique is performed by mean of catheters incorporating 36 or more pressure sensors spaced 1 cm apart.

Thanks to the greater accuracy of HRM, three clinically relevant sub-classifications of achalasia have been distinguished on the basis of the pattern of contractility in the esophagus^[45].

Type I (classical achalasia; no pressurisation to over 30 mmHg in distal esophagus and failed relaxation on swallow), type II (achalasia with compression or compartmentalisation in the distal esophagus > 30 mmHg), and type III (two or more spastic contractions) (Figure 2).

TREATMENT

Since the underlying defect cannot be reversed, the treatment of achalasia remains palliative. Current therapeutic options include pharmacologic therapy, endoscopic treatment and surgery. The primary goal of all therapies is the improvement of the esophageal food passage by reducing the distal esophageal obstruction.

Pharmacological treatment

Nitrates and Calcium-channel blockers are the most widely used drugs for the treatment of achalasia^[46-49]. Nifedipine is administered 15-60 min before meals in sublingual doses of 10-20 mg. It inhibits the cellular calcium uptake resulting in inhibition of LOS muscle contractions and lowering of the LOS resting pressure by 30%-60%^[46-48]. Side effects are seen in up to 30% of patients and include hypotension, headache, and dizziness even if tolerance develops over time.

Only two poorly designed randomized controlled trials have been identified in a Cochrane review by Wen *et al*^[50] about the use of nitrates in achalasia so no solid recommendations can be given at present about this treatment.

Botulin toxin A is a neurotoxin blocking the release of acetylcholine from the synapsis terminals. It can be

Figure 1 Barium swallow esophagograms showing typical bird-beak appearance of the distal esophagus.

injected during upper endoscopy through an injection needle directly in four or eight quadrants into the LOS at the dose of 80-100 units^[51,52].

This combined endoscopic/pharmacological treatment has proven itself safe and effective. More than 80% of patients have clinical response by one month even if response fades quickly and only about 60% of patients are still in remission at 1-year follow-up^[53].

Botulinum toxin compared with pneumodilatation^[54-58] and laparoscopic myotomy^[59] shows initial comparable relief from dysphagia but a rapid relapse of symptoms after 6-12 mo. So, botulinum toxin, as calcium-channel blockers or nitrates use, should be used as a temporary option before a more durable treatment or in high risk patients who are poor candidates for surgery or pneumodilatation.

Pneumatic dilatation

Pneumatic dilatation stretches and tears the LOS fibers with air-filled balloons, the most widely used ones are Rigidflex Balloon System (Boston Scientific, Marlborough, MA, United States). The balloons are available in three sizes (30, 35 and 40 mm) made of non-compliant polyethylene; they are placed over a guide-wire at endoscopy, positioned across the LOS and inflated under fluoroscopic guidance, a graded dilation protocol starting with a 30 mm balloon is usually preferred^[60] (Figure 3).

An esophageal lavage with large-bore tubes might be needed in patients with mega-esophagus before the procedure. In patients with previous pneumodilatation failure, younger than 40 years or after a previous Heller myotomy it is possible to begin with a 35 mm balloon. The balloon positioning is checked with fluoroscopy or, sometimes, endoscopy; the waist caused by the non-relaxing LOS should impinge on the middle portion of the balloon. After careful positioning, the balloon is inflated until the waist is flattened; the pressure needed in the balloon is 7-15 psi of air and is held for 15-60 s.

Patients must be on a liquid diet for several days and fast for 12 h prior to procedure. The procedure is usually performed as an outpatient surgery under conscious

Figure 2 High-resolution manometric types of achalasia according to the Chicago Classification: Type 1, characterized by the absence of peristalsis (A); type 2, defined by the presence of esophageal compression, named panesophageal pressurization (B); type 3, characterized by the presence of peristaltic fragments or spastic waves (C).

sedation in the morning, the patient is then kept under observation for 2-6 h and can return to normal activities the subsequent day. During observation, patients should be assessed for chest pain and fever. A Gastrografin swallowing assessment should be performed in patients complaining with significant pain in order to exclude esophageal perforation.

Subsequent dilatations can be performed after a 2 to 4 wk interval if needed on the basis of symptom relief, LOS pressure measurements or improvement in esophageal emptying^[36,61-63].

Pneumatic dilatation with 30, 35 and 40 mm Rigidflex Balloons results in good to excellent symptom relief in 74%, 86% and 90% of patients respectively at 3-year follow-up but nearly two thirds of patients have

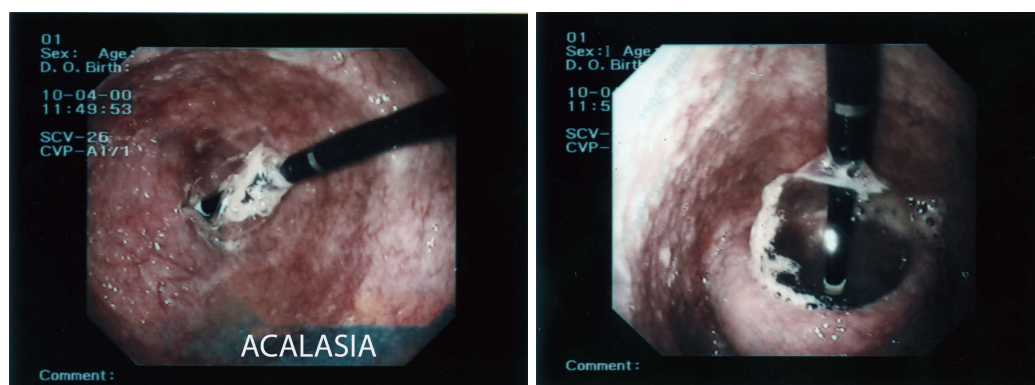

Figure 3 Pneumatic dilation with a Rigidflex balloon under endoscopic control.

symptom relapse over a 4-6 years^[38,63,64].

Long term relapses can be managed to obtain long-term remission by a repeat dilatation strategy. Best outcomes are seen in patients with type II pattern by HRM, women and in those older than 40 years^[1,38,41,65,66].

Patients with type III seem to have better results if treated with Heller myotomy compared to pneumatic dilatation, no significant differences are seen in type I and II. The different response in type III patients seems to be due to the fact that Heller myotomy results in a more extensive and proximal disruption of oesophageal muscle fibers^[67].

At present, pneumatic dilatation has proven itself to be the most cost-effective treatment for achalasia over a 5-10 year period^[68,69]. Up to one third of patients have complications after pneumatic dilatation, most of them are minor such as bleeding, fever, chest pain, mucosal esophageal hematoma and mucosal tear without perforation. Even though severe gastro-esophageal reflux disease is rare after pneumatic dilatation, 15-35 of patients experiences heartburn which can be treated with proton pump-inhibitors^[70]. Perforation is, by far, the most serious complication occurring in about 2.0% of patients^[71] (reported rate of 0%-16%), about 50% of perforated patients require surgery thus, poor surgical candidates are poor candidates to pneumatic dilatation as well. In a recent series, 16 consecutive transmural perforations were managed conservatively^[72]. Small perforations are usually treated with total parenteral nutrition and antibiotics for days to weeks. Large perforations will require surgical repair by thoracotomy. Difficulty in keeping the balloon in place is a reported risk factor for perforation^[73]. Also, performing the initial dilatation with a 35 mm balloon seems to put the patient at risk for perforation, compared to an initial dilatation performed with a 30 mm balloon^[66].

Per-oral endoscopic myotomy

Ortega first described a series of 17 patients affected with achalasia and treated with a direct trans-mucosal lower esophageal sphincter myotomy and good clinical, radiologic and manometric results in 1981. No confirmatory work was published, perhaps due to complications such as

perforation and mediastinitis^[74]. Natural orifice transluminal endoscopic surgery made its appearance in 2004 and there has been a tendency towards the development of less invasive alternative to transcutaneous surgical interventions since then. To obtain an access to the mediastinum or the peritoneum, a technique consisting in the creation of a submucosal tunnel closed by a mucosal flap was developed^[75].

Per-oral endoscopic myotomy (POEM) was developed from this technique and features the creation of a submucosal tunnel enabling the LES myotomy to be performed away from the mucosal entry site which is closed at the end of the procedure.

In 2007, the first LES myotomy was performed in a porcine survival model^[76] and in 2008, Inoue *et al.*^[77] used the technique of submucosal tunneling to perform the first endoscopic LES myotomy on humans and coined the term POEM for *per oral endoscopic myotomy*. Even though, POEM is mainly performed for achalasia, it can be successfully applied in diffuse esophageal spasm, nutcracker and jackhammer esophagus^[78,79]. POEM can be also used in patients with prior Heller myotomy and previous endoscopic pneumatic dilatation^[80,81].

POEM contraindications include severe pulmonary disease, bleeding disorders esophageal irradiation or esophageal malignancy and endoscopic intervention including endoscopic mucosal resection and^[82] endoscopic submucosal dissection (ESD). POEM requires general anesthesia with the patient in supine position. It is recommended to use anesthesia with positive pressure ventilation to prevent severe mediastinal emphysema^[83]. A traditional forward-viewing endoscope and equipment employed in ESD are used. Carbon dioxide is used for insufflation. The esophageal submucosal space is expanded with injection of indigo carmine-saline mixture (typically, 0.3% indigo carmine). The submucosal tunnel is initiated 10-15 cm above the gastroesophageal junction (GEJ). The recommended mucosal entry site is, generally, on the anterior wall between 11 and 2 o'clock^[83,84]. In case POEM is performed in patients in which a balloon dilatation has been performed with poor results, since the anterior route can be seriously scarred, the incision is usually performed at the 7 o'clock position^[85]. After a

2 cm mucosal incision is made, the submucosal tunnel is extended downward by using a technique similar to ESD to reach the gastric cardia 2-3 cm distal to the GEJ.

Accurate identification of EGJ is essential. Delineation of the GEJ is done in a variety of ways like monitoring the endoscope insertion length, identification of the longitudinal palisade vessels in the submucosal layer, change in the submucosal vascular pattern (from palisade to reticular) at EGJ, stenotic segment of the submucosal tunnel, tattooing at the gastric cardia using indocyanine green (ICG) and even transillumination viewed by a second endoscope^[86]. The myotomy is performed starting at 2-3 cm distal to the mucosal entry, thus, more than 10 cm above the GEJ and carried up to, at least, 2 cm distally to the GEJ.

At the beginning of the procedure, the circular muscle is dissected and the longitudinal muscle layer is identified; the inter-muscular space is the correct dissection plane. Some authors favor the dissection of the sole circular muscle fiber, since these are regarded as having the major function in muscle contraction and the risk of surrounding structures injury is reduced by keeping the outer muscle intact^[87]. The outer longitudinal muscle layer can be extremely thin, the injury to this muscle fibers and the exposure of the mediastinal structures does not cause any sequelae if the mucosa is still intact, thus an inadvertent mucosal flap injury must always be repaired promptly with clip placement, endoscopic suturing or fibrin spray glue^[88].

The incision at 2 o'clock position leads to the lesser curvature of the stomach, in contrast, the hiss angle is located at 8 o'clock. Anterior myotomy potentially avoids damage to the sling muscle, and especially His angle so that no anti-reflux procedure is needed. The 2 o'clock approach might be less efficacious at the LES disruption which is the main goal of the achalasia surgery leading to less relieve of dysphagia but may be useful in avoiding symptomatic GERD after the procedure. In contrast, the 5 o'clock position for the myotomy may lead to less dysphagia but could theoretically have more GERD which can be treated with PPI^[83].

Using CO₂ for insufflation and positive-pressure ventilation prevents severe pneumomediastinum should a perforation occur. The muscle layer cutting is continued for at least 2 cm distal to the GEJ; closure of the mucosal entry site can be performed with either hemostatic clips or endoscopic suturing (OverStitch™ Endoscopic Suturing System; Apollo Endosurgery Austin, Texas), no statistically significant difference in mean closure time, complications or mean cost have been noted^[83].

Closure might also be performed with over-the-scope clip and fibrin glue^[89,90]. Whatever closure technique is used, Gentamicin infusion within the submucosal tunnel is reported. After the procedure, patients should have a radiographic study (either plain or contrast enhanced chest and abdominal X-ray) to exclude perforations leading to pneumomediastinum or pneumoperitoneum. Antibiotics are usually given during the procedure and for

several days after the discharge^[83,87].

Some authors perform an EGDS and a timed barium esophagogram (TBE) on the 1st post-operative day to confirm mucosal integrity. If mucosal integrity is confirmed by these studies, the patient may be allowed to drink on day 1, soft diet is started on day 2 and normal diet can be restarted on day 3^[87]. Post-operative TBE can also be used to confront the Vaezi score before and after the procedure. Reported results of POEM are excellent with dysphagia efficacy using Eckardt score in > 90% of subjects, no mortality is reported this far^[82,91-100]. On the subject of POEM complications, pneumoperitoneum and pneumomediastinum are usually managed with either paracentesis and by inserting a small caliber of intercostal drainage for a couple of days^[87].

Acute intraoperative bleeding can be managed, if the bleeding point can be identified, by mean of normal coagulation techniques used in ESD (Coaggrasper, APC, etc.). In case of an unidentified bleeding point, applying pressure with the tip of the endoscope in the submucosal space or from the natural lumen is suggested. A post-operative hematoma may occur; conservative treatment, keeping the patient fasting with intravenous antibiotics is suggested. The hematoma, usually, resolves spontaneously within 1 to 2 wk.

Post-operative hematemesis, melena, hypotension, retrosternal pain may be the hallmark of a delayed bleeding. CT-scan and emergency upper GI endoscopy are mandatory to confirm the diagnosis. The bleeding point is usually located at the edge of the sectioned muscle; in case the bleeding point cannot be identified, placing a Sengstaken-Blakemore tube is an adequate treatment^[101].

GERD is the most frequent adverse event after POEM, prevalence varies considerably^[82,90-92,95,96,100,101] and can be as high as 40%.

Self-expanding metallic stent

Early reports regarding the use of self-expanding metallic stent (SEMS) in the treatment of achalasia unresponsive to conventional treatments were published in 1998^[102]. SEMS permanently disrupt the muscular fibers of the cardia and represents a safe and effective measure for patients not fit for more invasive therapeutic options; Nitinol coil (InStent Inc., Eden, Paire, United States), Ultraflex (Microvasive, Boston Scientific, Natick, MA, United States) or specially designed (Z-stent, Sigma, Huaian, China) stents have been tested, keeping them in place for 3-7 d^[103,104] or 30 d^[105].

All the trials regarding the use of metal stents in achalasia reported a technical success of 100% and early clinical success of 87%-100%^[102,104-107].

Success rates largely depend on the stent diameter, being higher for 30 mm stents compared with either 25 and 20 mm (87% vs 73% vs 43% clinical remission rate respectively)^[107].

Complications reported were migration (5.3% to 37.5%) and chest pain (17% to 40%)^[102,104-107], one single case series of 4 patients reported the occurrence of

dysphagia recurrence secondary to food bolus impaction or inflammatory stricture (100%)^[108], one patient died secondary to aorto-enteric fistula. Even complication rate depends on the diameter, the wider the stent, the lower the migration rate (6.6% vs 13.3% vs 26.7%) and the higher the chest pain rate (40% vs 33% vs 17%, respectively)^[107]. All the authors concluded that temporary stent placement is an effective treatment for achalasia and could be used for treating carefully selected cases.

DECISION MAKING IN THE TREATMENT OF ACHALASIA

About 90% of patients treated for achalasia can return to good quality of life and normal swallowing function^[109]. On the other hand, few can be cured with only one treatment, repeat procedure might be needed as many patients relapse over time.

Success rates for Heller myotomy and dilatation defined as relieve from dysphagia or regurgitation are quite similar as shown in a study from the Cleveland Clinic^[63]. Moreover, a large retrospective longitudinal study from Canada shows that the cumulative risk for any subsequent treatment (dilatation, myotomy, or oesophagectomy) after 1, 5, and 10 years was slightly higher for pneumatic dilatation compared to HLM (36.8%, 56.2%, and 63.5% after initial pneumatic dilatation vs 16.4%, 30.3%, and 37.5% after initial myotomy (HR 2.37; 95%CI: 1.86-3.02) but this risk difference only occurred when repeat was recorded as an adverse event^[110].

Physiological studies can predict long-term success of therapeutic maneuvers. Eckardt *et al.*^[61] reported that remission rates at 2-year follow-up largely depended on post-procedural LOS pressure being 100% for LOS pressure less than 10 mmHg, 71% for post-procedural LOS pressure between 10 and 20 mmHg and 23% for pressure over 20 mmHg.

The timed barium oesophagram is also a better predictor of success than LOS pressure is; patients with complete symptom relief and improvement in oesophageal emptying were likely to fare better than those with symptom relief but poor oesophageal emptying (82% vs 10%) at 3-year follow-up as Vaezi *et al.*^[41] reported.

Age, sex, and manometric type by HRM are also predictors of responsiveness to treatment. Success rates for pneumatic dilatation are higher for type II achalasia than for type I and type III (96% vs 56% vs 29% respectively) as Pandolfino *et al.*^[45] reported. Type III achalasia might be best treated by laparoscopic Heller myotomy (LHM). It is still unclear whether the fact that a patient had been previously treated endoscopically may hamper the results of a LHM.

Some studies suggest that previous treatments could negatively impact the results of the laparoscopic operation^[111-114] whereas other authors reported that

only patients who had been previously treated with both botulin toxin injection and pneumatic dilatation had worst results.

With reference to the age factor, patients younger than 40 years need repeat pneumatic dilatations more often than those older than 40 years usually do; also, male respond less well than women do to pneumatic dilatation^[1,61,63,66,115]. Similarly, women younger than 35 years do not respond well to pneumatic dilatation^[63]. These findings are probably due to stronger LOS tone in younger patients. Myotomy is, then, the best treatment for adolescents and young adults. Also, pseudoachalasia is best treated by LHM.

Botulinum toxin injection should be considered as a first line therapy for elderly patients or those in which severe comorbidities make them poor surgical candidates since it is safe, effective and might need to be repeated no more than once a year.

The role of POEM as a substitute for myotomy will have to be defined over time with longer follow-up studies, at present, Inoue highlights its usefulness as a re-do procedure in case of LHM failure.

Due to the difficulty to resect adhesions in redo surgery and high morbidity of esophagectomy, POEM is a better choice for treatment recurrence achalasia. Also, a POEM can be useful in these cases as it allows to perform another myotomy in a different location from the prior surgery^[87].

Abstract

Over the last few years, endoscopic submucosal dissection (ESD) has shown to be effective in the management of early colorectal neoplasms, particularly in Asian countries where the technique was born. In the Western world, its implementation has been slow and laborious. In this paper, the indications for ESD, its learning model, the available methods to predict the presence of deep submucosal invasion before the procedure and the published outcomes from Asia and Europe will be reviewed. Since ESD has several limitations in terms of learning achievement in the West, and completion of the procedure for the first cases is difficult in our part of the world, a short review on colorectal assisted ESD has been included. Finally, other endoscopic and surgical treatment modalities that are in competition with colorectal ESD will be summarized.

Key words: Endoscopic submucosal dissection; Endoscopic full-thickness resection; Endoscopic mucosal resection; Hybrid endoscopic submucosal dissection; Early colorectal cancer; Assisted endoscopic submucosal dissection; Magnification chromoendoscopy; Colorectal surgery; Colorectal neoplasm; Submucosal invasion; Predictive factors; Training; Learning curve

INTRODUCTION

Current colorectal cancer (CRC) screening population-based programs^[1,2] will increase the detection of early neoplastic lesions suitable for endoscopic resection^[3]. Although endoscopic mucosal resection (EMR) is appropriate to resect large flat or sessile colorectal lesions^[4-8], recurrence after piecemeal resection is still a limitation^[9,10]. In recent years, endoscopic submucosal dissection (ESD) has been endorsed as an ideal technique for *en bloc* resection of large colorectal neoplasms with high risk of focal adenocarcinoma or submucosal fibrosis^[11]. Nevertheless, the optimal outcomes of colorectal ESD (CR-ESD) achieved in Japanese series^[12,13] are constrained by the long learning curve and high complication rate when trying to introduce it in Western countries^[14-16]. Thus, there is some controversy regarding the best approach to the management of large early neoplastic lesions in the colon^[17]. Some authors advocate for the refinement of piecemeal EMR or a hybrid method of combined submucosal incision and EMR as a more realistic option for Western endoscopists^[7,10,18], whereas others support progressive embracement of CR-ESD through a well-defined training strategy^[19-21]. Different topics related to CR-ESD, including training, indications, outcomes, adjunctive devices to simplify the procedure and results when ESD is compared to alternative techniques, will be reviewed.

TRAINING: JAPANESE VS WESTERN MODEL

ESD is a complex procedure and the mastery of technical skills by new trainees has been based on a traditional mentor-pupil close teaching relationship in Japan since the introduction of the technique^[22,23]. However, recent expansion of ESD in Western countries has been led by a small group of experienced endoscopists that have usually performed a self-learning process based on observation and animal model training^[24-27]. Obvious reasons for this different approach are the lack of ESD experts in Western countries and the low detection rate of early gastric cancer as the ideal setting for beginners.

Japanese training model for ESD

In Japan, the traditional model of teaching ESD has

consisted of senior experts in large referral centers directly supervising new trainees in a step-by-step scheme^[28-30]. Firstly, there is a selection of potential candidates based on prior achievement of good skills on endoscopic diagnosis of early gastrointestinal cancer and therapeutic maneuvers^[28]. Secondly, the apprentice has to observe a certain number of ESD procedures performed by the mentor, occasionally participating as an assistant to become familiar with the special devices used. If possible, the trainee should complete this initial training period with some hands-on exposure to animal models^[31]. The trainee is then invited to perform some partial phase of the ESD (marking, initial circumferential cutting, final dissection, preventive coagulation...) under close supervision by the mentor^[32]. The ideal setting that has been suggested to begin with is performing ESD in selected lesions at an easily accessible gastric location^[30]. When considered ready, the trainee is finally encouraged to perform a complete gastric ESD. Increasing number of cases completed eventually grant enough skills to move on to more difficult locations in the stomach. Several Japanese authors have suggested a number ranging from 20 to 80 cases to be considered proficient in gastric ESD^[29,30,32]. Afterwards, the trainee may continue with other areas of the GI tract: esophagus, rectum and colon. Difficult colonic cases are generally restricted to experts with outstanding skills and extensive experience^[33].

CR-ESD training in Japan

CR-ESD represents the last step in the natural evolution of ESD training. Colonic lesions are commonly located in difficult areas, where positioning of the endoscope may be extremely challenging, and there is general agreement that prior experience with gastric ESD is needed^[34,35]. Several studies have investigated the appropriate number of CR-ESD to achieve proficiency. Some authors have proposed a minimum number of 20-30 cases under close supervision to achieve a certain level of competence^[36], and it is advisable to begin with rectal and smaller lesions^[37]. Nevertheless, the numbers needed to secure a high profile of successful R0 resection with few complications are closer to 80-100, according to some reports^[38].

Western training model for ESD

Small groups of endoscopists with particular interest in the technique have commonly promoted initiation of ESD in Western countries. The typical profile is that of an experienced attending gastroenterologist with extensive background in interventional endoscopy (EUS, ERCP, EMR...) ^[39]. Preliminaries could be either self-study based on articles and videos of procedures, attending ESD courses with hands-on training in animal models, etc. It is of particular interest to complete a visit to Japanese centers, where the trainee can benefit from first-hand experience observing experts performing ESD cases^[25,26]. This is a good opportunity to learn the basics of chromoendoscopy and magnification for lesion

assessment, different knives and ancillary devices used, steps of the ESD procedure including management of early and late complications, as well as specimen fixation and pathological assessment^[27]. Additional extensive hands-on training using animal models is essential for the next steps in skills acquirement, up to the point when main outcomes are good enough to encourage completion of the first human ESD cases^[19,24,25]. The fulfillment of the first human ESD cases should be based on a careful selection with preference for small gastric or rectal lesions. All these steps have been recommended in a European Society of Gastrointestinal Endoscopy position statement^[40], and a training algorithm comprising most of them has been recently proposed^[19].

Unfortunately, in many centers this training pathway must be self-teaching and is limited by the unfeasibility to obtain access to animal laboratory resources. Frustration from technical struggle or frequent complications may lead the process to a premature dead end. In addition, the bulk of potential candidates for ESD according to current recommendations are colorectal lesions^[11,39], which makes it ever more arduous and disheartening. There are some approaches to overcome these limitations: proposing a Japanese expert to come to your institution for direct supervision during the first ESD cases^[24,27,41] or attending hands-on courses in animal models in Japan to practice ESD under expert supervision have been suggested^[42].

Colorectal ESD training in Western countries

There are several studies in Europe focused on CR-ESD training. Initial reports showed suboptimal *en bloc* and R0 resection rates at the beginning^[15,43], but rapid progression was observed within a relatively a short time^[14,20,21,41]. The majority of endoscopists begin with selected small rectal lesions, to later move on to other colonic locations.

Some authors have proposed that a minimal intensive training may be sufficient for expert Western endoscopists to complete a sequential learning curve in rectal and colonic ESD, with a minimum of 20 untutored cases each after a short initial animal hands-on period (< 10 cases)^[41]. Nevertheless, such an approach should be carefully considered since reports from high volume Japanese centers recommend a minimum of 80 cases to obtain adequate skills, both in terms of speed (< 15 min/cm²), perforation (< 6%), *en bloc* (> 95%) and R0 (> 90%) resection rates^[38]. These numbers must be considered in light of the well-established scenario of close expert supervision in Japanese centers, which is frequently not the case in Europe^[16]. Some experts have recommended for inexperienced Western endoscopists to complete at least 40 cases before attempting large or fibrotic CR lesions^[44], two characteristics commonly present in the eligible population for CR-ESD^[11].

In summary, it has been shown that the ESD training process in Europe in a prevalence-based approach will be undoubtedly shaped by a significant number of

colonic and rectal cases^[39]. Untutored ESD training can achieve good outcomes in CR-ESD, but it is encouraged that initial cases are early neoplastic lesions with a low risk of invasion due to the fact that R1 resection is common in inexperienced endoscopists^[39]. Western reports have generally considered a resection rate > 80% acceptable; however, if Western endoscopists wish to pursue excellence in ESD, target outcome standards should probably not be less than those established in Japan, *i.e.*, *en bloc* and R0 resection rate > 90%.

HISTOLOGICAL PREDICTION AND INDICATIONS IN THE WEST

Intramucosal lesions and those well or moderately differentiated T1 adenocarcinomas with submucosal invasion less than 1000 µm and no lymphovascular infiltration, have little or no risk of metastasis^[45] and therefore constitute a typical indication for endoscopic treatment and especially for ESD. In a retrospective series of patients treated at the National Cancer Center Hospital (NCCH) in Tokyo, it was noted that the mucosal morphological pattern accurately predicted the risk of submucosal invasion. In this study, the laterally spreading tumor non granular (LST-NG) type lesions showed a higher risk of submucosal invasion compared with granular (LST-G) type lesions with a statistically significant difference (14% vs 7%; $P < 0.01$)^[46]. On the other hand, the presence of large nodules in LST-G type lesions, the finding of an invasive pit-pattern, "sclerotic" changes in the colorectal wall and a larger size in LST-NG type neoplasms, were also predictors of submucosal invasion. In this series, whereas submucosal invasion in LST-G most often occurs beneath the largest nodules and less frequently under depressed areas, 28% of LST-NG showed multifocal submucosal invasion in areas where there was no endoscopic warning signs. These findings were recognized as evidence of a different biological behaviour and drew attention to the need for an *en bloc* resection of these neoplasms.

The development of magnification chromoendoscopy (MCE) allowed Japanese endoscopists to describe different pit-patterns^[47] as well as microvascular structures^[48] in early CRC, increasing the accuracy of the histopathological prediction and improving the therapeutic decision-making process. When performed by Japanese expert endoscopists, MCE achieved a diagnostic accuracy of 98.8% in differentiating intramucosal or submucosal sm1 superficial invasion from sm2-sm3 deep submucosal invasion^[49]. In another seminal study, the identification of a type III A microvascular pattern by Narrow Band Imaging was predictive of intramucosal or sm1 neoplasia in 94.5% of cases, while a type III B pattern was associated with sm2-3 carcinomas in 72% of cases^[50].

We have fewer data from European or American centers, but a major Australian series of colorectal tumors treated by EMR^[7] found that LST-NG type with a Paris 0-II a +

Table 1 Indications for colorectal endoscopic submucosal dissection (Japan Gastroenterological Endoscopy Society)

Lesions for which endoscopic <i>en bloc</i> resection is required
(1) Lesions for which <i>en bloc</i> resection with snare EMR is difficult to apply
LST-NG, particularly LST-NG pseudo-depressed type
Lesions showing a Vi-type pit pattern
Carcinoma with shallow T1 submucosal invasion
Large depressed-type tumors
Large protruded-type lesions suspected to be carcinoma. Including LST-G, nodular mixed type
(2) Mucosal tumors with submucosal fibrosis as a result of a previous biopsy or prolapse caused by intestinal peristalsis
(3) Sporadic localized tumors in conditions of chronic inflammation such as ulcerative colitis
(4) Local residual or recurrent early carcinomas after endoscopic resection

EMR: Endoscopic mucosal resection; LST-NG: Laterally spreading tumor non granular; LST-G: Laterally spreading tumor granular.

II c morphology and a Kudo crypt pattern V had a risk of submucosal invasion of 55.5%. On the other hand, LST-G homogeneous type tumors presented submucosal invasion in only 1.5% of cases. These figures reflect that superficial colorectal neoplasms behave similarly to those described in Japanese series and therefore morphological pattern and epithelial crypt analysis can be used for histological prediction and treatment decision-making in Western patients.

Many studies confirm the accuracy of Western endoscopists in differentiating between neoplastic and non-neoplastic polyps, but few reports have focused specifically on their ability to predict the presence of deep submucosal invasion prior to an endoscopic resection attempt. A study from the United Kingdom^[51] showed that Western endoscopists achieved a diagnostic accuracy of 78% in predicting deep submucosal invasion in Paris 0-II lesions by analyzing epithelial crypts and vascular patterns with MCE. In this study, high frequency miniprobe ultrasound examination improved the accuracy up to 94%.

Nevertheless, the limited data available from surgical series, including lesions deemed as endoscopically non-resectable, have demonstrated that between 10% and 20% of the specimens showed deep colonic wall invasion (stages T2-T4) or lymph node metastases that had not been suspected in the endoscopic assessment^[52-55], indicating a lower than expected accuracy in real life conditions.

The role of endoscopic ultrasonography (EUS) in the diagnosis of submucosal invasion or nodal involvement has been controversial. In one small study from Western Europe, endoscopic ultrasound with a 20 MHz probe was better than MCE in determining the depth of invasion and nodal staging^[56], but these results have not been consistently observed in other series of patients. In a study including more than 430 neoplasms treated in a single center in Japan, no significant differences were noted in the diagnostic accuracy between MCE and EUS^[57].

In general terms, ESD is indicated for the treatment of colorectal neoplasms that show no suspicion of deep submucosal invasion assessed by MCE and that cannot be resected *en bloc* by EMR. Given the technical

characteristics of ESD, the size of the lesion is not a limitation, although circumferential lesions are generally considered a contraindication given the high risk of stenosis.

In the absence of local evidence, most Western endoscopists performing ESD have traditionally followed Japanese guidelines. Table 1 shows ESD indications of the Japan Gastroenterological Endoscopy Society^[11]. In Europe, the Spanish Society of Digestive Endoscopy^[58] and the European Association of Endoscopic Surgery^[59] have adopted most of the Japanese indications for ESD as a standard treatment for superficial neoplasms larger than 20 mm in which *en bloc* EMR is difficult. These statements include mixed type LST-G, LST-NG, especially the pseudo-depressed type (Figure 1), large depressed lesions with a noninvasive pattern as assessed by MCE and neoplasia with fibrosis in the context of prior biopsy, attempts of resection or chronic inflammation.

Despite the gradual incorporation of Japanese knowledge about diagnosis and prediction of histological findings into European and American practices, major differences exist between Eastern and Western viewpoints on the endoscopic treatment of colorectal neoplasms. While ESD is widely accepted in Japan, and Japanese National Health Insurance has been covering its cost since 2012, in most Western hospitals a significant number of patients with endoscopically treatable lesions are still referred for surgery. In our part of the world, EMR is the preferred technique for the treatment of superficial neoplasms. As an alternative modality, ESD is still in the early steps of development, with a lack of a clear definition of its place in the treatment algorithms and significant uncertainties about the coverage of its costs.

These differences are clearly due to the greater experience of Japanese endoscopists, but also and significantly, because in Japan there has been little controversy about the importance of *en bloc* resection of tumors in which a risk of submucosal invasion is foreseeable. On the contrary, many Western endoscopists would contend that since most T1 adenocarcinomas with deep submucosal invasion can be identified in the histopathological study of piecemeal EMR, the benefits of *en bloc* resections are limited to a relatively small number

Figure 1 Endoscopic assessment and endoscopic submucosal dissection for a laterally spreading tumor non granular pseudodepressed type in the transverse colon. A: High resolution white light endoscopy; B: Targeted chromoendoscopy with indigo carmine (0.4%) highlights the border and characteristics of the lesion; C: Magnification chromoendoscopy with crystal violet (0.05%) shows a Kudo's Vi pit-pattern; D: Performing ESD with a 1.5 mm Flush-knife BT (Fujinon, Tokyo, Japan); E: Submucosal dissection of the lesion with an IT nano (Olympus, Tokyo, Japan); F: Residual scar after completion of the procedure; G: Resected specimen of CR-ESD stretched with pins on foam. Maximum diameter of the lesion was 32 mm; H: Specimen sectioned into pieces for histological assessment in the Department of Pathology. ESD: Endoscopic submucosal dissection; CR-ESD: Colorectal endoscopic submucosal dissection.

of lesions with sm1 infiltration which, in the case of R0 resections, could avoid surgery. Others would however argue that even intramucosal large LST-NG that can be difficult to resect by EMR because of partial non-lifting, could itself justify the implementation of the procedure.

OUTCOMES IN ASIAN AND IN EUROPEAN COUNTRIES

The tortuous morphology of the large intestine, a thinner wall when compared with the stomach, and the strong peristaltic motion of the colon, leads to a higher likelihood of complications during the procedure. It is very likely that the ESD learning curve is slower in the colon than in the stomach, and it has been overcome for many years in the experienced Asian centers.

As mentioned before, the experience with colorectal ESD out of the Asian countries is scarce. In European countries, our limited experience has shown less

favourable results than those coming from the East, with lower *en bloc* and R0 resection rates and higher perforation rates.

Tables 2 and 3 summarize the most relevant data of the published series. Many of them have methodological limitations and an intention-to-treat analysis is lacking. Although it is commonly reported that the cases are consecutively enrolled, other information is often not provided. In most cases, they are cross-sectional studies and when follow-up is included, this is usually for a period less than 3 years. More importantly, considering that we are talking about oncological outcomes, the 5-year survival rate has been assessed in only one study^[60].

The percentage of non-curative resections oscillates between 3.6%^[61] and 22.7%^[62]. Furthermore, it is noteworthy that the percentage of aborted procedures is scarcely reported. This is particularly striking when a complex procedure, with a prolonged learning curve, comes into focus. Reviewing the published series,

aborted ESD procedures of between 3.6% and 15.9% have been described^[14,61,62].

Additionally, regarding complications, the perforation rate requiring surgery is seldom described, within a range of between 0%^[61-67] and 2.8%^[68]. Similarly, the need for transfusion or urgent endoscopic therapy due to severe gastrointestinal bleeding are, fortunately, rare, between 0%^[12,64,65,69-71] and 2.2%^[72].

Since ESD is accompanied by risk of delayed perforation and bleeding the postoperative course needs to be monitored carefully. However, no recommendations have been established for patient discharge after the procedure. Some Japanese authors have suggested a 5-d hospital stay for ESD^[73]. In South Korea and some European countries, duration of the hospital stay is 2-3 d unless complications develop^[16,72]. Recently, a Japanese group has published a clinical pathway to shorten hospital stays after the procedure. The authors concluded in the study that a three-day stay may be sufficient when no abnormalities occurred during ESD or on the first day after the endoscopic resection^[74]. In our center, a stay that lasts 3 d is typically the case when no complications are observed. No delayed perforations have been identified after those 3 d in our experience; indeed, this complication is more likely to happen during the first 24 h after the procedure.

COLORECTAL ASSISTED ESD

A good visualization of the submucosal layer is one of

the key factors for performing an effective and safe CR-ESD, and this can only be achieved by proper traction of the tissue.

Benefits of applying traction during ESD are the following: (1) It can provide better submucosal exposure and consequently decreases the risk of perforation; and (2) Traction decreases the contact area between the tissue and the endoknife, enabling a more effective cut^[75].

However, achieving good traction using only one knife through the scope is not easy. Unlike surgeons, who maintain tension and visibility by the hands of assistants, or by more than one device, the endoscopist who performs ESD can be considered as a one-armed person. In order to improve this disadvantage, a number of adjunctive devices have been designed.

Sinker-assisted ESD

A sinker-assisted ESD for colorectal neoplasms was reported by Saito *et al*^[76]. A 1 g sinker is attached to a metallic clip by a nylon thread. After the initial dissection of the submucosa, the clip is deployed to the edge of the mucosa. The sinker will then pull down the partly resected tumor. Finally, changing the position of the patient, will allow gravity to expose the submucosal layer in order to enhance visibility for the remaining dissection.

The Sakamoto and Osada clip

The S-O clip (Sakamoto and Osada clip) consists of

a metal clip attached to the end of a spring. A double nylon loop is connected at its other end. This system passes easily through the working channel of the endoscope. The device is attached to the mucosal flap and a second clip grasps the distal nylon loop to insert this end of the S-O clip to the wall opposite the lesion^[77].

Thin endoscope-assisted ESD

A double-scope method for large LSTs in the distal sigmoid colon or rectum has been reported by Uraoka *et al*^[78]. When partial dissection of the submucosa has been performed, a clip is attached to the edge of the mucosal flap. A thinner endoscope is then passed through the anus and the primary endoscope is removed. At that point, a snare grasps the clip and pulls the lesion away from the muscle layer. This maneuver allows retraction of the submucosa and improves visualization. The primary scope is inserted again to resume the dissection. A limitation of this method is that the thin endoscope is not stiff enough to achieve deep intubation and using it for proximal lesions is not possible.

"Clip-flap" method

Yamamoto *et al*^[79] reported recently a simple procedure requiring only common clips. After the mucosal flap has been created and the submucosal layer partially dissected, the edge of the mucosa is grasped with an endoclip. The cap attached to the tip of the endoscope is slipped under the clip and the dissection can be resumed as normal. One endoclip can be used for one region and other endoclips can be deployed in additional regions as needed. It is also possible to use two clips crossing one another. However, this method has several

limitations. When the colonic lumen narrows or the position of the endoscope becomes unstable, it may be difficult to grasp the mucosa with the clip and slip the cap under the device.

COLORECTAL ESD VS OTHER THERAPEUTIC STRATEGIES

EMR

Currently, ESD is the only technique that allows *en bloc* resection of colorectal mucosal or submucosal neoplasms of any size except for the full-thickness resection procedures. In the Western world, however, most lesions larger than 20 mm are still treated by piecemeal EMR.

In a prospective study of a large series of patients treated in 18 Japanese reference centers, it was observed that the rate of *en bloc* EMR was significantly reduced as the diameter of the lesion increased, reaching 66.5% in lesions of 20-29 mm, but was only 12.3% in lesions larger than 40 mm. Conversely, ESD *en bloc* resection rates remained above 90% regardless of the size of the lesion^[80].

The first study comparing retrospectively the results of colorectal EMR and ESD included 373 (145 ESD/228 EMR) resected tumors between 2003 and 2006 by expert endoscopists at the NCCH in Tokyo^[81]. As a result of differences in the indications of both procedures, the ESD group included larger lesions (37 ± 14 mm vs 28 ± 8 mm; *P* = 0.0006). However, the *en bloc* resection rate was significantly higher when performing ESD (84% vs 33%; *P* < 0.0001). An increased risk of tumor recurrence at follow-up colonoscopies was observed after EMR when compared with ESD (2% vs 14%;

$P < 0.0001$). It is worth noting that, in this study, all recurrences detected in the ESD group occurred after treatment of lesions previously treated by piecemeal EMR. The mean procedure time was nevertheless more than three times longer in patients treated with ESD (108 min vs 29 min; $P < 0.0001$) and perforations were almost five times higher (6.2% vs 1.3%), although differences were not statistically significant.

Some Japanese and South Korean studies^[73,82-85] have shown better outcomes for ESD in terms of *en bloc* and R0 resections and lower recurrence rates. In addition, higher perforation rates and an increased length of the procedure time have been also observed. Some of these studies, however, excluded patients who underwent surgery because of submucosal invasion, which could represent an overestimation of the clinical effectiveness of this procedure^[73,82]. Furthermore, it has been shown in both Eastern and Western series of ESD that its benefits on a lower rate of local recurrence rely on the ability of the procedure to achieve *en bloc* resections and only become evident in those procedures performed by endoscopists with a high proportion of R0 resections^[14].

The endoscopic resection of recurrent adenomas is another matter of concern. Although ESD may be used in endoscopic salvage procedures for recurrent lesions, performing this procedure is extremely difficult because of the presence of submucosal fibrosis attributable to previous resection. For this reason, in the Western world, the most commonly endoscopic procedure for treating recurrent adenomas after EMR is one additional EMR, although fibrosis after a previous resection often prevents lifting of the lesion after submucosal injection and causes the snare to slip off the tumor. There are very limited published data on the results for this strategy, with more than 10% of the patients needing surgery in this scenario^[7].

In a retrospective case series that included 67 cases of a second endoscopic resection for recurrent neoplasias, ESD achieved a 56% *en bloc* resection rate compared with 39% in the EMR group. Both of these results are lower than expected for primary colorectal tumors^[86]. In contrast, another study observed that 27 out of 28 patients were successfully treated using ESD for residual or recurrent colorectal tumors^[67].

More recently, underwater EMR (UEMR) has been evaluated for the treatment of these recurrences. When colon water distension is used instead of gas, the mucosa and submucosa involute, keeping the muscle layer in place, and there is no need for submucosal injection. Thus, the tumor can be snared easier than with conventional EMR. In a retrospective study, the *en bloc* resection and endoscopic complete removal rates were higher in the UEMR group when compared with the EMR group, and these differences were statistically significant. In addition, argon plasma coagulation ablation of residual tumor was lower in the UEMR group^[87]. Although the study had several limitations, UEMR appears to be useful for salvage endoscopic management of recurrent lesions

after a previous EMR.

Finally, some aspects remain to be clarified concerning the use of these endoscopic procedures for the treatment of defiant colorectal polyps. Thus, isolated cases of submucosal recurrences after piecemeal resection for intraepithelial or intramucosal neoplasms have been reported^[73,81]. This complication has been attributed to staging errors derived from the histopathological study of a piecemeal resection. Additionally, there is no data concerning the impact of perforations that occur during ESD on oncological prognosis.

ESD vs surgical procedures

The two main surgical options at present are laparoscopic-assisted colorectal surgery (LACS) and transanal endoscopic microsurgery (TEM). Several non-randomized controlled studies have compared ESD and surgical modalities for management of colorectal lesions, but good quality evidence is lacking to allow substantial recommendations. ESD has been shown to be a good option for early colorectal neoplastic lesion with absent or shallow submucosal invasion^[12,20,72], but diverse results have been reported when compared with alternative surgical modalities. Recent European guidelines for early rectal cancer do recommend either ESD or TEM, both with optimal curative resection rate, and discourage against conventional transanal excision unless both ESD and TEM are not feasible^[59].

LACS

LACS has widely succeeded as a less invasive technique compared with conventional open surgery^[88,89]. One retrospective study performed at the NCCH in Tokyo compared ESD with LACS for colorectal early carcinoma^[90]. The study population comprised T1m/T1sm1 in the ESD group and T1sm2 in the LACS group. Lesions were located from cecum to rectum, with double the proportion of rectal lesions in the ESD group (38% vs 17%). Results showed that ESD was associated with a shorter procedure time (106 min vs 206 min), shorter hospital stay (5 d vs 13 d) and lower complication rates (6.4% vs 13.6%). Nevertheless, *en bloc* and curative resection rates were lower in the ESD group (87.2% and 80.4%, respectively), compared to 100% for surgical patients. Similarly, a recent retrospective study comparing a series of 300 colorectal ESD to 190 LACS revealed high *en bloc* and curative resection rates for ESD (> 90%), with a shorter procedure time and hospital stay, and a lower complication rate compared with LACS (90 min vs 185 min; 5 d vs 10 d; 7% vs 15%, respectively)^[91]. It should be noted, however, that this report might be shaped by selection bias since a significant proportion of cases in the LACS group (35%) were post-EMR "lesions/scars" vs no cases in the ESD group, and apparently different from what was defined as local recurrence on ESD. Additionally, the ESD group included more than 75% of the lesions as LSTs vs only 10% in the LAC group.

In terms of hospital stay, five days or longer in LACS groups are common in Japanese studies. However,

other studies have reported shorter periods when an elective surgery has been performed, ranging from 3^[52] to 6 d^[92-94].

TEM

TEM is a technique for *en bloc* full-thickness rectal wall excision up to the level of the perirectal fat that can be applied for lesions located as far as 18-20 cm from the anal verge. The minimal distance from the anal verge is 5 cm due to the rigid structure of the rectoscope, making it troublesome to approach a lesion next to the anal verge^[95]. Developed more than 25 years ago as an alternative to standard transanal surgery^[96], TEM has become one of the gold standards for early rectal cancers, whenever available^[59]. There is increasing evidence that TEM is superior to conventional transanal resection (TAR) in terms of *en bloc* and R0 resection rates, and thus, lower recurrence, together with lower complication rates^[97-99]. Some of the limitations of TEM include the long learning curve^[100], similar to ESD, and the need for quite expensive special equipment.

Contradictory results have been obtained when comparing TEM with ESD. Whereas a recent meta-analysis showed better outcomes for TEM^[101], single center-based studies, either head-to-head between both techniques, or only limited to rectal location, showed better outcomes for ESD, with fewer complications or a shorter length of the hospital stay. In the aforementioned meta-analysis, TEM appeared more effective than ESD in terms of *en bloc* and R0 resection rates (98.7% vs 87.8% and 88.5% vs 74.6%, respectively), with a shorter procedure time (67 min vs 96 min) and with no significant differences in the complication rate or the need for additional surgery due to adverse events. Adenoma recurrence rate was, however, higher in the TEM group (5.2% vs 2.6%). Nevertheless, this study included small ESD series, most of them with less than 50 cases and published before 2010^[101]. A report with a small study population in both groups of ESD and TEM (< 20) showed comparable *en bloc* (91%-84%) and R0 (81%-84%) resection rates, with no differences in complications or length of hospital stay^[102]. A South Korean single center retrospective study included patients with flat lesions with suspected high grade dysplasia or submucosal invasive carcinoma who underwent ESD or TEM^[103]. *En bloc* and R0 resection rates were similar in both groups (ESD vs TEM: 96.7% vs 100% and 96.7% vs 97.0%, respectively), with no statistically significant differences in complication rate (3.3% vs 6.1%, respectively). Hospital stay was significantly lower after ESD (3.6 d vs 6.6 d). It should be noted that over 20% of patients in both groups required additional treatment, mostly due to histological risk factors for lymph node metastasis.

Regarding hospital stay with TEM, this outcome may vary significantly across centers. Thus, some authors have reported a median hospital stay of 2-3 d^[104-107], while other studies suggest even shorter stays and

have reported a 24 h discharging policy^[108]. To our knowledge, prospective direct comparisons between TEM and ESD that address the question of superiority in terms of length of hospital stay have yet to be published.

In summary, in an ideal scenario of a well-trained endoscopist, ESD might be the best option for early colorectal neoplasia as it combines a high rate of curative resection, similar to surgical procedures, while maintaining a low profile of invasiveness and less need for general anesthesia^[109]. But frequently this is not the case in most institutions in Western countries, and standard surgical techniques are commonly more accessible to physicians. Favorable results for ESD compared to surgical procedures published recently were only based in retrospective analysis studies, with significant risk of selection bias. There is a lack of randomized controlled trials to establish good quality evidence regarding both techniques. Nevertheless, it seems that if colorectal ESD expansion backed with encouraging outcomes continues, it might be difficult to complete such ideal head-to-head randomized studies since less invasive procedures with good results frequently gain spontaneous acceptance by patients and physicians.

Endoscopic full thickness resection

Since CR-ESD is a technically demanding procedure, with a long learning curve and requires more time for its completion when compared with other resection techniques, simpler and more standardized methods are required for the treatment of colorectal neoplasms. Furthermore, performing CR-ESD is challenging in the presence of technically difficult lesions with severe fibrosis, recurrent lesions, or difficult locations (at the bottom of the cecum, near the terminal ileum, and in the appendix). The advantage of the full thickness resection is the ability to easily and quickly resect the main lesion and quickly close the colon wall defect. However, large-sized lesions are difficult to resect when using only a device that depends on a snare to achieve the resection^[110]. To date, endoscopic treatment for this type of lesion requires additional devices to support closure and suturing. Unfortunately, most of them are not commercially available for widespread use.

Recently, a novel over-the-scope (OTSC) device has been developed for colorectal endoscopic full-thickness resection (eFTR). Although, colonic eFTR is not widely available in clinical practice, the initial results of this procedure have been published recently^[111].

The full-thickness resection device (FTRD) consists of an OTSC System cap with a preloaded clip and a snare integrated into cap's distal end. The lesion that has been previously marked with a marking probe included in the kit is then identified with the colonoscope. The tumor is then pulled into the cap using a grasping forceps. After ensuring that all the marked tissue is completely included into the cap, the OTSC is deployed. Finally,

the lesion is resected after closing the snare, applying electrosurgical current, and retrieved from the colon with the endoscope.

In the study mentioned above the main indication for eFTR was the presence of residual or recurrent neoplasm after a previous endoscopic resection. The median time to complete the procedure was 50 min. The mean diameter of the resection specimen was 24 mm within a range of 12 to 40 mm. The *en bloc* resection rate, R0 resection rate and the percentage of histologically confirmed full-thickness resection were 83.3%, 75.0% and 87.5%, respectively. There were no perforations or severe bleeding episodes. A postpolypectomy electrocoagulation syndrome was observed in 8% of the patients that was successfully treated with antibiotics.

The FTRD has, however, several limitations. The diameter of the outer cap does not allow the system to pass through the oral route. Consequently, it cannot be used for resection in the upper gastrointestinal tract. In the colon, the main limiting factors are the size of the lesion and the presence of submucosal fibrosis. Tumors over 25 millimeters in diameter might not easily fit into the cap and lack of elasticity of the colonic wall because of severe fibrosis often makes the resection difficult. Additionally, in the rectum, the perirectal tissue that fixes it prevents the achievement of a full-thickness resection.

CONCLUSION

CR-ESD is a major advance for the treatment of colorectal neoplasms: it has well-established indications, achieves higher *en bloc* resection rates when compared with EMR and is less invasive and costly than surgery.

Nevertheless, ESD also has several disadvantages: It has a long learning curve and the training process is not well established outside of Asian countries. These problems still have to be resolved in Europe. Additionally, complications in terms of bleeding and perforation rates are higher than those associated with EMR, a more established endoscopic procedure in Western countries.

Despite the many devices commercially available to perform the technique, standardization of CR-ESD still needs to be defined. Indeed, to date, the skill of the endoscopist seems to be the determining factor to achieve excellent outcomes.

Finally, simpler and more time-efficient methods for the treatment of colorectal tumors are required and new developments in this area are very likely to appear in the next few years. Probably, in the near future, methods such as FTRD will be competing treatments for CR-ESD in selected patients. More importantly, innovative methods and new devices for eFTR and suturing are evolving and may change the way the colorectal neoplasms are managed, blurring the boundaries between advanced endoscopy and surgery.

Abstract

Esophageal achalasia in children is rare but ultimately requires endoscopic or surgical treatment. Historically, Heller esophagomyotomy has been recommended as the treatment of choice. The refinement of minimally invasive techniques has shifted the trend of treatment toward laparoscopic Heller myotomy (LHM) in adults and children with achalasia. A review of the available literature on LHM performed in patients < 18 years of age was conducted. The pediatric LHM experience is limited to one multi-institutional and several single-institutional retrospective studies. Available data suggest that LHM is safe and effective. There is a paucity of evidence on the need for and superiority of concurrent antireflux procedures. In addition, a more complete portrayal of complications and long-term (> 5 years) outcomes is needed. Due to the infrequency of achalasia in children, these characteristics are unlikely to be defined without collaboration between multiple pediatric surgery centers. The introduction of peroral endoscopic myotomy and single-incision techniques, continue the trend of innovative approaches that may eventually become the standard of care.

Core tip: Laparoscopic Heller myotomy (LHM) is safe and effective in the pediatric achalasia population. Published studies are limited by their retrospective nature and small

sample sizes. Further information regarding the need for and type of concurrent fundoplication, a more complete description of complications, and long-term (> 5 years) outcomes is needed. Peroral endoscopic myotomy and the single-incision approach are innovative techniques that may eventually prove to be the standard of care. Herein, we review the available literature on LHM in children with achalasia.

INTRODUCTION

Achalasia overview and diagnosis

Achalasia is a motility disorder characterized by abnormal esophageal peristalsis and partial or complete failure of the lower esophageal sphincter (LES) to relax during deglutition. The condition was first described in 1674 by physician and neuroanatomist Sir Thomas Willis of England^[1,2]. It is an uncommon diagnosis with an overall incidence of 1.6 per 100000 individuals^[3]. Less than 5% of patients present under the age of 15^[4,5]; the childhood incidence is only 0.11 per 100000^[6]. The etiology of achalasia is not fully understood but it may result from degeneration of neurons in the esophageal wall^[1,7]. Associations with Down syndrome and Chagas disease have been described^[8]. Between 0.5% and 7% of children with Down syndrome have been found to have achalasia^[8,9]. Children with the autosomal recessive Allgrove syndrome (triple A syndrome) suffer from alacrima, achalasia, ACTH-insufficiency, autonomic dysfunction, and neurodegeneration^[10]. These patients initially present with alacrima but achalasia is generally the first symptom which prompts pursuit of medical attention and diagnosis^[11].

Clinical suspicion for achalasia should be raised in children with dysphagia to solids and liquids and regurgitation of undigested food or saliva^[12]. Symptoms may progress to chest pain, emesis, aspiration, weight loss, and failure to thrive^[8]. Table 1 summarizes common symptoms and associated conditions of achalasia in children. Manometry is the most sensitive diagnostic tool^[13] characterizing incomplete or complete absence of LES relaxation with concurrent distal esophageal aperistalsis. For patients with equivocal motility testing, a barium esophagram will reveal a proximally dilated esophagus with distal tapering (Figure 1), the classic "bird-beak" appearance^[14]. An abnormal esophagram should be followed by upper endoscopy, to rule out a structural abnormality such as a Schatzki ring or congenital cartilaginous stricture^[15]. Newer methodologies for diagnosis include high-resolution manometry (HRM)

and multichannel intraluminal impedance pH monitoring (MII-pH); both of which can offer additional physiological details in diagnostic dilemmas^[16]. Specifically, HRM can plot the pressure generated by the esophagus, creating a topographical map which allows classification of achalasia into additional subtypes (I - III)^[16]. This information can then be used to provide tailored treatment. Using a series of electrodes, MII-pH can measure the intraluminal impedance of a food bolus^[16]. In general, HRM and MII-pH are not necessary if manometry is diagnostic.

Achalasia treatment overview

Treatment options for achalasia include pharmacological, endoscopic, or surgical methods. The primary goal is to decrease the pressure gradient across the LES. Calcium channel blockers are the most common pharmacological agents but their use in children is discouraged due to short-term effectiveness and concerning side effects^[16-19].

Few reports focus on the endoscopic injection of botulinum toxin for achalasia in the pediatric population; however available data suggest the duration of therapeutic effect is short-lived and may be beneficial as a bridge to more definitive treatment modalities^[16,20-22]. Randomized controlled trials (RCT) in adults confirm that laparoscopic surgical esophagomyotomy (Heller myotomy, LHM) is as safe, more durable^[23], and similar in cost long-term^[24], than injection of botulinum toxin.

Endoscopic pneumatic dilation (EPD) for achalasia in children has been described for many decades. Older reports identified favorable efficacy and durability^[4,25-29] as the reason for EPD as the initial procedure of choice^[4,27-30]. More recent literature with longer follow-up is mixed; some data suggest high rates of symptom recurrence necessitating repeat EPD^[17,31], while one study found an 87% overall 6-year success rate^[32] in children. In adults, a 2011 RCT reported equivalent therapeutic success of LHM and EPD at 2 years^[33]. Recent meta-analyses however, established that LHM results in few adverse events and higher rates of response compared to EPD^[34] and all other treatments^[35].

Based on the aforementioned literature, it is clear that randomized trials are needed to differentiate the effectiveness and resilience of EPD and LHM in children. Despite the lack of conclusive evidence, refinement of laparoscopic techniques in pediatrics, low complication rates associated with LHM, and high rates of success have shifted treatment preferences toward LHM^[17]. Herein, we aim to provide an overview of laparoscopic esophagomyotomy for achalasia in children and examine the current literature on this procedure.

PROCEDURE DETAILS

Evolution from open to laparoscopic esophagomyotomy

Heller *et al.*^[36] performed the first esophagomyotomy in 1913 via an open transabdominal approach and completed anterior and posterior myotomies on the distal esophagus (Figure 2A). The operation has undergone gradual modification including restriction to only an anterior

myotomy^[37], either a transthoracic or transabdominal approach^[38], and the addition of antireflux procedures to the transabdominal method^[39]. However, the past three decades have witnessed the development of minimally invasive (MIS) approaches that have led to significant change in the management of achalasia in adult and pediatric patients. The first minimally invasive Heller myotomy (MIS-HM) was performed by Shimi *et al*^[40] via laparoscopy in 1991 on a 30-year-old female. This patient was discharged on postoperative day (POD) #3 and was symptom-free at 3 mo. Pellegrini *et al*^[41], then adapted the procedure for a thoracoscopic approach (THM) and this was well tolerated in 17 patients, with two conversions to open for mucosal lacerations. Dysphagia did not improve in the initial 3 patients however follow-up surgery extended the myotomies distally with favorable results. Originally, THM was the MIS procedure of choice and only patients with previous myotomies or thoracotomies underwent a laparoscopic operation^[42]. However, in the mid-1990s, groups began comparing THM and LHM and indicated that LHM with partial fundoplication led to reduced perioperative pain, shorter length of stays (LOS), less conversions to open procedures, improved relief of dysphagia and lower incidence of postoperative reflux^[43]. The risk of an incomplete myotomy with THM^[44], as well as the addition of an antireflux fundoplication by laparoscopy^[45,46] were

Figure 2 Esophageal myotomies. A: The original Heller myotomy, consisting of both anterior and posterior disruption of esophageal fibers; B: The most commonly performed Heller myotomy, with extension onto the stomach for 2-3 cm; C: Heller myotomy with minimal extension onto the stomach.

two key features that led to LHM gradually becoming the standard of care^[47].

Operative steps for esophagomyotomy

Some surgeons prefer that patients are limited to a liquid diet for 1-2 d preoperatively to minimize the amount of debris in the esophagus^[48]. After induction of general anesthesia, we perform esophageal suctioning prior to intubation to prevent the risk of aspiration. Patients are positioned in a modified lithotomy position and secured to the operating table such that there is low risk of slippage when placed in steep reverse Trendelenburg. An orogastric tube is placed and the surgeon stands between the legs of the patient (Figure 3). A total of 4-5 trocars are placed and similarly positioned as in an antireflux procedure (Figure 4). In adults, the port immediately cephalad to the umbilicus is typically used for the camera (30° laparoscope), whereas a transumbilical location is preferred in children. The remaining ports are utilized for retraction, dissection, and laparoscopic suturing. The size, location and role of each port is based on the child's size and body habitus as well as surgeon preference^[16,48-52].

Once pneumoperitoneum is established and all ports are placed, the operation is begun by cephalad retraction of the liver and incision of the gastro-hepatic ligament to identify the right crus of the diaphragm (Figure 5). The peritoneum and phrenoesophageal membrane are divided and dissection is carried across the anterior midline to identify the left diaphragmatic crus. Dissection is continued cephalad, staying anterior and lateral to expose 6-7 cm of the lower thoracic and abdominal esophagus. Care must be taken to identify and preserve the anterior and posterior vagus nerves.

Figure 3 Patient positioning and operating room setup. The patient is placed in the modified lithotomy position and the surgeon stands between the patient's legs. First and second assistants are to the right and left of the patient.

Figure 4 Trocar placement. Example trocar arrangements. A: Laparoscope; B: Babcock clamp or instrument to divide short gastrics; C: Liver retractor; D and E: Ports for dissecting and suturing; E: Electrocautery or ultrasonic shears for myotomy. The laparoscope is generally placed through a transumbilical port in children. The remaining ports are usually placed more caudad than in adults, with variable size (3 mm or 5 mm, rarely 10 mm), location, and function depending on patient body size/habitus and surgeon preference.

If an anterior (Dor) fundoplication is planned, further posterior dissection is not necessary. If a hiatal hernia is present, the crura are re-approximated posterior to the esophagus using interrupted sutures. For children undergoing fundoplication, the stomach is mobilized by dividing the short gastric vessels along the greater curvature from its midpoint to the angle of His.

To begin the myotomy, the esophageal fat pad is removed and the gastroesophageal junction (GEJ) is exposed. An esophageal dilator or bougie is placed transorally, to assist in splaying of the muscle fibers and to provide support during the myotomy. Traction is applied caudad and to the patient's left, to expose

Figure 5 Incision of the gastrohepatic ligament. After retraction of the liver cephalad, the gastrohepatic ligament is incised and the lesser sac is entered. Blunt dissection is used to first identify the right crus of the diaphragm.

Figure 6 Myotomy with hook cautery. Electrocautery is used to begin the myotomy. It is performed at the 11 o'clock position on the anterior surface of the esophagus, taking care to avoid injury to the overlying vagus nerve. Once the submucosa is visible, blunt dissection is then typically employed to fully expose the mucosa.

the anterior surface of the esophagus. The myotomy is performed at the 11 o'clock position, typically using hook electrocautery (Figure 6). Many surgeons prefer to separate the longitudinal and circular muscle fibers of the esophagus bluntly after initial scoring sharply with electrocautery (Figure 7) or with other energy devices such as ultrasonic shears. The myotomy is then extended approximately 6 cm cephalad onto the esophagus, across the GEJ, and 2-3 cm onto the stomach (Figure 2B). Disruption and appropriate separation of muscle at the GEJ is often difficult due to decussation of the esophageal and gastric muscle fibers. The relationship between recurrence of dysphagia and length of myotomy extension onto the stomach is discussed in subsequent sections. While completing the myotomy, great care should be taken to avoid injury to the newly exposed mucosa. Previous Botox injections or EPD, prior to LHM may lead to scarring near the GEJ and portend a higher theoretical risk of perforation^[48,53,54]. Post-surgical data is mixed about this increased risk; at least one study suggests the risk is higher^[55] but others have shown there is no difference^[56,57]. If a perforation is suspected, it can be confirmed with endoscopy or esophageal water submersion and orogastric air insufflation. Mucosal

Figure 7 Myotomy with sharp and blunt dissection. Sharp and blunt dissection avoid the risk of thermal injury to the mucosa during myotomy.

Figure 8 Anterior (Dor) fundoplication. The anterior (Dor) fundoplication is the most common fundoplication performed in children undergoing laparoscopic Heller myotomy. The fundus of the stomach is rolled over the myotomy and secured to the right and left edges of the cut esophageal muscle and crura. The myotomy is concealed. Additional stitches are placed from the anterior gastric fundus to the rim of the esophageal hiatus to relieve tension from the right-sided sutures.

disruptions are typically repaired in a primary fashion with interrupted absorbable suture.

Operative steps for partial fundoplication

The options for an antireflux procedure include a partial or complete fundoplication. Most surgeons favor a partial fundoplication due to the risk for high LES pressures and progression of esophageal dilation when a full 360° wrap is performed^[16,48-51,56-59].

If a 180° anterior (Dor) fundoplication (Figure 8) is planned, the short gastrics are divided and the gastric fundus is completely mobilized. In total, 2 rows of sutures between stomach and esophagus are used. The first row of 3 sutures is placed along the left esophageal wall. The cephalad-most stitch is triangular and incorporates the left diaphragmatic crus, the left side of the esophageal wall and the gastric fundus. The 2nd and 3rd stitches incorporate the fundus and left esophageal wall only. The more lateral portion of the fundus is then placed over the myotomy and is secured to the right esophageal wall in a similar fashion, utilizing a triangular stitch in the most cephalad position. The

Figure 9 Passing gastric fundus posteriorly for Toupet fundoplication. A: Once the fundus is fully mobilized, it is handled by passing a grasper from right to left, posterior to the esophagus and gastroesophageal junction; B: The fundus is then pulled to the right and toward the right cut edge of the myotomy.

2nd and 3rd stitches incorporate the fundus and right esophageal wall only. An additional 2-3 stitches are then placed from the anterior gastric fundus to the rim of the esophageal hiatus to relieve tension from the right-sided sutures.

To complete a 270° posterior (Toupet) fundoplication, the gastric fundus is mobilized as above. The fundus is then passed posterior to the GEJ junction (Figure 9) to be secured to the right crus of the diaphragm (1-3 stitches) and the right edge of the myotomy (3 stitches). This is then repeated on the left esophageal wall (Figure 10).

Operative time, postoperative care, and cost

Published mean operative times for LHM with an antireflux procedure in children range from 120-190 min^[17,52,54,60-65]. Although there is some variation in hospital and surgeon postoperative LHM protocols, patients are often allowed to have sips of water or clear liquids on the day of surgery^[51,64,66] and an advancing diet beginning on POD #1^[48-51,66] or #3^[52,63,64]. Discharge often occurs on POD #3 or #4 (range POD 1.5-8)^[52,61-64,67]. At our institution, we begin an oral diet on the day of surgery and discharge children between POD #1-3 contingent on pain and dietary tolerance. Differences in institutional and surgeon experience with LHM likely explain the wide ranges reported in operative time and LOS.

To date, there is no description of associated hospital charges or cost of LHM for children in the literature. At our institution, the estimated average charge for LHM alone (without consideration of fundoplication or hospital stay) is \$5277. In the adult literature, a study by Shaligram *et al.*^[68] reported an average hospital cost of \$7441 for LHM with an antireflux procedure (exclusive of hospital stay) and that this cost was significantly lower than the open or robotic approach.

OUTCOMES

Overview

In general, outcomes of pediatric laparoscopic esophag-

Figure 10 Posterior (Toupet) fundoplication. The stomach is secured to the right and left crura as well as the right and left cut edges of esophageal muscle, completing the posterior fundoplication. The myotomy remains exposed.

omyotomy to relieve dysphagia have been favorable. The majority of data is based on small, single-center experiences with published success rates ranging from 43%-100%^[6,17,52-54,60,62-64,66,67,69-72]. The adult literature suggests success rates in the 80% range^[16,73-75]. It is important to note however, that the definition of "success" has not been fully delineated. Some reports classify treatment as effective only if patients did not have any dysphagia recurrence at the longest available follow-up. Others believe success was achieved if reoperation was not necessary, even if other adjunctive treatments such as EPD were required postoperatively. Unfortunately, long-term outcome data (> 5 years) is sparse.

The two main postoperative complications available in the pediatric LHM literature are recurrence of dysphagia and symptoms of gastroesophageal reflux (GER). A summary of these and all intraoperative complications reported is provided in Table 2.

Effectiveness of LHM and adequate myotomy

The three largest pediatric LHM studies in the literature consist of 26^[67], 28^[53], and 31^[62] patients. We published our experience with this procedure in 2009. Seven (27%) of the 26 children who underwent LHM at our institution had symptom recurrence within 5 years^[67]. Among these 7 patients, 3 underwent a second LHM, 3 received EPD and/or injection of botulinum toxin^[67], and 1 patient had an unspecified procedure at a different institution. The 3 patients who underwent reoperation had extension of the myotomy proximally and/or distally. Similarly, in a United Kingdom based study by Pachl *et al.*^[53], 8 of 28 children required additional intervention within 3 years; 7 underwent EPD, of which 4 ultimately had a reoperation. The 8th patient proceeded directly to reoperation without EPD. Reoperative patients had revisions or extensions of the original myotomy^[53]. Esposito *et al.*^[62] published a 3-center experience in 2013 and found 5 of 31 children experienced recurrent dysphagia after LHM. Among these 5 patients, 2 had spontaneous resolution, 2 underwent EDP, and 1 underwent reoperation.

These results highlight the importance of performing an adequate myotomy. In a study by Tannuri *et al.*^[65],

15 children underwent LHM with a myotomy that extended 3-4 cm onto the stomach in contrast to the generally recommended 2-3 cm. Among these patients, 3 developed dysphagia; 2 cases resolved spontaneously and 1 patient required a single botulinum toxin injection. Traditionally, a longer myotomy in adults was thought to portend higher rates of GER (especially if done without an antireflux procedure)^[30,65,76] or formation of epiphrenic pseudodiverticula^[77]. This has not been definitively proven and continues to be debated with some authors claiming the contrary^[44,78]. What is known however, is that the esophageal muscular fibers need to be fully disrupted and the underlying mucosa exposed to prevent recurrence of dysphagia^[41]. The development of GER after LHM and data relating to an antireflux procedure are presented in subsequent sections.

Complications

Intraoperative complications during LHM in children include mucosal injury or perforation, aspiration, conversion to an open procedure, and hemorrhage. Mucosal injury and perforation appear to be the most common, with rates ranging from 0%-15% with the majority of studies reporting numbers < 10%^[6,17,52-54,62-67,69,71]. Almost all injuries were noted at the time of surgery, however a study by Rothenberg *et al.*^[72] did reveal a perforation that was discovered as late as POD #5. If discovered at the time of operation, a perforation should be closed primarily with interrupted absorbable suture^[48-50]. Children found to have perforation beyond the initial operative day, all underwent reoperation^[52,62,72]. Adult studies reveal similar rates of perforation and conversion to an open procedure^[73,74].

In general, rates of adverse events are low when children undergo laparoscopic esophagomyotomy. However, the available studies are nearly all single-center experiences and the largest experience consists of only 31 patients. Heterogeneity between and within studies makes it difficult to draw causal relationships and define etiologies for complications. As evidenced by Table 2, there is a significant amount of missing complication data. Only 2 of the 15 studies included in this review discuss other postoperative events and none report rates of infection. This may represent the relative safety of LHM or may be a reflection of the low numbers of patients. Due to the rarity of achalasia in children, prospective, multi-institutional studies are needed to provide a more comprehensive picture of LHM safety.

COMPARISONS

Laparoscopic vs thoracoscopic Heller myotomy

The available literature reveals a larger experience with LHM than THM as a form of MIS-HM in children. There are few studies which directly compare these two approaches in the pediatric population. Mehra *et al.*^[70] reported their experience with MIS-HM in 2001. In this study, 18 of 22 patients underwent LHM compared to 4 patients with THM. Mean duration of hospitalization

Table 2 Complications

-/-: Not explicitly stated in the study; a: Complication reported as average score or unclear description of number; b: Multiple myotomy approaches (laparoscopic, thoracoscopic, *etc.*) utilized in study cohort with unclear delineation of complications between groups; LHM: Laparoscopic Heller myotomy; DVT: Deep venous thrombosis.

and mean time to resumption of soft feeds were lower for those undergoing LHM^[70]. Similarly, Rothenberg *et al*^[72] found that THM resulted in slightly longer operative times and hospital stay in a study of 9 patients (4 THM, 5 LHM). In a 2011 review article assessing available adult meta-analyses, the authors conclude that LHM results in shorter hospital stays and reduced operative time, but that overall outcomes are similar to THM^[79].

The pediatric evidence comparing LHM and THM is not robust but extrapolation from adult studies suggests LHM is superior. Although not explicitly considered in the literature, postoperative pain and the necessity for tube thoracostomy are likely lower in children undergoing LHM.

The evidence for fundoplication

The need for a concomitant fundoplication during LHM to prevent postoperative GER continues to be debated both in the pediatric and adult populations^[17,53]. Among reported pediatric experiences, the study by Corda *et al*^[66] in 2010 included 20 patients, none of whom underwent an antireflux procedure. In this series, no patients suffered from postoperative GER^[66]. The

authors believe there is a higher chance for recurrent dysphagia when a fundoplication is performed and that it is easier to treat postoperative GER than dysphagia^[66]. Interestingly, another study by Pachl *et al*^[53] found that only 1 of 18 patients without an antireflux procedure had postoperative GER compared to 4 of 10 who suffered from symptoms in the fundoplication group. Of the remaining pediatric LHM studies which explicitly discuss this complication, most performed a Dor fundoplication with low rates of postoperative GER^[52,54,63-65,67].

The adult literature has higher level evidence and appears to favor performance of a partial fundoplication. In a 2004 RCT, Richards *et al*^[59] showed that the incidence of postoperative GER was significantly lower in patients who underwent a Dor fundoplication (9.1% vs 47.6%, $P < 0.05$). In addition, a recent review article assessing multiple prospective studies, meta-analyses, and RCTs in adults concluded that a partial fundoplication is indicated after Heller myotomy to reduce incidence of GER^[80].

Based on the available results, it is not clear whether all children should undergo a concomitant antireflux procedure during LHM. Multi-institutional randomized trials are needed to better answer this question. In the

interim, surgeons should treat each patient individually and base the decision to proceed with a fundoplication on preoperative existence of GER or presence of predisposing risk factors for GER.

Type of fundoplication

If the decision to proceed with an antireflux procedure is made, the surgeon must decide what type of fundoplication to perform. The main advantage of a fundoplication is to prevent reflux and disadvantages include possible postoperative dysphagia or formation of diverticula. As evidenced in Table 2, the majority of LHM procedures performed in children are anterior or Dor fundoplications and most have favorable results. There are no pediatric studies comparing the various types of fundoplications directly. In the Mayo Clinic experience published in 2009, we found that only 1 out of 23 patients undergoing Toupet fundoplication experienced postoperative GER^[67]. In other studies with multiple types of fundoplications^[17,63,70], it is not clear if patients suffered from postoperative GER and if they did, which fundoplication group performed better.

Katada *et al.*^[81] reported on 30 adults who underwent a Toupet fundoplication with concurrent LHM. The authors found that this combination helped to straighten the esophagus, reduced LES pressure, and relieved dysphagia^[81]. They did find however, that 2 patients developed esophageal diverticula postoperatively. A recent review article assessing multiple prospective studies and RCTs comparing LHM with various types of concomitant fundoplication in adults concluded that a partial fundoplication (Dor or Toupet) were superior based on higher rates of dysphagia and slightly lower rates of GER when a full (360° Nissen) fundoplication was performed^[80].

There is an obvious paucity of data to definitively recommend one type of antireflux procedure over another when performing LHM in children. Due to low rates of GER and complications found with various types of fundoplication, a multi-institutional RCT would be a valuable and feasible method to better understand this component of the LHM operation.

FUTURE DIRECTIONS

Peroral endoscopic myotomy

In the last decade, a new approach to performing esophageal myotomy has been gaining interest and attention. Peroral endoscopic myotomy (POEM) was developed as a multi-institutional endeavor and initially described in 2007 after performance on pigs^[82]. It is performed entirely endoscopically. A small incision is made in the esophageal mucosa and a balloon dilator is passed into the submucosal space and inflated^[82]. Following this, the esophageal muscular fibers are separated with electrocautery and once the myotomy is complete, the small incision in the mucosa is closed with endoscopic clips or suturing^[82]. The major advantage of this technique is that it is incision-free and performed

through a natural orifice. Since 2007, a number of small studies have been published on the human experience. A recent "white paper summary" found that therapeutic success was achieved in greater than 80% of these patients, self-limited adverse events occurred in < 10% of cases, and rates of post-procedure GER ranged from 20%-46%^[83].

To date, 3 studies have assessed peroral endoscopic myotomy in pediatric achalasia patients^[52,84,85]. The first published report was in a 3-year-old female with severe developmental issues in which total operative time was 198 min^[85]. There were no intraoperative or postoperative complications and the patient remained symptom-free at 1-year follow-up^[85]. A 2013 study completed the procedure on 3 patients with a mean age of 9.6 years in an average of 60 min^[84]. One patient had a small perforation of the mucosal flap and all 3 were discharged 4-7 d post-procedurally^[84]. One-year follow-up on 2 patients revealed that they remained symptom-free; the third patient was 1 mo post-procedure at the time of publication and also had no symptoms. The most recent and largest POEM study in children included a total of 9 patients and compared their outcomes directly with 9 patients undergoing LHM^[52]. The authors found that mean operative time was significantly lower (62 min vs 149 min, $P < 0.01$), myotomy length was longer (11 cm vs 7 cm, $P = 0.26$), postoperative oral intake occurred sooner (POD #2 vs POD #3, $P < 0.01$), and hospital stay was shorter (4.1 d vs 6 d, $P < 0.01$) in patients undergoing POEM^[52]. Operative and postoperative complications (mucosal perforation, GER) were similar, however, 2 patients in the LHM group had recurrence of dysphagia and 1 POEM patient required evacuation of a pneumoperitoneum during the procedure^[52].

Although the POEM experience for children with achalasia is limited, preliminary data suggests that it may be a viable and safe option when performed under experienced hands. Further studies are needed and ongoing.

Single incision LHM

Single-incision laparoscopic surgery for children has been gaining attention over the last 20 years^[86]. A number of procedures have been performed *via* 1 incision including appendectomy, cholecystectomy, colonic resections, pyloromyotomy, nephrectomy, and many others^[86]. In 2011, Kobayashi *et al.*^[87] reported their experience with single incision LHM (SI-LHM) in a 9-year-old boy. Operative time was 273 min, LOS was 8 d, and the patient had complete resolution of dysphagia with no symptoms of GER^[87]. Although further studies are necessary, this may be an additional operative approach to consider for children with achalasia.

CONCLUSION

Laparoscopic Heller myotomy has become the preferred treatment for pediatric patients with achalasia. Existing literature is limited to small retrospective studies. Available

data suggest that LHM is safe and effective in children. A number of related issues are yet to be definitively proven. The need for and type of concurrent fundoplication, a more comprehensive description of complications, and long-term (> 5 years) outcomes information are poorly defined and require additional evaluation. Due to the rarity of achalasia in children, these characteristics will require collaboration between multiple pediatric surgery centers and should be performed in a prospective randomized fashion when appropriate. Finally, the advent of POEM and SI-LHM techniques could ultimately change the approach chosen for esophagomyotomy and may become the standard of care in the future.

Abstract

Endoscopic ultrasound (EUS) has become an important component in the diagnosis and treatment of carcinoma pancreas. With the advent of advanced imaging techniques and tissue acquisition methods the role of EUS is becoming increasingly important. Small pancreatic tumors can be reliably diagnosed with EUS. EUS guided fine needle aspiration establishes diagnosis in some cases. EUS plays an important role in staging of carcinoma pancreas and in some important therapeutic methods that include celiac plexus neurolysis, EUS guided biliary drainage and drug delivery. In this review we attempt to review the role of EUS in diagnosis and management of carcinoma pancreas.

Key words: Carcinoma pancreas; Endoscopic ultrasound; Treatment

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Endoscopic ultrasound (EUS) is becoming increasingly important in the diagnosis and management of carcinoma pancreas. It helps in identification of small tumors, histological diagnosis by fine needle aspiration, staging of the disease and its treatment. Palliation of pain with celiac plexus neurolysis and palliation of jaundice by biliary drainage can be achieved with EUS guided techniques. In this review we attempt to review the role of EUS in different aspects of diagnosis and treatment of carcinoma pancreas.

INTRODUCTION

Pancreatic cancer, according to SEER database in the United States, constitutes 3% of all new cancer cases. The number of new cases of pancreas cancer was 12.4 per 100000 men and women per year and the number of deaths were 10.9 per 100000 men and women per year based on 2008-2012 cases. It is more common with increasing age and slightly more common in men than women. The median age of diagnosis was 71 years, the median age of death being 73 years. It is estimated that there will be 48960 new cases of pancreas cancer and an estimated 40560 people will die of this disease in 2015. Using statistical models for analysis, rates for new pancreas cancer cases have been rising on average 0.8% each year over the last 10 years but the death rates have been stable, the 5 year survival being a dismal 5%-7.2%^[1,2]. This spells out the magnitude of the problem with this disease.

The role of endoscopic ultrasound (EUS) evaluation of pancreatic cancer was suggested as an independent predictor of survival and improvement in patients with loco regional pancreatic cancer in a recent study^[3]. We will highlight the various aspects of the role of EUS in the setting of pancreatic cancer.

EUS FEATURES OF NORMAL PANCREAS AND PANCREATIC MALIGNANCY

Nattermann *et al*^[4] and Catalano *et al*^[5] described the pancreatic parenchyma as a homogeneous fine granular, reticulated pancreas with smooth margins without evidence of side-branch ectasia. The pancreatic duct diameter in the body was 1.7 to 1.9 mm on average (range, 1-3 mm), a ventral anlage (echogenic difference between the ventral and dorsal pancreas) was seen in up to 68% of controls. These data from control populations and healthy volunteers provide important standards for the normal endosonographic appearance of the pancreas but are limited by their small numbers and potential biases in control populations.

On the other hand, neoplastic masses may obscure the normal parenchymal and ductal features. They are generally more homogeneous; hypoechoic compared to surrounding tissue and are rarely calcified. In a calcified pancreas, neoplastic lesions frequently push the calcified parenchyma towards the periphery. In addition signs of vascular invasion are highly suggestive of malignancy^[6].

DIAGNOSTIC ROLE OF EUS IN PANCREATIC CANCER

EUS has high sensitivity for detecting pancreatic neoplasms and further provides the ability to obtain samples from suspected lesions by fine needle aspiration (FNA) contributing to its accuracy in the diagnosis of pancreatic cancer. It has been considered one of the most precise methods for the detection of pancreatic

focal lesions, especially in patients with small tumors of 3 cm or less^[7,8] (Figure 1). The reported sensitivity and accuracy of combined EUS-FNA for detecting pancreatic malignancy usually exceeds 90%^[9-14]. A recent meta-analysis mentioned the pooled sensitivity and specificity of EUS FNA ranging between 87% and 96%, respectively, for diagnosing a solid pancreatic mass lesion^[15]. The sensitivity and accuracy of EUS are slightly higher than the sensitivity and accuracy of computed tomography (CT) and Magnetic resonance imaging (MRI) in detecting small pancreatic lesions^[16-19].

EUS can be used to assess TNM staging of pancreatic tumors. T1 lesions are smaller than 2 cm, T2 are lesions larger than 2 cm, tumor extending beyond the pancreas is either a T3 (portal vein, duodenum, or ampulla of Vater) or T4 lesions (extending to the celiac artery or superior mesenteric artery; being unresectable). Malignant nodes around the pancreas are N1 lesions and rarely distant metastasis may be seen (M1 lesion). The accuracy of CT, MRI, and EUS in assessing TNM staging of pancreatic cancer was compared by Soriano *et al*^[20] wherein EUS had the highest accuracy for N-staging (65%) although CT was more accurate in assessing vascular invasion and T-staging. However in a retrospective study from Russia by Egorov *et al*^[21], arterial encasement on CT did not necessarily indicate arterial invasion and in unresectable pancreatic cancers (on CT), EUS data for peripancreatic involvement might suggest possible radical resection, providing survival benefits. It has also been used as a screening tool for individuals at a high risk for pancreatic cancer with incidence of clinically relevant findings at first screening being 7% with asymptomatic cancer and 16% premalignant IPMN-like lesions in a study by Poley *et al*^[22].

The diagnostic reliability of EUS-FNA in the evaluation of pancreatic lesions is predictably affected by operator expertise, cytopathologic interpretation, and other variables including the presence of inflammatory changes^[9,23]. A definite diagnosis cannot be ascertained in a significant minority of EUS-FNA samples alone, resulting in a cytological diagnosis of suspicious or indeterminate for neoplasm which is seen in approximately 8% to 10% of EUS-FNA samples, representing a challenging diagnostic dilemma^[12,23,24]. In addition, presence of chronic pancreatitis may decrease the sensitivity of EUS-FNA as noted by Varadarajulu *et al*^[25] where in the sensitivity was ranging from 73% to 91%, being lower in patients with chronic pancreatitis; and the No Endosonographic Detection of Tumor study^[26] had revealed 60% patients with co-existing chronic pancreatitis and 15% patients with a diffuse malignancy which was not detected earlier. Furthermore Siddiqui *et al*^[27] in their retrospective cohort trial found a false positive rate for EUS-FNA of solid pancreatic lesions of 1.1% as a result of cytologic misinterpretation in the setting of chronic pancreatitis.

Few basic remedial factors to improve the yield of EUS FNA were the use of 25 gauge needle as less blood is aspirated instead of conventional 22 gauge needle^[28-30], combining cytologic and histologic analyses of the specimen to decrease the number of passes to 2^[31] from 4 to 7

Figure 1 Endoscopic ultrasound appearance of mass lesions in pancreas. passes^[32] (higher in pancreatic cancer than in other lesions), to cater for rapid on-site cytological evaluation^[33-35], the use of serum CA19-9^[36] and fluid CEA and CA19-9 for increasing the ability to diagnose malignancy especially in suspicious cases^[37].

WHAT IS NEW FOR DETECTION OF PANCREATIC MALIGNANCY?

Developments have taken place to further refine the ability to differentiate a malignant lesion from a benign one with a reasonable certainty and overcome other limitations. There have been improvements in the imaging techniques with EUS as well as advances in cytopathology analysis. Among the newer technologies there are EUS elastography, contrast enhanced EUS and use of chromosomal detection techniques in FNA specimen.

EUS elastography is a noninvasive technique that measures elasticity in real time by registration of differences in distortion of the EUS image after application of slight pressure by the EUS probe (Figures 2 and 3). Tissue elasticity may be altered by inflammation, fibrosis and cancer resulting in distinct elastographic appearance. Initial studies were based on qualitative elastography evaluation, using a hue-color scale representing different degrees of tissue elasticity. Giovannini *et al*^[38] had sensitivity and a specificity of 100% and 67% respectively while analyzing pancreatic masses using a scoring

system based on different color patterns to differentiate between benign and malignant pancreatic masses. In a subsequent multicenter study^[39], the sensitivity and specificity of EUS elastography to differentiate benign from malignant pancreatic lesions were 92% and 80.0%, respectively, compared to 92% and 69%, respectively, for the conventional B-mode images. In another paper by Iglesias-Garcia *et al*^[40], malignancy could be diagnosed by qualitative EUS-elastography using color patterns with a sensitivity, specificity and overall accuracy of 100%, 85.5% and 94%, respectively. Recently quantitative EUS elastography has been developed in an attempt to make the elastography interpretation less subjective. Quantitative elastography gives a numeric result, either as mean value of hues in a selected area (mean hue histogram) or as a ratio of elasticity in the target area over soft reference tissue (strain ratio). Iglesias-Garcia *et al*^[41], have evaluated strain ratio in 86 consecutive patients with solid pancreatic masses and found the strain ratio was significantly higher among patients with malignant pancreatic tumors compared to those with inflammatory masses (Normal pancreatic tissue: 1.68; inflammatory masses: 3.28; pancreatic adenocarcinoma: 18.12; and the highest strain ratio was found among endocrine tumors). The sensitivity and specificity of the strain ratio for detecting pancreatic malignancies using a cutoff value of 6.04 were 100% and 92.9%, respectively, exceeding the accuracy obtained with qualitative elastography. Săftoiu *et al*^[42] evaluated the usefulness of the hue-

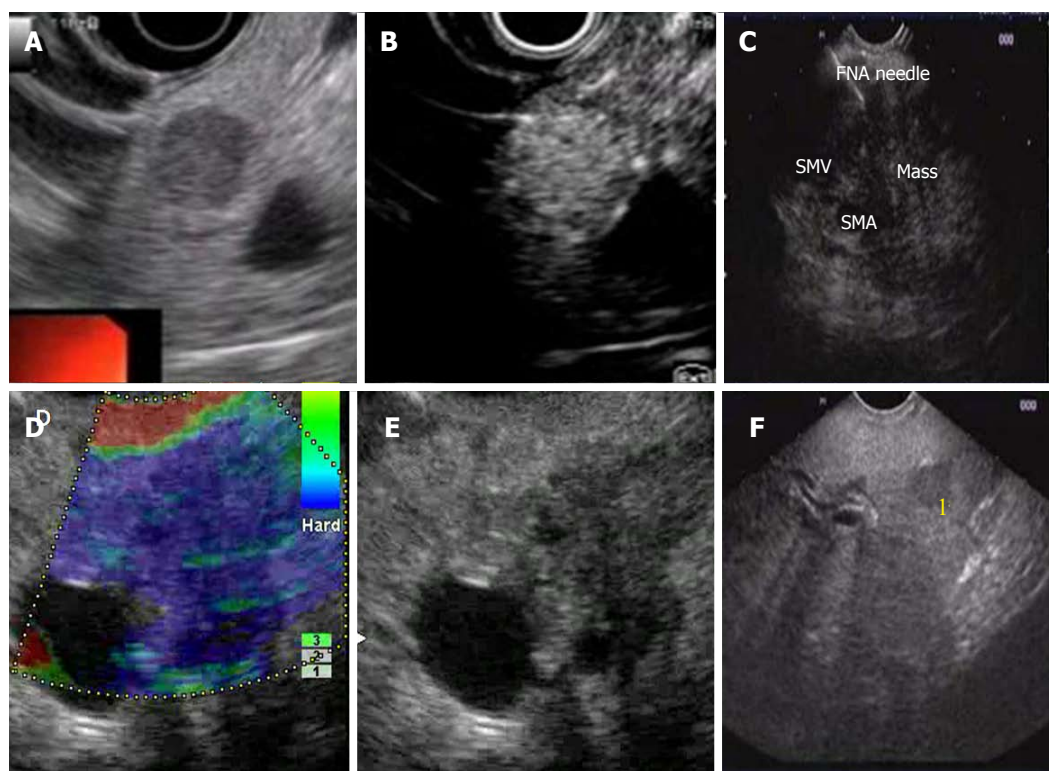

Figure 2 Contrast enhanced endoscopic ultrasound and endoscopic ultrasound elastography. A and B: Neuroendocrine tumor in the head of pancreas (HOP) before (A) and after (B) contrast administration; C: Fine needle aspiration (FNA) of mass in the HOP; D and E: Carcinoma HOP, EUS elastographic (D) appearance and B mode EUS appearance (E); F: Carcinoma HOP with metastasis (1) in the left lobe of liver..

histograms in a multicenter study wherein a sensitivity of 93.4%, a specificity of 66.0%, a positive predictive value of 92.5% and an overall accuracy of 85.4% for the mean hue-histogram in the detection of malignancy were observed. In a further development, Schrader *et al*^[43] had 100% sensitivity and specificity in differentiating benign from malignant lesions in tissues with blue color (hard tissue), on histogram with less discrimination on evaluating areas with red or green colors representing softer tissue. The role of this modality is still evolving to reduce the various biases of calculation of strain.

Contrast-enhanced (CE)-EUS consists of administration of contrast agents through the blood stream. The contrast agent contains microbubbles that can be detected by EUS in the small, low-velocity vasculature of pancreatic tumors on real-time evaluation. Initial studies using Levovist®, Albutex and FS 069 Optison as contrast agents demonstrated that the hyper vascular aspect of neuroendocrine tumors and the hypo vascular aspect of pancreatic adenocarcinoma^[44-48]. Modern contrast enhanced EUS relies on a dedicated contrast harmonic echo-EUS (CHE-EUS) technique that detects signals from micro bubbles delivered by new contrast agents like Sonovue® in vessels with very slow flow as they have longer perfusion time and stronger backscatter without the burden of Doppler-related artifacts. Fusaroli *et al*^[49] investigated 90 patients with solid pancreatic lesions by CEH-EUS, using Sonovue® as contrast agent. The finding of a hypo-enhancing mass with an inhomogeneous pattern diagnosed pancreatic adenocarcinoma with a

sensitivity of 96% and an accuracy of 82%. The study also indicated that this CEH-EUS pattern diagnosed malignancy more accurately than the finding of a hypo-echoic mass on standard EUS. Hyper-enhancement specifically excluded adenocarcinoma (98%), although sensitivity was low (39%). In a study by Napoleon *et al*^[50], the finding of a hypo-enhanced lesion was able to detect malignancy with a sensitivity, specificity and accuracy of 89%, 88%, and 88.5%, respectively. Seicean *et al*^[51] investigated the possibility to use quantitative CEH-EUS data in the differential diagnosis between pancreatic cancer and chronic pancreatitis. A hypo-enhanced pattern was the most common finding both in pancreatic adenocarcinoma and in mass forming chronic pancreatitis. However, an index of contrast uptake ratio was calculated and this was significantly lower in adenocarcinoma compared to cases with mass-forming chronic with a sensitivity of 80% and a specificity of 91.7%. A recent prospective study by Kitano *et al*^[52] showed that when CH-EUS was combined with EUS-FNA, the sensitivity of EUS-FNA increased from 92.2% to 100%. Data from South Korea showed a sensitivity and diagnostic accuracy of 93% and 92%, respectively for the diagnosis of pancreatic cancer^[53]. In a recent retrospective study by Park *et al*^[54] pancreatic adenocarcinomas showed a hypo-enhanced pattern on CH-EUS with a sensitivity of 92%, the specificity of 68% and the accuracy approximately 82%.

In a recent review, Kitano *et al*^[55] have mentioned that CH-EUS identifies pancreatic adenocarcinomas

Figure 3 Endoscopic ultrasound guided interventions. A and B: fiducial placement for mass in the head of pancreas (HOP); C: celiac plexus neurolysis (CA-celiac artery, SMA-superior mesenteric artery); D: fine needle aspiration of mass in the HOP; E radiofrequency ablation (RFA) of mass in the HOP; F,G and H: choledochoduodenostomy for biliary stricture due to mass in the HOP; I and J: hepaticogastrostomy and placement of metal stent.

as solid lesions exhibiting hypo-enhancement with a sensitivity and specificity of 88%-96% and 88%-94%, respectively. In particular, 80%-100% of false-negative cases in EUS-FNA are correctly classified by CH-EUS, suggesting its complementary role. In addition, it improves depiction of some subtle lesions in conventional EUS, thus facilitating EUS-FNA. For quantitative perfusion analysis, a time-intensity curve (TIC) for the region of interest can be generated during CH-EUS. The maximum intensity gain and the echo intensity reduction rate from the peak at 1 min obtained by TIC can be used for differentiation of pancreatic adenocarcinoma from other tumors. CH-EUS is also useful for differentiation of invasive intraductal papillary mucinous neoplasms (IPMN) from non-invasive IPMN^[55]. Thus, CH-EUS technology is very promising and is likely to play a role in the precise diagnosis of malignant pancreatic lesions.

The detection of various chromosomal abnormalities in FNA aspirates is a field which is rapidly evolving. It is useful in cases with indeterminate results and might help in confirming the diagnosis of a malignancy. Among the earlier studies, telomerase activity was studied by Mishra *et al.*^[56] which on combination with cytology results increased the sensitivity from 85% to 98% with 100% specificity. The use of fluorescence *in situ* hybridization (FISH) analysis by Kubiliun *et al.*^[57] on FNA specimens with inconclusive results revealed a sensitivity of 74% for detecting pancreatic cancer which increased to 85% on combining with cytology. Reicher *et al.*^[58] from US demonstrated the use of detecting K-ras mutation in addition to FISH analysis in precisely identifying 60% of atypical FNAs with final malignant diagnosis yielding 88% sensitivity and 94% specificity with 90% accuracy. The pooled sensitivity of EUS-FNA for the differential diagnosis of pancreatic

adenocarcinoma was 80.6%, specificity was 97% and probable sensitivity and specificity were 76.8% and 93.3% for K-ras gene analysis, respectively. For combined EUS-FNA plus K-ras mutation analysis it was 88.7% and 92%, in a meta-analysis by Fuccio *et al.*^[59]. Overall, K-ras mutation testing applied to inconclusive cases by EUS-FNA reduced the false-negative rate by 55.6% albeit with a false-positive rate of 10.7%. Layfield *et al.*^[60] in their guidelines mention that many gene mutations (*KRAS*, *GNAS*, *VHL*, *RNF43*, and *CTNNB1*) may be of aid in the diagnosis of cystic neoplasms. The shortcoming of detecting chromosomal abnormalities in FNA specimens is that pancreatic cancers may express multiple mutations, detecting more might increase the sensitivity but with doubtful cost effectiveness.

ROLE OF EUS IN THERAPEUTICS OF PANCREATIC CANCER

The increasing use of EUS as a diagnostic modality has also led to its importance as an interventional tool in the management of pancreatic cancer. It ranges from assisting in radiotherapy, delivery of chemotherapeutic agents to palliation by celiac plexus neurolysis and biliary drainage wherever ERCP fails.

EUS delivery of antitumor agents is largely investigational and is still in experimental stage. The requirement to develop this option is due to pancreatic carcinoma having a poor response to chemotherapeutic agents and radiation; and neoadjuvant chemotherapy can lead to a desmoplastic reaction further impairing drug delivery. Chang *et al.*^[61] used cytoimplant (Allogenic mixed lymphocyte culture) advanced pancreatic cancer with partial response noted in two patients. TNFerade biologic

is a replication-deficient adenoviral vector that expresses tumor necrosis factor- α (TNF- α), regulated by a radiation inducible promoter; inducible by chemotherapy and radiation has been used by various authors. Hecht *et al*^[62] had shown one complete response, 3 partial responses, and 12 patients with stable disease, overall 3 survived > 24 mo. Subsequently Herman *et al*^[63], reported in the randomized phase III trial among patients with locally advanced pancreatic cancer (LAPC) that though it is safe in combination with chemotherapy, it does not increase survival. ONYX-015, an adenovirus which preferentially replicates and kills malignant cells was studied by Hecht *et al*^[64] wherein 2 patients had partial regression of the injected tumor, 2 had minor responses, 6 had stable disease, and 11 had progressive disease with 2 patients each having sepsis and duodenal perforation. The injection of immature dendritic cells, which induce T-cell immune response against malignant cells, was used by Irisawa *et al*^[65] successfully into the tumors of 7 patients with unresectable pancreatic cancer, with a cohort median survival of 9.9 mo. Thereafter, Hirooka *et al*^[66] using the same therapy demonstrated effective responses in three of five patients; 1 had partial remission and 2 had long stable disease of more than 6 mo. This combined therapy was synergistically effective. Despite these studies, much more large prospective studies are required before these techniques are translated into clinical practice.

EUS guided brachytherapy has been carried out with radioactive seeds being placed into the tumour with the help of linear echoendoscope. The most popular radioactive seeds are Iodine 125, palladium 103 and iridium 192; iodine being the preferred radioactive material due to its long half life of 60 d in pancreatic cancers with rapidly dividing cells. Jin *et al*^[67] in their experience achieved partial remission in three cases, estimated median survival time of nine months with improvement in pain but no survival benefit.

EUS guided fiducial insertion is being done in pancreatic malignancy to place markers inside the tumor for guiding stereotactic body radiotherapy. These markers can be radioactive spheres, coils or seeds. Its feasibility was shown by Pishvaian *et al*^[68] wherein he reported a technical success of 85%. Subsequently in a prospective study by Park *et al*^[69] fiducial insertion was successful in 88% of the 57 patients, Sanders *et al*^[70] had a success rate of 90% for EUS fiducial insertion in a prospective study of 51 patients while DiMaio *et al*^[71] achieved a success rate of 97% with a 22-gauge needle. Law *et al*^[72] found this technique safe and feasible to assist intraoperative localization of small pancreatic neuroendocrine tumors. The 2 types of fiducials were compared by Khashab *et al*^[73] in 39 patients with advanced pancreatic cancer. Traditional fiducials of 5 mm length had better visibility scores with similar migration rates as compared to viscoil fiducials of 10 mm length.

EUS-guided cryothermal ablation has been studied by Arcidiacono *et al*^[74] in 22 patients with unresectable stage

III pancreatic adenocarcinoma with a feasibility of 73% with insignificant tumor size reduction. Further studies are required to demonstrate progression-free survival and local effects. Recently Pai *et al*^[75] used radiofrequency ablation (RF) which was applied with a monopolar RF probe (1.2 mm Habib EUS-RFA catheter) placed through a 19 or 22 gauge FNA needle after FNA was performed in patients with a tumor in the head of the pancreas with a 100% success rate. The response ranged from complete resolution to a 50% reduction in size. Oh *et al*^[76,77] used EUS-guided ethanol lavage with paclitaxel injection (EUS-EP) for cystic tumors of the pancreas in two studies and found a 62%-99% resolution rate with adequate safety and feasibility. These data indicate the need for further large prospective studies to ascertain their roles in the management of pancreatic cancer.

EUS guided celiac plexus neurolysis (CPN) provides pain relief, palliation and reduces narcotic use in patients with unresectable pancreatic cancer^[78]. The injection of a neurolytic drug into the celiac plexus disrupts the signal transmission to spinal cord and central nervous system. Due to the anatomical location of the celiac plexus around the origin of the celiac trunk and the superior-mesenteric artery, EUS- CPN provides real-time visualization for a safe approach.

EUS-CPN was demonstrated to be safe and effective in alleviating refractory pain due to pancreatic cancer in a meta-analysis of 8 studies by Puli *et al*^[79]. Alcohol-based EUS-CPN was found safe and effective in this setting providing pain relief to 73% patients^[80]. A recent RCT by Wyse *et al*^[81] in 96 patients demonstrated greater pain relief in the early EUS-CPN group at three months than in conventional management group. As compared to opioids, EUS-CPN reduced pain at four and eight weeks and significantly reduced opioid consumption^[82]. In addition a single central injection was found to be as effective as bilateral or multiple injections^[83,84]. In another comparison between EUS-CPN and EUS-celiac ganglia neurolysis (CGN), Doi *et al*^[85] observed higher treatment response rate and complete response rate in the EUS-CGN group compared to the EUS-CPN group.

EUS guided biliary drainage is another important area where therapeutic EUS is helpful. With failed ERCP, biliary drainage can be established by 3 endoscopic methods (1, transluminal biliary drainage with hepaticogastrostomy or choledochoduodenostomy, 2, EUS antegrade drainage and 3, EUS rendezvous drainage)^[86]. In 7% to 13% of patients with pancreatic head malignancy have duodenal stenosis, making ERCP technically challenging or impossible^[87].

The role EUS guided biliary drainage in pancreatic cancer in failed ERCP has been recently demonstrated by Weilert^[88] in 21 patients, 52% patients with pancreatic cancer wherein he achieved technical success in 20/21 (95.2%) and clinical success 19/21 (90.4%). He noted that EUS-guided antegrade biliary drainage using the intra-hepatic access route had high technical and clinical success with low adverse rate. In a recent study of 208

patients with malignant distal CBD obstruction requiring SEMS placement, authors compared the short-term outcome of single session EUS guided biliary drainage with ERCP^[89]. SEMS placement was successful in 97 and 98 patients in the respective groups (93.26% vs 94.23%, $P = 1.00$). The incidence of pancreatitis was higher with ERCP, and EUS group had superior treatment success rates in patients with duodenal stenosis.

CONCLUSION

EUS is rapidly becoming a sensitive and specific modality for diagnosing pancreatic cancer especially on combining with EUS-FNA albeit with difficulty in the presence of chronic pancreatitis. With the advent of newer technology in the form of EUS elastography, CE-EUS, and gene mutations detection in FNA specimens the diagnostic dilemma is better resolved. The availability of interventional EUS has allowed gastroenterologists to make significant difference in management of pancreatic cancer by its various therapeutic options including areas which have been traditionally dealt by surgeons and interventional radiologists. It is likely to become an important modality in the multidisciplinary management of pancreatic cancer.

Abstract

Biliary stenting is clinically effective in relieving both malignant and non-malignant obstructions. However, there are high failure rates associated with tumor ingrowth and epithelial overgrowth as well as internally from biofilm development and subsequent clogging. Within the last decade, the use of prophylactic drug eluting stents as a means to reduce stent failure has been investigated. In this review we provide an overview of the current research on drug eluting biliary stents. While there is limited human trial data regarding the clinical benefit of drug eluting biliary stents in preventing stent obstruction, recent research suggests promise regarding their safety and potential efficacy.

Key words: Bile ducts; Cholangiocarcinoma; Endoscopy; Pancreas

Core tip: Despite the short life expectancies of patients with biliary tract cancers, biliary stenting suffers from high stent re-obstruction rates, provoking unneeded costs, morbidity and mortality. Drug eluting stents offer the possibility of decreasing stent failure rates from both biliary stent clogging, and external obstruction from tumor and epithelial ingrowth. In this inclusive review we outline the current body of experimental literature on drug eluting stents including bench, animal and human trials, and discuss possible targets for future research.

INTRODUCTION

Obstruction of the bile duct results in serious clinical consequences such as cholangitis and death. Biliary stenting is an effective means of relieving obstruction, and is the preferred method of palliating patients with malignancy^[1]. Malignant obstructions in particular cause high stent obstruction rates, despite the relatively short lifespan of patients with biliary tract cancers (Table 1). Stent failure is associated with recurrent morbidity, and often necessitates repeat endoscopy with stent retrieval and replacement. These procedures carry an increased risk for procedural complications such as pancreatitis, and can result in additional hospital admissions.

Stent failure can be stratified into four primary etiologies: Internal stent failure from biliary clogging, external failure caused by tumor ingrowth or overgrowth of excessive epithelial or malignant cells, and stent migration. The incidence of each type of failure in malignant obstruction has been documented in several small prospective trials (Table 2). For the purposes of this review, only internal and external failure will be addressed.

Drug eluting stents have been used for several decades in the setting of coronary artery disease to decrease the incidence of stent failure. Currently there have only been a limited number of human trials evaluating drug eluting biliary stents to prevent external obstruction^[2,3], none of which showed a significant effect in decreasing stent failure rates. However, only one agent (paclitaxel) has been trialed in humans with malignant obstruction^[2,3]. Both trials showed the hybrid stent was safe and well tolerated when compared to traditional stenting. There is a growing body of literature looking at *in vitro* and *in vivo* models of drug eluting biliary stents as prophylaxis against internal and external sources of failure. In this review, we divide stent failure pathophysiology into internal and external mechanisms and analyze the current literature on the use of stent drug elution as prophylaxis against the respective failure types.

INTERNAL STENT FAILURE

Internal stent failure results from the accumulation of obstructing material in the stent lumen. It is a complex process involving microbial colonization and biofilm generation^[4]. This process is exacerbated by, but not dependent on, the reflux of duodenal contents into the biliary system.

A normal functioning sphincter of oddi helps to

preserve the relative sterility of the biliary tree compared to the duodenum. Stenting across the papilla allows for the reflux of intestinal contents and bacteria into the biliary system^[5]. After placement, biliary stents are quickly colonized by a diverse poly-microbial community^[6-10]. Aerobic and anaerobic bacteria are readily isolated from occluded biliary stents with *Enterococcus*, *Escherichia coli* and *Klebsiella* the most common aerobic bacteria isolated from biliary sludge, while *Clostridium* is the most common anaerobe isolated^[6-8,11]. Anaerobic bacteria may be the first to attach and may play a crucial role on biofilm initiation^[7].

Electron microscopy and biochemical analyses of explanted stents has shown that the occluding material is formed by the accumulation of multispecies bacterial colonies, fungi, microbial byproducts, crystals of calcium bilirubinate, crystals of fatty acid calcium salts, and by semi digested fibers arising from duodenal reflux^[6,7,12-14]. Surface irregularities in the stent have been postulated to facilitate the initial biofilm generation^[6,12,15].

The process of internal failure is self-perpetuating. As the stent lumen narrows with increasing biofilm generation, or external compression, bile flow decreases by an exponential rate. The precipitous decrease in bile flow seen with small decreases in stent diameters is explained by Poiseuille's law, which states that when a fluid with a stable viscosity flows through a tube, halving the radius of the tube will decrease the flow rate to 1st/16th the original flow^[9] (Figure 1). Viscous fluids also display a parabolic flow, with the lowest flow rates against the surfaces of the tube. Slowing of bile flow promotes both spontaneous and bacteria-driven bile salt precipitation, thus exacerbating the likelihood of internal failure^[4]. This has been proven clinically as failure rates have been shown to be well correlated with the diameter of the stent^[16].

DRUG ELUTION TO PREVENT INTERNAL FAILURE

Drug insertion into the biliary stent lumen can theoretically improve internal failure rates by decreasing bacterial colonization and biofilm formation. There has been a small amount of research looking at internal drug coating or drug elution to prevent internal failure (Table 3), comprising *in vitro*, *in vivo* animal and one human trial. Drugs selected for analysis can be loosely grouped into two categories: those theorized to inhibit bacterial attachment and biofilm generation and antimicrobials theorized to inhibit bacterial growth and induce sterilization of the biliary tree.

The first published example of incorporating pharmaceuticals into the internal stent lumen was bench modeling done in the late 1990's. An *in vitro* model was developed by submerging test material in culture broth and bile; it was shown that an addition of benzalkonium chloride, a commonly used antiseptic, as well as Teflon, decreased the incidence of microbial colonization^[17]. However, these studies did not accurately model the

Table 1 Current stent failure rates

Stent type	Stent failure rates in malignant obstruction
Plastic stents	30%-70%
Self expanding metal stents	19%-46%

Adapted from Ref.^[31-37].**Table 2 Causes of stent failure**

Causes of stent failure	Percent of total failures
Tumor ingrowth	66%-68%
Epithelial ingrowth	
Biliary clogging	17%-21%

polymicrobial environment of the biliary tree, utilizing just 3 cultured pathogens.

Several more *in vitro* models have been reported in the literature evaluating luminal drug elution. Of the materials tested, heparin coating has proven promising in both *in vitro* and human trials. Cetta *et al*^[18] examined stents internally coated with heparin and hyaluronic acid. The coated stents were then placed in bacterial cultures which were generated from culturing previously occluded biliary prostheses. Compared to uncoated polyurethane stents, heparin coated stents had significantly reduced biofilm formation. Later, some researchers found that stents coated with both hydrophobin and heparin decreased encrustation detected by the electron microscopy compared to hydrophobin alone in their *in vitro* model. This work was followed up by Farnbacher *et al*^[19], who devised a prospective human trial. In their study they found that explanted heparin coated stents had significantly decreased rates of luminal encrustation by visual inspection and weight.

Antibiotics, while an intuitive possibility for decreasing bacterial colonization, have failed to show any effect in decreasing internal failure rates when given both systemically or locally through drug elution. There has been a continuous effort since 1989 to identify systemic treatments which could decrease internal stent failure rates, among which antibiotics, ursodiol, mucolytic agents, and anti-inflammatory agents have been trialed (Table 4). Multiple studies as well as meta-analysis^[20] have failed to show a direct benefit from any systemic treatment in decreasing internal failure rates.

Along with a lack of benefit when given systemically, antibiotics have also failed to show any benefit when given locally. In 2011, Weickert *et al*^[21] analyzed the effect of antibiotic elution on internal failure by incubating stents in human bile. Their experiment examined the combined effect of stents combined with hydrophobin and ampicillin/sulbactam, as well as hydrophobin and levofloxacin showed that the neither antibiotic

Figure 1 Change in biliary flow determined by stent radius, as described by Poiseuille's law (A) and laminar flow of viscous fluids (B). Flow = $(\pi \cdot \text{pressure difference} \cdot \text{radius}^4) / (8 \cdot \text{viscosity} \cdot \text{length})$.

reduced the amount of biofilm generation compared to hydrophobin alone. In 2012, Gwon *et al*^[22] developed a cefoxitine eluting stent and for testing in a canine model. Upon both gross inspection and analysis with electron microscopy they found no effect from cefotaxime in preventing biofilm development. The reasons behind the lack of local antibiotic efficacy can only be surmised, but may include the selection of resistant organisms in the polymicrobial biliary environment, the inability of antibiotics to permeate through biofilms, or local breakdown and inactivation of antibiotics.

EXTERNAL STENT FAILURE

Biliary obstruction is the first presenting sign of disease in 70% of patients with cancer of the pancreas and biliary system^[23]. Pancreatic cancer is common and carries significant morbidity and mortality. In the year 2000 for example, there were 217000 new cases of pancreatic cancer with 213000 pancreatic cancer deaths worldwide^[24]. Survival rates are dismal at an estimated five-year rate of 5%^[25] and have been generally stagnant with no recent advances improving mortality^[26]. Although biliary duct and gallbladder cancers have a lower incidence, their mortality is equally dismal. External stent obstruction is not only a concern in patients with pancreatobiliary malignancy, as there is also a notable population of patients with nonmalignant obstructions at risk for stent failure who could benefit from drug elution as a possible means of decreasing failure risk. Prospective studies on patients with chronic pancreatitis, autoimmune pancreatitis, and liver transplants for instance have shown that respectively up to 20%^[27], 83%^[28], and 22%-49%^[29] of patients developed biliary strictures.

There are two main categories of commercially available biliary stents for endoscopists to select from:

plastic or metal-based stents. In regards to malignant obstruction, self-expanding metal stents (SEMS) have been found to have a decreased incidence of cholangitis, stent failure, and overall hospitalizations when compared to plastic stents^[30]. Median patency rates for SEMS have been evaluated in several studies and generally found to be at approximately 270 d in malignant obstruction^[31-33]. Biliary stents have a sub-optimal failure rate, and will occlude in 30%-70% of patients with plastic stents and in 19%-46% of patient with bare metal stents (Table 1)^[31,32,34,35]. The most common cause of failure are tumor or epithelial ingrowth (66%-68%), followed by sludge and clogging (17%-21%), tumor overgrowth (2%-11%), and stent migration (0%-4%) (Table 2)^[33,36,37].

From analysis of biopsied obstructing tissue, it was found that 44% of the tissue ingrowth was non-malignant in nature, suggesting epithelial hyperplasia plays a significant role in stent obstruction^[35]. Other studies have suggested that up to 50% of SEMS occlude secondary to epithelial hyperplasia^[35]. Considering the major mechanisms of stent obstruction, tumor ingrowth, tumor overgrowth, and epithelial hyperplasia, a stent externally coated with agents that effectively hinder tissue growth could theoretically reduce failure rate by 50%-79%. Drug incorporation into the external stent membrane appears to be an intuitive next step in stent development capable of significantly reducing stent obstruction rates^[34].

CURRENT RESEARCH ON DRUG-ELUTING BILIARY STENTS TO PREVENT EXTERNAL FAILURE

Drug-eluting stents have been well validated in the

intravascular setting and have become a staple in the management of coronary artery disease for several decades. However, despite the theoretical promise of drug-eluting biliary stents (DEBS), there has been little research on the subject to date (Table 5). Ideal agents to incorporate into the stent exterior would serve to (1) effectively inhibit the growth of malignant pancreaticobiliary cells; (2) retard the proliferation of biliary epithelial hyperplasia; and (3) display favorable histologic changes when exposed to biliary epithelium, without necrosis or risk of biliary perforation.

ANIMAL MODELS OF DRUG ELUTING BILIARY STENTS

Lee *et al*^[38] developed the first published animal models of DEBS in 2005. Their team developed a paclitaxel eluting stent for trial in a porcine model. The decision to use paclitaxel was based on bench data from Kalinowski *et al*^[39] which showed that paclitaxel, inhibited human gallbladder cells, human fibroblasts, and pancreatic cells in a dose-dependent fashion. Their model was designed to evaluate drug release dynamics and bile duct histological changes resulting from extended direct stent contact after implantation in pigs for 4 wk. Stents were developed with paclitaxel concentrations of 0%, 10% and 20%. Inflammatory cell infiltration and fibrous reactions were the commonly noted histologic changes which corresponded to the level of paclitaxel incorporated into the stent. Although the model was not designed to evaluate long term failure rates, no pigs showed clinical or laboratory signs of biliary obstruction during the trial. Their results were promising, finding acceptable histologic changes at all drug levels. Epithelial denudation, mucin hypersecretion, and epithelial metaplasia were noted in

<i>In vitro</i> Tsang <i>et al</i> ^[52]	<i>Journal of Laboratory and Clinical Medicine</i> (1997)	<i>In vitro</i> 4 - porcine bile 4 - porcine bile + ampicillin + sulbactam	Ampicillin and sulbactam inhibited biofilm formation

the bile ducts that were in contact with stents containing 20% weight/volume (wt/v) paclitaxel; there was no incidence of transmural necrosis or perforation in any animal. Furthermore, the amounts of paclitaxel released over 1 wk and over 6 wk were similar, regardless of the concentration of paclitaxel incorporated in the stent. The authors ultimately found that stents with 10% (wt/v) paclitaxel in the covering membrane was superior to those with 20% (wt/v) in regards to histologic changes and drug release dynamics. The 10% (wt/v) paclitaxel stent had a more favorable histologic profile without evidence of epithelial metaplasia or other concerning local changes from excessive cytotoxic effects which could suggest a risk for necrosis or perforation, while still displaying a favorable drug release profile.

There are four other previously published animal studies involving paclitaxel eluting stents. In 2009, Lee *et al*^[40] undertook a canine model also to assess biliary duct histological changes, evaluating 20% wt/v paclitaxel DES. The authors noted biliary mucosal hyperplasia in 3/6 dogs who received paclitaxel stents (none in the control group) along with no distinct stent complications. They concluded that more research is warranted to determine the proper concentration of drug to obtain optimal tumor control in and histological remodeling of the biliary duct. In 2012, Jang *et al*^[41] used a porcine model to examine a 10% wt/v paclitaxel-eluting biliary stents using a membrane containing Pluronic F-127 in an attempt to bolster drug delivery. They again found acceptable histologic changes based on inflammatory cell infiltration and fibrotic reaction, with no incidence of obstruction or perforation. Paclitaxel was detected for 28 d in porcine serum with the 10% Pluronic concentration. However, released paclitaxel was observed for only 7 d with incorporation of higher or

lower concentrations of Pluronic. Most recently, Shi *et al*^[42] used a canine model to study the effect of paclitaxel biliary stents when used as biliary-enteric anastomosis following Roux-en-Y cholangiojejunostomy. Histology of the bile duct was observed 1, 3, 6, 9 and 18 wk following the surgery. Paclitaxel-coated stents were found to release paclitaxel for 9 wk, and dogs that had paclitaxel-coated stents placed had less granulation tissue and granular hyperplasia of the biliary-enteric anastomosis. No adverse effects of paclitaxel were observed. Lastly, Bang *et al*^[43] recently developed a mouse model xenografted with both pancreatic cancer and cholangiocarcinoma cell lines which they exposed to paclitaxel-eluting membranes, in an attempt to determine the molecular mechanisms of tumor inhibition. Paclitaxel, they discovered, inhibited tumor angiogenesis, through multiple mechanisms including suppression of mammalian target of rapamycin (mTOR) through regulation of hypoxia inducible factor 1 and increased apoptosis, as well as inhibiting tumor-stromal interaction by effecting regulation of CD44, SPARC, matrix metalloproteinase-2, and vimentin.

Besides paclitaxel, two other chemotherapeutics have been evaluated in DEBS animal models. In 2012, Lee *et al*^[44] developed a gemcitabine eluting stent membrane applied to a self-expanding Nitinol stent. They performed both *in vitro* modeling using a SK-ChA-1 cholangiocarcinoma cell line as well as *in vivo* modeling using a mouse model with colorectal carcinoma cells (CT-26). They analyzed stents developed with 0%, 8%, 10%, and 12% gemcitabine PU by weight and found the 12% concentration to be superior in terms of tumor inhibition and pro-inflammatory markers in both the *in vivo* and *in vitro* models. The authors concluded that gemcitabine eluting stents show considerable feasibility for the treatment of malignant obstruction^[44]. Furthermore, in 2012, Chung

Humans			
Suk <i>et al</i> ^[2]	<i>Gastrointestinal Endoscopy</i> (2007)	Randomized prospective 21 patients - 10% wt/v paclitaxel	Paclitaxel-eluting stents are safe and effective. Occlusion in 9 patients, mean patency was 429 d
Jang <i>et al</i> ^[3]	<i>Digestive Diseases and Sciences</i> (2013)	Randomized prospective 46 patients - control (metallic) 60 patients - 10% wt/v paclitaxel	No significant differences in stent patency or patient survival, but stents proved safe to use in humans

et al^[45] developed a porcine model to analyze gemcitabine eluting stents, analyzing 0%, 10%, 15% and 20% gemcitabine wt/v drug DEBS. They found mild to severe inflammation in the 15% and 20% groups compared to mild inflammation in the 10% group. Fibrous reactions in the submucosal layer did not differ among groups and no biliary obstruction, necrosis or perforations were observed during the study. They found that the 10% GEM stents produced mild histologic changes and are likely most appropriate for clinical application.

Most recently in 2013, Kim do *et al*^[46] loaded sorafenib on PCL film, which was then wrapped around a metal biliary stent. They cultured human cholangiocellular carcinoma cells with the PCL films in order to examine the effect of sorafenib on angiogenesis and tumor cell growth. Additionally, a mouse model was developed using

human cholangiocarcinoma cells. The study concluded that sorafenib successfully inhibited local angiogenesis and tumor cell growth both *in vitro* and in murine models.

HUMAN TRIALS OF DRUG ELUTING BILIARY STENTS

There have been limited human trials involving DEBS. The initial human trial of paclitaxel DEBS was a single arm trial of 21 patients undertaken by Suk *et al*^[2] in 2007 in which a mean patency of 429 d and a mean survival of 350 d were found. Occlusion was observed in 9 patients due to bile sludge or clogging in 4, tumor overgrowth in 3, and tumor in-growth in 2. Furthermore, cumulative patency rates at 3, 6, and 12 mo were 100%, 71%,

and 36%, respectively. Blood levels of paclitaxel were monitored in 6 patients showing systemic levels were low, peaking between 1-10 d, suggesting systemic effects are minimal compared to local effects. This trial showed promising safety and efficacy data and prompted a follow up prospective trial^[3], comparing a 10% wt/v paclitaxel eluting bare metal stent with a traditional covered metal stent. Stents were 5-8 cm in length and 10 mm in diameter in both groups. The study was altered due to a patient preference for the DEBS, and the planned randomized controlled trial was changed to consecutively enrolling 60 patients to the paclitaxel-coated stent arm and then enrolling 46 patients to standard covered SEMS^[41]. Mean duration of stent patency was 199 ± 235 d in the paclitaxel-DEBS group and 149 ± 99 d in the covered SEMS group. Mean survival was 270 in the in the paclitaxel-DEBS arm vs 260 d in the control arm. The rates of cholangitis, pancreatitis, and stent migration were similar between the two groups. Although there was a trend towards improved patency and survival in the DEBS arm, the results did not display statistical significance. The authors concluded that although no significant difference was detected with paclitaxel DEBS, they were shown to be equally safe in human use, and further research is needed. The relatively small number of patients, as well as the shift from a prospective concurrent randomized trial to a trial with staggered accrual likely inhibited the power of the study to detect a clinical benefit from paclitaxel eluting biliary stents. These studies aside, there are multiple avenues for future human research, as well as a significant need to perform large prospective trial to evaluate the effectiveness of drug eluting biliary stents, both with paclitaxel and innumerable other compounds.

CONCLUSION

The amount of direct research involving drug eluting biliary stents has been limited, with only a few drugs having been directly examined. Considering the myriad of possible drugs which could decrease the incidence of internal failure, external failure, or both, there is ample room for further research. As described earlier, small amounts of luminal narrowing from external compression can have exponential effects on the rate of biliary flow, resulting in a significantly increased propensity for internal failure. Drug elution has theoretical benefit in decreasing internal stent failure rates, and heparin coating in particular has shown promise in small studies, which warrants further research. However, antibiotic elution has not shown a benefit in decreasing biofilm formation, which parallels trials looking at the use of systemic antibiotics to prevent stent failure. This may be secondary to multiple possible etiologies including the inability of antibiotics to permeate within biofilms, or the polymicrobial environment of the biliary tree which may quickly lead to bacterial resistance.

Only three drugs, paclitaxel, gemcitabine and sorafenib have been evaluated as possible candidates to decrease the incidence of external failure, where

paclitaxel is the sole drug evaluated in human trials. There are multiple drugs which theoretically could show a clinical benefit in decreasing stent failure rates in both malignant and nonmalignant sources of biliary stenosis. Development of an effective drug eluting stent would likely be cost effective due to the high costs involved in stent failure and has the possibility of directly decreasing patient morbidity and mortality. The high costs, and extensive time and labor requirements of large animal modeling, as well as the lack of an established reproducible bench model have likely inhibited the process of stent development thus far. Despite this, the raw theoretical benefit is evident, where the demand for new devices that reduce restenosis rates with their associated morbidity and mortality is ever present.

Among the possibilities for future DEBS research, the possibility of combination drug stents holds theoretical promise. In order to maximize stent patency rates, the ideal stent would feature both internal and external drug elution. Also, previously trialed drugs which failed to show efficacy as a single agent may have added efficacy when combined with other agents such as heparin or antibiotics, which could prove to have increase efficacy when used in concert. Future animal and human trials will benefit from the analysis of drug combinations.

One of the main limitations to the development of DEBS is the lack of cheap, reproducible models which accurately reflects the human bile duct. Internal stent failure can be reasonably modeled on the bench top by systems which propel biologically active bile through the stent^[47]. Biofilm development can then be measured by direct inspection, weight and electron microscopy^[17-19,21,22]. This model may be used to select optimal agents for further analysis. However, there are no cheap reproducible models which accurately depict the human biliary ducts tolerance to direct contact with drug elution. Drug eluting stents, particularly those with external drug elution, require animal modeling in order to assess histological changes resulting from the stent. As there are no adequate small animal models available for biliary stenting, this has previously been performed with porcine or canine modeling. This has multiple downsides including the high costs of endoscopists or surgeons to place stents, veterinarians, and the animal husbandry required for the several weeks while stents incubate in the bile duct. As the large animal model is also required to establish the ideal drug elution dosage based on histologic changes, costs inhibit the number of drug dosages trialed. Future investigators would benefit from the development of more streamlined and standardized bench top and animal models.

In conclusion, although the current research on DEBS is limited, promise is evident and holds the possibility for significantly increasing the rates of long-term stent patency. Drugs that inhibit malignant cells and non-malignant epithelia hyperplasia, while displaying reasonable histologic tolerance after exposure to the biliary epithelium, should be further examined. Previous models that are well defined can be implemented to

streamline further research. There is an obvious need in this population to decrease morbidity, and DEBS hold the possibility of a significant improvement in outcomes. Further analysis of both new pharmaceuticals and further modeling of current and combinatory drug eluting stents is needed.

minimally invasive, endoscopic treatment for esophageal achalasia and other esophageal motility disorders, emerged from the natural orifice transluminal endoscopic surgery procedures, and since the first human case performed by Inoue in 2008, showed exciting results in international level, with more than 4000 cases globally up to now. POEM showed superior characteristics than the standard 100-year-old surgical or laparoscopic Heller myotomy (LHM), not only for all types of esophageal achalasia [classical (I), vigorous (II), spastic (III), Chicago Classification], but also for advanced sigmoid type achalasia (S1 and S2), failed LHM, or other esophageal motility disorders (diffuse esophageal spasm, nutcracker esophagus or Jackhammer esophagus). POEM starts with a mucosal incision, followed by submucosal tunnel creation crossing the esophagogastric junction (EGJ) and myotomy. Finally the mucosal entry is closed with endoscopic clip placement. POEM permitted relatively free choice of myotomy length and localization. Although it is technically demanding procedure, POEM can be performed safely and achieves very good control of dysphagia and chest pain. Gastroesophageal reflux is the most common troublesome side effect, and is well controllable with proton pump inhibitors. Furthermore, POEM opened the era of submucosal tunnel endoscopy, with many other applications. Based on the same principles with POEM, in combination with new technological developments, such as endoscopic suturing, peroral endoscopic tumor resection (POET), is safely and effectively applied for challenging submucosal esophageal, EGJ and gastric cardia tumors (submucosal tumors), emerged from muscularis propria. POET showed up to know promising results, however, it is restricted to specialized centers. The present article reviews the recent data of POEM and POET and discussed controversial issues that need further study and future perspectives.

Core tip: Submucosal tunnel endoscopy: Peroral endoscopic myotomy (POEM) and peroral endoscopic tumor resection (POET), constitutes a novel terrain for miniinvasive endoscopic treatment of diseases, where the surgical alternatives are totally incomparable, particularly in elderly. POEM showed exciting results in international level in treating all types of achalasia [classical (I), vigorous (II), spastic (III)], including advanced sigmoid type, failed surgical or laparoscopic Heller myotomy cases, and other esophageal motility disorders (diffuse esophageal spasm, nutcracker and jackhammer esophagus). POET was spawned from the success of POEM, and slowly expanded worldwide to treat muscularis based esophageal, esophagogastric junction and cardia submucosal tumors. Submucosal tunnel endoscopy further inspired other applications and opened promising future perspectives.

Submucosal tunnel endoscopy: Peroral endoscopic myotomy and peroral endoscopic tumor resection. *World J Gastrointest Endosc* 2016; 8(2): 86-103 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i2/86.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i2.86>

INTRODUCTION

Peroral endoscopic myotomy (POEM)^[1] is a novel, incisionless, minimal invasive endoscopic surgical procedure, which has been derived from the era of natural orifice transluminal endoscopic surgery (NOTES)^[2], intended for long-term recovery from symptoms of esophageal achalasia.

POEM has successfully spread internationally, with more than fifty centers to have performed POEM worldwide^[3], following the excellent initial results from pioneering centers^[1,4] and definitely open the era of submucosal tunnel endoscopy in clinical practice. POEM has been extended to treat not only all types of esophageal achalasia [classical (I), vigorous (II) or spastic (III), Chicago classification^[5]], but other spastic esophageal motility disorders as well^[6-9].

There were modest variations among centers in technique and periprocedural management, which are currently under investigation, but all centers uniformly reported excellent efficacy and safety outcomes^[3]. POEM has been also extended to include failure of previous therapies, such as botulin toxin injection (BTI) or pneumatic balloon dilatation (PBD)^[10] or failed surgical or laparoscopic Heller myotomy (LHM)^[11,12], advanced sigmoid-type achalasia^[13-15], and also after failure of previous POEM^[13]. Up to know more than 4000 POEM cases have been successfully performed worldwide, and

currently there is an explosion of publications regarding POEM^[3].

As an extension of the POEM technique and submucosal tunnel endoscopy, peroral endoscopic submucosal tumor resection (POET) is also introduced, and is currently increases in experience, however restricted to specialized centers^[16,17].

Successful POET of esophageal and gastric SMTs is possible, due to direct access through the submucosal tunneling far from the mucosal entry, followed by successful mucosal closure even for inadvertent mucosal tunnel perforations with many techniques, such as standard clips, combined clip-endoloop technique^[18], the over-the-scope clips (OTSC)^[19], and finally the most recent technological progress of the endoscopic suturing device (OverStitch™; Apollo Endosurgery Austin, Texas)^[20].

POET is far less invasive than the surgical alternatives, which are either gastrotomy or gastrectomy and esophagectomy for gastric and esophageal SMTs respectively, while POET can be also applied in case of contraindications or serious comorbidities^[16]. However, further international experience with longer follow-up is necessary and awaited. Finally, POEM also opened other applications as well, such as endoscopic gastric pyloromyotomy for refractory gastroparesis^[21].

POEM

Historical perspective of POEM

The concept of endoscopic myotomy for treatment of achalasia, was first reported in case series in 1980^[22], but it was only in 2008 when Inoue *et al*^[1] performed the first successful clinical case of endoscopic myotomy in humans with achalasia, based on experimental data by Pasricha *et al*^[23], Sumiyama *et al*^[24] and Perretta *et al*^[25]. Inoue *et al*^[1] coined the term POEM and subsequently extended its use to treat not only achalasia, but other spastic esophageal motility disorders as well^[26].

Indications and contraindications

Currently, all types of symptomatic esophageal achalasia [classical (I), vigorous (II) or spastic (III), Chicago classification^[5]] diagnosed by high quality (preferably high resolution) esophageal manometry^[5] can be treated by POEM^[27], including failure of previous therapies, such as BTI or PBD^[10] or failed surgical or LHM^[11,12], advanced sigmoid-type achalasia^[13-15] and also after failure of previous POEM^[3,13] (Table 1). POEM has been also reported in post-gastric bypass patients with achalasia^[28].

According to international IPOEMS database 43% of subjects had prior intervention such as PBD, BTI or LHM^[3]. Previous therapies make POEM technically more challenging due to the presence of inflammatory fibrosis, adhesions and scars^[12].

Maselli *et al*^[29] also reported the first successful clinical case of POEM in a 3-year-old child with achalasia and Down syndrome, while lately other groups also reported POEM in children and adolescents^[30,31], making

Table 1 Indications and contraindications of peroral endoscopic myotomy

Indications
Absolute indications
Primary idiopathic achalasia of all types [classical (I), vigorous (II), spastic (III)] (Chicago Classification)
Relative indications
Other hypertensive motor disorders (diffuse esophageal spasm, nutcracker or jackhammer esophagus). HRTM necessary
Failed surgical myotomy (POEM at the opposite site mainly posterior POEM)
Failed pneumatic balloon dilatation
Failed previous POEM. Redo POEM at the opposite site mainly posterior POEM necessary
Advanced sigmoid type achalasia with mega esophagus (bilateral POEM may be necessary)
Children with achalasia (relative indication in experienced hands and specialized centers only)
Elderly with achalasia and comorbidities and non-surgical candidates (relative indication in experienced hands and specialized centers only)
Contraindications
Absolute contraindications
Severe cardiopulmonary disease or other serious disease
Pseudoachalasia
Failure in creating the submucosal tunnel because of severe fibrosis and adhesion
Relative contraindications
Severe esophagitis and/or very large ulcer in the lower esophagus
Recent endoscopic treatment such as EMR, ESD

POEM: Peroral endoscopic myotomy; HRTM: High resolution topographic manometry; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection.

age, no limitation for POEM. Currently, the pioneer centers^[1,11] have no exceptions when considering the application of the POEM.

Moreover, Inoue first extended the indications of POEM to other spastic esophageal motility disorders, such as diffuse esophageal spasm, nutcracker, and jackhammer esophagus^[7,8,32]. According to international survey (IPOEMS), 28% of the reported POEMs performed for other esophageal motility disorders, than achalasia^[3]. In these disorders POEM permitted the longer myotomy required, which cannot be achieved *via* the laparoscopic approach^[6-8,32].

POEM contraindications, according to the consensus, include severe pulmonary disease, esophageal irradiation, esophageal malignancy, bleeding disorder, including coagulopathy and recent esophageal surgery or endoscopic intervention, including endoscopic mucosal resection and endoscopic submucosal dissection (ESD)^[3].

POEM procedure

POEM starts with a mucosal incision, followed by submucosal tunnel creation crossing the EGJ and myotomy inside the tunnel and away from the mucosal entry. Finally the mucosal entry is closed with endoscopic clips. The equipment required for POEM are the same used for ESD, while carbon dioxide insufflation is obligatory through the entire procedure.

It is recommended to use spray catheter for reinjection or the injection needle to remain inside the plastic sheath, to prevent damage to the muscular layer or to mucosal flap. The width of the tunnel should be about one-third of the circumference of the esophagus. A challenge with POEM concerns the identification of the EGJ while in the tunnel, which is discussed below. At the completion of myotomy smooth passage of the endoscope through the EGJ provides confirmation of

complete myotomy. Figure 1 demonstrates the critical steps of POEM.

One day postoperatively, gastroscopy and esophagogram should be routinely performed to confirm mucosal integrity and exclude complications. Adequate esophageal empty controls the efficacy of myotomy and enables oral intake. In uncomplicated cases, patients begin by drinking liquid on day 1, a soft diet on postoperative day 2, and a normal diet on postoperative day 3, while an intravenous infusion of antibiotics should be delivered for one to three days after POEM, followed by an additional four days of oral antibiotics.

The debatable issues of POEM that need further clarification are presented in detail below (Table 2).

Knives

Currently, an important issue for discussion regarding POEM is: Which knife should be used? Inoue *et al*^[1] introduced the triangular TT-knife, that has the advantage of permitting selective dissection of the circular muscle layer, which is the responsible muscle for achalasia, while the thin outer longitudinal muscle may remain as intact as possible, as another safety margin from mediastinum and as a guide to keep a correct dissection plane.

The flat triangular base of the TT-knife is safely touched to the longitudinal layer permitting catching and selective dissection of circular muscle bundles, while lowering the risk of damage to surrounding structures, particularly for inexperienced operator (Figure 1E).

Other knives have been also successfully used for POEM, with the Water-jet (WJ) and ERBE knives the most competitive to TT-knife^[33]. They have the advantage of flushing during POEM, which, according to single center, comparative studies, resulted in shorter procedure time, mostly due to less replacement of accessories and permitted full-thickness myotomy^[33,34]. The authors

Figure 1 Peroral endoscopic myotomy stages. A: Mucosal entry after longitudinal incision at the 2-o'clock position; B: Submucosal tunneling. Ectopic innermost longitudinal muscle bundles in front of the circular muscle layer are recognized; C: Palisade vessels at the EGJ inside the tunnel; D: Blue dye at retroversion in the stomach confirms tunnel extension to gastric side; E: The sharp tip of the TT-knife is used to catch circular muscle bundles and then retract them toward the esophageal lumen; F: Longitudinal muscle is identified at the bottom of myotomy site. Longitudinal muscle fibers split each other and a gap is recognized, creating an unintentional, partly full-thickness myotomy; G: Mucosal closure with endoscopic clips. EGJ: Esophagogastric junction.

comparing WJ to TT-knife also reported larger injection volume and fewer bleeding episodes with WJ, which attributed to easier reinjection^[33,34]. However, reinjection is important only during submucosal tunnel creation and not during myotomy, which is the most important and durative part of POEM.

Lastly, a simple and efficient modified POEM technique using TT-knife and a new method of injecting dyed saline through an integrated water jet channel, to avoid exchanging the knife for a spray catheter, which is time consuming, has been described^[35].

As POEM is an innovative technique, operating time is not anymore a taboo, while the significant time variation between different groups and within the same group related to obvious inhomogeneity of achalasia patients and irrespective of the knife used, made comparative

studies difficult.

In contrary, while TT-knife permits also full-thickness myotomy, selective circular myotomy is more difficult using WJ or ERBE knife, because of the round tip of the knife that does not permit easy catching of individual muscle fibers. These knives are found more appropriate to perform intentional full-thickness myotomy, although not necessary, for treating achalasia.

To our knowledge there is no sufficient international independent data, comparing different knives and up to know no knife has been proved to be more efficacious, although the largest international experience is with the less expensive TT-knife in terms of safety and efficacy.

How the risk of mishaps related to POEM can be diminished?

POEM: Peroral endoscopic myotomy; LHM: Laparoscopic Heller myotomy; GERD: Gastroesophageal reflux; PPIs: Proton pump inhibitors.

300D ERBE; Tübingen, Germany) that enables a spray-coagulation mode with noncontact tissue dissection was the standard preference of Inoue *et al.*^[1] for both submucosal tunneling and myotomy during POEM. The spray-coagulation mode makes the submucosal dissection during tunnel creation much easier, faster, and with less bleeding. Settings can be individually adjusted during the operation.

However, other coagulation modes (*i.e.*, forced coagulation) are also acceptable during submucosal dissection and myotomy, with comparable quality to spray coagulation, in terms of safety and efficacy during POEM with excellent results.

CO₂ insufflation

After frequent serious complications with room air, the POEM groups have been converted to exclusively carbon dioxide insufflation during POEM^[1]. Currently, CO₂ gas insufflation through the endoscope, during POEM, in concordance to laparoscopic techniques, is mandatory not only to reduce mediastinal emphysema, but also to reduce the risk of air embolization.

Intratracheal intubation with positive pressure ventilation should be maintained at higher pressures than those generated by endoscopic CO₂ insufflation, to reduce the risk of mediastinal emphysema during submucosal endoscopy^[26,27]. Mild subcutaneous emphysema, mediastinal emphysema or pneumoperitoneum after POEM, however, should not be considered as complications but as part of this procedure in concordance to pneumomediastinum or pneumoperitoneum after laparoscopic surgery.

Circular *vs* full thickness myotomy

One of the major concerns during POEM was how deeply the muscle layer should be divided. In surgical myotomy, full-thickness myotomy is performed, as the surgeon cut from outside first the external longitudinal muscle layer to approach the inner circular muscle layer.

In initial series of POEM performed by Inoue *et al.*^[1] and subsequently by other groups^[36-39], muscle cutting was intended to dissect only the circular muscle bundles,

which is the responsible muscle for achalasia, while the thin longitudinal muscle layer was left intact as a safety margin between submucosal space and mediastinum.

Full-thickness myotomy is not necessary for treating esophageal achalasia and other esophageal motility disorders, and selective circular myotomy can solve the problem, according to excellent results from more than 3000 selective circular POEM cases. So intentional full-thickness myotomy is not recommended to treat achalasia and other esophageal motility disorders.

However, complete true selective circular myotomy is not possible as longitudinal muscle bundles are naturally thin enough to be widely stretched and split each other during POEM, only by mild compression of the endoscope tip, creating partially full-thickness gaps, without clinical relevance or consequences^[26].

With the increasing experience in POEM and the development of sophisticated endoscopic techniques for closing mucosal gaps, some specialized centers performed intentionally full-thickness myotomy, even for achalasia, although not necessary^[40,41]. However, no significant difference to selective circular myotomy was found in all parameters studied (symptom relief, procedure related parameters, manometry) except of reduced procedure time in the group of full-thickness myotomy.

In terms of safety however, nobody knows the real risks of potential complications in inexperienced hands and the consequences of the severe capnomediastinum and capnoperitoneum, following full-thickness myotomy than selective circular myotomy. Moreover, the gastroenterologist who performs POEM is not familiar to mediastinal anatomy and may have higher risk of complications, such as making accidental injuries to structures beyond the esophageal wall.

However, full-thickness myotomy opened new perspectives in the era of NOTES for further investigation, as structures beyond the esophageal wall, such as mediastinum and retroperitoneum are directly endoscopically accessible and also structures, such as the angle of His and vagus nerve^[42] may be recognized during POEM. Potential future endoscopic procedures could be endoscopic retroperitoneoscopy or mediastinoscopy in a similar fashion to laparoscopy and thoracoscopy. However, these areas need further investigation.

Myotomy length

Myotomy length in POEM is also another controversial issue for discussion. POEM permitted control of myotomy length to be as long as we wish, and achievement of longer myotomy than any surgical myotomy^[8,26]. In initial POEM cases, a relatively short myotomy was performed, however long enough to achieve complete release of high LES pressure and resolve achalasia symptoms. Based on clinical results, the recommended myotomy length during POEM should be a minimum of 7 cm, with 2 cm gastric extension.

With the introduction of high resolution topographic manometry (HRTM)^[43] and Chicago classification^[5], achalasia is accurately classified in three major groups,

which permitted better pre-POEM evaluation of these patients.

Based on these manometric studies, patients with type II (vigorous, panesophageal pressurization) and III (spastic) achalasia, with chest pain because of spasm and/or another high-pressure zone, or other mixed esophageal motility disorders, such as diffuse esophageal spasm, nutcracker and jackhammer esophagus^[7-9], longer myotomy of more than 7 cm is necessary for appropriate symptom resolution.

Khashab *et al.*^[9] recently reported the international multicenter experience from 73 patients with spastic esophageal disorders with mean myotomy length 16 cm and maximum up to 25 cm. However, myotomy length should be individualized, based on HRTM results before POEM.

According to the consensus from IPOEMS and other studies, POEM has significant efficacy in nutcracker esophagus, hypertensive LES, diffuse esophageal spasm and type III (spastic) achalasia, because in those disorders often a longer myotomy is required than cannot be achieved *via* the laparoscopic approach^[3,6,7].

Identification of EGJ

Another fundamental issue in POEM is the extension of myotomy beyond the EGJ about 2-3 cm at the gastric side. So identification of the EGJ in the submucosal space during POEM has significant importance. As clear markers for identifying the EGJ, should be checked: (1) the insertion depth of the endoscope from the incisors; (2) a marked increase of resistance when the endoscope approaches the EGJ, followed by a prompt easing when the endoscope enters the gastric submucosal area; (3) the working space in the submucosal tunnel becomes gradually narrower when the endoscope approaches closely to the LES; (4) endoscopic visual identification of palisade vessels in the submucosal layer (Figure 1C); (5) a change of vasculature in the submucosal layer in the esophageal submucosal space few vessels are observed, while gastric submucosal vasculature suddenly becomes rich looking like a spider web and finally; and (6) the ectopic innermost longitudinal muscle bundles in front of the circular muscle layer at the level of the EGJ, finding in more than 30% of cases^[44].

Tattooing at the gastric cardia using indocyanine green (ICG) before POEM is reported to be one trick for identifying EGJ during POEM by recognition of the green dye at the EGJ within the submucosal tunnel^[32]. However, tattooing may be impractical, time consuming, and confusing particularly in sigmoid type achalasia with dilated and helicoid esophagus. However, this issue may need further study.

Orientation within the submucosal space

Ensuring that the submucosal tunnel stays in line with the esophagus is another issue with significant importance, especially in esophageal motility disorders with tight contractions during POEM and sigmoid and dilated

esophagus. There is little data regarding orientation during submucosal tunneling, and although this issue is very important it is not included in up-to-date protocols.

According to Inoue *et al.*^[26], when the cap-fitted endoscope introduced into the submucosal space and then pushed, tends to advance only in line with the esophagus and its round tip tends to move to the center of the elliptical cross-section of the submucosal tunnel.

However, this is not always the case, especially during anterior myotomy to the lesser gastric curvature, because there are no objective markers to sustain correct direction and inexperienced endoscopists may easily lose the orientation, when they are inside the submucosal space (tornado tunnel).

Orientation within submucosal space may be easier during posterior myotomy to the greater gastric curvature because the existence of more objective guiding anatomic markers, such as the ankle of His, and the compression from the spinal cord^[13]. However this issue needs further confirmation in comparative studies.

Myotomy site

Another question regarding POEM, is on which side myotomy should be done? In initial POEM cases, Inoue *et al.*^[1] performed anterior myotomy, to avoid damage to the angle of His and sling muscle bundles that are located at opposite direction at the greater gastric curvature, which might be a natural barrier to postoperative reflux of gastric contents. Since then anterior myotomy has been established and accepted by most endoscopists worldwide^[36-39]. In fact, the International Peroral myotomy survey (IPOEMS), showed that 14 of 16 centers preferred the anterior approach^[3].

Alternatively, posterior myotomy at 5 o'clock position, leading to the greater gastric curvature, is a promising safe modification of the POEM technique, with high rates of technical and clinical success, according to few centers^[13,45]. Posterior myotomy has the theoretical advantage of easy access to EGJ and better orientation within the submucosal tunnel, because of spinal cord and the ankle of His^[13].

Moreover, anterior myotomy is precluded by previous procedures such as failed surgical Heller myotomy or by other anatomic considerations that obscure the normal dissection planes^[12,13]. Also, in patients with advanced sigmoid type achalasia with megaesophagus, the identification of the EGJ may be difficult during anterior myotomy, resulted in an incomplete gastric myotomy and poor symptom relief^[13].

Posterior myotomy may be especially useful in cases of redoPOEM^[32], POEM post-Heller myotomy^[11,12] or when the EGJ is difficult to recognize because of supervening anatomic constraints or in sigmoid type achalasia with megaesophagus (Figure 2)^[15]. However, no comparative studies have been yet published. A multicenter prospective single blind randomized clinical trial is currently underway, to investigate the optimal technique to myotomy (anterior vs posterior approach)

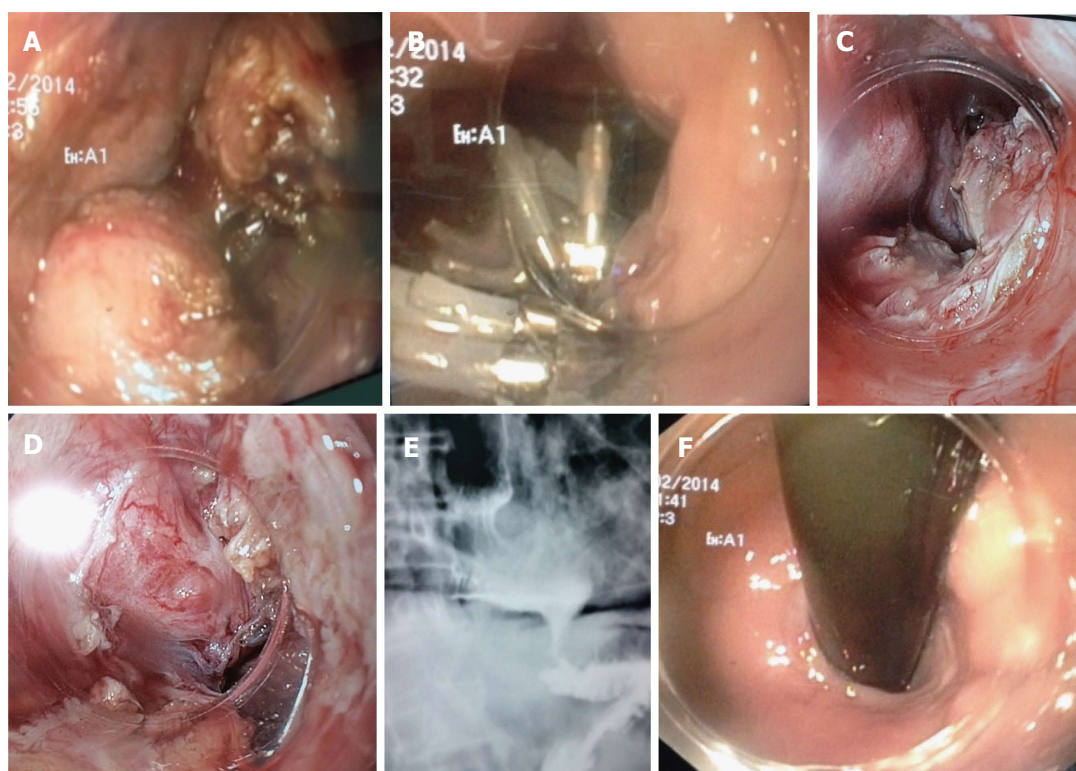

Figure 2 Bilateral peroral endoscopic myotomy in advanced sigmoid (S2) type achalasia with mega esophagus and severe dysphagia in a 74-year-old male with 35-year-old history of achalasia. A: Anterior myotomy. Circular muscle is too thick; B: Closure of the mucosal entry by clips after anterior POEM; C and D: Posterior myotomy at the opposite site. We recognize the mucosal flap and myotomy site; E: Esophagogram after redo-posterior POEM showed sigmoid and dilated esophagus but satisfactory passage of contrast; F: Open EGJ at retroversion. POEM: Peroral endoscopic myotomy; EGJ: Esophagogastric junction.

for POEM.

Mucosal closure

Maintaining the integrity of the mucosal flap and the reliable closure of the mucosal entry during POEM is paramount in preventing leakage of esophageal contents into the mediastinum. Most centers employ clips for closure of the mucosal entry of the tunnel^[1,36-39]. When a completion of the closure with standard clips is unsuccessful, the combined clip-endoloop technique has been successfully applied, comparable to endoscopic full-thickness resection in other areas of the GI tract^[18].

Alternatively, in failed cases, successful mucosal closure has been reported with the OTSC in two POEM cases^[19], and fibrin sealant^[46], however these techniques are more expensive.

There are also few groups who have also successfully used an endoscopic suture device (OverStitch™ Endoscopic Suturing System; Apollo Endosurgery Austin, Texas) for closure of inadvertent mucosal tunnel perforations, particularly for mucosal flap injuries at the EGJ^[20]. These groups^[11,20] are also more comfortable with full-thickness myotomy, because they have the possibility to close any perforation either by clipping or by suturing. They reported on 25 mucosal closures without statistically significant differences in closure time, complications or mean costs^[34], however these results are debatable. Moreover, there are no comparative studies between different methods of

mucosal closure, also regarding the cost-effectiveness.

Endoluminal Functional Lumen Imaging Probe system

During POEM the endoscopist is able to immediately assess the adequacy and completeness of myotomy by passing the endoscope through EGJ at the end of the procedure^[26]. The rationale of POEM is to extend myotomy 2-3 cm to the gastric side in order to cut all responsible for achalasia, circular muscle fibers at the EGJ. However, endoscopic measurements of adequate myotomy are subjective and empirical, often imprecise and may be affected by many biases.

Some POEM groups assess the EGJ distensibility quantitatively, immediately at the end of the procedure, with the EndoFLIP (Endoluminal Functional Lumen Imaging Probe) system, trying to objectively confirm the adequacy of myotomy, however without clear results and no real benefit^[47,48]. The EndoFLIP (Crospon Ltd., Galway, Ireland) system, uses impedance planimetry for real-time measurements of the EGJ diameter, through a specific balloon-tipped catheter^[48].

The rationale of the EndoFLIP use during POEM is that the possibility to measure the diameter of the EGJ before and after POEM may reveal cases of incomplete myotomy, before the closure of mucosal entry as it was the case in one patient reported by Familiari *et al.*^[48]. The endoscope was inserted again in the submucosal tunnel and additional muscular bundles were cut at the

EGJ.

According to these studies, EndoFLIP was found to be potentially useful during LHM, but no real benefit was proved in POEM cases^[48,49]. Obviously, the effects of myotomy on the diameter of EGJ are often unpredictable and not really controllable with POEM. Some authors studied the EndoFlip technique, concluded that EndoFLIP during POEM may be impractical and the real role, if any, should be evaluated in further multicenter studies^[48]. To our opinion EndoFLIP may be confusing, time consuming, troublesome, especially in advanced, sigmoid type achalasia and costly.

POEM in sigmoid-type achalasia

Sigmoid type achalasia subdivided into S1 and S2 subtypes based on radiological signs on computed tomography. In S1 achalasia, the esophageal lumen is tortuous, but the direction is still downward. S2 type is an extremely advanced sigmoid form, where the esophageal lumen is tortuous and turns upwards^[1].

Sigmoid type 2, (S2) was initially considered as an exclusion criterion for POEM. In this very advanced form of achalasia, the maximal tortuosity of the esophageal lumen does not allow smooth food passage, which occurs by gravity when the patient is upright. It was hypothesized that simple myotomy could not relieve symptoms and straightening of the curved esophagus was recommended in addition to laparoscopic myotomy^[1].

However, based on the excellent initial results, Inoue *et al.*^[1] first proceeded to successful POEM in 9 patients with sigmoid-type achalasia, and reported them in his initial publication^[1]. Since then other groups also reported successful POEM in advanced sigmoid achalasia^[14,15,50].

Currently sigmoid type of achalasia is not yet considered as a contraindication for POEM, although it may produce even more technical difficulties, especially in remaining perpendicular to circular layer during myotomy. Moreover, in advanced sigmoid type (S2) achalasia, which is usually presented in advanced age, with multiple comorbidities, and contraindications for major surgery such as esophagectomy, and with a history of potential multiple previous therapies, such as PBD or even surgery, POEM may be the only available therapy. In these advanced sigmoid type (S2) achalasia, with potential extremely thick circular muscle layer, posterior or bilateral POEM^[15] (Figure 2), may be the more appropriate approach, however without definite literature data. Further international experience in this specific subgroup is necessary and is awaited.

POEM for failed surgical myotomy

Although surgical or LHM resulted in good-excellent long-term results in 90% of achalasia patients, failures do occur^[51]. According to Gockel *et al.*^[51] the most common causes of surgical myotomy failures are persistent achalasia or early recurrence due to inadequate or incomplete myotomy; early scarring or fibrosis; early fusion or healed myotomy; while other causes are tight fundoplication; peptic stricture due to gastroesophageal

reflux (GERD); late recurrence due to progression to advanced sigmoid megaesophagus; diffuse esophageal spasm; progression to esophageal cancer; and others.

Treatment of failed surgical myotomy is a challenging, difficult urgent problem, with controversial data^[51]. Redo Heller myotomy has lower efficacy and more postoperative complications, because it is more technically demanding due to the presence of adhesions, fibrosis, and scars from previous surgery according to Wang and Li^[52].

Onimaru *et al.*^[12] and Zhou *et al.*^[11] reported successful rescue POEM on 10 and 12 achalasia patients respectively, with persistent or recurrent symptoms after previous surgical myotomy, with excellent (> 90%) short-term results and without complications.

Both LES resting pressure and symptom score were improved in short-term. The authors have not encountered any difficulties in extending the adequate POEM myotomy down to the stomach because of the presence of fundoplication.

In the rescue POEM, myotomy was performed at the axis opposite to the previous myotomy (mainly posterior axis), to avoid facing scars and submucosal fibrosis from previous surgery. In cases which the axis of previous surgical myotomy could not be clearly identified, myotomy was made at the standard 2 o'clock axis at the proximal esophagus and then rotated to a different axis at the area of the EGJ^[12]. Rescue POEM, however, is highly demanding procedure compared to standard POEM and may be better performed by experts.

POEM vs surgical myotomy for primary achalasia

As the positive international experience with POEM increases, with explosion of international centers performing POEM, there is a criticism in the literature regarding the superiority of POEM to alternative standard 100-year-old surgical or LHM^[53]. One of the major arguments for surgical myotomy is that "the approach is outside the mucosa"^[54]. However intact mucosa is not any more a "taboo" in the modern era of NOTES as mucosal gap can be safely and effectively closed after the procedure, according to excellent results from more than 4000 POEM cases worldwide, up-to date^[1,3,4,36-39]. Moreover, with surgery anatomical structures around EGJ are permanently cut and mobilized, and LHM should always be accompanied with partial fundoplication due to risk of severe GERD. Advantages and disadvantages of POEM vs LHM are presented in Table 3.

Furthermore, POEM permitted endoscopists to approach and cut the responsible muscle of achalasia (the circular muscle layer at the EGJ), through the submucosal space with the most delicate mode, leaving the surrounding structures intact^[1].

Few non-randomized studies^[53,55-57] exist comparing POEM to LHM, with conflicting results^[55]. A recent meta-analysis of comparative studies between LHM and POEM showed equivalent short-term outcomes and similar results for adverse events, perforation rate, operative time and a non-significant trend toward a reduced length of hospital stay in the POEM group^[54,58].

Table 3 Advantages and disadvantages of peroral endoscopic myotomy *vs* laparoscopic Heller myotomy

	POEM	LHM
Advantages of POEM		
Myotomy length	Longer myotomy up to 25 cm	Short myotomy maximum 6 cm
Hospitalization	Minimally invasive method	Invasive (major surgery)
Myotomy depth	Less hospitalization (1-5 d)	Longer hospitalization > 5 d
Other esophageal motility disorders	Selective circular myotomy possible	Only full-thickness myotomy
Sigmoid achalasia	Effective for esophageal spasm, nut cracker and jackhammer esophagus	Combined laparoscopic and thoracoscopic approach is necessary to obtain equivalent myotomy
Elderly patients	Effective in all types of achalasia even in end-stage, sigmoid type (S2) achalasia with megaesophagus	Major surgery such as esophagectomy may be necessary
In failed surgical	Effective in elderly with comorbidities and contraindications	Contra indication for surgery
Cost	POEM after failed surgical myotomy is effective	Redo-surgery often with high rates of failure and complications
GERD	Lower hospitalization and lower cost	Higher cost in combination to surgical procedure
	Less common and lower severity. No antireflux procedure (fundoplication) necessary at the moment.	Fundoplication necessary and routinely performed
	Further study necessary	Complications from fundoplication
	Does not preclude surgery	
	Bilateral POEM possible	POEM more difficult after LHM
Disadvantages of POEM		
Follow-up	POEM	Surgery
	Short follow-up (novel technique)	Longer follow-up
	POEM restricted to specialized centers	Common surgical or laparoscopic procedure overall available
Training	Difficult (no so many centers)	Overall available

POEM: Peroral endoscopic myotomy; LHM: Laparoscopic Heller myotomy; GERD: Gastroesophageal reflux.

Further, randomized comparative studies of LHM and POEM are required. However, conducting studies comparing a novel endoscopic procedure mainly performed by gastroenterologists to a standard LHM performed exclusively by surgeons, in a population of achalasia with large inhomogeneity regarding type, stage and severity are extremely difficult.

All studies comparing POEM to LHM have not focused to specific subgroups of achalasia patients, *i.e.*, end-stage achalasia, with sigmoid type and megaesophagus with contraindications for major surgery. In these particular cases, as well as in other mixed esophageal motility disorders, POEM is the potential only acceptable treatment, according to up-to date positive experience^[11,13,15,26]. The exciting results from POEM make objective, comparative studies to LHM difficult, with many ethical issues also emerged.

POEM after failure of previous POEM

Failure of POEM to control achalasia symptoms, does not exclude future surgery (LHM), because POEM does not involve adjacent tissues surrounding the lower esophagus^[13].

The most common causes of POEM failures are persistent achalasia or early recurrence due to inadequate or incomplete myotomy; end-stage, sigmoid type (S2) achalasia with megaesophagus, where one side (mainly anterior) myotomy is not sufficient and overlooked mixed esophageal motility disorders that need longer myotomy^[13]. In these failed POEM cases, redo-POEM at

the opposite (posterior) direction is recommended and it has been successfully reported^[13]. Longer follow-up, with greater number of patients and further studies focusing on failed POEM are necessary.

POEM RELATED COMPLICATIONS

Acute or late POEM related complications varied greatly among different reports^[59] (Table 4). According to recent pooled analyses, minor complications include: Gas-related complications, such as capno/pneumoperitoneum (30%), subcutaneous emphysema (32%), and capno/pneumomediastinum (10%-22%)^[39,58-60]. Major operative adverse events include tunnel mucosal perforation resulted to mediastinal or peritoneal leak, acute peritonitis, pleural effusion, GI fistula (0.3%), postoperative bleeding (1.1%) and a single death (1/4000 POEM cases, 0.025% mortality)^[58].

Major bleeding in the tunnel is unusual but may require reentry for hemostasis, longer hospitalization time or even blood transfusion^[29,46,61]. Post-POEM reflux esophagitis reported in 19% of patients, although there is controversy in the literature regarding incidence and severity of post-POEM GERD^[58].

Gas related complications

Minor pneumomediastinum, or mild subcutaneous emphysema, just after POEM, could be as high as 100%, with incidence between 10%-22%^[39,59,60], however, without clinical significance or requirement of special

Table 4 Complications of peroral endoscopic myotomy^[58]

Common complications
Gas-related complications (minor)
Subcutaneous emphysema (31.6%)
Capno/pneumomediastinum (10%-22%)
Capno/pneumothorax (11%)
Capno/pneumoperitoneum (30.6%) ^[58]
Mucosal injury-perforation (mediastinal or peritoneal leak) (0.3%) (major)
Mediastinitis (insufficient data)
Peritonitis (insufficient data)
Retroperitoneal abscess (2 proved cases reported)
Pleural effusion (insufficient data)
Pneumonitis (insufficient data)
GI fistula (insufficient data)
Fever (temperature > 38 °C)
Severe postoperative pain
Rare complications
Delay postoperative bleeding (1.1%)
Hematoma within the tunnel
Submucosal infection
Mortality (0.025%) (Single death/4000 POEM cases)

POEM: Peroral endoscopic myotomy; GI: Gastrointestinal.

treatment, and should not be considered as a complication. This phenomenon should be considered similar to the pneumomediastinum seen post thoracoscopic surgery or post-ESD^[26,60,62].

However, gas-related complications may cause discomfort, which is usually relieved through conservative treatment, while in more severe cases vast gas accumulation may occur in the chest, abdominal cavity, mediastinum or under the skin, while acute respiratory and circulatory failure may occur. In such setting emergency invasive interventions of deflation *via* subcutaneous puncture and if necessary closed thoracic drainage should be taken for symptom relief^[26,41,45].

Severe pneumothorax (up to 2.5%^[45]) need chest tube placement, reported in the very early series of POEM^[4], when air was insufflated instead of carbon dioxide gas, while thereafter no such severe complication is reported, at least from pioneering centers^[6,11,15].

Furthermore, despite the theoretical dangerous "downside", according to centers with large number of POEM cases, although long myotomy have been performed up to 25 cm^[8], no clinically severe mediastinitis has been reported at the moment^[4,11,26].

Selective circular myotomy is preferred by most researchers trying to preserve longitudinal muscular layer in order to reduce the chance of gas entry into the thoracic and abdominal cavity. Full-thickness myotomy, however did not increase the occurrence of gas-related complications, although further studies are necessary^[41].

Sigmoid-type esophagus was found to be independent risk factor for the occurrence of gas related complications, due to esophageal twisting, which might form a state of high pressure within the tunnel, so as to cause such complication as subcutaneous emphysema, pneumothorax and pneumoperitoneum^[59].

Tunnel mucosal perforation

Mucosal tear during POEM, particularly at the high-pressure zone of the EGJ or cardia, which are considered as true perforations, have been also reported (0.3%), particularly in early POEM series^[4,12,26,32,58]. These complications were usually treated conservatively with observation, prolonged fasting and longer intravenous antibiotic therapy. In two cases with sub diaphragmatic abscess, external drainage was necessary, with optional outcome thereafter.

The mucosal defects have been adequately closed by multiple clips^[12,26,32], fibrin sealant^[46], or by the clip-endoloop technique^[18] and lately by endoscopic suture device (OverStitch™ Endoscopic Suturing System; Apollo Endosurgery Austin, Texas)^[20]. Temporary dysphagia is also reported in one patient after multiple clipping at the EGJ^[26].

POEM-related mortality

According to International POEM group, only a single, unpublished^[58], POEM related death is currently reported and outside from the large POEM volume Asian centers, that reported no deaths^[32,50]. So, POEM related mortality at the moment, is estimated to be 0.025% (one out of 4000 POEM cases globally). However, POEM related mortality should be compared to mortality of the surgical alternatives, which are the surgical, or LHM. According to recent (2015) study on national outcomes, the mortality rate of LHM was (4/1237) 0.3%^[63] (almost 10-times more than POEM), with 2.4% major complications, 3.1% readmissions and 2.3% reoperation^[63].

Moreover, the existing international experience from great number of patients, showed that POEM is a totally safe procedure, applied safely and effectively to all age spectrum from children to octogenarians, and also to patients with severe co-morbidities and contraindications for surgery^[1,36-39,45,59,64,65]. However, future prospective, randomized, comparative, multicenter studies, on POEM related complications, also focusing on 30-d mortality rate after POEM (procedure and not procedure related), are necessary and awaited.

GERD after POEM

LHM is routinely accompanied by antireflux procedure, to prevent postoperative GERD, because the natural antireflux mechanisms are impaired, while in POEM no antireflux procedure is recommended, since the hiatal attachments are left untouched and the flap-valve mechanism intact^[1].

Theoretically to minimize the risk of post-POEM reflux, anterior myotomy has been recommended, to avoid damage to the angle of His, and the oblique muscle layer of the EGJ, which are natural barriers to postoperative gastric reflux, located posterior laterally^[1]. Sigmoid-type esophagus was found to be independent risk factor for the occurrence of GERD after POEM^[59].

There are controversial results regarding post-POEM GERD, with incidence varied between 5%-46%

Table 5 Efficacy and complications of peroral endoscopic myotomy

GERD: Gastroesophageal reflux.

in published series^[3,4,12,32,36-39,45,53,61,64,66] (Table 5). Inoue *et al*^[1] and other initial multicenter studies^[1,36-39,45,59], reported no symptomatic or mild endoscopic (LA grade A) post-POEM GERD, and concluded that GERD is minor or no problem after POEM. In contrary, according to a recent European multicenter study, GERD was the most common adverse event after POEM, with esophagitis diagnosed in 42% of patients, though usually mild^[60].

There is controversy between studies and within the same study regarding the definition of post-POEM GERD. GERD can be defined on base of symptoms, 24-h pH monitoring and endoscopy data. Familiari *et al*^[48] reported incidence of GERD of 57% based on pH monitoring, 33% based on endoscopic findings and 14% based on symptoms. This discrepancy is found to all studies, however, they all agree that GERD after POEM is not severe and can be successfully treated with proton-pump inhibitors.

In the largest POEM series with longer follow-up, the risk of GERD after POEM varies between 10%-30%, with average 10%, with excellent control under proton pump inhibitors (PPIs)^[32]. Although this issue needs further long-term studies, at the present no antireflux procedure is recommended during POEM.

Efficacy of POEM

The overall results of POEM worldwide, showed excellent symptom improvement (using Eckardt score pre- and post-POEM) between 82%-100%, (mean 90%)^[1,3,4,36-39]. Efficacy of POEM was also studied using manometry and timed barium esophagogram, showing significant

improvement in LES pressure and esophageal emptying in 66% and 80% post-POEM, respectively^[12,26,37,38,53,58] (Table 5). However, more data on long-term efficacy of POEM is needed, and awaited.

Training in POEM

As POEM constitutes a new endoscopic, pure NOTES procedure, which opens the era of submucosal endoscopy, emerged important ethical and training issues. Although theoretically POEM may have dangerous "downside" this has not been yet proved according to successful international experience from more than 4000 POEM cases globally. However, in order to diminish the risk of mishaps an appropriate training program for acquiring adequacy for performing safe and effective POEM is urgently needed.

A simple, cheap and reproducible, non-survival porcine animal model has been established for training in POEM, without the need for concern about complications^[67-69]. Pig is the most appropriate animal model for training in POEM, due to its similarities to the human anatomy, while the porcine esophagus has the advantage of easy mobilization due to absence of tight junctions to surrounding organs.

However, there are significant differences between the porcine and human esophagus, particularly in patients with achalasia. Human submucosa is more hard than porcine's and esophageal circular muscle layer in achalasia is thicker, with multiple high-pressure contractions, while in cadaveric pig model the muscle is thin and without any contraction. Thus, mucosotomy and submucosal tunneling dissection are difficult in porcine due to tissue pliability and poor tissue distention^[68].

The low incidence of achalasia (0.3%-1% per 100000 population)^[70], in combination with the risk of serious complications, related to the technically demanding POEM procedure, has made training difficult^[68,71]. Neither gastroenterologists nor surgeons are absolutely familiar with submucosal endoscopy. While endoscopists are familiar with endoluminal procedures and more experienced in handling endoscope within the natural lumen, surgeons, are familiar with laparoscopic/thoracoscopic procedures and can more easily recognize the structures beyond the mucosa^[68,71].

POEM however is a procedure that requires both capabilities. Good endoscope manipulation, recognition of luminal structures and surgical knowledge of extraluminal structures especially vessels, nerves and mediastinal anatomy. Moreover, delicate skills are also needed^[68,71]. With the worldwide expansion of centers starting performing POEM training program, in POEM procedure is more urgent. Until recently, there are no standard training guidelines for training. The pioneers in POEM proposed a two stage training system for POEM.

First is preclinical training, during which the experienced trainee -which is familiar with handling GI endoscope, has perfect knowledge of esophageal and EGJ anatomy, knowledge of the pathophysiology of achalasia and knowledge of the POEM procedure, including set up of device and patient care during perioperative period- has to follow observation of POEM performed by specialists, and then practice in the animal or cadaveric model, about 46 (range 12-154) hours, according to recent international consensus^[26,27,67-69,71]. Some other centers proposed use of clinical proctor system with 2 median number of proctored cases^[71].

Second step is the clinical training, with POEM in humans with achalasia, performed under careful guidance and observation by specialists, and finally, performance of POEM in humans, with 20 POEM procedures needed to cover the learning curve^[67,68,71]. However, there is still controversy in the literature regarding POEM operator background and training program focusing on "learning curve", while objective, neutral studies in this issues are difficult^[72-74].

POET

Historical perspective

The exciting results of POEM^[1,3,11,36-39] for esophageal achalasia, has further inspired other endoscopic miniinvasive treatments, such as POET^[16,17] for *en bloc* resection of SMTs using the submucosal tunnel technique, particularly for esophageal, EGJ and gastric cardia tumors originating from the muscularis propria.

Endoscopic resection of SMTs originating from the muscularis mucosa (such as leiomyomas) and possibly the submucosa, has been also reported, with a variety of other techniques^[75], from simple snaring to endoscopic submucosal dissection (ESD), because the muscle layer can be preserved^[76,77]. Tumors however, originating from the muscularis propria have to be resected by

thoracoscopy or laparoscopy^[78].

Endoscopic snare full-thickness resection with adequate closure of the perforation with OTSC^[19], or clips and an endoloop^[18] or endoscopic suturing^[20] has been successfully reported for small gastric SMTs (diameter < 2-3 cm)^[79]. ESD has been also reported for the removal of EGJ SMTs, with satisfactory results^[80]. Endoscopic partial resection using the unroofing technique has been also safely and effectively applied for definite pathological diagnosis of small SMTs^[81].

The EGJ, however, is a difficult location for endoscopic resection because it is adjacent to the diaphragm, complicating the endoscopic resection with movement from breathing as well as esophageal peristalsis, in combination with narrow lumen or sharp angle, while SMTs of the EGJ are often irregular, lobulated and may grow annularly, with potential increased risks of perforation and mediastinal infection, especially for SMTs originating from the muscularis propria. Conventional endoscopic muscularis excavation causes large mucosal defects which are difficult to close and often result in strictures^[17].

Submucosal tunnel endoscopy, permitting approach to SMTs through a submucosal tunnel, tumor dissection within the tunnel, "*en bloc*" removal through a mucosal opening far from the tumor, and finally mucosal closure by clips. Submucosal tunnel endoscopy, permitted a controlled, standardized assess to previously taboo spaces, such as the muscle layer, mediastinum and peritoneum, which has been popularized with POEM^[1,3,11,36-39].

Xu *et al*^[17] and Inoue *et al*^[16], based upon the POEM concept for treatment of achalasia, further described the technical principles for POET and performed the first successful POET clinical cases for esophageal, EGJ and gastric cardia SMTs originating from the muscularis propria. Since then POET has been used by other centers^[16,17,82,83] as well. However, further international experience is necessary and awaited before the popularization of POET.

Indications and contraindications

The absolute and relative indications and contraindications of POET are described in Table 6. POET for esophageal, EGJ or gastric cardia SMTs, is far less invasive than, the technically demanding and invasive, surgical alternatives, which are either partial proximal gastrectomy for EGJ SMTs and esophagectomy for esophageal SMTs, while for lesions in the middle or distal stomach can be resected easily *via* laparoscopic approach^[16,27] (Table 7). Moreover, surgical resection of cardia SMTs, have high risk of esophageal stricture development.

Based on the experience from specialized centers^[16,27,80,82], absolute indication for POET includes suspected or confirmed gastrointestinal stromal tumor (GIST) and leiomyoma of the esophagus, gastric cardia and EGJ larger than 2-3 cm, if they are causing symptoms, increasing in size on follow-up or have high risk features on biopsy, endoscopic ultrasound (EUS) or computed tomography^[16,27]. SMTs lower than 2 cm are low risk lesions and life-long surveillance by endoscopy/EUS is indicated. Some authors stated that in these small size (<

Table 6 Indications and contraindications of peroral endoscopic tumor resection

Absolute indications	
Suspected or confirmed GIST of the esophagus and gastric cardia larger than 2-3 cm and lower than 5 cm, and tumor growth on follow-up	
Suspected or confirmed leiomyoma of the esophagus and gastric cardia larger than > 2-3 cm and < 5 cm	
Esophageal or gastric cardia SMTs in elderly with comorbidities and non-surgical candidates completed the above criteria (only in experienced hands and specialized centers)	
POET does not exclude surgery. Complete histological diagnosis possible with POET	
Relative indications	
Esophageal and gastric SMT more than 5 cm (full-thickness resection using submucosal tunnel technique possible) (in experienced hands and specialized centers only and within studies)	
Contraindication	
Suspected or proved malignancy of SMTs	

GIST: Gastrointestinal stromal tumor; POET: Peroral endoscopic tumor resection; SMT: Submucosal tumor.

Table 7 Advantages and disadvantages of peroral endoscopic tumor resection vs surgery

Advantages of POET		
Hospitalization	POET	Surgical myotomy
	Minimally invasive method	Invasive (major surgery)
	Less hospitalization (1-5 d)	Longer hospitalization > 5 d
	Specimen for complete histology possible	
Elderly patients	Does not preclude surgery	
	Effective in elderly with comorbidities and contraindications (only specialized centers)	Contra indication for surgery
Cost	Lower hospitalization and lower cost	Higher cost in combination to surgical procedure
Disadvantages of POET		
Follow-up	POET	Surgery
	Short follow-up (novel technique)	Longer follow-up
POEM	POET restricted to specialized centers	Common surgical or laparoscopic procedure overall available
Training	Difficult (only few centers worldwide)	Overall available
Outcome	Complete curable resection may be not possible in malignant GIST cases	Complete resection possible

GIST: Gastrointestinal stromal tumor; POET: Peroral endoscopic tumor resection; POEM: Peroral endoscopic myotomy.

2 cm) SMTs, POET may offer definitive histologic diagnosis by achieving en bloc resection and may eliminate the need for life-long surveillance^[40], however the current surveillance practice has not yet changed. Contraindication for POET is suspected or confirmed malignancy. In suspected malignant cases, EUS puncture is indicated for tissue diagnosis and if malignant, the patients were primarily referred for surgical resection.

POET is also advantageous because it could be also applied in case of contraindications for the above-mentioned major operations, particularly in patients with serious comorbidities^[16]. Although, initial experience of POET in a small series of patients and from specialized centers, was exciting in terms of safety and efficacy, further international experience with greater number of patients and longer follow-up is necessary and awaited.

POET procedure

The general set up of POET is the same as during POEM procedure^[1], including longitudinal mucosal incision, entrance to the submucosal space, creation of the submucosal tunnel, and approaching the SMTs. Only the final step is different and individualized based on the specifics of each case (Figure 3).

In POET the initial 2-cm longitudinal mucosal incision, is made at approximately 5 cm orally to the proximal margin of the SMT. The submucosal tunnel is created in the same way as Inoue *et al*^[1] first described for POEM. The submucosal tunnel advanced towards the SMT and then extended beyond the tumor to prepare enough space to finally resect the tumor under direct vision.

In the final stage of POET the SMT is enucleated using combination of electrocautery knives [TT-knife and insulated tip (IT) knife] after dissection of muscle fibers connected to the SMT. The IT-knife is useful to dissect from the distal to proximal direction, and to mobilize the SMT. Then, extraction of the mobilized SMT is followed by suctioning the tumor into the cap device and removes it through the mucosal entry. Finally, the mucosal entry was closed tightly in similar manner as in POEM^[1], mainly with endoscopic clips. Endoscopic suturing is alternatively used in difficult cases, by other groups^[40].

The follow-up includes gastroscopy the following day to evaluate the mucosal integrity and contrast media swallow to check for leakage, and if normal started clear liquid diet and gradually regular diet the next days. Annual endoscopic follow-up was then recommended.

Figure 3 Schema of stages of peroral endoscopic tumor resection. A: Gastric cardia SMT in retroversion view; B: Submucosal tunneling. After initial mucosal incision approximately 5 cm proximal to the edge of the SMT, saline and indigo carmine are injected to create a mucosal bleb. A submucosal tunnel is created by dissecting the submucosal fibers. Submucosal dissection is advanced beyond the distal tumor edge; C: Tumor excision. The submucosal tumor is dissected from the muscle layer. All muscle bundles that connect to the submucosal tumor are cut with the triangle-tip knife; D and E: Removal of the submucosal tumor. The totally mobilized tumor is extracted from the submucosal space (D) through the mucosal incision (E). The submucosal tumor is caught tightly by endoscopic suction at the tip of its distal attachment. Submucosal tumors generally have an oval shape, which enables smooth removal out through the mucosal entry; F: Submucosal tunnel after removal of SMT; G: Closure of the mucosal entry incision. After confirmation of complete hemostasis in the submucosal tunnel (F), the mucosal entry is tightly closed with hemostatic clips. POET: Peroral endoscopic tumor resection; SMT: Submucosal tumor.

POET efficacy and related complications

Inoue *et al.*^[16] described successful complete POET in seven patients, four cardia and three esophageal SMTs, without complications. Histologically, one GIST, five leiomyomas and one aberrant pancreas were found. Only in the rare case of aberrant pancreas, additional mucosal resection was required, while in the other six tumors, resection margins were clear. No short-term complications reported^[16].

POET also showed excellent results in long-term, according to a recent report from a pioneering center with large number of patients (290 patients with 4 years follow-up), showing no residual tumor, local tumor

recurrence or distant metastasis^[82]. According to literature available to us, no POET-related deaths were currently reported.

However, taking into account that POET is a relatively new technique with potential dangerous “downside”, future international, prospective, multicenter studies, focusing also on complications (procedure and not procedure related), are necessary and awaited. At the moment POET is restricted only to pioneering centers and within protocols. On the other hand, POET should be also considered as endoscopic surgical procedure and should be compared to surgical equivalents, which are for esophageal and EGJ lesions the esophagectomy

Table 8 Future perspectives of submucosal tunnel endoscopy

Endoscopic vagotomy?
Endoscopic thoracoscopy?
Endoscopic retroperitoneoscopy?
Endoscopic peritoneoscopy?
Endoscopic sympathectomy

and esophagogastrectomy, respectively.

Submucosal tunnel endoscopy opened other possibilities as well, such as exploration of peritoneal and thoracic cavities through transgastric peritoneoscopy^[84] (Table 8). Lastly, another application of submucosal tunnel endoscopy, is the peroral pyloromyotomy as a potential treatment of gastroparesis using endoscopic submucosal tunneling similar to the concept of POEM^[21].

CONCLUSION

Submucosal tunnel endoscopy, including POEM and POET, constitutes a novel terrain for minimal invasive endoscopic treatment of various diseases, such as achalasia and other esophageal motility disorders and esophageal, EGJ and gastric cardia SMTs, which showed exciting results in international level, and superior characteristics than the standard 100-year-old surgical alternatives.

Technological advancements in the era of NOTES, such as endoscopic suturing techniques, permitted endoscopists to become more aggressive, with submucosal tunnel endoscopy including endoscopic full-thickness resections, to be performed safely and successfully. Submucosal tunnel endoscopy opened many possibilities for miniinvasive endoscopic treatment in diseases where the surgical equivalents in terms of aggressiveness are totally incomparable, particularly in elderly patients with comorbidities.

POEM has been globally popularized, with excellent results even from small centers, while it has been extended further to become the treatment of choice not only for all types of achalasia [classical (I), vigorous (II), spastic (III)], including advanced sigmoid (S1 and S2) type, but also for failed surgical or LHM cases, and other esophageal motility disorders (diffuse esophageal spasm, nutcracker and jackhammer esophagus).

POET was spawned from the success of POEM, and slowly expanded worldwide to safely and successfully treat muscularis propria based SMTs in challenging locations in esophagus, EGJ and gastric cardia, with minimally invasive endoscopic procedure.

However, larger number of patients and long-term outcome of POEM and more experience of POET is necessary and is awaited. POEM and POET inspire many other NOTES interventions utilizing the submucosal tunnel approach.

Abstract

Endoscopic ultrasound (EUS) was introduced in 1982

and has since become a popular advanced procedure for diagnosis and therapeutic intervention. Initially, EUS was most commonly used for the diagnosis of pancreatobiliary diseases and tissue acquisition. EUS was first used for guided cholangiography in 1996, followed by EUS-guided biliary drainage in 2001. Advancements in equipment and endoscopic accessories have led to an expansion of EUS-guided procedures, which now include EUS-guided drainage of intra-abdominal abscesses or collections, intra-vascular treatment of refractory variceal and nonvariceal bleeding, transmural pancreatic drainage, common bile duct stone clearance, enteral feeding tube placement and entero-enteric anastomosis. Patients with surgically altered upper gastrointestinal anatomies have greatly benefited from EUS also. This systematic review describes and discusses EUS procedures performed in uncommon diseases and conditions, as well as applications on more vulnerable patients such as young children and pregnant women. In these cases, routine approaches do not always apply, and thus may require the use of innovative and unconventional techniques. Increased knowledge of such special applications will help increase the success rates of these procedures and provide a foundation for additional advances and utilizations of the technique.

Key words: Children; Endoscopic ultrasonography; Intra-abdominal abscesses; Pregnancy; Special situation; Surgically altered anatomy; Therapeutic; Uncommon

Core tip: This article reviews the clinical applications of endoscopic ultrasound-guided interventions reported to date, including drainage of intra-abdominal collections, gallbladder and pancreas. Procedures used in pregnant women and children are also described. The aim of this review was to promote knowledge of special clinical applications in which endoscopic ultrasound is applicable.

INTRODUCTION

Human endoscopic ultrasound (EUS), first described in 1982 by Dimagno *et al*^[1], has become a popular procedure for diagnosis and therapeutic intervention. Since the first report on EUS-guided cholangiography, advances in equipment and the development of endoscopic accessories have led to a substantial growth in the number and types of EUS-guided therapies^[2]. These techniques allow for real-time visualization of structures beyond the endoscopic view, thus increasing the success rate and minimizing complications associated with the procedures. As a result, EUS has also been applied to uncommon or special clinical scenarios recently, such as intra-abdominal abscesses or collections, refractory variceal and non-variceal bleeding, and transmural pancreatic drainage. Furthermore, pregnant women and children have greatly benefited from EUS applications. The aim of this review was to identify and highlight these additional uses for EUS. The PubMed database was searched for human studies written in the English language and published between 1990 and March 2015. The following keywords were used either alone or in combination with EUS: Children, pregnancy, pancreatic drainage, surgically altered anatomy, refractory bleeding and angio-therapeutic interventions, tumor ablation, tumor injection, anti-tumoral therapy, and common bile duct (CBD) stone. The references in the identified articles were also searched for potentially relevant studies. The initial search identified 196 articles, of which 89 full-text articles were considered to be related to this topic and were chosen for review and analysis.

COMMON EUS-GUIDED INTERVENTIONS

Currently, the most common EUS applications are for diagnosing pancreatobiliary disease and tissue acquisition. EUS provides a precise evaluation of the pancreas, peripancreatic organs, CBD and gallbladder. Soon after its original use for pancreatic pseudocyst drainage, EUS was utilized for biliary drainage in cases where endoscopic retrograde cholangiopancreatography (ERCP) had failed. In fact, EUS produced superior outcomes in patients with post-surgical altered anatomy, according to both technical and clinical success rates compared to enteroscopic-based ERCP-related procedures (89%-100% vs 50%-95%, respectively)^[3-11]. The complication rates in the EUS-guided procedure, such as procedures with a transpapillary approach, using transgastric or transduodenal routes for EUS-guided rendezvous, or a transmural approach in EUS-guided hepaticogastrostomy or choledochoduodenostomy, were in an acceptable range (25%-35%)^[5-11]. However, despite their relative success and routine performance,

the feasibility and possibility of complications should always be considered when performing these advanced procedures^[12,13]. EUS-guided pancreatic pseudocyst drainage is commonly accepted in the treatment of fluid collection due to acute pancreatitis; however, this particular application will not be reviewed in the present article.

SPECIAL EUS-GUIDED INTERVENTIONS

EUS-guided interventions have also been utilized when dealing with uncommon diseases or conditions. More susceptible patients, such as young children and critically ill or pregnant patients, have greatly benefited from EUS-guided procedures. Since these groups of patients usually require alternative approaches, each application will be reviewed and described in detail.

EUS-guided pancreatic drainage

EUS-guided pancreatic duct drainage is one of the most difficult and advanced endosonography-based interventions. This procedure is associated with relatively high complication rates, up to 43%^[14-20], and thus should be carried out only by dedicated and highly skilled endoscopists with extensive experience in therapeutic ERCP and EUS procedures. Although similar to EUS-guided biliary drainage, EUS-guided pancreatic drainage is limited to patients in whom ERCP has failed, such as those with symptomatic chronic pancreatitis and pancreatic duct obstruction (due to stone or stricture).

EUS-guided pancreatic duct drainage can be performed in two ways: EUS-guided rendezvous of the pancreatic duct and EUS-guided pancreaticogastrostomy. For EUS-guided rendezvous of the main pancreatic duct, the approach involves puncture from a gastric site and guidewire manipulation until it is passed down to the ampulla, followed by guidewire grasping and scope exchange. For EUS-guided pancreaticogastrostomy, the main pancreatic duct is punctured using a transgastric approach, which is followed by neo-tract creation-dilation and stent insertion from the pancreatic duct through the gastric cavity. The success of both of these procedures is due in part to improvements in the techniques and use of the proper instruments (dilating catheters, dilating balloons, or cauterizing devices for pancreatogastric tract creation). The case series and case reports^[21-26] involving EUS-guided pancreatic duct drainage are shown in Table 1.

EUS-guided biliary interventions due to surgically altered anatomy

ERCP with overtube-assisted enteroscopy has a success rate average of 75% with 3%-5% complication rates, while percutaneous biliary drainage, with similar success rate, has 0.5%-15% complication rates, including 0%-4.9% mortality^[27,28]. Currently, EUS-guided biliary drainage is a preferred alternative treatment option when the patient with surgically altered anatomy prefers internal drainage. Approximately one-third of the patients

N/A: Data not available; FU: Follow-up.

who undergo EUS-guided pancreatic duct drainage and one-fifth who undergo EUS-guided biliary drainage have surgically altered anatomies. This is typically due to a preceding Whipple's operation (pancreaticoduodenectomy-choledochojejunostomy and pancreatojejunostomy), post-gastrectomy, or other internal bypass surgeries. Prior to the advent of EUS procedures, the only treatment options for these patients were percutaneous drainage or repeat surgical operations. Advancements in EUS techniques provided alternatives, including EUS-guided rendezvous followed by ERCP or enteroscopy-assisted ERCP, EUS-guided transmural drainage procedures (hepaticogastrostomy, choledochoduodenostomy, or pancreaticogastrostomy), and EUS-guided antegrade stent insertion. The techniques for these EUS-guided interventions are the same as the ones used for conventional (non-altered anatomy) cases, with technical and clinical success rates of 85%-100% and acceptable complications^[28]. The EUS-guided biliary drainage is performed as follows: the punctured site is first localized (intra or extra-hepatic bile duct), followed by a neo-tract creation (either by cauterization or non-cauterization methods), neo-tract dilation (either by graded dilation or balloon dilatation techniques) and finally a stent placement (either plastic or metallic stents)^[5,6,28,29]. Details of the case series and case reports involving EUS-guided interventions in patients with surgically altered upper gastrointestinal anatomy are shown in Table 2.

EUS-guided CBD stone clearance

The conventional CBD stone removal fails in 5%-10% of cases^[30,31], half of which require other treatments such as intraductal therapy (laser lithotripsy or electrohydraulic lithotripsy)^[32,33]. Patients with a surgically altered anatomy are at an increased risk for clearance failure. Itoi *et al*^[29] reported a case series of 5 patients with surgically altered upper gastrointestinal anatomy who underwent EUS-guided transhepatic antegrade CBD stone removal. The success rate of complete CBD stone clearance in one

session was 60%. The group used transgastric (3 cases) or transjejunum (2 cases) puncture of the CBD with a 19- or 22-gauge needle and a contrast study to evaluate the CBD stones. Next, a guidewire was introduced, traversing the ampulla down to the duodenum, and the papilla was dilated in an antegrade fashion *via* inflation of a balloon catheter to push the stones down until they passed the ampulla. In cases of incomplete CBD stone clearance, a stent was inserted.

A randomized controlled trial showed an equivalent success rate of EUS-guided CBD stone removal compared to standard ERCP for the treatment of small (< 10 mm) CBD stones^[34]. The success rate was calculated based on the CBD clearance rate, procedure time, and complications. In the trial, CBD cannulation was performed only under EUS guidance to demonstrate the feasibility of EUS-only CBD stone removal. Hence, the need for fluoroscopy was eliminated, providing a feasible alternative for treatment of pregnant patients or in bedside procedures performed in the intensive care unit.

EUS-guided enteral feeding tube placement and enteric anastomosis

EUS guidance can be utilized for placement of enteral feeding tubes, such as in the case of gastrostomy or internal anastomosis. Khashab *et al*^[35] described a case report involving EUS-guided gastroenterostomy. For this technique, the desired duodenal or jejunal loop closest to the EUS curvilinear echoscope was identified, and the lumen was punctured to allow passage of a 0.035-inch guidewire. The sphincterotome was inserted over the guidewire for infusion of water (< 500 mL to avoid metabolic derangement), and the gastroenteric tract was dilated in preparation for placement of the anastomotic stent. There is a risk of leakage with this technique due to the mobility of the small bowel, particularly the jejunum. A recent report by Ikeuchi *et al*^[36] described an endoscopic treatment in a patient with afferent loop syndrome who underwent surgical bypass. The neo-gastrojejunal

tract was created using a curvilinear echoscope, and a 19-gauge needle passed from the stomach into the bowel lumen. After guidewire insertion, the two lumens were stabilized, and a lumen-apposing metal stent was inserted and deployed. This neo-type of lumen secures the tract and prevents leakage, the most common problem encountered with this type of procedure. Recently, Itoi *et al*^[37] reported a case series of EUS-guided gastrojejunostomy using a special gastrojejunal tube with balloon fixation technique. This specific instrument was developed to stabilize the jejunal lumen allowing for easier creation of a neo-gastrojejunal tract while minimizing the occurrence of complications, especially of leakage or perforation. Firstly, the gastroscope with overtube was inserted into the strictured region, followed by placement of a guidewire *via* the strictured region to the jejunum. After the scope was removed, a special gastrojejunal tube with balloon fixation was inserted over the guidewire down to the jejunum (in the same fashion as a naso-jejunal tube placement). Secondly, the two balloons were inflated separately using contrast media followed by water infusion through the catheter (the opening of the water channel was located between these two balloons) to form a fixed jejunal segment-like tubular structure that was easy to find with an echoscope. Therefore, this particular jejunal segment was fully dilated and very close to the gastric wall. Then, EUS was performed to locate the puncture site, which appeared on the endosonographer as a sausage-like hypoechoic structure very close to the gastric wall. A 19-gauge needle was used to puncture into that segment and a guidewire was inserted and looped. Finally, a single-step lumen-apposing stent with cautery enable-access catheter unit (Hot AXIOS stent; Xlumen Inc., Mountain View, CA, United States) was inserted over the guidewire and deployed. EUS-guided gastrojejunostomy performed by Itoi *et al*^[37] appears to be safer than two other techniques mentioned previously. The new incoming type of lumen-apposing stent is currently being developed, aiming at the possibility of greater ease of deployment compared to the previous model^[38].

EUS-guided intra-abdominal abscess and collection drainage

EUS-guided drainage of an intra-abdominal abscess was first reported by Giovannini *et al*^[39] in 2001. EUS-guided procedures have also been reported in the drainage of pelvic and hepatic abscesses (tuberculous,

pyogenic/ruptured, and concealed), as well as for prostatic, mediastinum, sub-phrenic and retroperitoneal abscesses^[40-50]. These procedures use the curvilinear echoscope to locate the abscess and verify that it is well formed. After ensuring that there are no intervening blood vessels, the abscess is punctured and contents aspirated with a 19-gauge needle. Next, a guidewire is inserted into the abscess and a contrast agent is injected to allow for visualization. Then, a small-caliber sphincterotome or catheter is inserted to flush the abscess cavity with saline (50 mL). The tract is then gradually dilated using either a graded dilation technique or a balloon dilation to allow for insertion of a 7 Fr, 8.5 Fr or 10 Fr straight stent, or a single/double pigtail stent with or without nasal-abscess drainage catheter for routine flushing of saline to enhance the drainage. Follow-up studies are still needed to verify resolution of the abscesses. The size of abscesses involved varied from 4 cm to 12 cm in diameter, and the time for resolution of these abscess ranged from 3 mo to 10 mo. Details on the case series involving EUS-guided intra-abdominal abscess drainage are shown in Table 3.

EUS-guided arteriovenous interventions

In 2000, Lee *et al*^[51] was first to report EUS-guided injection of cyanoacrylate for stoppage of gastric variceal bleeding. In 2008, Levy *et al*^[52] combined the glue injection with microcoil embolization to treat refractory gastric variceal bleeding. Since then, there have been additional reports demonstrating success of this procedure, with variceal and non-variceal re-bleeding rates of < 10% in most cases^[53-58]. A similar clinical outcome was reported by Kinzel *et al*^[59] for a 31-year-old man with duodenal variceal bleeding.

Kuramochi *et al*^[60] used EUS to demonstrate the increased risk of recurrence of esophageal varices in high-risk patients who exhibited anterior branch dominance and flow velocity of 12 cm/s. EUS was found to be a very sensitive tool for early detection of heightened portal pressure, observed as dilation of the collateral circulation and small gastroesophageal varices, which are often missed *via* endoscopic evaluation^[61]. EUS has been shown to improve the detection and diagnosis of gastroesophageal varices and collateral veins. Furthermore, EUS can be used as an endoscopic therapy of gastroesophageal varices, such as EUS-guided sclerotherapy of esophageal collateral vessels and EUS-

guided cyanoacrylate (glue) injection of gastric varices. EUS can also provide knowledge on the efficacy of pharmacotherapy of portal hypertension. Furthermore, EUS can provide assessment and prediction of variceal recurrence after endoscopic therapy and assessment of portal hemodynamics, such as the E-Flow Doppler ultrasound study of the azygous and portal veins. Additionally, Giday *et al*^[62,63] demonstrated the feasibility of portal vein puncture for measuring pressure and injection of contrast agents without inducing liver injury in an animal model. This was followed by a case report by Buscaglia *et al*^[64] describing EUS-guided insertion of an intrahepatic portosystemic shunt. Matthes *et al*^[65] demonstrated the feasibility of EUS-guided portal vein embolization using Enteryx, a swine model. However, there is no report in the literature of these invasive portal vein interventions being applied in a clinical setting as of yet.

EUS-guided interventions in gastrointestinal oncology

Patients with pancreatobiliary malignancy who were not surgical candidates benefited from EUS-guided interventions for local control and treatment of tumors. Many treatment applications have been used in these cases, including ablative therapy (by absolute alcohol

injection), thermal ablative therapy using radio frequency ablation, or cold therapy by the cryo-based probe, or a combination of the techniques. In all these techniques, the catheter was introduced through the echoscope channel, localizing the treatment location under EUS guidance^[66,67]. Intra-tumoral injections of cell products such as tumoral dendritic cells, TNFerade or brachytherapy using I¹²⁵ have also been reported^[68,69]. However, the clinical outcomes of these therapeutic platforms were not impressive. Although newer treatment modalities, such as new cell types and new chemical situations, are being developed, there is yet too little information available for a reasonable discussion in this review. The large case series on local tumor treatments are shown in Table 4^[70-74].

EUS in pregnancy

The incidence of pancreatobiliary disease, including choledocholithiasis, in pregnant women, is estimated to be 2%-6%^[75]. However, ERCP, the conventional method for CBD clearance, is not appropriate for these patients due to risks associated with fluoroscopy. Thus, EUS-guided CBD stone removal with or without intraductal visualization *via* spyglass or cholangioscopy represents a suitable alternative. With this method, CBD diagnosis

can be confirmed *via* radial EUS, followed by intraductal evaluation or CBD cannulation *via* duodenoscopy^[76-78]. The position of the CBD stone can be confirmed through detection of aspirated bile content allowing for a complete stone removal and/or a stent placement to avoid recurrence.

EUS in children

EUS-guided interventions are equally feasible in pediatric patients. However, compared to adults, the child's organs and ducts are smaller, requiring extra care by the endoscopists who perform the procedures. The first EUS-guided intervention in a pediatric patient was reported in 1993, and it used a fine-needle aspiration (FNA)^[79]. Since then, additional advanced procedures have been performed in pediatric patients^[80,81]. In 2009, Attila *et al.*^[82] reported a case series of EUS procedures performed in 38 children. Of these, 30% of the cases used EUS with FNA, which established the correct diagnosis in 75% of the patients who underwent FNA without any complication. Recently, Scheers *et al.*^[83] also reported a case series of EUS procedures in 48 children. In this case series, 13 therapeutic EUS procedures, including 9 combined EUS-ERCP procedures, were performed without adverse events. The authors also proposed that the adult endoscopes and accessories can be used safely in children > 3 years of age (or > 15 kg body weight) and that a single endoscopic treatment session is feasible in children.

CONCLUSION

EUS-guided interventions can be used to treat various conditions, with favorable outcomes in most cases. In addition to pancreatic and biliary draining procedures, EUS guidance has been utilized in CBD stone clearance, enteral feeding tube placement, enteric anastomosis, and intra-abdominal abscess drainage. Such techniques are particularly well suited for patients with altered anatomy, pregnant women, or children. Increased knowledge of such special applications will help increase the success rates of these procedures and provide a foundation for additional advances and utilizations of EUS.

Abstract

AIM: To determine variations in colonoscopy real-time insertion pain among investigators using three different insertion techniques.

METHODS: From March 2013 through June 2014, 18-85-year-old diagnostic and 50-70-year-old screening patients were enrolled at each center to on-demand sedation colonoscopy with water exchange (WE), water immersion

(WI) and insufflation with air or CO₂ for insertion and withdrawal [air or carbon dioxide (AICD)]. Data were aggregated for analysis. Primary outcome: Variations in real-time maximum insertion pain (0 = none, 1-2 = discomfort, 10 = worst).

RESULTS: One thousand and ninety-one cases analyzed: WE ($n = 371$); WI ($n = 338$); AICD ($n = 382$). Demographics and indications were comparable. The WE group had the lowest real-time maximum insertion pain score, mean (95%CI): WE 2.8 (2.6-3.0), WI 3.8 (3.5-4.1) and AICD 4.4 (4.1-4.7), $P < 0.0005$. Ninety percent of the colonoscopists were able to use water exchange to significantly decrease maximum insertion pain scores. One investigator had high insertion pain in all groups, nonetheless WE achieved the lowest real-time maximum insertion pain score. WE had the highest proportions of patients with painless unsedated colonoscopy (*vs* WI, $P = 0.013$; *vs* AICD, $P < 0.0005$); unsedated colonoscopy with only minor discomfort (*vs* AICD, $P < 0.0005$), and completion without sedation (*vs* AICD, $P < 0.0005$).

CONCLUSION: Aggregate data confirm superiority of WE in lowering colonoscopy real-time maximum insertion pain and need for sedation. Ninety percent of investigators were able to use water exchange to significantly decrease maximum insertion pain scores. Our results suggest that the technique deserves consideration in a broader scale.

Core tip: Randomized controlled trials (RCTs) have shown water exchange (WE) to have considerable advantage in decreasing colonoscopy insertion pain. Assessment of individual investigators' performance using WE in RCTs is usually not reported. We assessed the performance of individual investigators in 3 RCTs comparing WE, water immersion and gas insufflation (with air or carbon dioxide) during insertion, to determine whether observations are reproducible across investigators and what factors might contribute to variations. Aggregate data show that individual investigators had significant variations in insertion pain scores and use of adjunct maneuvers together with short insertion time, but the pain alleviating impact of WE occurs in 90% of them. WE has the highest proportions of patients with painless unsedated colonoscopy; complete unsedated colonoscopy with only minor discomfort and completion without sedation.

INTRODUCTION

Water exchange (WE) and water immersion (WI) are two colonoscopy techniques that entail infusion of water to distend the lumen during the insertion phase. Randomized controlled trials (RCTs) have shown WE (airless insertion, infused water aspirated predominantly during insertion to clear the view and minimize distension) to have considerable advantage in decreasing colonoscopy real-time maximum insertion pain when compared with WI (water infused as adjunct to insufflation, and aspirated predominantly during withdrawal without attempting to maximize colon cleanliness during insertion) and air^[1-3] or carbon dioxide insufflation^[3,4]. WE is a relatively new technique, and requires new maneuvers not entirely intuitive to colonoscopists^[5]. In spite of this, in a previous report focused on individual investigators' performance^[6], WE has shown reproducibility and repeatability in decreasing maximum insertion pain, usually not reported in RCTs. Some of the factors associated with difficult colonoscopy (e.g., prior abdominal surgery, low body mass index) and insertion pain are favorably influenced by WE^[2,3,7,8].

We assessed the performance of individual investigators in three recently completed RCTs in a multinational setting, to determine whether the effect of WE in reducing real-time maximum insertion pain is reproducible across investigators and what factors (e.g., use of adjunct maneuvers of loop reduction and abdominal compression, insertion time, etc.) might contribute to variations among them.

MATERIALS AND METHODS

Patient-related and procedure-related factors were collected prospectively at our centers (NCT01781650, 01780818, 01954862): St. Barbara Hospital, Iglesias (Italy); N. S. di Bonaria Hospital, San Gavino Monreale (Italy) and the Vitkovice Hospital, Ostrava (Czech Republic).

From March 2013 through June 2014, 18-85-year-old diagnostic and 50-70-year-old screening patients were enrolled and randomized to WE, WI or insufflation with air or carbon dioxide (AICD) at each site. Sedation was available on-demand at patients' request^[2,3]. Local Ethics Committees approved the protocols. Written informed consent was obtained from all patients at enrollment. All authors had access to the study data, reviewed and approved the final manuscript. Statistical review of the study was performed by a biomedical statistician.

Study procedures

Colonoscopies were performed by 10 board-certified endoscopists, five with experience in about 10000 AICD, 260 WE and 120 WI. One investigator had experience in about 7200 AICD, 260 WE, 800 WI. The last four investigators had experience in about 3000-7000 AICD and 150 WE. One had experience in 800 WI, the

remaining three in 90 WI.

A split-dose bowel preparation was used to clean the colon^[2,3]. Enrolled patients were assigned to the different insertion techniques by computer-generated lists, with block allocation and stratification based on participating endoscopists. Group assignment was kept in sealed envelopes that were opened just before the start of the procedure. The patients, but not endoscopists and assisting nurses, were blinded to the insertion method used: The monitors were concealed from patients' view. Endoscopists were blinded to insufflation gas used: Light source and insufflators were concealed from the view. At discharge patients were asked to guess which insertion method had been used (infusion of water or insufflation), and investigators which gas had been insufflated. If no more than half of the responses were correct, their blinding was considered adequate^[2,3].

Colonoscopy began with the patients in the left lateral position without premedication. High-resolution wide-angle variable-stiffness adult video colonoscopes (Olympus HD 180) were used. Variable stiffness was used at the discretion of the investigators, but its record was not kept^[2,3]. Cardiopulmonary function was monitored throughout.

In patients randomized to WE and WI, insufflation was turned off before starting the procedure. After the rectosigmoid junction was reached, the colon was irrigated with water at 37 °C using flushing pumps^[2,3].

Water exchange involved infusion of water during insertion to distend the lumen to the minimum required to reach the cecum. When opaque water was encountered, infusion and near-simultaneous suction were applied until clear water was in front of the instrument. Residual air pockets, feces and infused water were removed predominantly during insertion^[2,3].

Water immersion involved the infusion of water during the insertion phase to aid passage to the cecum without attempting to clear the colon contents, with limited use of insufflation when necessary^[2,3]. Infused water was removed predominantly during withdrawal.

In the AICD group colonoscopy was performed in the usual fashion with the minimal insufflation required to reach the cecum^[2,3]. In all arms insufflation was used during withdrawal to obtain adequate distension of the lumen for exploration^[2,3].

In all groups loop reduction, position change and abdominal compression were applied in that sequence as needed when the instrument failed to advance, and not per protocol at determined anatomic locations. Cecal intubation was defined as reaching beyond the ileocecal valve with adequate visualization of the appendix orifice.

Pain assessment and sedation

Pain was assessed using a numeric rating scale (NRS) with faces outlines and verbal descriptors, with a score 0 = absence of pain, 1-2 = simply "discomfort", 10 = the worst possible pain. Before the procedure, a

nurse explained the NRS to the patients. They were informed that the request for pain information was meant to assess the need and dosage of sedation^[2,3], and to let the colonoscopist be alerted to the need to use maneuvers to minimize discomfort (e.g., removal of colonic content, loop reduction, change in patient position and/or abdominal compression). At the discretion of the assisting nurse, at irregular intervals, patients were asked about discomfort or pain several times during the procedure and encouraged to report it spontaneously. Responses were recorded and the real-time maximum insertion pain score noted. On-demand sedation was offered at a NRS score ≥ 2 (discomfort). If patients accepted, sedation was started with an intravenous dose of 2 mg of midazolam, with step-ups of 1 mg (up to 5 mg) if the patients continued to report pain^[2,3]. To avoid bias by the colonoscopist, medication was administered based on the patients' confirmation that the pain was no longer tolerable, and not at the discretion of the endoscopist. No other analgesic or sedative medications were administered. At discharge, a blinded nurse recorded patients' recalled maximum insertion pain using the same NRS in the absence the personnel who performed the procedure.

Study endpoints

The primary outcome was real-time maximum insertion pain score recorded during the insertion phase of colonoscopy. Secondary outcomes included recalled pain at discharge, individual performance of investigators in terms of several procedural outcomes; analysis of painless unsedated colonoscopy, unsedated colonoscopy completed with only discomfort (NRS = 1-2), and complete unsedated colonoscopy with any pain score.

Statistical analysis

Standard descriptive statistics were used to assess the distribution of the study variables and to compare them. Pain values were computed using mean at 95%CI and analyzed by using the *t*-test and analysis of variance (ANOVA) where appropriate. *P* values < 0.05 were considered significant.

RESULTS

The database stored data relative to 1091 patients randomly allocated to WE (*n* = 371), WI (*n* = 338) or AICD (*n* = 382). Overall, demographics, body mass index (BMI), previous abdominal surgery and indications were comparable (Table 1).

In greater detail, age was comparable among the study groups and individual investigators. Abdominal pain had comparable proportions among methods and individual investigators, except for Investigator number 1 and Investigator number 8 that had significantly higher proportions in the WE group. The other indications were comparable among methods, except for Anemia (0.048).

Table 2 shows that female patients were equally

distributed among study groups and individual investigators. There were significant differences in terms of BMI within the WE and WI groups ($P = 0.025$ and $P < 0.0005$, respectively). The AICD group had the lowest proportion of patients with previous abdominal surgery, comparable among individual investigators ($P = 0.405$). Among

the 10 individual investigators there were significant differences in terms of use of abdominal compression, loop reduction and cecal intubation time.

Females with previous abdominal surgery, any indication for colonoscopy	6 (21.4)	24 (7.0)	0.018 ¹

¹ χ^2 .**Table 4** Investigator number 8, significant differences associated with increase in real-time maximum insertion pain score among methods, *n* (%)

	WE (<i>n</i> = 28)	WI (<i>n</i> = 28)	AICD (<i>n</i> = 24)	<i>P</i> value
Females and males, abdominal pain as indication	11 (39.3)	2 (7.1)	7 (29.2)	0.017 ¹ WE <i>vs</i> WI 0.004 ² WE <i>vs</i> AICD 0.446 ² WI <i>vs</i> AICD 0.064 ²
Females with abdominal pain as indication	9 (32.1)	1 (3.6)	3 (12.5)	0.008 ¹ WE <i>vs</i> WI 0.005 ² WE <i>vs</i> AICD 0.059 ² WI <i>vs</i> AICD 0.352 ²
Females with abdominal pain as indication and previous abdominal surgery	6 (21.4)	1 (3.6)	1 (4.2)	0.031 ¹ WE <i>vs</i> WI 0.043 ² WE <i>vs</i> AICD 0.069 ² WI <i>vs</i> AICD 0.911 ²

¹ANOVA; ² χ^2 ; *n*: Number of patients; WE: Water exchange for insertion, insufflation with air or CO₂ for withdrawal; WI: Water immersion for insertion, insufflation with air or CO₂ for withdrawal; AICD: Insufflation with air or CO₂ for insertion and withdrawal; SD: Standard deviation; BMI: Body mass index.

ranged from 12 to 80 per group.

Table 2 shows the analysis of the performance of the individual investigators. There were significant differences of mean real-time maximum insertion pain score among WE, WI and AICD, mean (95%CI): WE 2.8 (2.6-3.0), WI 3.8 (3.5-4.1) and AICD 4.4 (4.1-4.7), *P* < 0.0005; differences were significant also within each study group. WE consistently showed the lowest real-time maximum insertion pain scores, and with the exception of Investigator number 8, who showed WE to have higher pain scores than all the other insertion techniques, the trend that WE was the least painful was observed in all the rest of investigators, regardless of their prior experience with the insertion technique used (Table 2). The WE group showed significant variations in terms of BMI, previous abdominal surgery, abdominal compression, loop reduction and insertion time among individual investigators.

Table 3 shows that, compared with all the other investigators, the WE group of Investigator number 8 had a significantly higher proportion of patients with abdominal pain as indication (39.3% *vs* 16.6%, *P* = 0.003), cohort that included mostly irritable bowel syndrome (IBS) patients; and a significantly higher proportion of female patients (32.1% *vs* 7.0%, *P* < 0.0005) with a significantly higher incidence of previous abdominal surgery: 21.4% *vs* 7.0%, *P* = 0.018 (Table 3).

The same analysis across Investigator's number 8 study groups (Table 4) showed that his WE group had a higher proportion of cases with abdominal pain as indication (ANOVA among groups *P* = 0.017; WE 39.3% *vs* WI 7.1%, *P* = 0.004); in particular women (ANOVA among groups *P* = 0.008; WE 32.1% *vs* WI 3.6%, *P* = 0.005; *vs* AICD 12.5%, *P* = 0.059). This WE group of female patients with abdominal pain as indication showed also a higher incidence of previous abdominal surgery (ANOVA among groups *P* = 0.031): WE 21.4% *vs* WI 3.6%, *P* = 0.043; *vs* AICD 4.2%, *P* = 0.069. The comparisons of WE *vs* AICD lacked enough power (type II error) to show significance.

Investigator number 10, with infrequent use of loop reduction or abdominal compression and short mean insertion time (Table 2), had high real-time maximum insertion pain scores in all groups, but the use of WE brought insertion pain down in this investigator: ANOVA among groups *P* = 0.004.

Secondary outcomes analysis

Compared with AICD and WI, WE had the highest proportion of patients with painless unsedated colonoscopy (Table 5): 13.5%, *vs* WI 7.7% (*P* = 0.013); *vs* AICD 6.0% (*P* < 0.0005). Compared with AICD, WE and WI showed a significantly higher proportion of unsedated colonoscopies with only discomfort, corresponding to NRS values of 1-2: WE 36.1%, *vs* WI 31.4% (*P* =

Table 5 Pain during insertion, patients' tolerance and sedation, *n* (%)

	WE (<i>n</i> = 371)	WI (<i>n</i> = 338)	AICD (<i>n</i> = 382)	<i>P</i> value
Painless unsedated colonoscopy ²	50 (13.5)	26 (7.7)	23 (6.0)	WE vs WI 0.013 ¹ WE vs AICD < 0.0005 ¹ WI vs AICD 0.374 ¹
Unsedated, completed with only discomfort ²	134 (36.1)	106 (31.4)	87 (22.8)	WE vs WI 0.180 ¹ WE vs AICD < 0.0005 ¹ WI vs AICD 0.009 ¹
Completed without sedation	321 (86.5)	287 (84.9)	292 (76.4)	WE vs WI 0.537 ¹ WE vs AICD < 0.0005 ¹ WI vs AICD 0.004 ¹
On-demand sedation	50 (13.5)	51 (15.1)	90 (23.6)	WE vs WI 0.537 ¹ WE vs AICD < 0.0005 ¹ WI vs AICD 0.004 ¹

¹χ²; ²Pain score based on numeric rating scale (NRS): 0 = absence of pain, 1-2 = discomfort, 10 = maximum pain. *n*: Number of patients; WE: Water exchange for insertion, insufflation with air or CO₂ for withdrawal; WI: Water immersion for insertion, insufflation with air or CO₂ for withdrawal; AICD: Insufflation with air or CO₂ for insertion and withdrawal; SD: Standard deviation.

0.180); vs AICD 22.8% ($P < 0.0005$); WI vs AICD $P = 0.009$ (Table 5). WE and WI achieved also a significantly higher proportion of procedures completed without sedation: WE 86.5%, vs WI 84.9% ($P = 0.537$); vs AICD 76.4% ($P < 0.0005$); WI vs AICD $P = 0.004$ (Table 5). Accordingly, WE and WI showed low proportions of patients requesting on-demand sedation: WE 13.5%, vs WI 15.1% ($P = 0.537$); vs AICD 23.6% ($P < 0.0005$); WI vs AICD $P = 0.004$ (Table 5).

Procedural outcomes

Cecal intubation rates (WE 98.7%, WI 97.9% and AICD 97.9%; $P = 0.692$) and total procedure times [minutes (\pm standard deviation, SD): WE 23 (9.7), WI 22 (11.7) and AICD 22 (11.0), $P = 0.177$] were comparable. A complete report has already been presented elsewhere^[2,3]. Comparisons of amount of water infused and aspirated during insertion and during withdrawal attested to the correct application of WE and WI methods^[2,3].

DISCUSSION

In this study aggregate data confirm superiority of WE in lowering insertion pain compared with WI and AICD. The pain alleviating impact of water exchange shows the lowest mean real-time maximum insertion pain scores in 90% of the investigators, despite their pain scores were significantly different within the WE, WI and AICD groups, and regardless their significantly different individual performances in terms of use of adjunct maneuvers and insertion time (Table 2). A plausible explanation of the effect of WE in decreasing real-time maximum insertion pain is the avoidance of the variable elongation of the colon induced by different amounts of insufflated gas, with the associated loop formation^[9] that leads to insertion pain^[10]. Full understanding, however, will require additional investigation.

Previous abdominal surgery is associated with higher colonoscopy pain score^[11-14] or with difficult procedures^[15]. The AICD group showed the lowest

proportion of patients with previous abdominal surgery and had comparable BMI values among individual investigators; nevertheless, AICD pain scores were almost invariably higher than the other two groups (Table 2). Compared with WE, WI had a lower proportion of patients with previous abdominal surgery; and yet also WI showed a trend toward higher pain scores than WE (Table 2).

With the exception of Investigator number 8, the consistent pattern of pain scores being lowest in the WE group qualifies WE as the best method for achieving low pain scores during the insertion phase of colonoscopy, with a reproducible effect among different colonoscopists. Several factors contributed to the aberrant finding of Investigator's number 8 higher real-time maximum insertion pain score in the WE group compared with the WI and AICD groups: His WE group had a significantly higher proportion of female patients with abdominal pain as indication (this cohort comprised IBS cases) and with previous abdominal surgery. All these are risk factors for difficult^[15] or painful colonoscopy^[1,11-14,16-22], with expected laborious intubation and increased need for sedation^[11,22,23].

Moreover, Investigator number 8 had experience in only 150 WE and 90 WI procedures. WE is a relatively new technique, and requires new maneuvers not entirely intuitive to colonoscopists. Collectively, all these factors contributed to the higher real-time maximum insertion pain score achieved in his WE group of patients.

Our data show that WE is effective in achieving significantly higher proportions of painless unsedated procedures, completion with only minor discomfort or without sedation. These two last outcomes are also achieved by WI.

Unsedated colonoscopy represents an important option for many patients^[24,25] and has important implications in terms of patient satisfaction, medical related complications^[26,27] and cost savings in health care systems, particularly in settings where the use of sedation is discretionary and targeted also to low-risk patients^[28,29].

The scheduled unsedated option may also have an impact on no-show due to lack of an escort, improving patients' adherence to colonoscopy, particularly important in screening settings^[30].

Promotion of on-demand sedation colonoscopy and successful completion of the unsedated option minimizes institutional resources and lessens patients' burdens^[6,31].

Multiple published reports have indicated colonoscopists around the world were able to harness the pain reduction impact of WE^[2,3,7,8,32-40].

The limitations of our study require comment. The endoscopists and the nurse assistants were not blinded to the WE and WI insertion techniques. However, interactions with patients were standardized, colonoscopists' bias was minimized and pain recording was very accurate^[2,3]. The unblinded real-time maximum insertion pain scores obtained during colonoscopy were internally validated by correlating them with the blinded recalled maximum insertion pain scores recorded at discharge: the Pearson correlation range was 0.6-0.9 ($P < 0.0005$)^[2,3]. The blinded pain recording after the procedure validated the unblinded one collected during the examination^[2,3]. Mean correct patients' guesses about insertion method used (36%) and investigators' about insufflated gas (41%) confirmed their adequate blinding^[2,3].

Our study has certain notable features. To the best of our knowledge, it has the largest sample of multiple individual investigators' real-time maximum insertion pain scores obtained in a head-to-head randomized controlled comparison of WE, WI and AICD. Patients were recruited from a routine clinical setting in different community hospitals at multinational sites. The important finding is the reproducibility and repeatability of WE in attenuation of maximum insertion pain when compared with WI and AICD.

In summary, in this head-to-head randomized controlled comparison of WE, WI and AICD with reliable real-time maximum insertion pain scores, minimization of investigators' bias and adequate patient blinding, despite variations in pain scores by individual investigators, WE is superior to WI and AICD in attenuating real-time maximum insertion pain.

We conclude that the high proportion of colonoscopists able to use WE to decrease insertion pain in the current study, as well as in previous published reports, suggest that the technique deserves consideration in a broader scale.

COMMENTS

Background

Water exchange (WE) and water immersion (WI) are two colonoscopy techniques that entail infusion of water to distend the lumen during the insertion phase. WE is characterized by airless introduction to the cecum, infused water is aspirated predominantly during this phase to clear the view and minimize distension. In WI water is infused as an adjunct to insufflation and aspirated predominantly during withdrawal, without attempting to maximize colon cleanliness during insertion. Randomized controlled trials (RCTs) have shown WE to have considerable advantage in decreasing colonoscopy real-time maximum insertion pain when compared with WI or with air or carbon

dioxide insufflation. WE shows its beneficial effect in decreasing colonoscopy pain also in patients presenting with factors associated with difficult and painful colonoscopy (e.g., prior abdominal surgery, low body mass index).

Research frontiers

The authors assessed the performance of individual investigators in three recently completed RCTs in a multinational setting, to determine whether the effect of WE in reducing real-time maximum insertion pain is reproducible across investigators, and what procedural factors (e.g., use of adjunct maneuvers of loop reduction and abdominal compression, insertion time, etc.) might contribute to variations among them.

Innovations and breakthroughs

The study has the largest sample of multiple individual investigators' real-time maximum insertion pain scores obtained in a head-to-head randomized controlled comparison of WE, WI and air or carbon dioxide (AICD). Patients were recruited from a routine clinical setting in different community hospitals at multinational sites. The data confirm superiority of WE in lowering insertion pain compared with WI and AICD. Its pain alleviating impact shows the lowest mean real-time maximum insertion pain scores in 90% of the investigators, despite their significantly different insertion pain scores within the WE, WI and AICD groups, along with significantly different individual performances in terms of use of adjunct maneuvers and insertion time.

Applications

WE achieves higher proportions of painless unsedated procedures, or completed with only minor discomfort, decreasing the need for sedation. Promotion of on-demand sedation colonoscopy and successful completion of the unsedated procedures lessens patient's burdens.

Terminology

WE: A colonoscopy insertion technique that entails airless insertion; water is infused to facilitate progression of the instrument to the cecum and is aspirated predominantly during this phase to clear the view and minimize distension. WI: A colonoscopy insertion technique that entails infusion of water as an adjunct to insufflation to help reaching the cecum; water is aspirated predominantly during withdrawal, without attempting to maximize colon cleanliness during insertion.

Peer-review

The article described the difference in colonoscopy real-time maximum insertion pain among WE, WI and AICD and among individual investigators in routine clinical settings. It is useful to analyze colonoscopy pain produced by different techniques in order to reduce the suffering of patients. It is a meaningful research in clinical practice. The study had a logical design in methods, the analysis of the difference of pain among WE, WI and AICD was detailed and produced credible results.

World Journal of *Gastrointestinal Endoscopy*

World J Gastrointest Endosc 2016 February 10; 8(3): 122-197

Editorial Board

2014-2017

The *World Journal of Gastrointestinal Endoscopy* Editorial Board consists of 330 members, representing a team of worldwide experts in gastrointestinal endoscopy. They are from 40 countries, including Australia (3), Austria (3), Brazil (6), Canada (3), China (62), Croatia (1), Czech Republic (1), Denmark (1), Ecuador (1), Egypt (3), France (1), Germany (8), Greece (10), Hungary (2), India (11), Indonesia (1), Iran (6), Iraq (1), Ireland (2), Israel (1), Italy (37), Japan (43), Lebanon (1), Lithuania (1), Malaysia (1), Mexico (4), Netherlands (1), Norway (2), Poland (4), Portugal (5), Romania (1), Singapore (3), Slovenia (2), South Korea (19), Spain (9), Thailand (2), Turkey (11), United Arab Emirates (1), United Kingdom (14), and United States (43).

Contents

Biweekly Volume 8 Number 3 February 10, 2016

TOPIC HIGHLIGHT

- 122 Use of water jet instruments in gastrointestinal endoscopy
Nakano T, Sato C, Sakurai T, Kamei T, Nakagawa A, Ohuchi N

REVIEW

- 128 Diagnostic and therapeutic biomarkers in pancreaticobiliary malignancy
Viterbo D, Gausman V, Gonda T
- 143 Biliary and pancreatic stenting: Devices and insertion techniques in therapeutic endoscopic retrograde cholangiopancreatography and endoscopic ultrasonography
Mangiavillano B, Pagano N, Baron TH, Arena M, Iabichino G, Consolo P, Opocher E, Luigiano C

MINIREVIEWS

- 157 Review of current and evolving clinical indications for endoscopic ultrasound
Luthra AK, Evans JA
- 165 Treatment of gastric outlet obstruction that results from unresectable gastric cancer: Current evidence
Miyazaki Y, Takiguchi S, Takahashi T, Kurokawa Y, Makino T, Yamasaki M, Nakajima K, Mori M, Doki Y
- 173 Second-look endoscopy and factors associated with delayed bleeding after endoscopic submucosal dissection
Kim SJ, Choi CW, Kang DH, Kim HW, Park SB

ORIGINAL ARTICLE

Retrospective Cohort Study

- 180 Safety of immediate endoscopic sphincterotomy in acute suppurative cholangitis caused by choledocholithiasis
Ito T, Sai JK, Okubo H, Saito H, Ishii S, Kanazawa R, Tomishima K, Watanabe S, Shiina S

Retrospective Study

- 186 Percutaneous endoscopic gastrostomy under steady pressure automatically controlled endoscopy: First clinical series
Imaeda H, Nakajima K, Hosoe N, Nakahara M, Zushi S, Kato M, Kashiwagi K, Matsumoto Y, Kimura K, Nakamura R, Wada N, Tsujii M, Yahagi N, Hibi T, Kanai T, Takehara T, Ogata H

CASE REPORT

- 192 Endoscopic ultrasound-guided ethanol ablation of pancreatic neuroendocrine tumours: A case study and literature review

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*,
Dimitrios Kapetanios, FEBG, PhD, Doctor, Gastroenterology Department, George
Papanikolaou Hospital, 55236 Thessaloniki, Greece

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

In recent years, water jet instruments have been used

in the field of gastrointestinal endoscopy, mainly in two clinical situations: Investigation and treatment under endoscopic view. Injecting water jet into the gastrointestinal lumen is helpful for maintaining a clear endoscopic view, washing away blood or mucous in the lumen or on the surface of the tip of the endoscope. This contributes to reducing time and discomfort of examination. Water jet technology is an alternative method for dissecting soft tissue; this method does not harm the small vessels or cause mechanical or thermal damage. However, its use in clinical settings has been limited to the transmucosal injection of water into the submucosal layer that elevates the mucosa to prepare for endoscopic mucosal resection or endoscopic submucosal dissection, instead of tissue dissection, which may occur because of the continuous water jet. A preclinical study has been conducted using a pulsed water jet system as an alternative method for submucosal dissection by reducing intraoperative water consumption and maintenance of dissection capability. This review introduces recent studies pertaining to using a water jet in gastrointestinal endoscopy and discusses future prospects.

Key words: Endoscopy; Water jet; Endoscopic submucosal dissection; Endoscopic mucosal resection; Pulse

Core tip: This review provides an overview of recent clinical and preclinical studies of water jet instruments in gastrointestinal endoscopy. Water jets have been used to keep the endoscopic view clear which contributed to reduce time and discomfort of endoscopic examination, and the technology provides an alternative method for endoscopic tumor resection. However, continuous flow is used in the transmucosal injection of water into the submucosal layer for elevating the mucosa to prepare for endoscopic mucosal resection. A preclinical study has used a pulsed water jet system as an alternative method to achieve dissection of submucosal layer.

INTRODUCTION

Incidences of colorectal cancer are increasing in the developed world; in comparison with other types of examinations such as the stool occult blood test, barium enema, and computed tomography colonography, colonoscopy enables enhanced diagnostic specificity and sensitivity^[1]. The incidence of gastric cancer remains high in Asian countries, including Japan. The demand for upper gastrointestinal endoscopy has been increasing annually, especially in Asian countries^[2]. It requires highly advanced techniques and a learning curve exists for digestive endoscopy^[1,2]. When the endoscope first appeared, it was a struggle to maintain a clear endoscopic view. The introduction of the forceps hole into the endoscope has been useful for injecting water vigorously into the gastrointestinal lumen to keep the endoscopic view clear. Endoscopes with incorporated water jet systems have been developed and released for clinical practice and are in widespread use. Water jets have also been recently used for endoscopic treatment, *i.e.*, in endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). This review provides an overview of recent clinical and preclinical studies of water jet instrument in gastrointestinal endoscopy.

WATER JETS FOR MAINTAINING ENDOSCOPIC VIEW

Water jet instruments were initially used to facilitate endoscopic observation. During gastrointestinal endoscopy, blood, food residue, and bubbles can impede the endoscopic view. Specifically in colonoscopy, colonic cleaning with polyethylene glycol method (PEG) helps with finding small lesions^[3]. However, PEG can result in a lot of bubbles forming, hindering observation as much as the feces^[4]. It is necessary to wash these out to discover the minute lesions or to treat under a clear endoscopic view. During gastroendoscopy, premedication with mucolytic agents, such as pronase, N-acetylcysteine, or dimethylpolysiloxane before upper gastrointestinal endoscopy improves the mucosal visibility of the stomach^[5,6]. It is still necessary to wash away the bubbles caused by saliva or mucus (Figure 1). Recently, upper gastrointestinal endoscopy using nasal endoscope has rapidly become popular, as it is less painful and causes minimum vomiting reflux^[7-10]. However, problems to be solved with this technique

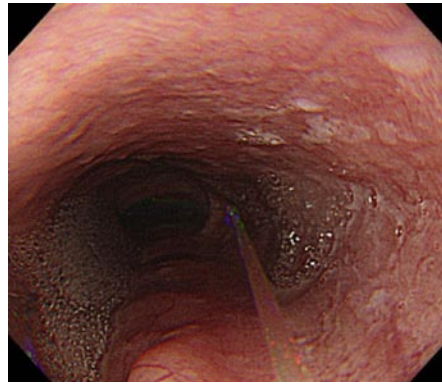

Figure 1 Endoscopic view of the esophagus shows that water jet flow washes away the bubbles caused by saliva or mucous in the esophagus.

include lower camera resolution, insufficient light intensity, and the longer duration of the procedure as compared with that of an oral endoscopy. Attempts to use fluids such as oolong tea to clean the lens surface have been reported^[11]. Manual water jet pumping prolongs inspection time^[12]; Takahashi *et al.*^[13] reported that the introduction of a water jet operated by a foot switch in the nasal gastrointestinal endoscopy reduced the average inspection time from 561 ± 123 s to 503 ± 98 s ($P = 0.0002$). Using a water jet to maintain a clear endoscopic view is useful for reducing time and the discomfort of examination. A water jet from an automatic lavage pump is useful to keep endoscopic view clear^[14]. This is currently supplied in products from several companies. Some models of upper gastrointestinal and colonic endoscope have separate water supply and forceps holes, which make it possible to inject water during endoscopic treatment such as hemostasis, EMR, or ESD (Figure 2). Hemostatic procedure is one of the important techniques during endoscopic treatment like EMR or ESD. So water jet systems are widely used to find the bleeding point and to make a view during hemostasis.

WATER JETS AS OPERATIVE INSTRUMENTS

Water jet technology was used in liver^[15] and cardiovascular^[16] surgeries, as well as in neurosurgery in the late 1980s^[17]. When used in liver surgery, this system reduces blood loss and parenchymal trauma better than both ultrasonic aspiration and blunt dissection^[18,19]. Using the water jet instrument as a surgical device provides energy using the kinetic energy of the water flowing from a nozzle at the tip of the delivery device. This energy is transmitted to the tissue surface where it ejects particles of tissue, making an incision through the organ or tissue. Mass reduction can also be achieved using water jets^[15,20]. Water jet has several features pertaining to dissection that are superior to conventional instruments, including selective tissue removal with vessel pre-

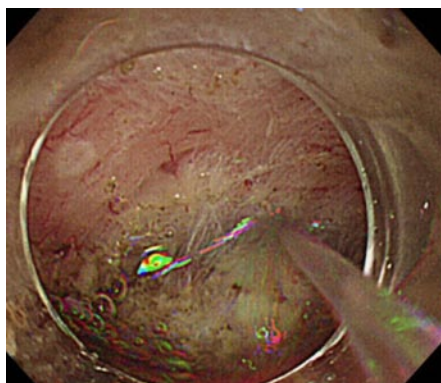

Figure 2 A water jet is useful to keep endoscopic view clear. Hemostatic procedure is one of the important techniques during endoscopic treatment like endoscopic mucosal resection or endoscopic submucosal dissection. So water jet systems are widely used to find the bleeding point and to make a view clean.

servation based on the different tensile strengths of the tissues. Water jet devices using a continuous water flow^[20] allow organ dissection while preserving vessels that are > 100-200 μm in diameter^[21,22]. Another notable advantage is that it helps avoid thermal damage to the surrounding parenchyma, which would otherwise be inevitable using an electric scalpel, electromagnetic, ultrasonic, and laser instruments^[23,24]. However, limitations have been reported to arise from the formation of air bubbles, which obscure the operative field, and the splashing of blood fluid, which could subject surgeons and nurses to cross infection^[16]. These limitations may be resolved when using the instrument in a luminal organ such as the gastrointestinal tract or in laparoscopic or thoracoscopic surgery. In addition, the development of a treatment instrument with lower water consumption would help address the limitations. Endoscopic treatment such as ESD in a narrow surgical field requires the application of highly advanced techniques by the operator. A lack of instruments that can aid this procedure preventing the risk of potential complications (thermal injury and vascular damage) is a drawback of the current ESD technique using an electric scalpel^[25]. Water jet technology, which is based on a conventional, pressure-driven continuous jet^[15,26] or a laser/electrically-induced pulsed pressure jet^[27-29], could provide an alternative method or novel procedure for the dissection of soft tissue without impairing small-diameter vessels or causing mechanical or thermal damage during endoscopic therapy.

WATER JET INSTRUMENTS FOR ENDOSCOPIC THERAPY FOR TUMOR RESECTION

Endoscopic resection has become the standard of care for the treatment of early stage gastrointestinal tumors. EMR is performed on relatively small lesions. ESD enables the resection of large lesions in a single piece, and has low local recurrence rates^[30,31]; how-

ever, operation time and the risk of complications are increased^[31,32]. Various knives such as the dual knife (Olympus Medical Systems Co., Tokyo, Japan), B-knife (Zeon Medical, Tokyo, Japan), IT-knife, or Hook knife (Olympus Medical Systems Co., Tokyo, Japan) are used in ESD^[33,34]; these are devised for safety and ease of use. As a preparation for safe EMR or ESD, it is useful either to inject fluids such as saline or hyaluronate or inject carbon dioxide into the submucosal layer to lift the lesion from the muscular layer^[35,36]. Various water jet dissectors have been developed, such as the Flush knife (Fujifilm Medical, Tokyo, Japan), Splash needle (Pentax Co., Tokyo, Japan), HybridKnife (ERBE, Tübingen, Germany), and the ENKI-2 water-jet system (NESTIS, Lyon, France)^[37-40]; these use continuous water flow to incise mucosa and inject fluid into the submucosal layer to lift the lesion. In contrast, the applying conventional pressure-driven continuous water jets endoscopically is limited to transmucosal injection of water into the submucosal layer for mucosal elevation prepare for EMR instead of tissue dissection^[40,41]. This may be because of the continuous water jet. An advantage of these water jet devices is that washing of the surgical field or additional submucosal injection can be performed by flushing water through the knife without changing the instrument; this results in marked improvements pertaining to the efficiency and safety of the procedure^[42]. Incision capability of these devices would be mostly due to the cooperation of water jet and electric cautery. Although Lesser *et al.*^[43] attempted to use a water jet dissector to cut polyp stalks clinically in the airway; the attempt to cut or dissect a submucosal layer under gastrointestinal endoscopy has been performed only in preclinical animal experiments. A continuous water jet flow of 30 kgf/cm² (Angiomat 3000, Liebel-Flarsheim, United States) was necessary to cut mucosa and mucosal muscle; however, injection fluid was spread in the submucosal layer in the swine stomach^[44]. Kaehler *et al.*^[41] reported that a continuous water jet dissector, the Helix Hydro-Jet (ERBE), is capable of penetrating the mucosa and creating highly selective fluid accumulation in the submucosal layer, using a water pressure of 50-70 bar and an application angle of 20°-90°^[41]. Lepilliez *et al.*^[45] reported a porcine gastric ESD where continuous jet dissection using a WJ medical system (Eschmann Equipment, West Sussex, England) *in vivo* was technically difficult due to the lack of visual control. Using continuous water jet also poses a potential risk of obscuring the narrow endoscopic operative view due to the large amounts of water. To date, there has been no report of continuous water flow being used to dissect the submucosal layer effectively. It has been reported that a pulsed water jet was feasible at 120 mL/min of water supply, but pulsed dissection was slower than IT knife dissection in the porcine stomach^[45]. That volume of water would interfere with the endoscope view in a narrow lumen such as the esophagus or large intestine. On the other hand, Sato *et al.*^[46] reported that laser-induced pulsed water jet dissection in the

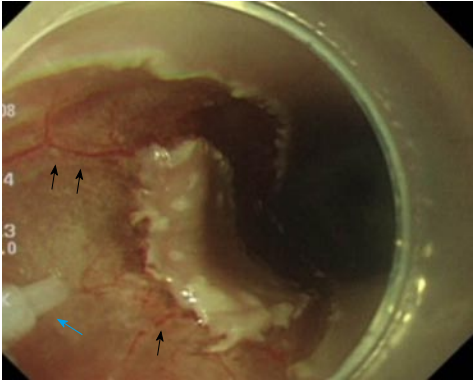

Figure 3 Preserved vessels using by pulsed water jet, which could be treated with pin-point ablation by hemostatic equipment would contribute to reliable hemostasis. Black arrows show small vessels preserved by the laser induced pulsed water jet. A blue arrow shows a nozzle of pulsed jet system.

porcine esophagus was performed safely and effectively, and the dissection rate was not different from hook knife dissection. Preservation of the vessels by water jet, which could be treated with pin-point ablation by hemostatic equipment would contribute to reliable hemostasis (Figure 3). They reported the feasibility of ESD of the esophagus with very small amounts of water (1.6 mL/min) and preserved micro-vessels. The optimal conditions for submucosal dissection are still unclear for both continuous and pulsed water jets, including the best size or shape of the nozzle, water pressure of the jet, pulse rate or volume of water supply. Since the required condition of the jet also depends on the physical properties of the tissue to be dissected^[47], the conditions may vary between the esophagus, stomach, and large intestine. Further study is needed to elucidate the optimal conditions for dissection by water jet.

CONCLUSION

In gastrointestinal endoscopy, using a water jet to maintain a clear endoscopic view is useful for reducing time and the discomfort of examination; furthermore, water jets contribute to endoscopic therapy such as ESD or EMR. Using the water jet as an operative instrument is a recent development. A continuous water jet is used to lift up the mucous layer to pretreat EMR or ESD. Hybrid products combining water jet and electric scalpel have also been developed, and their results reported. It may be difficult to dissect the submucosal layer directly using continuous flow due to its nature, but use of a pulsed water jet is feasible, with a lower volume of water consumption. Although the research reported is mostly based on animal studies limited, further research is expected in the future.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) and cholangio-

carcinoma (CCA) are two malignancies that carry significant morbidity and mortality. The poor prognoses of these cancers are strongly related to lack of effective screening modalities as well as few therapeutic options. In this review, we highlight novel biomarkers that have the potential to be used as diagnostic, prognostic and predictive markers. The focus of this review is biomarkers that can be evaluated on endoscopically-obtained biopsies or brush specimens in the pre-operative setting. We also provide an overview of novel serum based markers in the early diagnosis of both PDAC and CCA. In pancreatic cancer, the emphasis is placed on prognostic and theranostic markers, whereas in CCA the utility of molecular markers in diagnosis and prognosis are highlighted.

Core tip: The poor prognoses of pancreatic ductal adenocarcinoma (PDAC) and cholangiocarcinoma (CCA) are strongly related to lack of effective screening modalities as well as few therapeutic options. Several novel biomarkers have been studied that have shown promise for early diagnosis and targeted therapy of these malignancies. These biomarkers provide a strong background for future clinical studies to screen for PDAC and CCA in the general population as well as to investigate molecularly targeted therapies.

INTRODUCTION

The focus of this review will serve to summarize diagnostic, prognostic and predictive tumor markers in pancreatic cancer and cholangiocarcinoma (CCA). Despite major advances in the therapies of many solid tumors, survival in pancreatic cancer has not improved^[1]. Delayed diagnosis, aggressive biology and marked chemoresistance have all contributed to this disappointing trend. Improving the sensitivity of diagnostic modalities, such as imaging or endoscopic tests and molecular markers, as well as innovation in surgical strategies and novel chemotherapeutic regimens had opened the possibility for significantly changing the status-quo. Although gemcitabine remains the back bone of chemotherapy in this disease, novel regimens have been introduced and some have demonstrated significantly better survival^[2,3].

CCA arises from the neoplastic proliferation of cholangiocytes, the epithelial cells in the biliary tree^[4]. It is an aggressive malignancy, characterized by early lymph node involvement and distant metastasis, with 5-year survival rates of 5%-10%^[5]. The identification of new biomarkers with diagnostic, prognostic or theranostic value is especially important as resection (by surgery or combined with a liver transplant) has shown promising results and novel therapies are emerging^[6]. However, the relatively low incidence of CCA, high frequency of co-existing cholestasis or cholangitis, and difficulties with obtaining adequate samples have complicated the search for accurate biomarkers.

DIAGNOSTIC SERUM MARKERS

Pancreatic cancer

Non-invasive blood-based biomarkers with high diagnostic accuracy would be ideal for the early diagnosis of pancreatic cancer. Current tumor markers [cancer antigen 19-9 (CA 19-9), carcinoembryonic antigen (CEA), *etc.*] do not have adequate accuracy. The most commonly used marker, CA 19-9, has been reported to have sensitivity and specificity rates ranging from 60%-90% and 65%-92%. Both tumor size^[7], concurrent biliary or pancreatic obstruction and the presence of Lewis antigen has significant impact on CA 19-9 levels, making them even less useful as a diagnostic modality. Therefore novel molecular markers may fill an important void in non-invasive testing for early detection of pancreatic ductal adenocarcinoma (PDAC).

MicroRNAs (miRNAs) are highly stable 18-25 nucleotide single-stranded transcripts that function primarily as negative regulators of gene expression by inhibiting translation of their target messenger RNA. Emerging evidence suggests that initiation and progression of PDAC involves aberrant expression of miRNAs. Nearly 100 miRNAs are differentially expressed in pancreatic cancer. Many of these miRNAs are overexpressed and promote tumorigenesis by targeting tumor suppressor

genes^[8,9]. miRNAs have recently gained attention as potential diagnostic biomarkers and have been analyzed in human blood, bile, pancreatic juice, pancreatic cysts and stool. Relevant articles pertaining to miRNA and pancreatic cancer are summarized below.

Much of the research effort in this field was initially devoted to the characterization of miRNAs in pancreatic cancer. Bloomston *et al.*^[10] was one of the first to compare the global miRNA expression pattern of resected pancreatic cancer with healthy pancreatic tissue and chronic pancreatitis. He identified miRNAs miR-21, miR-155, miR-221 and miR-196a as key oncogenic miRNAs that correlated with aggressive tumors. In a similar fashion, miRNAs-221, -376a, -301, miR-93, -196a, -196b, -203, -205, -210, -221, -222 and -224 were found to be overexpressed in pancreatic cancer^[11,12]. A supportive study by Sadakari *et al.*^[13] showed the relative expression levels of microRNA-21 and microRNA-155 in pancreatic juice was significantly higher when compared to chronic pancreatitis. Elevated levels of miR-196a and miR-10b were subsequently discovered in pancreatic intraepithelial neoplasia (*PanIN*) lesions suggesting these molecular compounds may be important for early carcinogenesis^[14]. The prognostic significance of miRNA in pancreatic cancer was demonstrated by one study which associated elevated levels of miR-21 and miR-31 and low levels of miR-375 with poor clinical outcomes after surgical resection^[15].

Circulating miRNAs in whole blood have been investigated in patients with pancreatic cancer. Whole blood miRNA analysis is an attractive screening test because of its easy clinical application and minimal patient involvement. Table 1 summarizes the largest and most recent studies to analyze the utility of novel serum-based miRNAs in the diagnosis of PDAC.

Given the overall stability of miRNA and the large abundance of hepatobiliary juice in stool, analysis for miRNA biomarker expression in feces offers another noninvasive screening option to evaluate for pancreatic cancer. Fecal miRNA expression profiling by Link *et al.*^[16] showed that dysregulated miRNAs can be found in stool. They report miRNAs-196a, -216a, -143 and -155 are differentially expressed in patients with PDAC when compared to controls. The purpose of this study was to evaluate the feasibility of stool miRNAs as novel biomarker for PDAC screening^[17].

CCA

Acquisition of tumor tissue for histology or biomarker testing can be difficult and requires even more invasive and potentially risky procedures than diagnostic studies for PC. The most frequently used serologic markers of CCA are CA19-9 and possibly CEA. CEA has a sensitivity/specificity of 33%-84%/50%-87.8%^[18-20]. CA 19-9 not only has a wide variation of sensitivity/specificity: 38%-93%/67%-98%^[18-22], but can also be undetectable in 7% of the general population due to absence of the Lewis antigen^[23]. Although CA 19-9 may have a role in the diagnostic algorithm, especially in

All markers identified with ELISA, except for ¹Western blot. All cases of cholangiocarcinoma are histologically-proven. Control patients for CCA include those with benign liver diseases, HCC and healthy controls. Combo: Combination; PDAC: Pancreatic ductal adenocarcinoma; CCA: Cholangiocarcinoma; CYFRA 21-1: Cytokeratin 19 fragment; MMP-7: Matrix metalloproteinase-7; CEA: Carcinoembryonic antigen; CA 19-9: Cancer antigen 19-9; IL-6: Interleukin-6; SSP411: Sperm-specific protein 411; MUC5AC: Mucin 5AC; AFP: Alpha-fetoprotein; ELISA: Enzyme-linked immunosorbent assay; HCC: Hepatocellular carcinoma.

patients with primary sclerosing cholangitis (PSC) in the absence of concurrent cholangitis or pancreatitis, the low accuracy of the test limits its role in screening and early diagnosis. Thus, novel biomarkers with potential diagnostic utility have been studied (Table 1).

In malignant epithelial cells, activated proteases release cytokeratin-19 fragments (CYFRA 21-1) into the bloodstream^[24]. CYFRA 21-1 levels have previously been shown to be a sensitive biomarker in non-small-cell lung cancer^[25], gastric cancer^[26], breast cancer^[27], bladder cancer^[28] and cervical carcinoma^[29]. Several studies have shown elevated CYFRA 21-1 expression in CCA, but sensitivity varied depending on the cut-off value^[18,24,30]. High matrix metalloproteinase-7 (MMP-7) expression has been found to be associated with cancer invasion in esophageal^[31], colon^[32] and pancreatic^[33] cancers. The elevation of CYFRA 21-1 and MMP-7 in various malignancies can preclude their use as CCA-specific diagnostic biomarkers. Thus, combinations of serum markers can be used to improve sensitivity without compromising specificity. Using CYFRA 21-1 and MMP-7 in a multi-marker panel along with CEA and CA 19-9 demonstrated the highest diagnostic accuracy of 93.9%^[24].

Interleukin-6 (IL-6) has been shown to be a growth factor for bile duct epithelium^[34] and has demonstrated sensitivity as high as 100% in diagnosing CCA^[35]. However, IL-6 is also elevated in many patients with hepatocellular carcinoma, benign biliary disease, and metastatic lesions, limiting its specificity^[36]. This reinforces the need for more serum-based CCA-specific proteins that are not normally expressed in healthy

liver tissue nor elevated in other malignancies. Sperm-specific protein 411 (SSP411) is one such protein which is elevated in the bile of CCA patients and recently found to successfully distinguish CCA from choledocholithiasis as a single serum-based biomarker^[37].

miRNAs are usually stable in the circulation when bound to proteins. When miRNAs are dysregulated in cancers, they enter the circulation in free form and can be detected as potential diagnostic markers^[38]. The utility of miRNAs lies in their tissue-specific patterns of expression. miRNAs commonly upregulated in other epithelial cancers (miR-192, 194 and 215 in colon, liver, pancreas and stomach cancer^[39]) are not altered in CCA, while CCA-specific miRNA expression profiles exist (miR-125a, -31, and -95 are downregulated, while multiple miRNAs are upregulated as compared to nonmalignant cholangiocytes)^[40,41]. The role of miRNAs in tumor invasion in CCA is supported by similar miRNA profiles between tumor tissue and adjacent non-tumor tissue as compared to normal tissue^[42,43]. The most commonly overexpressed miRNA in CCA is miR-21^[44-46]. However, it is also up-regulated in a variety of other cancers (gastric^[47], breast^[48] and colon^[49]), suggesting that the most effective use of miRNAs is likely as multi-marker panels specific for CCA. MicroRNA biomarker discovery has extended from serum and plasma samples to the utilization of bile vesicles, which have demonstrated high accuracy in PSC patients^[50].

The presence of circulating tumor cells (CTCs) in other solid cancers (including breast^[51], prostate^[52], colon^[53] and pancreatic^[54]) is associated with more aggressive disease and increased metastasis. Similarly,

CTCs in CCA were found to be prognostic of poor overall survival^[55,56]. Using a cut-off of 2 CTCs/7.5 mL of peripheral blood, the sensitivity of CTCs for CCA diagnosis is only 17%-23%^[55,56]. Despite their poor diagnostic utility, CTCs are potentially useful in detection and monitoring treatment of metastatic spread in real time.

DIAGNOSTIC BRUSH OR BIOPSY-BASED MARKERS

Pancreatic cancer

The diagnostic approach to pancreatic masses is dominated by endoscopic ultrasound-fine needle aspiration (EUS-FNA) and histologic or cytologic analysis. EUS-FNA is highly sensitive and specific for solid pancreatic lesions, with sensitivities as high as 85%-95% and specificities of 90%-95%^[57].

The two areas where reliance on cytology is not supported by sufficient diagnostic accuracy are cystic neoplasms and inflammatory masses that may mask an underlying neoplasm. EUS-FNA is critical for the evaluation of pancreatic cystic lesions. It is beyond the scope and focus of this review to provide a summary of the data available on the accuracy of cyst fluid based cancer markers and molecular markers. Overall, these markers generally perform well in distinguishing mucinous type lesions from non-mucinous lesions but have thus far shown limited accuracy in identifying high-risk lesions (high grade dysplasia or carcinoma) from lower risk lesions^[58-60]. Molecular analysis for DNA disruptions, *Kras* mutation and miRNAs has enhanced the diagnostic capability of EUS-FNA analysis of pancreatic cysts^[61-64]. Similarly, molecular markers are promising in the relatively infrequent setting when a pancreatic mass is noted concurrent with inflammation (either with autoimmune pancreatitis or in the setting of chronic pancreatitis). For example, the presence of *Kras* mutations in FNA specimens has been shown to be a highly sensitive marker^[65].

CCA

Despite advances in sampling techniques and visualization of the bile duct, obtaining representative tissue from the bile duct remains difficult. A single biliary stricture that occurs without associated suspicion of PSC has a different risk of being malignant than biliary strictures, even dominant strictures, identified in a patient with known PSC. Therefore, we consider the diagnostic tests used in these conditions separately.

PSC associated strictures: PSC is a chronic liver disease characterized by cholestasis, inflammation, multifocal biliary strictures and a 7%-12% lifetime risk of CCA^[66,67]. A minority of CCA patients are surgical candidates and resection carries a 5-year survival rate of only 18%-32.5%^[68-71]. The specialized protocol for PSC-associated CCA developed at the Mayo Clinic

(neoadjuvant radio- and chemo-therapy with liver transplantation), has the highest 5-year survival rate of 79%^[72]. Inclusion requires early-stage disease, thus excluding the majority of patients diagnosed by standard methods. Because the clinical presentation of CCA can mimic benign dominant biliary strictures, the major challenge lies in identifying potential biomarkers that detect early dysplasia and CCA (Table 2).

Conventional cytology has a low sensitivity due to inadequate cellular yield, but a near 100% specificity. Fluorescent *in situ* hybridization (FISH) trisomy/tetrasomy-positive results have a limited role in the detection of CCA in PSC because they were found to have a similar outcome to FISH negative patients^[73]. However, polysomy has been shown to increase the sensitivity of routine cytology. There may be some reduction in specificity with FISH as PSC patients may have benign strictures that manifest with chromosomal abnormalities. The importance of sampling the biliary tree at multiple locations, regardless of the location of the dominant stricture, was demonstrated in a recent study that found that multifocal polysomy carried a greater risk of CCA diagnosis than polysomy detected at a single location^[74]. Therefore, FISH should be part of the evaluation of PSC patients presenting with dominant strictures. In one retrospective study of PSC patients with polysomy on initial FISH testing but no signs of CCA, polysomy detected on repeat FISH was associated with increased incidence of CCA compared to patients with non-serial polysomy (polysomy present only on initial FISH)^[75]. Repeat sampling without ongoing symptoms or signs remains an area of uncertainty but may be the most effective way to survey patients.

Kirsten rat sarcoma viral oncogene homolog (*Kras*) is a GTPase downstream of the epidermal growth factor receptor (EGFR) receptor that activates proteins involved in cell growth and proliferation. The high specificity of *Kras* analysis in biliary strictures can be useful, but the low sensitivity precludes it from diagnostic use as a sole biomarker. When used in combination with cytology, sensitivity increased to 100%^[76].

Indeterminate biliary strictures: In certain series, up to a quarter of patients who undergo surgical resection for suspected CCA-related strictures turn out have benign etiology^[77]. The utility of a highly sensitive modality beyond cytology or histology may therefore reduce the number of unnecessary surgeries. Thus far, assessment of polysomy by FISH has shown the greatest accuracy in brush cytology specimens. Some studies have found that the inclusion of the 9p21/p16 deletion in FISH analysis of indeterminate strictures increased the sensitivity of FISH-polysomy for pancreaticobiliary tract cancers from 58% to 89% and from 70% to 76%^[73,78,79].

PROGNOSTIC MARKERS

General prognostic markers, not specific to a defined

Table 2 Tissue-based diagnostic biomarkers for cholangiocarcinoma

Some studies included all biliary tract cancers (cholangiocarcinoma, gallbladder, pancreatic and ampullary), but sensitivity and specificity values were similar, so data is merged. Endobiliary sampling technique for cytology and FISH: ERCP or PTC brushing; Biopsy technique: Standard forceps, mini-forceps or transpapillary biopsy. FISH: Fluorescent *in situ* hybridization; PTC: Percutaneous transhepatic cholangiography; CCA: Cholangiocarcinoma; PSC: Primary sclerosing cholangitis; p53: Tumor protein p53; KRAS: Kirsten rat sarcoma viral oncogene homolog; CEA: Carcinoembryonic antigen; CA 19-9: Cancer antigen 19-9; FNA: Fine-needle aspiration.

therapeutic regimen, can be useful in distinguishing which patients are at higher risk of a poor outcome and should therefore be managed more aggressively. Table 3 summarizes the dysregulation of certain markers in PDAC and CCA and their effect on overall survival and/or rate of metastasis.

Pancreatic cancer

Secreted protein acidic and rich in cysteine: Secreted protein acidic and rich in cysteine (SPARC) is a matricellular glycoprotein with important implications in pancreatic cancer. SPARC undergoes epigenetic silencing in pancreatic adenocarcinoma, but is often strongly expressed at the interface between the tumor and stroma by stromal fibroblasts^[80]. Supporting data suggest this interaction is important for tumor progression, metastasis and protects against chemotherapeutic agents. Stromal SPARC expression is observed in all disease stages suggesting early expression is critical for tumor progression^[81].

Numerous studies have identified stromal SPARC as a negative prognostic marker in pancreatic cancer^[81]. Strong stromal SPARC expression in patients with well to moderately differentiated cancer who underwent surgical resection was associated with decreased overall survival when compared to patients with no SPARC expression^[81,82]. Furthermore, patients with diffuse stromal SPARC expression extending beyond the peritumoral region had a significantly worse prognosis^[83]. Interestingly, many report cytoplasmic SPARC expression

by malignant pancreatic cells to have no prognostication value^[81]. Others have revealed both stromal and cytoplasmic SPARC expression is associated with decreased overall survival in patients who were treated with gemcitabine^[84]. Similarly, elevated SPARC mRNA expression in pancreatic cancer is also associated with worse patient outcome^[85].

Human equilibrative nucleoside transporter 1:

Human equilibrative nucleoside transporter 1 (hENT1) plays a major role in the internalization of (transportation of) gemcitabine by cancer cells. Among patients who did not receive gemcitabine in one study, hENT1 levels did not have any prognostic or predictive value^[86]. Conversely, another study showed high hENT1 expression was a poor prognostic factor for early disease recurrence in the absence of gemcitabine therapy^[87].

miRNAs: A large supportive study analyzing miRNA levels in PDAC revealed high expression of miR-21 and miR-31 with low expression of miR-375 were associated with poor overall survival following surgical resection^[15].

CCA

miRNAs: Recent studies have been successful in establishing miRNA signatures that can discriminate between CCA and normal tissue as well as provide prognostic clues^[41,88]. As various miRNA expression patterns correlate with overall survival and rate of metastasis, the identification of accurate and predictive

Table 3 Prognostic markers in pancreatic ductal adenocarcinoma and cholangiocarcinoma

	Marker	Country	Total patients, <i>n</i>	Marker positive PDAC	Type of dysregulation	Prognostic value, OS months	HR or <i>P</i> value for OS

	EGFR ^[93,94]	Japan	373	338	Up-regulated	Shorter survival	5.655 (2.72-11.74) ^[93] 2.67 (1.52-4.69) ^[94]

¹Liver fluke-associated CCA. PDAC: Pancreatic ductal adenocarcinoma; CCA: Cholangiocarcinoma; mets: Metastases; OS: Overall survival; SPARC: Secreted protein acidic and rich in cysteine; CYFRA 21-1: Cytokeratin 19 fragment; EGFR: Epidermal growth factor receptor; LN: Lymph node.

multi-marker panels can identify patients in need of more aggressive management earlier (Table 3). However, the majority of these studies analyzed histologic samples from tumor resections, and therefore their utility from samples obtained at time of ERCP has not yet been demonstrated^[44,88-92].

EGFR and CYFRA 21-1: Over-expression of EGFR^[93,94] and CYFRA 21-1 values above 2.7-3 ng/mL^[18,30] were each prognostic of decreased overall survival.

THERANOSTIC MARKERS

The goal of theranostic markers is to predict response to a specific therapy. In many other cancers, the role of targeted therapy has changed the approach to treatment. Various genetic mutations have been identified in PDAC and CCA (Table 4) that can be used to guide a personalized approach to therapy.

Pancreatic cancer

SPARC: One the most interesting clinical features of SPARC is its potential role as a predictive marker for

response to therapy with nab-paclitaxel. Von hoff *et al*^[2] identified stromal SPARC to be an important therapeutic marker in patients treated with combination nab-paclitaxel and gemcitabine chemotherapy. Specifically, patients with high SPARC expression treated with combination therapy had increased overall survival when compared to combination therapy in patients with low SPARC or absence of SPARC. This finding is thought to be due to nab-paclitaxel targeting stromal SPARC and is thought to facilitate delivery of gemcitabine by depleting tumor stroma. Contradictory results by Sinn *et al*^[84] revealed high stromal SPARC expression in patients with pancreatic cancer treated solely with gemcitabine resulted in decreased overall survival. Such studies suggest the theranostic impact of SPARC is restricted to patients who receive therapy with nab-paclitaxel.

hENT1: A great deal of enthusiasm surrounds hENT1 because of its potential to remodel chemotherapy regimens in pancreatic cancer. There is overwhelming data to support its use as a first line test in pancreatic cancer. hENT1 plays a major role in the internalization

Table 4 Theranostic markers in pancreatic ductal adenocarcinoma and cholangiocarcinoma

	Marker (drug)	Countries	Patients with + marker	Staining	Median survival (mo)	HR

¹Not reported; ²Results graphed. OS: Overall survival; PDAC: Pancreatic ductal adenocarcinoma; CCA: Cholangiocarcinoma; Kras: Kirsten rat sarcoma viral oncogene homolog; MEK: Mitogen-activated protein kinase/ERK kinase; EGFR: Epidermal growth factor receptor; ErbB2: Erythroblastosis oncogene B 2; VEGF: Vascular endothelial growth factor; CDO1: Cysteine dioxygenase type 1; DCLK1: Doublecortin-like kinase 1; ZSCAN18: Zinc finger and SCAN domain containing 18; SFRP1: Secreted frizzled-related protein 1; CNRIP1: Cannabinoid receptor interacting protein 1; SEPT9: Septin 9; VIM: Vimentin; IDH1/2: Isocitrate dehydrogenase 1/2; α -KG: Alpha-ketoglutarate.

of gemcitabine by pancreatic cancer cells^[95] and is an important prognostic and predictive biomarker for gemcitabine efficacy in patients with pancreatic cancer. Its value as a biomarker is supported by an abundance of clinical studies. Acceptance of its clinical use is limited by a lack of large prospective validation studies. Supportive data is reviewed in this review.

Clinical studies have demonstrated response to gemcitabine parallels hENT1 expression. Namely, patients with tumors that test positive for hENT1 have longer median survival with gemcitabine therapy than those for whom hENT1 was absent. Spratlin *et al.*^[96] revealed strong hENT1 expression in patients with pancreatic adenocarcinoma was associated with a 3 fold increase

in overall survival after treatment with gemcitabine. Subsequently, a range of studies have reinforced the positive relationship observed with hENT1 expression and gemcitabine efficacy. Interestingly, this positive finding was not observed with other chemotherapy agents^[97]. Additionally, several groups have reported a synergistic survival effect with hENT1 and other tumor markers including hCNT3 and deoxycytidine kinase (dCK) in subjects treated with adjuvant gemcitabine after curative resection^[98].

Interestingly, Poplin *et al.*^[99] discovered that hENT1 expression did not predict gemcitabine sensitivity in patients with metastatic pancreatic cancer. This may be due to increased tumor heterogeneity in select patients. Acquired resistance to gemcitabine is bound to happen and may be due to altered gene expression involving important transport proteins including dCK, ribonucleotide reductase M1 (RRM1), RRM2, and hENT1^[100]. Additionally, favorable single nucleotide polymorphisms (SNPs) of enzymes involved in the transportation or metabolism of gemcitabine have been identified and may be absent with an unfavorable phenotype^[101,102].

Implementing pretreatment analysis for hENT1 expression is feasible, requiring a small tissue sample which can easily be obtained by EUS-FNA. Quantitative mRNA analysis of HENT1 or protein analysis with immunohistochemistry are both useful approaches that are presently limited by a lack of large validation trials.

CCA

Small-molecule inhibitors have demonstrated a good response rate in lung carcinoma harboring a mutation in the tyrosine kinase domain of the *EGFR* gene^[103]. *EGFR* mutations can be unique to CCA^[104] or identical to those in non-small cell lung cancer^[105], highlighting the significance of genotyping in guiding therapy. A phase II study of single agent erlotinib in patients with advanced biliary cancer demonstrated disease stabilization in 17%^[106]. Upregulation of vascular endothelial growth factor (VEGF) is associated with an *EGFR* inhibitor-resistant phenotype^[107]. Vandetanib, a dual inhibitor of VEGF and *EGFR*, has shown prolonged time to metastasis in CCA tumors that harbor both mutations^[108].

Genes that function downstream of *EGFR* can also be important therapeutic targets. *Kras* is one of the most frequently mutated genes in CCA. *BRAF* mutations are most commonly associated with malignant melanoma, but have also been identified in up to 22% of CCAs^[109,110]. Several studies suggest the potential application for targeted therapy with vemurafenib in this population, while avoiding *EGFR*-inhibitors^[109,111]. There are no studies evaluating the response of *BRAF*-mutated CCA to vemurafenib therapy. However, there is an on-going phase II "basket" study of vemurafenib in non-melanoma solid tumors harboring *BRAF* mutations that demonstrated stable disease at 8 wk in 4/7 CCA patients, partial response in 2/7 at 24 wk and the

remaining 1/7 with disease progression (clinical trial# NCT01524978).

The small minority (4%-5%) of CCA cases that overexpress erythroblastosis oncogene B2 (ErbB2 or HER2)^[94,112] may benefit from targeted anti-HER2 therapy. One case study demonstrated a dramatic regression of metastatic CCA in a HER2-positive patient who was started on trastuzumab after failing third-line chemotherapy^[113].

A gain-of-function mutation in isocitrate dehydrogenase 1 (IDH1), leading to inhibition of α -ketoglutarate, has been seen in 23% of intrahepatic CCA cases^[114], and a minority (0%-7%) of extrahepatic CCA tumors^[114-116]. In-vivo studies have suggested that drugs mimicking α -ketoglutarate alone or in combination with inhibitors of mutant IDH1 can reverse the increased histone methylation^[116]. Additionally, IDH enzymes are stable therapeutic targets because the mutation appears early in oncogenesis and is maintained throughout progression to high-grade lesions^[115].

The increased expression of some miRNAs predicts a favorable response to gemcitabine treatment^[40,117]. The potential of miRNAs lies not only in their theranostic utility, but also as therapeutic agents. Treatment of cholangiocytes with miR-494, which is down-regulated in CCA, induced cell-cycle arrest in tumor cells while sparing normal cells^[92]. MicroRNA replacement therapy has seen success in phase I clinical trials for ovarian^[118] and hepatocellular carcinoma^[119] and appears promising as a therapeutic modality in CCA.

Another benefit of these genes and miRNAs as markers is that they can be identified by mutational analysis on DNA or RNA and are commercially available.

CONCLUSION

Our review focused on PDAC- and CCA-specific biomarkers that may help in the early diagnosis of cancer or guide therapeutic decisions in the case of inoperable malignancy. The general population will benefit from a non-invasive serologic screening test with a high sensitivity, with multi-marker panels appearing advantageous. Despite the more invasive nature of tissue markers, high-risk patients would benefit from their high specificity. Additionally, the utility of predictive biomarkers will soon pave the way for individualized biliary and pancreatic cancer therapeutics.

Abstract

Stents are tubular devices made of plastic or metal. Endoscopic stenting is the most common treatment for obstruction of the common bile duct or of the main pancreatic duct, but also employed for the treatment of bilio-pancreatic leakages, for preventing post- endoscopic retrograde cholangiopancreatography pancreatitis and to drain the gallbladder and pancreatic fluid collections. Recent progresses in techniques of stent insertion and metal stent design are represented by new, fully-covered lumen apposing metal stents. These stents are specifically designed for transmural drainage, with a saddle-shape design and bilateral flanges, to provide lumen-to-lumen anchoring, reducing the risk of migration and leakage. This review is an update of the technique of stent insertion and metal stent deployment, of the most recent data available on stent types and characteristics and the new applications for biliopancreatic stents.

Key words: Biliary stent; Pancreatic stent; Endoscopic retrograde cholangiopancreatography; Self-expandable

metal stent; Endoscopic ultrasonography

Core tip: Biliary and pancreatic stents have become one of the major advances made in therapeutic endoscopy and the endoscopic placement of these devices has a universally recognized role in the management of numerous pancreatobiliary diseases. This review is an update of the technical considerations and available devices for biliary and pancreatic stenting.

INTRODUCTION

In 1980 the first case of biliary stent placement for drainage of malignant obstructive jaundice was published^[1]. A single-pigtail stent was fashioned using the cut end of an angiography catheter. The procedure was technically successful, but ultimately, the stent migrated upstream.

Cotton^[2] reported the use of a stent made with a double-pigtail design to prevent upward migration and Huibregtse *et al.*^[3] described the creation of side flaps in the wall of a straight stent instead of pigtails to prevent migration.

Today a variety of plastic stents (PSs) with different designs, diameters, lengths and plastic materials have been investigated and available in the market. At the end of the 80s, some authors described the insertion of a self-expandable metal stent (SEMS) across biliary stenosis^[4,5]. Early SEMS had relatively poor stent patency because of over and ingrowth of tissue. Because of their non-removability partially covered (PC) and then fully covered (FC) SEMSs were developed. Such stents are covered by a biocompatible polymer resistant to organic degradation. Despite various original articles and reviews about the types and techniques of stenting for different bilio-pancreatic disorders^[6-9], the majority are focused only on one or more than one pathology or focused to pancreatic or biliary disease. The aim of our review is to emphasize the update of the technique of stent insertion and metal stent deployment, considering the most recent data available on stent types and characteristics and the new applications for bilio-pancreatic stents, both for endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasonography (EUS), considering also the gallbladder drainage and pancreatic fluid collections (PFC).

TECHNIQUES OF BILIARY AND GALLBLADDER STENTING AND TYPES OF STENTS

Plastic biliary stents

Ideally PSs should be technically easy to insert, should effectively relieve biliary obstruction, should not occlude, and should not cause injury to the bile duct or duodenal wall. Several different materials, sizes, and shapes have been used to optimize these aspects (Table 1 and Figure 1).

Plastic biliary stents are composed of polyethylene, polyurethane, polytetrafluoroethylene (Teflon) and other plastic polymers. The diameters of PSs are measured in French (Fr), corresponding to 0.33 mm, and diameters range from 5 Fr to 12 Fr.

PS with a diameter of 10 Fr require a 3.7 mm operative endoscope channel, and, when the diameter is larger (≥ 11.5 Fr) a 4.2 mm operative channel is needed.

PSs have lengths ranging from 1 to 18 cm, and custom-made models may be requested from some manufacturers. A given stent length represents the entire length of the stent, although for some it is the distance between the end flaps. The length of a PS is generally selected to allow the shortest length possible while simultaneously ensuring adequate drainage. The length of plastic stents chosen is that which allows the ends to extend one to two cm over the proximal edge of the biliary lesion and 1 cm inside the duodenum.

Different types of PSs are commercially available. Plastic pig-tail stents are coiled at their proximal and distal extremities, or only at the distal (double pig-tail or single pig-tail, respectively). Side hole are generally placed at the coiled end. PSs may be straight or curved, with a flap on the proximal and the distal end and a side hole or with 4 flaps at both ends, without side holes (Tannenbaum stent). The role of side holes is to maintain biliary or pancreatic flow if the ends of the stent became occluded by bile or food impaction.

However, it has been hypothesized that side-holes can contribute to the formation of sludge. Moreover, the Tannenbaum stent (with multiple flap at its extremities but without side-holes) was designed to prevent migration. The aim of the development in biliary stenting in the recent years has been to increase the patency of the stents, improving the materials used for coating, a double-layer design, and a star-shaped stent winged stent without a central lumen. Finally, PSs are visualized radiographically, and some stents contain radiopaque markers at the proximal and/or distal ends. Introducing kits can be included in the stent package or available individually.

Biliary SEMS

The first widely used SEMS were made of stainless steel, whereas today most SEMS are made of nitinol. SEMS are available as uncovered, partially (PC-SEMS) or fully covered (FC-SEMS) (Figure 2, Tables 2 and 3). Different

materials contribute to the cover of the PFC-SEMS and of the FC-SEMS such as polytetrafluoroethylene, silicone and polyurethane, present on the exterior or interior of the SEMS.

Mechanical properties of SEMS are related to the stent design, type of wire, and covering materials. As

a result of combinations of these variables, radial force and axial force were proposed as major mechanical properties that affect clinical outcomes. Radial force is well known as an expanding force, while axial force is a straightening or recovery force when SEMS are bent.

Radial force affects stent patency in that dilation of

a biliary stricture and maintenance of luminal patency depend on the expanding force of the SEMS. Two factors in radial force exist in terms of time course. Immediate stent expansion at the time of stent deployment affects short-term outcomes, and chronic resistant force against tissue compression affects long-term outcomes. In general, the chronic resistant radial force is higher than the immediate stent expanding force because SEMS are made of a type of shape-memory alloy. This characteristic

means that SEMS partially expand immediately after deployment and then gradually expand to their full extent, even though the radial force may be high. Axial force is considered to define conformability of SEMS in the bile duct and may have a greater relationship with clinical outcomes than radial force. After deployment in the bile duct, SEMS are fixed at the stricture by the tissue and axial force causes compression to the bile duct at both stent ends. As axial force increases, so does the

compression of the bile duct or cystic duct or pancreatic duct orifice. Clinically, this situation may cause kinking of the bile duct with resultant cholecystitis or pancreatitis. In addition, less conformability of SEMS in the bile duct leads to stent migration. In general, axial force affects clinical outcomes such as stent migration and pancreatitis more than radial force.

SEMS have lengths ranging from 4 to 12 cm and diameters from 6 to 10 mm. The stents are mounted on a delivery system accepting a wire of 0.035 diameter, and the newest models can be also used with a single operator system. The diameters of the delivery systems range between 5.0 and 10.5 Fr. The smaller the catheter the easier it is to cross the stenosis without mechanical or pneumatic dilation. The same can be said for patients with Klatskin neoplasia.

The majority of the delivery kits are resistant, avoiding kinking during insertion, allowing correct placement; the outer sheath of the kit is transparent for the visualization of the distal stent extremity during SEMS release. During stent placement, the outer sheath is gently pulled inside the operative endoscope channel to allow the release and expansion of the SEMS. Rarely, the stent is constrained by a thread that, when removed, allows SEMS expansion.

Generally, SEMS can be recaptured, until 80% of their opening and all metal stents are visible fluoroscopically. The majority of SEMS have a marker at both extremities and, in some models, one at the middle. Some models of FC-SEMS have anti-migration flaps or flared ends to avoid distal or proximal migration (Figure 3).

Recently, a new type of FC-SEMS is produced with the intent to diminish proximal and distal migration (Figure 4). The Hanaro, M.I. Tech, Seoul, South Korea has an "anchoring-flap" system made of four flaps in the proximal end, flared ends and one proximal and one distal lasso for retrieval. TaeWoong produces the Bumpy®-Niti-S stent, with a membrane of silicone (distal extremity) and polytetrafluoroethylene (body of the stent). This stent has both flared ends and a string for the removal, at the distal extremity. The characteristic of this FC-SEMS are the irregular meshes; it contributes to a different radial force in every point of the stent, conferring conformability and adaptability in the lumen of the duct, preventing migration.

Technique of transpapillary biliary stenting

Before stent placement a cholangiogram is performed to confirm successful biliary cannulation and to evaluate the

location and length of the stricture or leak^[10-12].

The correct choice of PS length is often based on operator's experience. Alternatively after bile duct contrast medium injection, or using a centimeter guidewire. An alternative way to measure the length of the strictures for the choice of the stent is to gently withdrawing the catheter from the proximal to the distal end of the strictures, measuring with a ruler the centimeters of the device out of the operating channel.

Endoscopic sphincterotomy (ES) is not necessary for inserting a single PS, while is indispensable for multiple plastic stenting. If the stricture is tight, dilation with a balloon or a bougie before stenting may be useful. Balloon dilatation of strictures is usually helpful for placement of hilar PSs, particularly when bilateral stenting is attempted. Moreover, in these strictures, there is still a role for stents of smaller diameter and the tapered pigtail stent design. For example, if bilateral stenting is required in patients with hilar obstruction, it is often easier to place two 7 Fr stents initially to gradually dilate the bile duct and then replace them later with 10 Fr stents. Tapered pigtail stents are sometimes helpful to allow passage across very tight strictures.

The PS stent is loaded on a guide-catheter, over the guidewire, with the pusher-catheter. The guide-catheter and guidewire need to be made wet using a saline solution because they are hydrophilic. The entire stent insertion loaded kit is introduced inside the operative channel. When the PS is placed across the stricture, moving the endoscope in anti-clockwise rotation and with alternately moving the elevator up and down, the guide-catheter is pulled back, pushing the stent inside the CBD with the pusher-tube. When the guide-catheter is completely pulled back, the pusher-catheter can be removed from the channel.

During stent placement, maintaining the endoscope close to the Vater's papilla facilitates tent insertion because it avoids looping of the delivery system in the duodenal lumen.

If the guide-catheter is inadvertently withdrawn from the inside of the PS, it may be possible to readvance it, continuing the stent placement. When stent insertion is

challenging, the "long position" of the endoscope might be useful. This position allows to the operator to then use the straightening maneuver and, maintaining the elevator in up position, insert the stent into the duct. If the PS is damaged during insertion in the bile duct it can be removed over-the-wire, by passing a dilation balloon inside the PS or by using the Soehendra retriever, leaving the wire in place, and replacing the a new PS delivery system.

A final radiographic image should be obtained to verify if contrast medium drains through the stent. For implantation of a SEMS an ES is often performed, though is not mandatory. Then, under fluoroscopic examination (for biliary strictures), the length, presence or absence of a gallbladder and the relationship of the cystic duct with the CBD is determined for the correct choice of the type of the SEMS (length, diameter and covered vs uncovered).

Because of a potential risk of cholecystitis, some endoscopists prefer to use uncovered SEMS in the presence of a gallbladder, to avoid the cystic duct occlusion, or to place a FCSEMS, when indicated and a small diameter plastic stent inside the cystic duct. Before their insertion into the duct, the uncovered SEMS and the FC-SEMS are generally wet with saline solution in the guidewire channel and inside the outer sheath.

The release of the SEMS is performed under X-ray control, withdrawing the outer sheath of the device, pulling down the elevator, maintaining the stent in the correct position during the release, pulling back the device as it tends to move away from the operator and proximally into the duct. Most of the stent can be recaptured until 80% of the complete release. At the end of the procedure, after metal stent release a cholangiography is required to confirm the correct position of the SEMS and flow of contrast medium flow into the duodenal lumen. If the SEMS is released too proximally, it can be withdrawn distally grasping the distal extremity, or the distal thread, with a rat-tooth forceps. If these attempts fail, a second stent can be deployed, with the distal extremity inside the proximal one of the previous stent. Contrariwise, if the SEMS is released too distally into the duodenum, it can be

Figure 5 The BPE stent (A), Hanaro MI Tech, and the Giobor Niti-S stent (B), Taewoong Medical.

completely removed by a rat-tooth forceps or the excess stent cut using argon plasma coagulation.

Different techniques are utilized for the drainage of the hepatic hilum. Preoperative magnetic resonance cholangiopancreatography or high-resolution CT should be performed in all patients with suspected proximal biliary stenosis to delineate the anatomy before the procedure. SEMS insertion can be performed using the "side-by-side" (SBS) or the "stent-in-stent" (SIS -"Y") technique.

When SBS technique is performed, two or more guidewires are placed inside different biliary ducts to be drained. After the release of the first metal stent, the insertion of the delivery system of the second SEMS can be difficult because of the impaction of the distal ends of the first SEMS with the delivery of the second one. A way to overcome this difficulty is the insertion of a temporary plastic stent to maintain an accessory space between the first SEMS and the duct wall. In SBS technique the first lobe to drain is the left because the SEMS insertion in the right lobe is easier.

With the SIS technique, the second stent is deployed inside the meshes of the first stent. Balloon dilation of the first SEMS meshes might be helpful to facilitate positioning of the second SEMS device. Some SEMS are designed with large diameter meshes of the middle part to facilitate the deployment of the second one (Y-shaped stent).

Endoscopic ultrasound-guided biliary drainage

In recent years, EUS has evolved from a diagnostic to a therapeutic procedure, and is now increasingly used to guide biliary drainage (BD) after failed ERCP. For therapeutic EUS, the use of a linear-array endoscope with a 3.8 mm operative channel is preferable to allow the passage of large diameter accessories. There are two possible puncture routes for EUS-BD; transgastric for the intra-hepatic bile duct drainage or transduodenal (bulb) for extrahepatic bile duct drainage. During therapeutic EUS Color Doppler is mandatory, to prevent damage to interposed vessels between the endoscope and the ducts. The puncture of the duct to drain can be performed with a fine needle aspiration (FNA) needle of 19- or 22-gauge (G). The 19 G needle is generally used because the capability of support a 0.035-inch guidewire, which provides more

stiffness. The 22 G needle accommodates only a 0.018-inch guidewire, which carries a greater risk of dislodgement of the guidewire during the procedure. After duct access with the EUS needle, contrast medium injection from the needle is required to perform cholangiography for the confirmation of the correct position of the needle inside the biliary tree. After that, under fluoroscopic guidance, the guidewire can be placed into the duct, advancing it inside the needle^[13-16].

If the drainage is performed transmurally from the stomach, only intrahepatic ducts can be drained [hepaticogastrostomy (HPG)], and if performed from the duodenal bulb the extrahepatic bile duct are more accessible [choledochoduodenostomy (CLD)]. If the guidewire exits the papilla, the drainage can be integrated by ERCP, using the *rendezvous* technique. When the deployment of the stent is performed through the puncture route or deployed across the stricture or the ampulla in an antegrade fashion, different devices can be used for dilation of the site, such as bougie (6 or 7 Fr), pneumatic dilation balloon (4 or 6 mm) or a cystotome (8.5 Fr). Both plastic and metal stents are used for HPG or CLD although PC and FC SEMS are most often used to prevent stent migration and bile leakage. Uncovered SEMS should not be used for HPG or CLD. Recently two new SEMS have emerged specifically designed for EUS-BD (Figure 5).

The Giobor Niti-S, Taewoong, is a PC-SEMS with the inner part (intra-biliary) uncovered to prevent intrahepatic bile duct obstruction and migration, and covered in the trans and intragastric part to prevent bile leakage; it also has a single lasso for possible retrieval. The BPE, Hanaro MI Tech, is a PC-SEMS, the proximal portion, which is 15 to 55 mm in length, is uncovered for the prevention of duct obstruction, while the distal end, 35 mm in length, has a silicone cover for the prevention of bile leakage. The BPE stent has anti-migration flaps at both extremities, for prevention of stent migration.

Technique of transpapillary gallbladder stenting

Cystic duct negotiation is the most challenging part of transpapillary gallbladder stenting. Methods to reach the cystic duct are cholangiography and fluoroscopy arm longitudinal and transversal axis rotation to allow for identification of the level of its insertion into the CBD^[17,18].

Table 4 Technical characteristics of the most commonly used pancreatic plastic stents

Producer	Model	Diameter (Fr)	Length (cm)	Shape	Material
Boston scientific	Advanix	3, 4, 5, 7, 10	2-18	Straight or single pigtail with or without internal flap	Polyethylene
Cook endoscopy	Geenan Sof-Flex	5	3-12	Curved with or without internal flap	Polyethylene and polyurethane blend

Hobbs medical	Freeman Flexi-Stents	3, 4, 5, 7	2-18	Straight or single pigtail with or without internal flap	Soft polymer
Olympus	Pancreatic PE	7, 8.5, 10	3-15	Straight, S-shaped	Polyethylene

For a left-side cystic duct take-off, a flexible-tip catheter or a rotatable sphincterotome may be used, while for a right-sided take-off, a standard sphincterotome may be used because it usually bows toward the cystic duct when it takes off on the right side. A 0.035" or 0.025" guidewire (stiff or hydrophilic) is used to enter into the cystic duct orifice. The angled tip guidewires are preferable to enter and pass through the spiral valves of Heister while minimizing the risk of perforation. In difficult cannulation of the cystic duct, an inflated Fogarty balloon up to the cystic duct insertion, with an angled-tip guidewire passed alongside may be useful for its negotiation. After cystic duct negotiation, the guidewire is advanced and coiled within the gallbladder lumen and an accurate study of the course and diameter of the duct must be performed for the correct choice of the stent. The catheter is then removed and the stent placed over the wire. Double pigtail 6 to 10 Fr PSs are preferable because of their superior anchorage into the gallbladder lumen compared with straight stents. The length of the stent is chosen based upon the distance between the major duodenal papilla and the gallbladder (usually 12-15 cm long stents are used) and the stent size according to the diameter of the cystic duct and common bile duct. When 10 Fr stents are placed, an ES should be performed to minimize the risk of post-ERCP pancreatitis caused by the fulcrum effect.

EUS guided gallbladder drainage

EUS guided gallbladder drainage (EUS-GD) is performed using a large channel (3.7 or 3.8 mm) echoendoscope with fluoroscopic guidance^[19-22].

The best way to visualize the gallbladder is the prepyloric area, in the stomach, or from the duodenal bulb. The puncture is performed in the site in which gallbladder is in contact with the bowel. The more stable the echoendoscope position the easier the procedure. Color Doppler is mandatory, before gallbladder puncture, to avoid puncture of interposed blood vessels.

A 19 G FNA needle is usually used to obtain gallbladder access. After gallbladder puncture and removal of the stylet, cholecystography is performed by injecting contrast medium through the needle. After cholecystography, a

guidewire is inserted and coiled inside the gallbladder. After the removal of the needle, the access-site can be enlarged using either a mechanical (6 or 7 Fr bougie or balloon catheters) or electrocautery (6 or 10 Fr cystotome or needle-knife) device. After dilation, the stent is advanced over the wire and into the gallbladder.

Recently, a single-step device allowing access, dilation and plastic stent placement has been developed for EUS-GD (Giovannini Needle Wire Oasis, Cook Ireland Ltd, Limerick, Ireland).

Plastic stents, standard or modified tubular covered SEMSs and lumen apposing metal stents (LAMSs) are used. Plastic stents were used for EUS-GD in early studies. However, the PSs can become occluded and may not allow complete sealing between the gallbladder and duodenal or gastric wall with a relative risk of bile leak in the abdomen.

To circumvent the limitations of plastic stents tubular FCSEMS were used for EUS-GD. Metal stents, with their high radial force and covering can reduce this risk. The larger diameters may facilitate draining of thick or necrotic debris, pus or sludge reducing the risk of stent clogging.

However when metal and plastic stents designed for ERCP are used migration remains an important risk. Recently LAMS have been developed to obtain better anchorage between the gallbladder or bile ducts and the bowel wall, reducing the risk of stent migration and bile leakage. These include the Axios stent (Boston Scientific, Natick, MA, United States) (Figure 6A) and Spaxus Niti-S stent (Taewoong Medical, Seoul, South Korea) (Figure 6B).

TECHNIQUES OF PANCREATIC DUCT AND PERI-PANCREATIC FLUID COLLECTION DRAINAGE AND TYPES OF STENTS

Pancreatic plastic stents

Pancreatic stents (Table 4 and Figure 7) are made of

Figure 6 A display of different types of lumen apposing metal stents available: The AXIOS (A) stent, Boston Scientific, the Spaxus (B) and NAGI (C) Niti-S stents, Taewoong Medical, the Aix (D) stent, Leufen Medical, and the BCF (E) stent, Hanaro MI Tech.

polyethylene; the shape and design resemble those of biliary stents, save for the presence of side holes along the length of the stent. The side holes allow draining of pancreatic juice from side branches.

Pancreatic stents have lengths between 2 and 25 cm and diameters between 3 and 11.5 Fr. Different types of stents are now commercially available, with different shapes as straight, winged or with curved distal end or wedged proximal end. Some of these have a "J" or single pigtail shape to prevent migration into the pancreatic duct. There is also an S-shaped stent with many side holes and made in ethylene-vinyl-acetate (EVA). EVA has more flexibility compared to polyethylene.

Pancreatic stents with S-shape are made for a better adapting to the profile of the main pancreatic duct. A winged stent (Via-Duct stent, GI Supply) is made to allow pancreatic juice to flow through the wings of the stent.

Pancreatic PSs without a proximal flap are designed to allow spontaneous distal migration, when the stent are only to be used for a short time. Pancreatic PSs with a distal end pig-tail are designed for avoidance of proximal migration.

The majority of pancreatic PSs are deployed over-the-wire, only with the push-catheter, without the use of the guide-catheter, because of their small diameter. Pancreatic plastic stent with a diameter more than 8.5 Fr requires the use of a guide-catheter.

Pancreatic self-expandable metal stents

The only self-expandable stent designed for drainage

of the main pancreatic duct (MPD) is the TaeWoong Bumpy® - Niti-S, that presents a non-regular cell mesh. It results in a different radial force in every part of the stent, avoiding compression of the side branches of the pancreatic duct.

However, other FC-SEMS are used off-label with good outcomes in selected situations, such as the WallFlex (Boston Scientific) and the Viabil (Gore Medical). The Viabil stent is fully covered and available with side holes designed to allow cystic duct drainage and which may allow drainage of some pancreatic duct side branches.

Technique of transpapillary pancreatic duct stenting

The pancreatic PSs placement technique is the same as used for the biliary tree. After MPD cannulation, the stent is inserted inside the duct over the wire; hydrophilic guidewire of 0.035" is used for placement of PSs from 5 to 10 Fr; 0.018" guidewires are used for 3 Fr PSs, generally reserved for cases of minor pancreatic duct stenting and temporary placement for prevention of post-ERCP pancreatitis. Pancreatic sphincterotomy is not always necessary for placement of PSs. In case of bilio-pancreatic sphincterotomy, pancreatic sphincterotomy is generally performed after biliary sphincterotomy^[23].

The PSs diameter must not be greater than the maximum diameter of the pancreatic duct. Five and 7 Fr PSs are generally implanted in absence of duct dilation; 10 Fr PSs, or more than 10 Fr, are instead used when MPD stenosis with upstream duct dilation occurs. When very tight strictures are present, the placement of a PSs

Figure 7 A display of different types of pancreatic plastic stents available.

can be challenging. In this situation balloon dilation or a bougienage dilation are often helpful to, allow stent placement.

For implantation of a SEMS a pancreatic sphincterotomy is typically performed (often also with biliary sphincterotomy). The metal stent diameter and length are determined on the basis of a combination of location of lesion (stricture or leak), ductal configuration and in cases of stricture the diameter of dilated upstream duct proximal to the lesion.

For MPD strictures dilation is typically performed before SEMS placement and the stent is deployed through the ductal lesion. The distal portion of the SEMS is left in the duodenum for prevention of proximal migration and easy removal.

EUS-guided pancreatic duct drainage

To perform EUS-guided drainage of the pancreatic duct (PDD) a large channel echoendoscope (3.7 or 3.8 mm)

is required. The most common site for pancreatic duct (PD) access is the stomach (gastric body), usually the most straightforward and stable, but also transbulbar access is used (impossible in those with prior pancreatoduodenectomy)^[24-28].

However, the route is selected on the basis of the pancreatic anatomical site to be treated. The aim of the drainage is to gain access the shortest way between the echoendoscope and the PD. The shorter the distance the easier the procedure, considering over-the-wire exchanges of devices. Pancreatic duct access may be performed with a 19-G FNA needle followed by either 0.035" or 0.025" guidewire placement *via* the needle or with a 22-G FNA needle that allows only the passage of an 0.018" guidewire.

After PD access, the wire is placed inside the duct, advancing it into the duodenal lumen, through the Vater's papilla, or into the jejunal lumen in presence of a pancreatico-jejunal anastomosis. During guidewire

placement and device exchanges, the use of fluoroscopy is helpful.

After guidewire placement, PD stenting can be performed in retrograde fashion, with EUS-guided PD rendezvous technique, with a side-viewing duodenoscope or with a frontal-viewing endoscope, in patients with postoperative anatomy, or in antegrade fashion, from the stomach or from the duodenal bulb, with EUS-guidance.

For antegrade stenting, dilation of the gastric wall or duodenal bulb wall and dilation of pancreatic parenchyma with a balloon is helpful before stent placement. In many cases a cystotome is used to gain access to the PD, after wire placement, creating an "electrocautery-tunnel", to allow subsequent stent deployment. During EUS-guided PDD, a plastic stent is generally preferred to a metallic one, considering the risk of leakage if uncovered SEMS are used. Finally, when PSs are used, to avoid leakage and migration, the diameter of the stent should not be less than the diameter of the dilated tract.

Endoscopic drainage of pancreatic fluid collections

Endoscopic drainage of PFCs are performed with different approaches as the trans-papillary (*i.e.*, using endoscopic retrograde pancreatography), or transmural (cystoenterostomy), or both^[29-35].

For transpapillary drainage, before implantation of the stent, a major or minor papilla pancreatic sphincterotomy is typically performed. Following this, a large-bore stent is placed. When the stent is placed, its proximal part can be placed inside the PFC or, in case of leakage, across the disruption of the PD. If a stricture of the PD is present downstream to the PFC, judicious dilation by bougie or dilation balloons needs to be performed before application of the stent.

PFC drainage can be performed or through the stomach (transgastric) or through the duodenum (trans-duodenal). More rarely drainage is performed through the esophageal wall (transesophageal). The drainage can be undertaken with or without EUS guidance.

When non-EUS-guided techniques are performed a large channel gastroscope or duodenoscope with a 4.2-mm working channel is used.

The side-viewing endoscope is most often used because it permits better visualization of the posterior wall of the gastric body, allowing placement of large diameter accessories (deployment of 10 Fr stents) with assistance of the elevator.

The initial PFC puncture for transmural drainage is generally performed at level of visible bulging on the gastric or duodenal wall. To obtain good endoscope stability, the short position, when possible, is recommended, and the angle between the needle and the gastric/duodenal wall needs to be closer to 90°. The closer to 90° results in shorter distance to traverse.

To access a PFC with the side-viewing endoscope, diathermic puncture technique or the Seldinger technique are used. The diathermic puncture technique involves the use of a needle-knife sphincterotome (double or triple-

lumen), or a 10-Fr cystotome that is a catheter with a diathermic ring and a 5-Fr inner catheter housing a low-profile, 0.38" needle knife to facilitate close apposition of the PFC to the enteral lumen. A pure cutting current is recommended and the electrocautery should be discontinued immediately upon entry of the needle into the PFC cavity to avoid thermal injury to surrounding structures.

Following this, aspiration of fluid (which can be sent for analysis) and gentle injection of contrast under fluoroscopic guidance confirm position within the cavity. The needle is exchanged for a standard catheter. After that, the guidewire is placed inside the PFC, and coiled for 2-3 times.

Following deep access with a guidewire, the catheter is exchanged for an 8 or 10 mm pneumatic balloon, to dilate the tract. After dilation, the balloon is removed and a plastic or metallic stent is deployed over the guidewire. Alternatively, a cystotome can be used for single-step drainage, avoiding balloon dilation.

When the Seldinger technique is used, a 19-G aspirating needle is used for initial puncture of the PFC. After fluid aspiration contrast is injected inside the PFC for the confirmation of the correct position of the needle. Through the needle a guidewire is passed, coiling it inside the fluid collection. Leaving the wire in place, the needle is withdrawn and a cystotome or a dilation balloon is passed over the wire. Finally the cystotome (or the dilating balloon) is removed and a stent is placed over the guidewire. Moreover balloon dilation can be performed after the creation of the fistula with the cystotome.

There are two techniques for EUS-guided drainage (EUS-GD) of PFC: The 2-step approach and the 1-step approach. For 2-step approach larger (3.7 or 3.8 mm) and smaller (2.8 or 3.2 mm) mm working channel echoendoscopes can be used.

The PFC is located and studied by EUS, identifying the best site for drainage of the collection which is closest to the transducer. Color Doppler helps to avoid puncture of interposed vessels during drainage. This site can be marked with a biopsy forceps, with a metal clip or with India ink and the echoendoscope withdrawn and replaced with a side-viewing duodenoscope to perform the drainage. Otherwise, the PFC puncture is directly performed with a 19 G needle and, after puncture, a guidewire is placed inside the collection. After wire placement, the echoendoscope can be withdrawn, leaving the guidewire in place inside the PFC, and replaced with a side-viewing endoscope over the guidewire, and the drainage can be performed using this endoscope. These exchange of endoscope approaches are now used infrequently.

With the 1-step approach the echoendoscope is used for the entire procedure. An echoendoscope with a large operative channel is required. It allows the use large diameter accessories (deployment of 10 Fr stents) with the assistance of an elevator.

The PFC puncture is usually performed using a

Table 5 Technical characteristics of the lumen apposing metal stents

Producer	Model	Internal diameter (mm)	Length (mm)	Flange diameter (mm)

**Figure 8** Traditional transmural endoscopic drainage of pancreatic fluid collections. PFC: Pancreatic fluid collections.

19-G needle under endosonographic view. The collection contents can be aspirated for biochemical analysis, gram stain, culture and cytology. Through the lumen of the needle a 0.025" or 0.035" guidewire is advanced until it coils in the PFC which adds stabilisation of the position and access by forming anchoring extra loops in the cavity.

Fistula dilation is achieved by balloon dilatation over the guidewire, or using a cystostome and diathermy needle. Finally the stent is placed over the guidewire.

The 1-step approach PFC drainage avoids guidewire displacement during the exchange of the echoendoscope with the side-viewing endoscope. When more than one stent, or an additional naso-cystic drainage (NCD) are placed, two guidewires can be inserted inside the same catheter to avoid recannulation of the PFC. Recently, a 3-layer puncture kit, allowing synchronous placement of two guidewires has been described. This kit is composed of a 6 Fr catheter made of Teflon, inside an outer catheter of 8.5 Fr and a 22G FNA needle inside the 6 Fr catheter. Puncture of the collection is performed with a 22 G needle using electrocautery, under EUS-guidance. After puncture the 6 Fr inner catheter and the 8.5 French outer catheter are advanced inside the PFC. When the entire kit is inside the PFC, both needle and inner catheter are removed, and two guidewires can be inserted into the PFC through the outer catheter. Then, two stents, or one stent and one NCD, are placed.

After initial puncture and dilation some endoscopists described the use of the Soehendra dilator or a cystotome 10 Fr outer catheter for passage of two guidewires.

The "Navix-access-device" (Boston Scientific, Natick, MA, United States) consists of a 19-gauge trocar with a short extendable side blade. The retractable blade creates a cystoenterostomy without the use of cautery. It has an anchoring and dilating balloon (10 mm), as well as 2 guidewire ports to permit double wire advancement with the same puncture for sequential stent placement.

Traditionally, more than one plastic pigtail stent is used for PFC transmurial drainage. The fistula tract between the gastrointestinal wall and the PFC is maintained by placement of double pigtail plastic stents for preventing dislocation and migration. When 7 Fr stents are used the occlusion rates are higher. To further improve transmural drainage of PFCs, tubular FCSEMS (available for the treatment of biliary strictures) have recently been used as an alternative for the traditionally used plastic double-pigtail stents. Fully covered SEMS have larger diameters (10 mm) and placement of a single stent can provide a wide drainage opening. Furthermore, due to the larger diameter, there is a reduced risk of occlusion, especially for collections containing a significant amount of solid debris.

However, these stents are designed for drainage related to a luminal stricture and not to a transmural route. When a bile duct stent is used for PFC drainage, protrusion of the ends of the stent both into the GI tract and inside the PFC can increase the risk of stent migration or bleeding, caused by a contact ulceration of the stent within the wall. They are not ideal in cases when the PFC is not firmly attached to the gastrointestinal wall because they do not apply any anchorage force and resultant leakage may occur.

To overcome limitations associated with the use of tubular biliary SEMS for transmural drainage, novel drainage stents have been developed.

These new lumen apposing metal stents (Table 5), are specifically designed for transmural drainage (Figure 6). These stent are fully-covered for preventing ingrowth of tissue and have large flanges at the distal ends, with a length from 10 to 40 mm. The flanges are designed to provide lumen-to-lumen anchoring and a low migration and leakage risk. The diameter of the stents, 10 and 15 mm, enable direct necrosectomy through the lumen of the stent. A flow-chart for the traditional transmural endoscopic drainage of PFC is summarized in Figure 8.

CONCLUSION

Biliary and pancreatic stents are important advancements

in therapeutic endoscopy and have revolutionized the approach to pancreaticobiliary disorders. The new designs of plastic and metal stents have allowed an increased use in a large, broad range of biliary and pancreatic benign and malignant conditions, replacing interventional radiologic approaches and surgery in most cases.

Abstract

For the first several years after its development,

endoscopic ultrasound (EUS) was primarily limited to identification of pancreatic malignancies. Since this time, the field of EUS has advanced at a tremendous speed in terms of additional clinical diagnostic and therapeutic uses. The combination of ultrasound with endoscopy provides a unique interventional modality that is a minimally invasive alternative to various surgical interventions. Given the expanding recommended indications for EUS, this article will serve to review the most common uses with supporting evidence, while also exploring innovative endeavors that may soon become common clinical practice.

Key words: Endoscopic ultrasound; Pancreatic carcinoma; Celiac plexus neurolysis; Mediastinal lymphadenopathy; Pancreatic fluid collection

Core tip: Endoscopy has presented the opportunity to improve outcomes and lessen complications in a multitude of diseases and disorders. Endoscopic ultrasound (EUS) in particular has been at the forefront in the development of novel treatment and diagnostic methods. While there have been prior articles reviewing common indications for the clinical use of EUS, the sheer volume of recent studies centered on this modality denotes an opportunity to provide an update on that information. Additionally, recent reports of using EUS with innovative techniques, such as anal dyssynergia refractory to standard therapy, warrant discussion in this forum.

INTRODUCTION

Advancement in the clinical application and use of endoscopic ultrasound (EUS) in recent years has transformed the field of gastroenterology, with the ability to identify and manage a wide variety of disorders, even extending beyond the gastrointestinal tract (GIT). EUS combines endoscopy with intraluminal ultrasonography using a high frequency transducer to produce high-resolution ultrasound (US) images. Prior to its development in the early 1980s, external US imaging was the primary means of diagnosing clinical problems related to the biliary system. However, trans-abdominal US was limited in providing a diagnosis in 30% of cases secondary to the presence of intestinal gas obstructing views^[1].

SRI international (Menlo Park, California) produced a high-resolution ultrasonic probe used in conjunction with a side-viewing endoscope with which to evaluate the ability to identify important vasculature and organs within the upper abdomen. This prototype EUS was used in a canine as the 80-mm rigid end prevented safe use in humans; it demonstrated real-time images of the aorta, spleen, gallbladder, left kidney and gastric rugae, as well as the hepatic and portal venous systems^[1].

The original EUS prototype to be used in humans was developed by Olympus Opt. Company (Tokyo, Japan) using a conventional gastroscope^[2]. This instrument consisted of attaching an ultrasonic probe to the rigid end of a fiberscope which transmitted at a frequency of 5 MHz to a depth of 3 cm. Strohm *et al*^[2] conducted a study in which this endoscope model was used to identify organs proximal to the stomach in 18 patients. Using the aorta and vena cava as landmarks, the pancreas was identified and measured in 9 of 18 patients. The gallbladder and distal bile duct were also found on imaging in some patients, but the scope's limited mobility prevented passage through the pylorus and, thus, visualization of the duodenum. They compared the quality of these images to those obtained with conventional US, and discovered that those obtained *via* EUS appeared equivocal. This new EUS, however, provided sharper visualization of the distal common bile duct (CBD) than transabdominal US^[2].

Both studies demonstrated a new means of acquiring high-resolution views of various organs and vessels that with further development could prove to be superior to transcutaneous US^[1,2]. With improvement in the echoendoscope, various groups began applying this technology to advance clinical diagnoses of upper abdominal pathology. Current guidelines for the diagnostic indication of EUS produced by the American Cancer Society and American Society for Gastrointestinal Endoscopy (ASGE) include evaluation of upper gastrointestinal malignancies, mediastinal adenopathy, pancreatic lesions and cancers, and submucosal tumors^[3,4]. The use of EUS has expanded beyond purely investigative uses to also become a minimally invasive means of

therapeutic intervention. This article will review the primary clinical uses for EUS along with fundamental supporting study data.

Diagnostic indications

Pancreatic cancer: EUS was first evaluated for its efficacy in confirming suspected pancreatic carcinoma in the mid-1980s. These early studies revealed EUS was superior to trans-abdominal US, including differentiating pancreatitis from a pancreatic tumor and identifying ampullary and papillary tumors^[4]. After multiple studies throughout the 1990s, EUS sensitivity approached beyond 90% in detecting malignant pancreatic tumors^[5]. One such study from Akahoshi *et al*^[6] sought to analyze the precision of EUS in earlier diagnosis of pancreatic cancer with accurate tumor staging. In this era, pancreatic cancers were identified primarily by abnormal laboratory results or abdominal US and computed tomography (CT), and thus found at very advanced stages. In the study's evaluation of 96 patients suspected of having pancreatic carcinoma based on abnormal labs or imaging and their clinical presentation, diagnosis was confirmed by post-operative histology, autopsy, or surgical exploration in non-resectable cases. They found EUS had a sensitivity of 83% in diagnosing malignant pancreatic masses less than 3 cm in size, and a sensitivity of 92% for those beyond 3 cm, with an overall specificity of 97%^[6]. This high sensitivity rate was not significantly decreased by location within the pancreas; although, masses in the pancreatic body or tail were identified with a sensitivity of 100% relative to 85% for the body of the pancreas. EUS in this study revealed 64% accuracy in pancreatic tumor staging T1-T3. The main etiology for incorrect staging was those patients with masses larger than 3 cm, which limited the tissue depth penetration of the 7.5 MHz transducer^[6]. These were, and remain, profound findings, as earlier diagnosis and more accurate local staging could improve patient survival. Current studies have demonstrated diagnostic sensitivity of EUS approaches 99% for malignant pancreatic tumors of 2-3 cm size which is far superior to other imaging modalities, including CT, transabdominal US, and magnetic resonance imaging (MRI)^[7-9]. This is likely due to the ability to have close proximity of the endoscope transducer to the lesion of interest. Of course, EUS is not without limitations in the accuracy of diagnosing pancreatic cancer. The presence of pancreatitis, which can result in significant heterogeneous appearance of pancreatic tissue, may result in highly trained endosonographers missing an underlying pancreatic neoplasm^[4,10]. As MRI techniques and equipment become more high-tech, magnetic resonance cholangiopancreatography (MRCP) has been used with increasing frequency in patients suspected of having a pancreatic malignancy. MRI has superior soft-tissue contrast compared to CT imaging, resulting in the ability to differentiate pancreatic masses^[4,11]. However, as EUS affords superb visualization of the

pancreas and remains one of the most accurate means for identifying pancreatic lesions, it is considered a first-line modality for diagnosing and staging of pancreatic adenocarcinoma.

EUS is not only accurate in detecting pancreatic malignancies, but is the primary tool to rule out pancreatic cancer^[8]. A large single study completed at UC Irvine by Klapman *et al*^[8] determined the negative predictive value (NPV) of EUS for patients with possible cancer of the pancreas. A total 693 patients were referred for EUS due to the potential of pancreatic cancer; focus was placed on the 155 with normal pancreatic imaging on EUS. Most of this group had been referred for EUS based on abnormal CT imaging. These patients were monitored for 24 mo, at the end of which none developed malignancy of the pancreas, resulting in a 100% NPV (95%CI: 98.2-100.0)^[8].

Today, EUS imaging is combined with fine-needle aspiration (FNA) to improve diagnostic accuracy of pancreatic masses. Cytological or histological confirmation of the lesion is required to determine the appropriate treatment, especially if the mass is unresectable. Retrospective reviews of EUS database information shows EUS-FNA diagnostic precision of 89% for solid pancreatic masses^[9,11,12,13]. The ability to obtain samples of pancreatic lesions concerning for malignancy during real-time imaging has a direct impact on the medical management of these patients. As only a minority of patients are candidates for curative surgery at time of presentation with pancreatic carcinoma, obtaining cytological or histological diagnostic confirmation is necessary to proceed with chemotherapy^[9,12,13]. Touchefu *et al*^[12] examined the influence of EUS-FNA on patient management in 100 patients; intention-to-diagnose analysis revealed the FNA results directly guided treatment plans in 62 patients.

It is additionally highly recommended, and in many healthcare settings standard of care, that a cytopathologist or cytology technician be onsite to guide FNA sampling. Various studies have demonstrated the likelihood of diagnosis obtained is much improved. A large prospective multicenter study conducted in the mid-1990s evaluated 474 EUS-guided FNA diagnoses of various sites and lesions. NPV was 72% without an on-site pathologist vs 100% in those centers with direct pathologist assistance^[4,14]. Furthermore, a retrospective study evaluating academic centers with cytopathologists on site ruled in or out a malignant diagnosis twice as often and were less likely to have unacceptable samples^[14-17].

Additional supportive data for on-site cytopathology with EUS-FNA of suspicious lesions was revealed in a recent large meta-analysis by Hébert-Magee *et al*^[16] reviewing 34 studies with approximately 3600 patients with solid pancreatic masses. Of those patients, a total of 2285 were found to have pancreatic adenocarcinomas. Sensitivity of FNA ranged from 0.50-1.00, with sensitivity rates notably lower in those studies without on-

site cytopathology, even when correcting for sources of heterogeneity of study size and diagnostic reference standard used^[16,17]. Thus, given the continued dismal survival rates for pancreatic cancer (approximately 24% survival at 1 year and 5% at 2 years) and increased chance of unresectability with late presentation, EUS-FNA biopsy can provide an earlier diagnosis and potential alternative diagnosis to decrease patient mortality. It remains superior in accurately identifying and ruling out pancreatic malignancies compared to imaging *via* CT, conventional US, and MR^[8].

Mediastinal adenopathy and non small-cell lung cancer:

Patients with suspected lung cancer often undergo further imaging to help with staging, as up to 26% of newly diagnosed lung cancers present with mediastinal lymph node involvement^[18,19]. Imaging modalities may vary between CT, MRI, or US. A 2003 CHEST systematic database review evaluated the accuracy of mediastinal staging in CT compared to positron emission tomography (PET), MR, and EUS^[19]. The analysis of EUS assessment consisted of five studies for a total of 163 patients and exhibited a pooled sensitivity of 78% (95%CI: 0.61-0.89) and specificity of 71% (95%CI: 0.56-0.82). However, PET scan demonstrated the highest accuracy in detecting malignant metastases to mediastinal nodes with sensitivity and specificity of 84% (95%CI: 0.78-0.89) and 89% (95%CI: 0.83-0.93), respectively. As EUS is often limited in its inability to image all node stations, this may partially explain its inferiority to PET imaging of the mediastinum^[19]. Specifically, EUS is unable to visualize anterior upper mediastinal nodes as a result of air within the trachea obstructing US imaging^[18,20].

While CT and PET detect mediastinal lymphadenopathy and suspicious masses on imaging, a lack of tissue sampling results in a presumptive diagnosis only. Thus, obtaining tissue samples is necessary to definitively confirm and stage a possible pulmonary malignancy. The American Society of Thoracic Surgery currently recognizes mediastinoscopy as the favored modality for biopsy^[18]. However, the 2011 ASGE Standards of Practice state that linear echoendoscopy can perform EUS-guided FNA of the posterior and inferior mediastinum with success in obtaining specimens from nodes 5 mm in size or larger. Additionally, nodal stations 8 and 9 and posterior nodes at station 7 are accessible by EUS with a sensitivity of 90% in confirming diagnosis. This accuracy drops to 66% for station 5 nodes based on one retrospective series by Eloubeidi *et al*^[21] due to logistical difficulties when inserting the biopsy needle in attempts to reach this sub-aortic locations^[18]. One prospective cohort study of 104 patients with malignant posterior mediastinal lymph nodes assessed the yield and precision of EUS-FNA using pathologic confirmation *via* thoracotomy^[21]. The accuracy of EUS-FNA was 97%, which was significantly increased from PET imaging alone. More invasive surgical intervention was

avoided in 57% of the patients to determine malignant spread to lymph nodes. No patients experienced major complications peri-procedurally or at 30-d follow up^[21]. EUS-FNA has been recommended by Maluf-Filho *et al*^[4] to detect metastasis to the posterior mediastinum in non-small-cell lung cancer (Grade A, evidence level 1). EUS-FNA of mediastinal lymphadenopathy averages a complication rate of 0.2%, compared to 1.3%-3.0% with mediastinoscopy. The American Society of Thoracic Surgery does recognize EUS-FNA as an efficient, minimally invasive alternative method to confirm and stage lung cancer involving mediastinal lymph nodes.

Choledocholithiasis, suspected: CBD stones remain a common complication related to the presence of gallstones, occurring in nearly 20% of patients with known cholelithiasis. Identifying CBD stones remains a challenge, as laboratory findings and clinical presentation is often nonspecific^[22]. EUS has been studied over several years in its ability to accurately detect choledocholithiasis. Endoscopic retrograde cholangiopancreatography (ERCP) remains standard of care, as rates for successful identification of bile duct stones approaches 100%, compared with abdominal CT and US where diagnostic accuracy approximates to 50%^[22,23]. ERCP is also not purely diagnostic, as it allows for CBD stone removal at time of detection; however, complication rates occur in up to 11% of patients^[23,24]. Various studies performed in the 2000s evaluated EUS ability to diagnose suspected choledocholithiasis, as this could negate ERCP and its associated risks in certain patient cases. However, the data was widely variable in rates of sensitivity and sensitivity^[22,23].

In order to more precisely estimate diagnostic accuracy of EUS for choledocholithiasis, Tse *et al*^[22] identified 27 prospective cohort studies consisting of EUS results compared with ERCP, intraoperative cholangiogram (IOC), or surgical exploration. Included studies also had a minimum of three months follow up if initially negative EUS results with suspicion of CBD stones based on history, exam, laboratory findings, or trans-abdominal US imaging. Studies were excluded if they lacked a comparison group, demonstrated possible bias, or insufficient data. Pooled diagnostic accuracy was 98% (area under the curve). EUS decisively ruled in and ruled out CBD stones with a positive likelihood ratio (LR) of 22.41 (95%CI: 12.53-40.08) and negative LR of 0.09 (95%CI: 0.06-0.12)^[22]. This impressive diagnostic ability of EUS is likely related to its high resolution down to 0.1 mm compared to ERCP or MRCP^[22].

IOC is often performed during laparoscopic cholecystectomy to evaluate biliary patency. CBD stones are present in up to 15% of these patients, but the false positive rate of IOC approaches 60% in some studies^[23]. Given the combination of IOC's high false positive detection of choledocholithiasis and the complication rates of ERCP, it would be ideal to have an alternative, less invasive modality of confirming CBD stones

with decreased risk in patients with low suspicion for requiring stone extraction. EUS may have a potential role in a diagnostic algorithm to stratify patients proceeding to ERCP vs EUS initially. EUS is felt to be as sensitive and more specific than ERCP or MRCP for the diagnosis of CBD stones, especially those of smaller size (Grade A, Evidence Level 1)^[4].

The use of EUS as the primary diagnostic tool, however, may be limited. While it is less invasive than ERCP resulting in lower rates of post-procedure pancreatitis, patients still require sedation. As with ERCP, EUS requires an experienced endoscopist to obtain acceptable images. Unfortunately if CBD stones are discovered on EUS imaging and require removal, these patients would require ERCP, an additional procedure.

Therapeutic indications

Pancreatic fluid collection drainage: Potential indications for intervention in pancreatic pseudocysts include abdominal pain, gastric outlet obstruction, early satiety, weight loss, jaundice, infection, or progressive enlargement^[3]. Surgery has historically been accepted as the standard of care for draining pancreatic pseudocysts and walled-off pancreatic necrosis. In recent years, multiple studies examining the success of EUS-guided drainage has resulted in this becoming an established technique with comparable outcomes and significantly lower medical costs^[17]. This procedure was first described in a 1992 case report by Grimm *et al*^[25] with management of a pancreatic tail pseudocyst^[17]. A randomized controlled trial conducted in 2009 directly compared surgical vs EUS-guided endoscopic pancreatic fluid collection (PFC) drainage in 40 patients^[26]. A pseudocyst was defined as "a fluid collection in... pancreatic...area (with) a well-defined wall and...no solid debris or recognizable parenchymal necrosis"^[26]. One-half of the patients were randomized to surgical cystogastrostomy under a single pancreatic surgeon while the other half underwent EUS with fluoroscopy. Endoscopic cystogastrostomy was achieved *via* EUS-guided 19-gauge-needle access of the fluid collection with subsequent deployment of two plastic stents to allow PFC contents to drain into stomach. ERCP was performed in the experimental arm following EUS in order to identify and treat pancreatic duct leaks, if present. Traditional surgical drainage resulted in a 100% successful treatment. However, several of these patients experience postoperative complications, including recurrent pseudocyst, surgical wound infection, inability to tolerate oral intake, and pancreatic tail stricture. EUS-guided pseudocyst drainage was efficacious in 95% of patients with pseudocyst resolution by 8 wk in all 20 patients. Most importantly, these patients did not experience peri- or post-procedural complications^[26]. Additional studies have since demonstrated clinical success rates of PFC drainage *via* EUS imaging approach 90% with complication rate of less than 5%^[17,24,26,27]. PFC drainage under EUS guidance is a minimally

invasive procedure, resulting in a shorter hospital length of stay, lower overall healthcare costs, and feasibility in vast majority (more than 90%) of patients^[24,26].

Prior to the establishment of EUS-guided PFC drainage, transmural drainage *via* esophagogastroduodenoscopy (EGD) had been accepted as a reputable technique to manage PFCs. This was attributable to data from two prospective nonrandomized trials in the early 2000s that revealed no statistical difference in treatment success or complication rates when compared with surgery^[26,27]. EGD identified the location of a PFC by evaluating for a site of stomach or duodenal lumen compression. The site was punctured by a needle to allow aspiration of pseudocyst fluid and placement of double pigtail stents to allow intraluminal drainage of PFC contents^[27]. Varadarajulu *et al.*^[27] conducted the first randomized control trial directly pitting EUS against EGD for transmural drainage of pancreatic pseudocysts in 42 patients. All patients initially underwent contrast-enhanced CT imaging to exclude those without a pseudocyst, then ERCP to assess and manage CBD stones or pancreatic duct stricture, if present. Patients were subsequently randomized to the EGD or EUS arms with treatment failures crossing over to the opposite arm. Ultimately, complete resolution of pseudocysts was achieved in 91% of the EGD arm vs 97% in the EUS group (10 of which crossed-over from EGD arm). Although no statistical significance was noted in improved safety with EUS, it did reveal a significantly higher technical success rate^[26,27]. This is likely due to the ability of directly imaging extramural lesions.

EUS provides additional benefits over EGD beyond definitive drainage of PFCs. EUS imaging can more clearly differentiate pseudocysts from cystic neoplasms and visualize pseudocysts that spontaneously resolved, thus negating a need for PFC drainage^[27]. Bleeding is one of the most common complications of endoscopic PFC drainage, occurring in up to 10% of patients. This often occurs due to the presence of gastric varices or collaterals not visible with EGD. As EUS allows real-time visualization of vasculature near a pseudocyst, one can identify a safe window for transmural puncture to achieve drainage^[26,27].

Celiac plexus neurolysis: Chronic pain is a common, and at times, debilitating complication of intra-abdominal malignancies and chronic pancreatitis. It is often difficult to control with opioid analgesics, and these medications have various adverse effects. Wiersema *et al.*^[28] first described a technique of treating intractable pain with EUS-guided celiac plexus neurolysis (CPN) in a prospective study of 30 patients with pancreatic carcinoma or intra-abdominal metastases in 1996^[17,24]. This procedure consisted of identifying the celiac trunk, as the celiac plexus is located anterolateral to this site, and injecting a local anesthetic such as bupivacaine followed by dehydrated ethanol^[24,28]. Data was notable for a 79%-88% improvement in the patients' pain

scores at a mean 10 wk post-procedure. Furthermore, 91% of these patients did not require increased dosages of their opioid analgesics, with nearly half using less pain medication by the last study follow up. The only complication was self-resolving diarrhea in four patients^[28].

While CPN was found to provide pain relief in patients with pancreatic and intra-abdominal malignancies, Levy *et al.*^[29] considered whether directly injecting the celiac ganglia with a local anesthetic might result in enhanced efficacy^[24]. Seventeen patients with unresectable pancreatic carcinoma and moderate to severe narcotic-dependent pain underwent EUS-guided direct celiac ganglia injections with bupivacaine and dehydrated alcohol. Immediate partial pain relief was experienced by 94% of patients. Opioid medication use decreased for 3 patients, while remaining equivalent in 13 patients. There were no major complications, suggesting this new technique for pain relief in certain patients is a safe alternative and potentially more efficacious than CPN^[29].

The most recent data demonstrates substantial pain relief coupled with a reduction in narcotic dosage for patients with intra-abdominal malignancies undergoing EUS-guided CPN or celiac ganglia neurolysis (CGN). A large meta-analysis from Puli *et al.*^[30] in 2014 pooled data from 8 studies (approximately 300 patients) comparing EUS-CPN to analgesics in unresectable pancreatic carcinoma^[24,30]. Review of data revealed EUS-guided CPN achieved pain relief in 80% of patients with bilateral celiac plexus injection. A majority of the studies again resulted in a reduction of opioid analgesic use and no major complications, thus reiterating this is a safe and effective treatment for pancreatic cancer-related pain^[24,30]. Another review of 6 studies consisting of 358 patients revealed statistically significant reduction in pain at four and eight weeks and superiority in pain reduction compared to narcotic medications^[24].

A multicenter randomized controlled trial by Doi *et al.*^[31] was the first to directly compare efficacy of EUS-guided CPN to EUS-guided CGN in reducing pain from upper abdominal malignancies. Four of the 34 patients randomized to the CGN arm crossed over to CPN due to inability to visualize the celiac ganglia. The EUS-CGN group had improved response (73.5% with decreased pain) relative to the EUS-CPN arm (45.5%), and EUS-CGN attained complete pain relief in 50% of patients compared to only 18.2% who underwent EUS-CPN^[24,31].

EUS-guided CPN and CGN both inhibit the transmission of pain signals from the pancreas and abdominal viscera to the central nervous system. The celiac plexus location permits successful direct EUS visualization, and allows a method of palliation for those with unresectable pancreatic carcinoma^[24,28-30]. Patients may thus require less opioid medications, which translates into fewer medication side effects of anorexia, constipation, nausea, and vomiting.

The celiac plexus is also accessible percutane-

ously when combined with CT or fluoroscopy imaging. Prior to the 1990s, this was the primary manner of performing CPN in settings of chronic abdominal pain secondary to intra-abdominal malignancies and chronic pancreatitis^[24,32]. Given EUS capability to visualize vascular structures in real-time and ability to perform FNA, EUS-guided CPN using ethanol was first developed in the late 1990s^[24]. To further assess this new technique, Gress *et al.*^[32] performed a randomized-controlled trial involving 22 patients receiving either CT-guided or EUS-guided CPN for persistent, uncontrolled abdominal pain due to chronic pancreatitis. Patients in the EUS arm had statistically significant ($P = 0.02$) reduced pain score. Neither group experience serious complications. Diarrhea was noted in three subjects (one from the EUS group, two from the CT arm) and attributed as a direct side effect of CPN^[32]. Nine patients in the experimental group had a prior CT-guided CPN; the majority preferred the EUS technique citing less post-procedure back pain and "more completed sedation"^[32]. Furthermore, the use of EUS in guiding CPN resulted in lower cost per patient relative to CT-guided CPN^[24,32].

FUTURE ENDEAVORS

Anti-tumor injection therapy

Several malignancies metastasize to the liver, which often complicates treatment with intent to cure. Patients with diffuse hepatic metastases have therapy options limited to systemic chemotherapy. In the recent years, drug-eluting microbeads have been introduced as a means of delivering treatment, primarily chemotherapy, into a target tissue^[24]. A relatively new study conducted by Faigel *et al.*^[33] evaluated the use of EUS-guided Portal Injection of Chemotherapy (EPIC) with irinotecan-containing microbeads in porcine subjects in comparison to the conventional systemic administration of irinotecan. EPIC achieved double the concentration of chemotherapy within the liver, and halved its concentration in plasma, bone marrow, and skeletal muscle, relative to what is seen with systemic irinotecan^[33,34]. This new method of delivery chemotherapy to target malignant lesions of the liver has the potential of increasing the efficacy of treatment while decreased adverse effects. It may be possible to extrapolate this technique in developing alternative management strategies for primary liver malignancies, such as hepatocellular carcinoma.

Anal sphincter dyssynergia

A hypertensive anal sphincter may result in severe constipation due to defecatory dyssynergia and subsequent rectal outlet obstruction. Biofeedback therapy to correct patient contraction of the pelvic floor muscles and external anal sphincter often results in clinical improvement superior to that of laxatives alone^[35]. Byrne *et al.*^[36] used EUS to guide injection of Botulinum toxin (Botox) into the internal anal sphincter of nine

patients who had failed biofeedback therapy for anal dyssynergia. Patients underwent anal manometry prior to the procedure and again at two weeks post-injection. Within the 8-wk follow-up, 89% of these patients had improvement in their constipation. Objective findings at this time included decreased anal sphincter pressure in all patients as well as improved defecatory index with balloon expulsion. A single patient developed fecal incontinence, which was the only associated complication from this procedure. While a larger study is needed, this novel technique may prove to be a formidable therapy option for those with constipation due to a hypertensive anal sphincter with alternative treatment failure^[34].

Novel peri-procedure analgesia

Traditional Chinese Medicine has included the use of electro-acupuncture for treatment of pain. Electro-acupuncture needles are placed in particular sites on the body to correlate with the specific source of pain. While endoscopic procedures such as EUS are minimally invasive, they are often uncomfortable for patients and necessitate the use of pain control and sedation with intravenous opioid analgesics and benzodiazepines, respectively. Teoh *et al.*^[37] hypothesized that electro-acupuncture could be used during EUS in order to decrease associated pain and the use of additional analgesics. This randomized, double-blind, sham-controlled trial applied electro-acupuncture to three acupoints related to upper abdominal pain and anxiety in 64 patients undergoing EUS. This study ended early as all patients in the electro-acupuncture group required lower doses of propofol, decreased use of patient-controlled analgesia pumps, and lower pain scores. These data points were all statistically significant^[34]. As administration of sedative analgesics is not without potentially dangerous adverse events, this novel technique could lead to fewer associated complications in patients undergoing endoscopic evaluation.

CONCLUSION

EUS has continued to evolve since its conception several decades ago. It is persistently at the forefront of gastroenterological procedures in expanding its diagnostic and therapeutic use for a variety of diseases and clinical presentations. EUS often provides a marginally invasive alternative to many treatments previously requiring surgical intervention, which ultimately may result in lower healthcare costs and fewer complications in patients.

Abstract

Malignant gastric outlet obstruction (GOO) is a com-

mon condition that results from locally advanced malignancies in the upper gastrointestinal tract, such as pancreatic, gastric, and other carcinomas. Two types of procedures for malignant GOO, namely, gastrojejunostomy (GJ) with laparotomy or a laparoscopic approach and endoscopic stenting (ES), are currently available. Although numerous previous reports have clarified the benefits and drawbacks of each procedure, whether GJ or ES should be used in patients with GOO that results from gastric cancer who may have a longer life expectancy than patients with other malignancies has not been determined. In this review, which focuses on gastric cancer-induced GOO, we analyzed the two systematic reviews and a meta-analysis that compared GJ and ES and outlined the current status of GOO treatment. We also provide an updated review that includes laparoscopic GJ. Various data from 13 studies in one review and 6 studies in another review were analyzed. Although the main results of the present review indicated that both GJ and ES were efficacious treatments in patients with GOO that resulted from gastric cancer, current evidence suggests that GJ may be the preferable procedure given its good performance status and improved prognosis in gastric cancer patients.

Key words: Gastric outlet obstruction; Gastrojejunostomy; Endoscopic stenting; Gastric cancer; Review

Core tip: Both gastrojejunostomy (GJ) and endoscopic stenting (ES) are effective treatments in patients with gastric outlet obstruction that results from gastric cancer. The advantages of GJ include fewer late complications and a long patency, whereas the advantages of ES include better short-term outcomes, including the length of the hospital stay. Although no large-scale randomized clinical trials have compared the safety and efficacy of the two procedures, this present literature review

indicates the superiority of GJ compared with ES given its good performance status and improved prognosis in gastric cancer patients as well as the widespread use of the less invasive laparoscopic GJ procedure.

INTRODUCTION

Malignant gastric outlet obstruction (GOO) is a clinical symptom of advanced malignancies in the upper gastrointestinal tract, most commonly pancreatic and gastric malignancies. Other causes include lymphomas, ampullary carcinomas, biliary tract cancers, and metastases^[1-3]. Associated symptoms, including nausea, vomiting, reflux, malnutrition, dehydration, and abdominal distention, reduce patient quality of life (QOL), and patients with malignant GOO often present with a poor condition and performance status (PS)^[4]. Furthermore, palliative treatment is important and required for patients with unresectable primary malignancies or metastatic lesions.

Treatments for malignant GOO include gastrojejunostomy (GJ), which is traditionally adopted, and palliative endoscopic stenting (ES), which is considered less invasive with a faster improvement of oral intake compared with GJ^[5]. Recently, the use of palliative ES has increased^[6]. In addition, various types of stents are now available, and the procedure has been established and advocated^[7-11]. However, the disadvantages of ES include a high rate of stent re-obstruction and migration as late complications, and pleural treatment is required with some frequency^[2].

Many comparative trials of GJ and ES in patients with malignant GOO have been performed to evaluate the safety, feasibility, costs, and patient QOL. However, to date, the available data regarding "gastric cancer" patients with GOO who could theoretically have a longer life expectancy than patients with other malignancies are not sufficient to definitively conclude the comparative benefits and limitations of GJ and ES. In this review, we outline the current status of GJ and ES treatment for malignant GOO, especially in gastric cancer, and provide a future perspective.

STUDY STRATEGY

Data source and search strategy

An increasing number of studies regarding ES, including novel devices, has been reported during the past decade, especially in the most recent five years; thus,

the outcome of GJ should be compared with recent ES. Literature searches of the electronic PubMed and Embase databases were performed. The searches were limited to articles published from January 2010 to December 2014 in English as well as human- and clinical trial-related articles to identify objective articles from January 2010 to December 2014. The following terms were utilized: "Gastric outlet obstruction", "GOO", "gastric cancer", and "gastric carcinoma". The abstracts were reviewed, and articles not related to the specific content were excluded. Duplicate references and repeated articles were also excluded. All articles considered eligible were selected, and the final selection was based on the full research papers.

Study selection

We included review articles, studies that reported randomized and controlled trials or experimental studies, and case studies. Articles were first screened and selected based on the titles. The full text was obtained for 45 articles.

MALIGNANT GOO THAT RESULTS FROM OF GASTRIC CANCER

Despite a decrease in the incidence of gastric cancer over previous decades, gastric cancer remains the fourth most common malignant disease and the second main cause of cancer-related death worldwide^[12]. To date, the curative resection ratio for newly diagnosed gastric cancer is approximately 50%, and 20% to 30% of patients with gastric cancer present with stage IV disease^[13,14].

Malignant GOO is a common condition among locally advanced gastric cancer patients and can lead to significant morbidity, including nausea, vomiting, abdominal pain, dehydration, malnutrition, and weight loss. Not surprisingly, these clinical symptoms have a negative impact on QOL^[15]. To avoid the disastrous consequences of malignant GOO, appropriate treatment is indispensable, which enables not only an amelioration of the patient's QOL but also the commencement of chemotherapy, including essential oral agents, such as S1 or capecitabine^[16]. These treatments are included in the first-line regimen for unresectable gastric cancer recommended in the Japanese gastric cancer treatment guidelines^[17].

GJ is traditionally the palliative treatment of choice for patients with malignant unresectable GOO, whereas the palliative endoscopic treatment of GOO with endoluminal self-expanding metallic stents has only recently become available. Both treatments have benefits and limitations associated with prognosis; thus, it is important to determine the optimal treatment approach. Although GOO may occur with other malignancies, such as pancreatic periampullary carcinoma, lymphoma, and metastases to the duodenum of jejunum^[1-3], GOO in gastric cancer should be considered separately. First,

gastric cancer has a longer life expectancy than other biological malignancies, and more chemotherapy agents have been developed for this malignancy compared with other diseases^[18-20]. Second, GOO that results from gastric cancer has a reduced possibility of co-occurring with an obstruction of the bile duct compared with biliopancreatic malignancies. Several studies have reported a median overall survival of 13 mo for unresectable or recurrent gastric carcinoma^[21], which is longer than pancreatic cancer (6.7-8.5 mo)^[22].

Therefore, the decision regarding whether to select GJ or ES should depend on the condition and PS of patients. Furthermore, prior to any procedure, information regarding the benefits and drawbacks of GJ and ES is necessary for well-informed consent.

TREATMENTS FOR GASTRIC OUTLET OBSTRUCTION

GJ

Traditionally, GOO caused by malignancy is treated with a palliative "open" GJ (OGJ), which is surgically performed^[23]. Although this modality has a favorable outcome and relieves many symptoms derived from GOO, it results in some morbidity and mortality given the poor condition of these patients^[1,24]. Several recent studies have reported the effectiveness of "laparoscopic" GJ (LGJ) with regard to safety, feasibility, and invasiveness; however, its role has not been clarified^[25,26]. Jeurnink *et al.*^[5] reported that LGJ appears to be more favorable regarding tolerable oral administration, the duration of the hospital stay, and the complication ratio compared with OGJ. However, no significant differences were identified between the two approaches^[27]. Navarra *et al.*^[28] also published a randomized controlled trial (RCT) that compared LGJ and OGJ ($n = 12$ patients each). LGJ resulted in significantly less intra-operative blood loss, a shorter time to tolerating solid food intake, and a reduced rate of complications; however, no significant difference was identified in the postoperative hospital stay^[28]. In contrast, older retrospective studies have reported benefits with regard to intra-operative blood loss and hospital stay as well as a high conversion rate to OGJ^[29,30]. Different outcomes of LGJ have been reported, and this variation can be explained by the small sample sizes and low power. However, no clinical trials with sufficient power have demonstrated the effectiveness of LGJ compared with OGJ, and LGJ is now the preferred standard for malignant GOO treatment^[31].

ES

Endoscopic treatment of GOO with endoluminal self-expanding metallic stents was first described by Topazian *et al.*^[6] in the early 1990s. Over the previous decade, experiences and reports of the use of ES have increased. In addition, various types of upper gastrointestinal stents have become available, and well-established ES procedures have been advocated

and performed^[32]. Recently, several articles have reported that patients who present with GOO with a long life expectancy should undergo ES given its safety, minimal invasiveness, and cost-effectiveness^[33]. Self-expandable metallic stents (SEMSs) are the standard devices for recanalization of an obstructed digestive lumen. However, some SEMSs exhibit re-occlusion because of tumor in growth through openings between the stent wire filaments or stent migration as late major complications^[34]. Covered SEMSs prevent ingrowth through the mesh wall, and they are advantageous compared with uncovered SEMSs in esophageal cancer^[35]. However, in malignant colorectal obstruction, covered stents do not exhibit an advantage compared with uncovered stents due to high migration rates^[36]. Several studies have also suggested that covered stents are associated with more frequent re-intervention despite approximately similar outcomes and complications in malignant GOO. Therefore, with regard to ES for GOO, the effectiveness and complications of covered and uncovered SEMSs in patients with GOO have recently been highlighted. Kim *et al.*^[37] reported a prospective RCT of covered vs uncovered stents for the palliation of GOO in gastric cancer patients and concluded that the overall stent patency did not differ between the two groups; moreover, frequent migration of the covered SEMSs offsets its advantages in the prevention of re-stenosis. Maetani *et al.*^[38] also reported similar results in a multicenter randomized trial in Japan, *i.e.*, no significant difference in the stent patency between triple-layered covered and uncovered metallic stents for the palliation of malignant GOO; however, the use of a triple-layered covered SEMS was associated with less frequent stent dysfunction more than 4 wk after the initial stent. Regardless of the stent configuration, covered or uncovered, the ES procedure for GOO caused by malignancy is considered safe and efficacious.

RECENT SYSTEMATIC REVIEW AND COMPARATIVE RESEARCH OF TREATMENTS FOR GOO THAT RESULTS FROM GASTRIC CANCER

Two systematic reviews

Two systematic reviews and a meta-analysis that compared GJ and ES have been published since 2010. In review 1 in 2010, Ly *et al.*^[27] performed a comprehensive search of the literature for the period from 1990 to 2008 using Medline, EMBASE, Google Scholar, ISI Proceedings, the Cochrane Library, and online registers of CCTs but not PubMed. This review included only clinical studies that directly compared GJ and ES for the palliative treatment of GOO, which included randomized clinical trials (RCTs) and prospective and retrospective cohort comparison studies. Thirteen studies were analyzed, including 10 retrospective cohort comparison studies^[1,26,39-46], 1 prospective study^[41], and 2 RCTs^[25,47]. In review 2 in

Table 1 Characteristics and main results of two reviews

Review	Year	Study type			Primary tumor			Procedure		Favorable group regarding several variables			
		Retro	Pro	RCT	Stomach	Pancreas	Others	GJ	ES	Toleration of oral intake ¹	Time to oral intake ² (d)	Hospital stay ³ (d)	Complication
1	2010	10	1	2	94 (18.3%)	240 (46.7%)	180 (35.0%)	255 (LGJ 37)	244	ES	ES (2.0 d)	ES (9.4 d)	GJ is approximately equal to ES
2	2012	0	3	3	55 (28.6%)	86 (44.8%)	51 (26.6%)	92 (LGJ 0)	74	GJ (not-RCT)	ES (2.1-5.0 d)	ES (2.5-7.0 d)	Major: GJ is approximately equal to ES Minor: ES

¹Patients were more likely to tolerate oral intake following ES than GJ in Review 1; however, Review 2 reported the opposite results. The difference was only significant in the non-RCT group; ²The mean time from the procedure to initiate oral intake was 7 d (Review 1) and 3.6 d (Review 2) less for ES compared with GJ; ³The mean length of hospital stay was reduced by 12 d (Review 1) and 7.5 d (Review 2) for ES compared with GJ. Retro: Retrospective; Pro: Prospective; RCT: Randomized controlled trial; GJ: Gastrojejunostomy; ES: Endoscopic stenting; LGJ: Laparoscopic GJ.

2012, Zheng *et al.*^[48] searched the PubMed, Embase, Chinese Biomedical Database, and Cochrane Library for all studies between 1996 and 2010. The inclusion criteria were as follows: controlled clinical trials (CCTs) and RCTs; analyses of “both” GJ (OGJ and LGJ) and ES; any sample size; full paper; and not a duplicate report. Six studies remained in the final analysis, including three RCTs^[25,47,49] and three CCTs^[41,50,51]. Both reviews included the same two studies. One study was a RCT reported by Mehta *et al.*^[25] in 2006, and the other study was a CCT reported by Johnsson *et al.*^[41] in 2004.

Table 1 provides the characteristics of the comparative data and main results for GJ and ES in the two reviews with regard to the study type, primary tumor site, number of procedures, and favorable procedure group with better results regarding: (1) the number of patients who tolerated oral intake; (2) time to oral intake (days); (3) length of hospital stay (days); and (4) complications. Ninety-four (18.2%) of 514 patients and 55 (28.6%) of 192 patients with GOO that resulted from “gastric cancer” were included. Technical success was only documented in Review 2, and GJ exhibited greater technical success than ES [odds ratio (OR) = 0.10, 95%CI: 0.02-0.47, $I^2 = 0\%$, $P = 0.0039$] according to a meta-analysis. However, the significant difference remained only in the non-RCT group. Nevertheless, both GJ and ES demonstrated satisfactory results regarding technical success (success rates of 99% to 100% and 8% to 100%, respectively). The ability to tolerate oral intake after palliative treatments for GOO is one of the most important endpoints and was documented as a “clinical success” in Review 2. With regard to the ability to tolerate oral intake, 11 studies included in Review 1 reported more favorable results following ES compared with GJ. Although no significant difference was identified in the two studies included in Review 2, one study reported that ES was associated with greater clinical success than GJ ($P = 0.007$). Regarding the time to oral intake after the palliative procedure, all reported

data in both reviews indicated that ES had clear merits compared with GJ. The average time from the procedure to the initiation of oral intake was approximately 3 d less for ES compared with GJ. Several studies have evaluated the length of hospital stay and medical costs. All studies reported a significantly reduced hospital stay for patients who underwent ES compared with GJ (mean difference of 12 d). One RCT and one CCT demonstrated reduced total medical costs and hospital stay costs with ES compared with GJ. In summary, approximately all studies indicated that ES has advantages compared with GJ. However, cost should not be the main factor in decisions regarding procedures for malignant GOO patients because the costs per day for patients who consumed at least a soft diet were quite similar between both procedures. Better long-term clinical outcomes after GJ compared with ES were noted in the major prospective randomized SUSTENT study, which was included in Review 2^[52].

Both reviews indicated that there are no significant differences in the major complication rates between GJ and ES (OR = 1.04, 95%CI: 0.47-2.29, $P = 0.93$ according to meta-analysis data in Review 1; OR = 3.76, 95%CI: 0.57-24.72, $P = 0.17$ in Review 2). The detailed major medical complications that result from GJ were reported as respiratory tract infections, myocardial infarction, and acute renal failure, whereas the complications of ES were procedure-related, including stent failure migration and obstruction. Although minor complications were described only in Review 2, they were less likely the result of ES compared with GJ (OR = 0.28, 95%CI: 0.10-0.83, $P = 0.02$). Regarding morality, both reviews indicated similar conclusions indicating no differences between the two treatments (OR = 0.58, 95%CI: 0.18-1.86, $P = 0.36$).

The length of survival was estimated in both reviews. Despite the inclusion of both randomized and non-RCT, no significant difference was identified between GJ and ES (mean difference 26 d; 95%CI: 69.03-16.40 d, $P = 0.23$ in Review 1).

Table 2 Patient demographics and main results in two reviews

Ref.	Study type	Procedure		Performance status		Comparison between GJ and ES regarding several variables

DISCUSSION

Comparative studies between GJ and ES for malignant GOO that results from gastric cancer

One non-randomized prospective study^[53] and two retrospective studies^[54,55] are available regarding malignant GOO caused by limited unresectable or metastatic gastric cancer. Table 2 provides patient demographics and the main results of three studies with regard to study type, number of procedures, PS, and the favorable procedure group with better results regarding: (1) the number of patients who tolerated oral intake; (2) time to oral intake (d); (3) length of hospital stay (d); and (4) complications.

In a prospective study of 18 patients (9 OGJ and 9 ES treatment)^[53], ES had more favorable results regarding the mean time to resume oral feeding (3.1 d) and mean length of hospital stay (4.8 d) compared with GJ (6.3 d and 10 d, respectively). Regarding the late results, such as the recurrence of GOO, late complications due to the procedure, overall survival, and patient satisfaction, no significant differences were identified between OGJ and ES. Recurrent symptoms of GOO were evident only in ES ($n = 3$ patients, 33%) due to stent migration and obstruction of the stent by food. Both procedures resulted in sufficient patient satisfaction.

In their retrospective study, No *et al*^[54] concluded that GJ is preferable to ES for the palliation of GOO that results from gastric cancer in patients with a good PS, especially Eastern Cooperative Oncology Group (ECOG) 0 to 1. In this study, 72 ES and 41 GJ (32 OGJ and 9 LGJ) patients were compared regarding patient demographics, early outcomes and adverse events, late adverse events, patency duration, and survival. The two groups did not differ in most characteristics with the exception of sex (more men in the GJ group). The technical success rates in both groups were excellent (ES: 95.8% vs GJ: 97.6%); however, three technical

failures were noted in the ES group. However, the time to oral intake was significantly less in the ES group compared with the GJ group (liquid diet: ES 2 d vs GJ 5 d, solid diet: ES 10 d vs GJ 16 d). Regarding adverse events, a higher rate of late adverse events was identified in the ES group compared with the GJ group (44.4% vs 12.2%, $P < 0.01$), whereas early adverse events were not significantly different between the two groups. The adverse events in the ES group were not significantly different according to the stent type ($P = 0.158$). Similarly, the number of re-interventions was significantly greater in the ES group compared with the GJ group (31 (43%) vs 4 (5.5%)), respectively, $P < 0.001$. Regarding the patency duration, the median duration of both the first stent patency and total stent patency, including the patency achieved by an additional stent, was 210 d shorter in the ES group compared with the GJ group ($P = 0.001$, $P = 0.044$, respectively). The interesting finding in this previous study was the analysis according to PS (ECOG status). Patients in the GJ group exhibited significantly longer overall survival compared with the ES group, but only for ECOG 0 to 1.

Keränen *et al*^[55] compared three palliative methods, including 50 ES, 26 palliative resections of the stomach (PR), and 21 GJ. All palliative surgeries were performed with laparotomy. Patients with ES presented with the poorest general condition among all groups in terms of the pre-procedure albumin level, PS, and amount of oral intake; thus, the ES group exhibited the worst survival. The main results regarding the palliation of GOO symptoms demonstrated that ES resulted in a faster improvement of oral intake, relief of GOO symptoms, and reduced hospital stay compared with GJ. The authors advocated considering how the clinical condition before treatment affects survival in malignant GOO that results from gastric cancer when determining the type of palliative procedures. Furthermore, the authors indicated that the study had several limitations. The study was non-randomized, retrospective, and

had a certain degree of defective follow-up data, which led to selection bias between the treatment groups. However, this retrospective study reported the time between ES treatment and re-obstruction; however, this information was described only in context, not in tables or figures. The median time to re-obstruction after ES was 95 d; thus, most patients had died before re-obstruction occurred. Therefore, re-obstruction of the stent is not a major problem for patients with a poor prognosis (< 3 mo), even in patients with gastric cancer and particularly in patients with pancreatic cancer or other malignancies with a worse prognosis.

In summary, the main findings of comparative studies between GJ and ES that focused on gastric cancer patients were similar to the findings of other RCTs, CCTs, and retrospective studies of patients with GOO that resulted from malignancies other than gastric carcinoma. In addition, no articles have referred to precise cost performance or compared LGJ and ES. Compared with GJ, ES is preferred for the rapid improvement of oral intake, relief of GOO symptoms, and reduced hospital stay, whereas the occurrence of late complications, such as stent obstruction or migration, is higher. The differences compared with other malignant GOOs are patient survival after GJ or ES and patient PS. The median survival durations in these three articles were 283, 189 to 293, and 50 to 241 d. Thus, the potential survival of GOO patients with gastric cancer may be increased by approximately 2 or 3 mo. Because several studies have reported that GJ is preferable for patients with a longer life expectancy^[49], GJ should be selected more frequently in clinical practice for good PS patients with GOO that results from gastric cancer.

CONCLUSION

Both GJ and ES are effective treatments in patients with GOO that results from gastric cancer. GJ exhibits better long-term outcomes with regard to fewer late complications and long patency, whereas ES exhibits better short-term outcomes, including the length of the hospital stay. Although no large-scale studies or RCTs have compared the safety and efficacy of the two procedures, literature reviews suggest that GJ may be the preferable procedure because of the good PS and long prognosis of gastric cancer patients.

However, the bypass procedure is currently performed laparoscopically (LGJ), and various novel devices in the ES field can minimize stent obstruction or migration. Therefore, to determine the more preferable procedure in patients with GOO that results from gastric cancer, a prospective RCT of LGJ and ES with current devices specialized for gastric cancer patients is warranted.

Abstract

Endoscopic submucosal dissection (ESD) is a widely

used procedure as curative treatment for superficial gastric neoplasms, including early gastric cancer without lymph node metastasis. However, ESD requires advanced endoscopic skill and there is a major concern regarding complications from bleeding. So far, extensive efforts have been made to develop strategies to reduce post-ESD bleeding. Use of proton pump inhibitors and coagulating exposed vessels on the ulcer floor after ESD are strategies known to reduce the risk of delayed bleeding. Second-look endoscopy (SLE) is also carried out to reduce delayed bleeding following ESD in many institutions. However, the incidence of bleeding still remains around 5%, and further measures are needed to reduce delayed bleeding after gastric ESD. Recently, three randomized studies indicated that routine SLE was unnecessary. Although routine SLE may not be recommended for all patients after gastric ESD, SLE might be an important tool for the prevention of the delayed bleeding in selected high-risk patients. Thus, the identification of the risk factors, such as large size of resected specimen and treatment with multiple antiplatelet medications, may help to further guide clinicians in deciding whether to perform SLE. Studies carried out on larger cohorts are necessary to clarify the efficacy of SLE after ESD in the prevention of post-ESD bleeding in potentially high-risk patients.

Key words: Endoscopic submucosal dissection; Second-look endoscopy; Early gastric cancer

Core tip: Second-look endoscopy (SLE) for selected patients might be an important tool for the prevention of delayed bleeding following endoscopic submucosal dissection (ESD). Risk factors for bleeding after ESD include large size of resected specimen and use of multiple antiplatelet agents. In addition, submucosal fibrosis and nausea might be risk factors associated with high-risk ulcer stigmata. Such risk factors require further evaluation as to whether SLE is indicated.

INTRODUCTION

In recent years, endoscopic submucosal dissection (ESD) for superficial gastric epithelial neoplasms including early gastric cancer has been commonly used in clinical practice in Asian countries. While a snare is used in conventional endoscopic mucosal resection (EMR), various types of endoscopic surgical knives are used in ESD for the purpose of mucosal incision and submucosal dissection. Therefore, this technique enables higher en bloc resection and histologic complete resection rates in patients with larger or ulcerated tumors^[1,2]. However, with ESD, concerns still exist regarding technical difficulties and a higher risk of complications, especially bleeding and perforation^[1,2]. Immediate intraoperative bleeding is easily recognized at the time of the procedure and can be treated endoscopically in most cases. However, delayed bleeding, manifesting as hematemesis or melena, may occur days after the procedure, occasionally even after discharge from hospital. The reported incidence of delayed bleeding after gastric ESD varies from 5.4% to 22%^[3-9]. As any delay in the recognition of such an event may result in serious cardiovascular complications, such as hypovolemic shock, prevention of delayed bleeding is an important clinical problem following ESD to address.

ESD causes large artificial ulcers, but there is no consensus regarding second-look endoscopy (SLE), and when or whether the procedure should be used. Although recent randomized studies demonstrated no benefit for the use of SLE in the prevention of post-ESD bleeding, a multicenter survey of patient management following gastric ESD demonstrated that SLE was utilized by most institutions^[9]. In the present review article, the optimal perioperative management to reduce bleeding following ESD, including SLE, and the high-risk patients SLE will benefit most will be discussed.

SLE after endoscopic submucosal dissection

Delayed bleeding still occurs in approximately 5% of patients who have undergone gastric ESD, despite proton pump inhibitor (PPI) neutralization of intragastric acidity and endoscopic hemostasis through prophylactic coagulation of visible vessels at the ulcer base^[3,5,10-12]. SLE is generally defined as repeat endoscopy within 24 h after the initial endoscopy and hemostatic therapy. For the management of peptic ulcer bleeding, routine SLE is not recommended following successful endoscopic hemostasis. Repeat endoscopy should be performed

on patients with clinical evidence of recurrent bleeding. Hemostatic therapy should furthermore be applied to patients with higher risk stigmata of hemorrhage^[13]. For the perioperative management of post-ESD bleeding, the benefit of SLE remains controversial. However, routine SLE continues to be performed in many medical centers which have inpatients-based ESD treatment setting, probably because the delayed bleeding rate overall remains at approximately 5%^[9]. If high-risk ulcer stigmata after ESD are treated only using PPI without endoscopic therapy, the bleeding risk might be higher, and more serious complication may develop following discharge. Recently, the efficacy of SLE for ESD induced ulcers was evaluated in several retrospective studies and three prospective randomized trials^[8,14-17] (Table 1). The results indicated that the incidence of post-ESD bleeding was not significantly affected by SLE. However, three prospective studies had several limitations that should be taken into account. Ryu *et al*^[17] reported that 12 patients (16.2%) in the SLE group and 9 (11.1%) in the no SLE group experienced bleeding after ESD ($P = 0.66$). The delayed bleeding was defined as the presence of any symptoms or signs of bleeding such as melena or hematemesis from 2 to 28 d. This definition can include the past bleeding episode and other site bleeding, therefore, it may be the reason of higher incidence of bleeding than other studies. The number of enrolled patients was smaller than the calculated sample size, it might be under powered to assess their statistics between two groups. Kim *et al*^[15] demonstrated that delayed bleeding occurred in 8 lesions (3.6%) receiving a SLE and 6 (2.8%) not receiving a SLE ($P = 0.79$). Delayed bleeding was defined as bleeding at 3 to 56 d requiring emergency hemostasis for bleeding on artificial ulcer sites because of hematemesis, melena, hematochezia. The sample sized was not calculated statistically in this study. Mochizuki *et al*^[8] reported that post-ESD bleeding occurred in 7 patients (5.4%) with SLE and five patients with (3.8%) non-SLE (95%CI: -6.7-3.5); meeting the non-inferiority criterion (7%). Delayed bleeding was defined as hemorrhage confirmed by emergency endoscopy from the time of the completion of ESD to 28 d and showed clinical symptoms including hematemesis, melena or a decrease in hemoglobin of > 2 g/dL. The sample sized was adequately calculated for the assessment of non-inferiority of the non-SLE compared with the SLE. The limitation of three randomized controlled trial (RCT) was different definitions of delayed bleeding used. In addition, the patients taking antiplatelet or anticoagulant drug during the perioperative period were excluded in all three RCT. Is it possible to conclude that the SLE is no longer necessary following gastric ESD? Unfortunately the results remain inconclusive, as the studies so far have been performed only on relatively small cohorts.

Most delayed bleeding events have been shown to occur within the first 24 to 48 h, but remained a possibility for up to 2 wk following ESD. In many institutions, SLE was routinely carried out within 1-2 d

Table 1 Influence of second-look endoscopy on the incidence of bleeding following endoscopic submucosal dissection

Ref.	Year	n	Study design	Bleeding: SLE vs no SLE (%)	Risk factors for delayed bleeding	SLE benefit
Ryu <i>et al</i> ^[17]	2013	182	Prospective, single center	16.2% vs 11.1%	No risk factors	No
Mochizuki <i>et al</i> ^[8]	2014	262	Prospective, Multicenter center	5.4% vs 3.8%	Resected specimen size > 40 mm	No
Kim <i>et al</i> ^[16]	2014	437	Prospective, single center	3.6% vs 2.8%	Large tumor size (> 20 mm)	No
Park <i>et al</i> ^[14]	2015	445	Retrospective	3.0% vs 2.0%	Tumor in the upper-third of the stomach, resected specimen size > 40 mm	No
Kim <i>et al</i> ^[15]	2015	502	Retrospective	1.0% vs 2.5%	Large tumor size (> 15 mm)	No

SLE: Second-look endoscopy.

following ESD as a precaution against the more serious clinical outcomes for delayed bleeding^[9]. The potential advantage of routine SLE is that the procedure can be used to evaluate the status of healing ulcers and to perform additional hemostasis if necessary. However, there are arguments concerning the cost/benefit of SLE for ESD ulcers as well as peptic ulcers. If a subgroup of patients at high risk for recurrent bleeding following ESD could be identified, this group potentially could derive benefit from SLE. Risk factors leading to postoperative bleeding remain controversial however because the perioperative management of gastric ESD has not been standardized. Although several factors are reported to be associated with an increased risk of delayed bleeding after ESD, none have been identified that reliably detect a high-risk population. It is therefore possible that risk factors for bleeding following ESD originate from technical parameters which are more difficult to assess objectively.

Role of proton-pump inhibitors in the prevention of bleeding events

Intraoperative bleeding is an unavoidable consequence during mucosal incision or submucosal dissections. Thus, most endoscopist never consider intraoperative bleeding as a complication except in cases requiring emergency surgery or blood transfusion, or in cases where ESD is discontinued because of bleeding^[18].

One strategy to control bleeding is to regulate intra-gastric acidity, as intragastric pH above 5.4 facilitates blood coagulation and platelet aggregation^[19]. In order to achieve this pH level, PPI is more effective than of H2RA. Previous meta-analysis result compared with PPI vs H2RA for the management of iatrogenic gastric ulcer after EMR or ESD showed that PPIs are more effective than H2RA^[20]. Therefore, PPI infusion therapy is routinely used to prevent bleeding and promote ulcer healing following ESD in most institutions. But, recent randomized controlled studies showed conflicting results that H2RA was comparable healing rate and delayed bleeding rate^[21-25].

Pre-endoscopic intravenous PPI therapy in peptic ulcer bleeding, which inhibits production of gastric

acid, significantly reduces the incidence of bleeding at higher risk stigmata of hemorrhage, such as active bleeding, non-bleeding visible vessels, and adherent clots^[26]. However, the effectiveness of preoperative administration of PPI in the management of artificial ulcers following ESD remains unclear. As raising intra-gastric pH preoperatively may lead to easy and complete endoscopic hemostasis during ESD and increases blood coagulation of iatrogenic ulcers, a randomized study has been conducted to determine the effectiveness of preoperative administration of a PPI for the prevention of bleeding. A trial of 24-h pre-administration of omeprazole increased intra-gastric pH at the time of ESD^[27]. However, results demonstrated no additional benefit of a higher intra-gastric pH in the prevention of bleeding, including intraoperative and post-operative delayed bleeding following the procedure.

Because intraoperative bleeding is generally characterized as spurting or oozing, a high intra-gastric pH might not be an effective preventive measure against intraoperative bleeding. In our opinion, the occurrence of intraoperative bleeding may be related not only to measurable risk factors, such as size of resected specimen and location, but also to unquantifiable technical factors, such as electrosurgical unit settings, the type of electrosurgical knife, injection solutions, and experience of the operator^[18,28]. Furthermore, this study was complicated by the fact that all patients in the study groups had been administered a regular dose of PPI for 4 wk. Thus, short course pre-operative administration of PPI might not be sufficient to produce a difference in the incidence of delayed bleeding events.

Prophylactic coagulation of visible vessel at the ulcer base following ESD

Recent guidelines for the management of peptic ulcer bleeding suggest that endoscopic therapy should be provided to patients with a non-bleeding visible vessel^[13,29]. In addition, endoscopic therapy may be considered for patients with an adherent clot resistant to vigorous irrigation. Furthermore, the benefit of endoscopy may be greater for patients with clinical features associated with a higher risk of rebleeding,

Table 2 Incidence of delayed bleeding and associated risk factors after gastric endoscopic submucosal dissection

Ref.	Year	n	Study design	Bleeding (%)	Risk factors	Remarks
Takizawa <i>et al</i> ^[5]	2008	968	Retrospective	5.8% (7.1% vs 3.1% with PEC)	Tumor location in middle and lower regions of the stomach, PEC	PEC of visible vessels in the resected area following ESD may lead to a decreased bleeding rate
Chung <i>et al</i> ^[30]	2009	952	Retrospective	15.60%	Upper region, size of the tumor (> 40 mm), recurrent lesion, flat morphology	A significant bleeding incidence was at 0.6%
Okada <i>et al</i> ^[10]	2011	582	Retrospective	4.81%	Resected specimen width (≥ 40 mm)	Mechanism of delayed bleeding may differ depending on the time elapsed between ESD and bleeding episodes
Toyokawa <i>et al</i> ^[11]	2012	1123	Retrospective	5.00%	Age ≥ 80 yr, extended duration of procedure	-
Goto <i>et al</i> ^[9]	2012	1814	Retrospective	5.50%	No statistical parameters	Multicenter survey clarified that post-ESD management (duration of PPI use, resumption of food intake, and performance of SLE) varied among the medical centers
Koh <i>et al</i> ^[12]	2013	1032	Retrospective	5.30%	Size of resected specimen	The incidence of delayed bleeding in patients with two risk factors was 11.6%
Choi <i>et al</i> ^[3]	2014	614	Prospective observation	Early (3.7%) Late (1.9%)	(> 40 mm), use of antithrombotic drugs (only for delay bleeding) Surface erosion, high risk of stigmata during SLE, location in the middle of the stomach	Nausea and submucosal fibrosis increase the incidence of high risk of stigmata in SLE

PEC: Post-endoscopic submucosal dissection coagulation; ESD: Endoscopic submucosal dissection; PPI: Proton pump inhibitor; SLE: Second-look endoscopy.

such as older age, concurrent illness, and inpatient status at occurrence^[13]. For the management of artificial ulcers generated during ESD, prophylactic coagulation of exposed visible vessels at the base of a mucosal defect following ESD was shown to lead to a reduction in the incidence of bleeding (7.1% vs 3.1%; $P < 0.01$)^[5]. Routine coagulation of all non-bleeding visible vessels at the ulcer base is thus performed as standard practice. However, both prophylactic coagulation of all visible vessels at the ulcer bed and administration of PPIs do not completely eliminate the possibility of delayed bleeding (Table 2).

Patient-related risk factors associated with delayed bleeding

Most studies reported large resected specimen size to be an independent risk factor for delayed bleeding^[10,12,30] (Table 2). Theoretically, a large lesion has a more expansive vascular network than a small lesion, which enhances the possibility of bleeding during and following ESD.

Still, risks of lesion location were variable. Intraoperative bleeding risk was reported to be higher in the upper region than in the middle and lower regions of the stomach. Arteries in the submucosal layer of the upper stomach are significantly thicker or more stubby than in other gastric sites, and the diameter of

submucosal arteries is larger in the upper area than in the middle or lower stomach^[5]. Therefore, the risk of intraoperative bleeding is greater in the upper stomach, and intraoperative hemostasis is more frequently necessary during removal of a lesion in this region. In contrast, a delayed bleeding risk was reported to be greater in the lower region of the stomach^[5]. In other words, while intraoperative hemostasis is less frequently necessary in the middle and lower gastric regions, bleeding may still occur here later if vessels in these areas are not coagulated at the time of procedure. The occurrence of delayed bleeding might not have been due to insufficient hemostasis, but rather to insufficient coagulation during resection, because the sites where delayed bleeding occurred were different than those where immediate bleeding has been controlled endoscopically^[31]. Antral peristaltic activity and bile juice reflux might also contribute to some degree.

The Forrest classification provides prognostic information regarding the risk of rebleeding, and the need for therapeutic intervention in ulcer disease. Endoscopic therapy is indicated for patients with high-risk ulcer stigmata (Forrest type I and IIa). For this reason, additional hemostasis for high-risk ulcer stigmata may decrease the chance of further bleeding and/or emergency intervention. In a prospective observation study, submucosal fibrosis [odds ratios (OR) = 3.91;

Table 3 Antiplatelet medication and the risk of delayed bleeding

Ref.	Year	<i>n</i>	Design	Method	Comparison of bleeding incidence	Comments
Lim <i>et al</i> ^[32]	2012	1591	Retrospective	ESD	No antiplatelet medication: 5.2% Antiplatelet withdrawal: 5.9% Antiplatelet continuation: 11.6%	Continuous administration of antiplatelet medication was not found to have an independent significant association with bleeding
Cho <i>et al</i> ^[33]	2012	514	Retrospective	ESD	No aspirin medication: 3.4% Aspirin withdrawal: 3.6% Aspirin continuation: 21.1%	Continuous aspirin use increases the risk of bleeding after gastric ESD
Sanomura <i>et al</i> ^[35]	2014	94	Retrospective	ESD	Aspirin interruption: 7.1% Aspirin continuation: 4.8%	Continued use of aspirin does not increase the risk of bleeding during or after ESD
Tounou <i>et al</i> ^[34]	2015	377	Retrospective	ESD	No aspirin medication: 6.1% Aspirin continuation: 14.4% Single antiplatelet: 15.5% Dual antiplatelet: 35.5%	Aspirin was not a significant risk factor for post-ESD bleeding
Ono <i>et al</i> ^[36]	2015	28	Prospective, observational	ESD/EMR	The study was terminated in accordance with predetermined safety criteria because 7 of 28 consecutive patients experienced major bleeding complications (25.0%)	Subanalysis of gastric ESD (23 lesions in 19 patients) confirmed that the administration of thienopyridine derivatives ($P = 0.01$) and multiple agents ($P = 0.02$) were the significant factors Continuation of aspirin alone during these endoscopic procedures may be acceptable

ESD: Endoscopic submucosal dissection; EMR: Endoscopic mucosal resection.

95%CI: 1.92-7.94] and nausea after ESD (OR = 4.76; 95%CI: 2.39-9.43) were risk factors significantly associated with high-risk ulcers^[3]. To resect submucosal fibrosis, deeper submucosal dissection is generally necessary, but superficial proper muscle damage might occur. Such manipulation of the tissue might lead to the development of ulcers with a high-risk of bleeding. Furthermore, the lesions with more submucosal vessels may require more frequent coagulation during ESD. This treatment may result in coagulation-induced gastric edema and a more intense inflammatory response, which will cause nausea. A significant amount of blood from an artificial ulcer can also induce nausea. In fact, despite additive coagulation in patients with high-risk ulcer stigmata, the rebleeding incidence on SLE was 8.6% relative to patients with low-risk stigmata. A potential explanation is that ulcers at high risk for bleeding tend to also be rich in vascularity.

Drug-related risk factors for delayed bleeding

An increasing number of patients are taking multiple antiplatelet medications or antithrombotic drugs as the incidence of cardiovascular disease rises. Antiplatelet or antithrombotic medications to prevent cardiovascular events in patients present an additional concern, as ESD is a procedure with high risk of bleeding. Most endoscopists prefer to interrupt the use of antiplatelet or antithrombotic drugs for as long as possible. In one retrospective observational study, continuous administration of antiplatelet medication was not found to be a significantly associated with bleeding^[32] (OR = 1.596; 95%CI: 0.877-2.903; $P = 0.126$), whereas in another retrospective study, the use of aspirin by itself was associated with post-ESD bleeding^[33] (OR = 4.49; 95%CI: 1.09-18.38). In the latter, the resumption

specifically of clopidogrel combined with aspirin use (OR = 26.71; 95%CI: 7.09-100.53) was significantly associated with post-ESD bleeding. In recent two retrospective studies to evaluate the hemorrhagic risk of ESD in patients on antiplatelet drug, Tounou *et al*^[34] demonstrated that dual antiplatelet therapy markedly increased the risk for bleeding (HR = 16.3; 95%CI: 3.4-78.2), but continuous low dose aspirin does not. Sanomura *et al*^[35] also reported that continued use of low dose aspirin does not increased the risk of bleeding during or after ESD. In a recent prospective study, subanalysis of gastric ESD showed that administration of thienopyridine derivatives ($P = 0.01$) and multiple antiplatelet agents ($P = 0.02$) were significant contributing factors to bleeding^[36] (Table 3), but the continuation of aspirin alone appeared to be acceptable.

In general, post-ESD bleeding in patients taking aspirin can be managed effectively without increasing long-term morbidity or mortality. However, cerebral infarction upon discontinuation of aspirin intake is a critical complication. Therefore, ASGE and ESGE and JGES guideline recommend low dose aspirin should be continued for endoscopic treatment with high bleeding risk when the risk of thromboembolism is high^[37-39]. Taken together, the results indicate that if a patient has a low risk for a thromboembolic event, aspirin use should be ceased. However, if a patient has a high risk for thromboembolism, aspirin may be continued as a thromboembolic event could otherwise result in more serious consequences affecting quality of life.

CONCLUSION

Bleeding is a major potential complication both during and post-ESD. Decreased incidence of delayed bleeding

is associated with the use of anti-secretory agents, especially PPI, and prophylactic coagulation of visible vessels at the ulcer base following ESD. However, despite these therapeutic interventions, delayed bleeding still occurs in approximately 5% of patients who undergo gastric ESD. To date, SLE after ESD has been a common therapeutic strategy in order to avoid a bleeding event. The results of recent randomized studies however were unfavorable for routine SLE after gastric ESD. Although routine SLE for all patients after gastric ESD might be unnecessary, SLE may be an important tool in the treatment of a subgroup of patients at risk for bleeding or high-risk ulcer stigmata. Well-known potential risk factors of delayed bleeding are large size of resected specimen and treatment with multiple antiplatelet agents. Submucosal fibrosis and nausea after ESD might be associated with high-risk ulcer stigmata. Thus, these factors can be considered as indications for the use of SLE following ESD. To establish the optimal perioperative strategies for safe ESD, well-designed prospective studies should be conducted in the future to more clearly identify at risk patients.

Abstract

AIM: To examine the safety of immediate endoscopic sphincterotomy (EST) in patients with acute suppurative cholangitis (ASC) caused by choledocholithiasis, as compared with elective EST.

METHODS: Patients with ASC due to choledocholithiasis were allocated to two groups: Those who underwent EST immediately and those who underwent EBD followed by EST 1 wk later because they were under anticoagulant therapy, had a coagulopathy (international normalized ratio > 1.3, partial thromboplastin time greater than twice that of control), or had a platelet count < 50000 × 10³/μL. One of four trainees [200-400 cases of endoscopic retrograde cholangiopancreatography (ERCP)] supervised by a specialist (> 10000 cases of ERCP) performed the procedures. The success and complication rates associated with EST in each group were examined.

RESULTS: Of the 87 patients with ASC, 59 were in the immediate EST group and 28 in the elective EST group. EST was successful in all patients in both groups. There were no complications associated with EST in either group of patients, although white blood cell count, C-reactive

protein, total bilirubin, and serum concentrations of liver enzymes just before EST were significantly higher in the immediate EST group than in the elective EST group.

CONCLUSION: Immediate EST can be as safe as elective EST for patients with ASC associated with choledocholithiasis provided they are not under anticoagulant therapy, or do not have a coagulopathy or a platelet count $< 50000 \times 10^3/\mu\text{L}$. Moreover, the procedure was safely performed by a trainee under the supervision of an experienced specialist.

Key words: Acute cholangitis; Complications; Endoscopic sphincterotomy

Core tip: Immediate endoscopic sphincterotomy (EST) can be as safe as elective EST for patients with acute suppurative cholangitis associated with choledocholithiasis, because there were no complications associated with EST in either group of patients, although white blood cell count, C-reactive protein, total bilirubin, and serum concentrations of liver enzymes just before EST were significantly higher in the immediate EST group ($n = 59$) than in the elective EST group ($n = 28$). Moreover, the procedure was safely performed by a trainee under the supervision of an experienced specialist.

INTRODUCTION

Acute suppurative cholangitis (ASC) is a life-threatening condition that requires prompt treatment^[1,2]. At present, endoscopic biliary drainage (EBD), including endoscopic nasobiliary drainage (ENBD) and endoscopic retrograde biliary drainage (ERBD), followed by elective endoscopic sphincterotomy (EST) is the established mode of treatment for ASC, with a high success rate and low morbidity and mortality^[3-7]. However, the validity of immediate EST with stone extraction is uncertain.

In the present study, we examined the success and complication rates of immediate EST for patients with ASC associated with bile duct stones and compared them with those of elective EST.

MATERIALS AND METHODS

Patient characteristics

Between January 2009 and February 2013, patients with acute cholangitis, suspected of having ASC due

to choledocholithiasis were enrolled for the present study. The diagnosis of acute cholangitis was based on clinical evidence of both infection (fever, chills, leukocytosis, or abdominal pain) and biliary obstruction (clinical jaundice or hyperbilirubinemia), and patients with any of the following at admission were suspected of having ASC requiring emergency endoscopic retrograde cholangiopancreatography (ERCP): (1) fever (temperature $> 39^\circ\text{C}$); (2) septicemic shock (systolic blood pressure < 90 mmHg); (3) increasing abdominal pain with clinical evidence of peritoneal inflammation (right upper quadrant pain with guarding on palpation); or (4) an impaired level of consciousness on admission. In the present study, ASC was defined based on the evidence of purulent bile. Therefore, patients were included in the current study after bile duct access was gained, the cholangiogram confirmed the presence of bile duct stones, and bile aspiration through the catheter showed the presence of purulent bile on ERCP. Exclusion criteria were prior sphincterotomy, concomitant pancreatic or biliary malignancies, and coexisting intrahepatic stones. Patients who died within 6 h after admission were also excluded.

Patients were allocated to two groups: Immediate EST with stone extraction, and EBD followed by elective EST 1 wk later because they were under anticoagulant therapy, had a coagulopathy (international normalized ratio > 1.3 , partial thromboplastin time greater than twice that of control), or had a platelet count $< 50000 \times 10^3/\mu\text{L}$.

Complete blood count, serum electrolytes, clotting profile, and biochemical tests of liver function were monitored daily. Blood pressure, pulse rate, and body temperature were monitored every 4 h. All patients were administered antibiotics intravenously and underwent abdominal CT before ERCP.

Written informed consent for the procedures and treatment was obtained from patients or their next of kin in accordance with normal clinical practice. This study was approved by the Institutional Review Board of Juntendo University.

Endoscopic procedure

ERCP was performed using a side-viewing duodenoscope (JF-240, JF-260V, TJF-260; Olympus, Tokyo, Japan). Electrocautery was administered using a 120-watt endocut current (ERBE International, Erlangen, Germany). One of four trainees (200-400 cases of ERCP) supervised by a specialist (> 10000 cases of ERCP) performed the procedures. If the trainee could not cannulate the bile duct within 3 min, the specialist did it, and then the trainee was in charge again after deep bile duct cannulation was attained in both groups. All the subjects in the present study started to receive drip infusion of protease inhibitors prior to EST to prevent the occurrence of pancreatitis. Following preparation with pharyngeal anesthesia and intravenous injection of midazolam (0.06 mg/kg), ERCP was performed. After deep cannulation into the bile duct, bile was aspirated to

Figure 1 Patient inclusion flow chart. EBD: Endoscopic biliary drainage; ENBD: Endoscopic nasobiliary drainage; EST: Endoscopic sphincterotomy; ASC: Acute suppurative cholangitis; ERCP: Endoscopic retrograde cholangiopancreatography.

reduce intrabiliary pressure, and low-osmolar nonionic contrast medium was carefully injected to confirm the etiology of cholangitis. After the cholangiogram confirmed the presence of bile duct stones and bile aspiration through the catheter showed the presence of purulent bile, EST or EBD including ENBD and ERBD was performed.

EST was performed with a 30 mm pull-type sphincterotome (Clever Cut 3; KD-V41M, Olympus) under the guidewire. For ENBD, a 6F nasobiliary tube (Gadellus, Tokyo) was inserted in the bile duct. For ERBD, a 7F double pig type plastic endoprosthesis (Wilson-Cook Medical Inc., Winston-Salem, NC) was placed across the papilla. For patients in the immediate EST group, stone removal by retrieval balloon catheter was tried at first ERCP, and EBD (ERBD or ENBD) was performed if the patient had or was suspected of having remnant stones. In the elective EST group, EST was performed 1 wk after EBD for stone removal. After ERCP, all the patients were kept under strict observation.

Procedure-related pancreatitis was defined as abdominal pain, with at least a 3-fold elevation of serum amylase more than 24 h after the procedure. Continuation of preexisting acute pancreatitis was not included as a complication. Hemorrhage was considered clinically significant only if there was clinical evidence of bleeding, such as melena or hematemesis, with an associated decrease of at least 2 g per deciliter of the hemoglobin concentration, or the need for a blood transfusion. Bleeding that was controlled during the procedure without hemodynamic instability or transfusion was not considered a complication^[8].

The clinical characteristics of both groups of patients were compared. The primary endpoints of the study were the success and complication rates of immediate EST compared with elective EST. Secondary endpoints were the period for normalization of body temperature, leukocytosis, and C-reactive protein (CRP) leading to

discharge from hospital in both groups of patients.

Statistical analysis

Statistical analyses were performed using SPSS version 17.0 for Windows. Data are presented as the mean \pm SD and were compared using paired *t*-test. Mann-Whitney *U* test was used for comparing continuous data with skewed distribution in the two groups. A χ^2 test with Yate's correction was used to analyze gender. Statistical significance was defined as a *P*-value < 0.05 (two tailed). The statistical methods of this study were reviewed by Jin Kan Sai from Juntendo University.

RESULTS

A total of 211 patients were hospitalized for acute cholangitis during the study period, and 124 of them underwent emergency ERCP within 24 h after admission. Sixteen patients were excluded because of prior sphincterotomy.

Thus, 88 had bile duct stones associated with the evidence of purulent bile and were diagnosed as having ASC. Among them, 27 had anticoagulant therapy, and 2 had a coagulopathy with a platelet count $< 50000 \times 10^3/\mu\text{L}$; one of these two patients died within 6 h after successful EBD because of uncontrolled sepsis and multi-organ failure and was excluded from the study. Therefore, there were 59 in the immediate EST group and 28 in the elective EST group (Figure 1). Patient characteristics and demographic data of the patients on admission are shown in Table 1. Patients were significantly older and PT (%) was significantly lower in the elective EST group. Peritonism and pre-existing pancreatitis were more frequent in the immediate EST group. All procedures of EBD were successful, but one patient in the elective EST group had pancreatitis associated with EBD. Demographic data of the two groups just before immediate and elective EST (1 wk after EBD) are shown in Table 2. Compared

Table 1 Characteristics of patients undergoing emergency endoscopic retrograde cholangiopancreatography

	Immediate EST group (n = 59)	Elective EST group (n = 28)	P value
Sex (M:F)	31:28	13:15	0.59
Age (mean ± SD, range)	68.76 ± 14.58	78.82 ± 9.07	0.0001

ALP	760.1 ± 404.9	494.5 ± 241.7	< 0.0001

CRP: C-reactive protein; EST: Endoscopic sphincterotomy; WBC: White blood cells; Plt: Blood platelet; T-Bil: Serum total bilirubin; AST: Aspartate aminotransferase; ALT: Glutamic-pyruvic transaminase; ALP: Alkalinephosphatase; γGTP: Serum gamma gamma glutamyl transpeptidase.

with the elective EST group, white blood cell count, CRP, total bilirubin, and serum concentrations of liver enzymes before EST were significantly higher in the immediate EST group, while the platelet count was significantly lower.

All EST procedures were successful, and there were no complications such as pancreatitis, bleeding (hemorrhage), or perforation in the two groups, although trainees achieved deep cannulation of the bile duct in 31 (35.6%) of them. Deterioration of pre-existing pancreatitis and cholangitis as a direct result of ERCP is difficult to assess; however, all indicators, including daily serum levels of amylase, liver enzymes, white blood cell count, and CRP, improved after the procedure (data not shown). In the immediate EST group complete stone extraction was achieved at once in 30.5% (18/59) of the patients while 69.5% (41/59) were suspected of having remnant stones and required EBD. Time for normalization of CRP and discharge was significantly

shorter in patients who underwent immediate EST and the stones were extracted at once, although the period for normalization of body temperature and leukocytosis was not significantly different between the two groups (Table 3).

DISCUSSION

ASC requires early drainage of the biliary system to reduce the incidence of septic complications^[1,2]. The endoscopic techniques used for biliary drainage include EST with stone extraction, and EBD, either ENBD or ERBD. EBD is an established mode of treatment for ASC, with a high success rate and low morbidity and mortality^[3-7]. Lin *et al*^[9] reported a 100% success rate and no mortality with ENBD in 40 patients with acute cholangitis. Leung *et al*^[1] treated 105 patients with acute cholangitis by ERBD, with a success rate of 97% and mortality of 4.7%. EBD can be performed easily, quickly, and safely at the endoscopy, avoiding the risk of bleeding in patients with coagulopathy.

On the other hand, EST with stone extraction is another mode of biliary drainage in ASC with an associated mortality rate of 4.7%-7.6%, although EST related complications, such as bleeding, retroduodenal perforation, and acute pancreatitis, may occur in 6%-12% of cases^[1,10-12]. The complications associated with EST are most undesirable in acutely ill patients. Moreover, EST cannot be performed in patients with coagulopathy. Therefore, most endoscopists currently prefer EBD to EST as the first treatment for ASC.

In the present study, immediate and elective EST was performed by one of four trainees supervised by one experienced specialist, and there were no complications associated with EST in either group. Therefore we think

Table 3 Outcome of patients subjected to endoscopic retrograde cholangiopancreatography

	Elective EST group (n = 28)		P value
Immediate EST group (n = 59)			
Normalization of body temperature	1.37 ± 1.86	1.68 ± 2.83	0.6
Normalization of WBC	2.19 ± 2.87	1.39 ± 1.13	0.06
Normalization of CRP	9.12 ± 7.73	13.75 ± 9.32	0.017
Time to discharge	16.79 ± 11.89	21.75 ± 14.1	0.09
Immediate EST with stone extraction group (n = 18)			
Normalization of body temperature	1.61 ± 0.98	1.68 ± 2.83	0.92
Normalization of WBC	1.78 ± 0.9	1.39 ± 1.13	0.53
Normalization of CRP	7.0 ± 5.7	13.75 ± 9.32	0.008
Time to discharge	13.2 ± 7.5	21.75 ± 14.1	0.02

CRP: C-reactive protein; EST: Endoscopic sphincterotomy; WBC: White blood cells.

that EST can be safely performed in patients with ASC by trainees supported by an experienced specialist, although it is undoubtedly that the frequency of post-EST complications is closely related to endoscopic techniques, case volume, skill, and training^[13]. Furthermore, despite EBD was conducted as the initial treatment in order to perform EST safely in the elective EST group, in the present study, immediate EST did not increase the risk of post-EST complications provided the patient was not under anticoagulant therapy, or do not have a coagulopathy or a platelet count $< 50000 \times 10^3/\mu\text{L}$, despite patients in the immediate EST group were in worse general conditions than those in the elective EST group at the time of EST. The immediate EST group patients were significantly younger and the occurrence of post-EST complication was not significantly higher than that in older patients of the elective EST group, although Ueki *et al*^[7] reported that younger patients with moderate acute cholangitis due to choledocholithiasis were likely to experience post-EST pancreatitis and hemorrhage. However, we do not have a clear explanation as to why no complication associated with EST was encountered in these groups of patients, although we suspect that with a larger sample size, complications would occur.

In this study complete stone extraction was achieved in 30.5% (18/59) of patients in the immediate EST group, and 69.5% (41/59) of them suspected of having remnant stones required EBD. Hui *et al*^[4] reported that when endoscopic sphincterotomy is performed with biliary stent insertion in patients with severe acute cholangitis, the procedure is prolonged and the patient is exposed to the risks associated with endoscopic sphincterotomy. However, immediate EST followed by EBD was not associated with an increased frequency of complications in the present study.

Hospitalization of immediate EST patients with stone extraction at once was significantly shorter than that of elective EST patients, and the validity of immediate EST followed by stone extraction was definitive in this aspect for patients with ASC caused by choledocholithiasis. Our results were in line with those of Jang *et al*^[14] who reported that hospitalization of patients with moderate cholangitis subjected to EBD plus EST as the initial

treatment (emergency EST) was significantly shorter than that of those who palliatively underwent EST after EBD.

The present study has several limitations. First, patients with anticoagulant therapy, coagulopathy, or platelet count $< 50000 \times 10^3/\mu\text{L}$ were included in the EBD group because they were at high risk for post-EST bleeding. This may have resulted in selection bias. Second, time for the procedure, the volume of contrast, and number of injections made into the bile duct were not monitored. Third, in a review by Freeman *et al*^[15], suspected sphincter Oddi dysfunction (SOD), history of post-ERCP pancreatitis (PEP), and absence of chronic pancreatitis on the pancreatogram were identified as independent patient-related risk factors for PEP. Moreover, significant procedure-related risk factors were the number of pancreatic duct injections, and difficult or failed cannulation. And we did not examine those factors in the present study, although it is noteworthy that pancreatography was not intended to be performed in the present study. Fourth, this study was done by very experienced endoscopists, limiting to generalize the trial findings. Finally, the present study was not a randomized study, although such trials would be of great interest.

In conclusion, the present study indicated that immediate EST may be equally safe and effective compared with elective EST, and can be definitive for patients with ASC caused by choledocholithiasis provided they are not under anticoagulant therapy, or do not have a coagulopathy or a platelet count $< 50000 \times 10^3/\mu\text{L}$. Furthermore, EST can be safely performed by a trainee supervised by an experienced specialist even in patients with ASC.

COMMENTS

Background

Acute suppurative cholangitis (ASC) is a life-threatening condition that requires prompt treatment. At present, endoscopic biliary drainage (EBD), including endoscopic nasobiliary drainage and endoscopic retrograde biliary drainage, followed by elective endoscopic sphincterotomy (EST) is the established mode of treatment for ASC, with a high success rate and low morbidity and mortality.

However, the validity of immediate EST with stone extraction is uncertain.

Research frontiers

To examine the safety of immediate EST in patients with ASC caused by choledocholithiasis, as compared with elective EST.

Innovations and breakthroughs

Patients with ASC due to choledocholithiasis were allocated to two groups: Those who underwent EST immediately and those who underwent EBD electively followed by EST 1 wk later. There were no complications associated with EST in either group of patients, although white blood cell count, C-reactive protein, total bilirubin, and serum concentrations of liver enzymes just before EST were significantly higher in the immediate EST group than in the elective EST group.

Applications

The paper may interest readers in particular because immediate EST can be as safe as elective EST for patients with acute suppurative cholangitis associated with choledocholithiasis.

Peer-review

This manuscript "Safety of immediate endoscopic sphincterotomy in acute suppurative cholangitis caused by choledocholithiasis" is very interesting.

Abstract

AIM: To elucidate the safety of percutaneous endoscopic gastrostomy (PEG) under steady pressure automatically controlled endoscopy (SPACE) using carbon dioxide (CO₂).

METHODS: Nine patients underwent PEG with a modified introducer method under conscious sedation. A T-tube was attached to the channel of an endoscope connected to an automatic surgical insufflator. The stomach was inflated under the SPACE system. The intragastric pressure was kept between 4–8 mmHg with a flow of CO₂ at 35 L/min. Median procedure time, intragastric pressure, median systolic blood pressure, partial pressure of CO₂, abdominal girth before and immediately after PEG, and free gas and small intestinal gas on abdominal X-ray before and after PEG were recorded.

RESULTS: PEG was completed under stable pneumostomach in all patients, with a median procedural time of 22 min. Median intragastric pressure was 6.9 mmHg and median arterial CO₂ pressure before and after PEG was 42.1 and 45.5 Torr (NS). The median abdominal girth before and after PEG was 68.1 and 69.6 cm (NS). A mild free gas image after PEG was observed in two patients, and faint abdominal gas in the downstream bowel was documented in two patients.

CONCLUSION: SPACE might enable standardized pneumostomach and modified introducer procedure of PEG.

Key words: Percutaneous endoscopic gastrostomy; Steady pressure automatically controlled endoscopy; Carbon dioxide

Core tip: We report the safety of percutaneous endoscopic gastrostomy (PEG) under steady pressure automatically controlled endoscopy (SPACE) using carbon dioxide (CO₂). Nine patients underwent PEG with a modified introducer method under conscious sedation. The stomach was inflated under the SPACE system. PEG was completed under stable pneumostomach in all patients. Median arterial CO₂ pressure before and after PEG was 42.1 and 45.5 Torr (NS). The median abdominal girth before and after PEG was 68.1 and 69.6 cm (NS). A mild free gas image after PEG was observed in two patients. SPACE might enabled standardized pneumostomach which leads to easier and safer PEG procedures.

Percutaneous endoscopic gastrostomy under steady pressure automatically controlled endoscopy: First clinical series. *World J Gastrointest Endosc* 2016; 8(3): 186–191 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i3/186.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i3.186>

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) has been

widely accepted for external feeding since Gauderer *et al*^[1] first reported it in 1980. A conventional on-demand insufflation using atmospheric air through the endoscope has been a gold standard in performing PEG, not only for optimal visualization but also for maintaining pneumostomach to keep puncture sites on the gastric/abdominal walls stabilized. Abdominal distension and pneumoperitoneum often occur after PEG^[2–7]. Carbon dioxide (CO₂) insufflation has been initially reported for colonoscopic electrosurgical polypectomy in the field of gastrointestinal (GI) endoscopy^[8]. CO₂ is now increasingly being used instead of atmospheric air in GI endoscopic procedures since CO₂ is rapidly absorbed *via* the gut lining. Total colonoscopy^[9–13], endoscopic retrograde cholangiopancreatography^[14–17], peroral cholangioscopy^[18], double-balloon enteroscopy^[19], PEG^[20], gastric and colonic endoscopic submucosal dissection (ESD)^[21–25], and upper GI intragastric endoscopy during laparoscopic surgery under CO₂ insufflation^[26] have been reported to be safe and more comfortable compared with air insufflation.

GI endoscopy has been performed under on-demand insufflation by endoscopists through the endoscope itself in a manual manner without pressure monitoring. This practice has been justified because the gastrointestinal tract allows migration of excessive gas into the upstream/downstream bowel. Excessive air supply may result in gaseous regurgitation, vomiting, and abdominal bloating. Steady pressure automatically controlled endoscopy (SPACE) using CO₂, developed by Nakajima *et al*^[27,28], Kato *et al*^[29] and Yamada *et al*^[30] is expected to improve and standardize endoscopic visualization and working space in the GI lumen. Although SPACE has been reported to shorten procedural time and improve the safety of endoscopic intervention^[28–30], CO₂ narcosis is of concern during PEG under sedation, since patients usually suffer from respiratory disease and/or consciousness disturbance. The SPACE system consists of a standard commercially available endoscope overtube (Top Co., Ltd., Tokyo, Japan) and a newly developed detachable leak-proof device with an anti-reflux valve and a Luer lock connection (Leak Cutter; Top)^[28,29]. A commercially available automatic surgical insufflator is then connected to the system. Esophageal ESD under SPACE has been reported to be feasible and safe^[28,29]. Recently, gastric ESD under SPACE has been also reported to be feasible and safe in an preclinical study^[30].

The aim of this study is to elucidate the safety of PEG under the SPACE system. To our knowledge, this is the first clinical study regarding application of SPACE technology in PEG.

MATERIALS AND METHODS

Ten patients undergoing treatment at our institutions were enrolled in the study. Patients who had CO₂ retention due to chronic obstructive pulmonary dysfunction were excluded. One of the ten enrolled patients was excluded because he withdrew his consent after informed consent

Table 1 Clinical characteristic of patients

Clinical characteristics	Data
Male/female	6/3
Mean age	78 (61-89)
Comorbid disease	
Parkinson's disease	4
Cerebrovascular disease	1
Amyotrophic lateral sclerosis	1
Necrotizing fasciitis	1
Disuse syndrome	1
Laryngeal cancer	1

was obtained. Therefore, a total of nine patients, six males and three females, underwent PEG under SPACE. The mean age of patients was 78 years (ranging from 61 to 89). Four patients had Parkinson's disease, one had cerebrovascular disease, one had amyotrophic lateral sclerosis, one had necrotizing fasciitis, one had disuse syndrome, and one had laryngeal cancer (Table 1).

PEG was performed under conscious sedation using intravenous injection of 35 mg pethidine chloride and 0.1-0.2 mg of flunitrazepam or 1-2 mg of midazolam and oxygen inhalation. A T-tube with two junctions (MD-807, Olympus Medical Systems Co. Ltd., Tokyo, Japan) was connected directly to the channel of the flexible gastroscope (GIF-H260, Olympus Medical Systems Co. Ltd., Tokyo, Japan) (Figure 1). One of the junctions was connected to a commercially available automatic surgical insufflator (UHI-3, Olympus Medical Systems Co. Ltd., Tokyo, Japan) that feeds 35 L of CO₂ per minute into the stomach through the channel (Figure 2). The intragastric pressure was kept between 4-8 mmHg. PEG was performed using a modified introducer procedure and a dedicated kit (Direct Ideal PEG kit, Olympus Medical Systems Co. Ltd., Tokyo, Japan). The gastroscope was inserted from the mouth to the esophagus under conventional manual air insufflation. After insertion into the stomach, conventional manual air insufflation was switched to the SPACE system. First, percutaneous gastropexy was conducted at two sites while the stomach was inflated under the SPACE system through the endoscope channel. Second, after puncture using an indwelling needle was performed between the two gastropexy sites, a guide-wire was replaced with the needle. Third, the PEG site was dilated by the dilator through the guide-wire. When the dilator was withdrawn, the CO₂ supply was temporarily stopped, the PEG tube was inserted through the guide-wire, and the CO₂ supply was restarted and checked to ensure it had been located correctly.

Data such as mean procedure time, intragastric pressure, mean systolic blood pressure, partial pressure of CO₂ (PaCO₂), abdominal circumference before and soon after PEG, and change of free gas and small intestinal gas on abdominal X-ray before and immediately after PEG were obtained and prospectively recorded in the database.

**Figure 1** T-tube attached to the endoscopic channel.**Figure 2** Automatic surgical insufflator connected to the T-tube.

The study protocol was in accordance with the tenets of the revised Declaration of Helsinki (1989) and was approved by the institutional review board at our institutions. Written informed consent was obtained from all the patients.

Statistical analysis

Statistical analysis was performed by Fischer's test using SPSS software, version 17 (SPSS Inc., Chicago, IL). For therapeutic performance, sensitivity, specificity, and accuracy are presented as percentages with 95% CIs. All probability values calculated in this analysis were sided, and $P < 0.05$ was considered significant.

RESULTS

The median procedural time was 22 min (14-38 min) (Table 2). It was possible to maintain a good endoscopic visualization and a sufficient pneumostomach to keep puncture sites stabilized during PEG, which was completed easily in all 9 patients. Visualization after intentional suction was regained more quickly than with conventional endoscopy (Video 1). PEG was established exactly in the scheduled puncture sites. Median intragastric pressure was kept at 6.9 mmHg as preset (5-8 mmHg). Median O₂ inhalation was 1.7 L/min (0-3). Median systolic blood pressure before and immediately after PEG was 129.3 mmHg (101-158 mmHg) and 120.6 mmHg (90-145

Table 2 Results of percutaneous endoscopic gastrostomy under steady pressure automatically controlled endoscopy

Clinical outcomes		P value
Median procedural time (min)	22 (14-38)	
Median intragastric pressure (mmHg)	6.9 (5-8)	
Median systolic pressure		
Before PEG (mmHg)	129.3 (101-158)	0.33
Soon after PEG (mmHg)	120.6 (90-145)	
Median PaCO ₂		
Before PEG (Torr)	42.1 (35.2-45.7)	0.10
Soon after PEG (Torr)	45.5 (41.0-54.6)	
Median abdominal girth		
Before PEG (cm)	68.1 (58-85)	0.38
Soon after PEG (cm)	69.6 (60-86)	
Mild free gas after PEG (n)	2	
Mild increase of small intestinal gas after PEG (n)	2	

PEG: Percutaneous endoscopic gastrostomy.

mmHg). There was no significant difference in these data ($P = 0.33$). Median PaCO₂ before and after PEG was 42.1 Torr (35.2-45.7 Torr) and 45.5 Torr (41.0-54.6 Torr). There was a tendency to an elevated median PaCO₂ after PEG compared with prior values ($P = 0.10$); however no CO₂ narcosis was encountered in the series.

The median abdominal girth before and immediately after PEG was 68.1 cm (58-85 cm) and 69.6 cm (60-86 cm), and there was no significant difference ($P = 0.38$). Mild free gas was observed postoperatively in two patients, and small intestinal gas was slightly increased in two patients (Figure 3). All these were subclinical, and no other serious adverse events were encountered in any patients.

DISCUSSION

Several endoscopic procedures under CO₂ insufflation have been reported to be safe and more comfortable compared with air insufflation because CO₂ is absorbed rapidly *via* the gut lining. CO₂ insufflation during PEG reduces risk of pneumoperitoneum and bloating^[8-25]. Technically, it is a key point to maintain pneumostomach stabilized during PEG so that PEG can be fashioned in the scheduled puncture sites.

In our study, although PaCO₂ was subclinically elevated during and after the procedure, there were no adverse events associated with CO₂ insufflation. The insufflation is mandatory in PEG for maintaining a pneumostomach to keep puncture sites stabilized. Nishiwaki *et al*^[20] reported that PEG under CO₂ insufflation compared with air insufflation was safer and more comfortable because of the lower incidence of pneumoperitoneum, less distension of the small bowel, and no adverse events. Our present data first showed that PEG is safely fashioned under SPACE.

Nakajima *et al*^[27] reported that a steady-pressure pneumostomach was successfully created and maintained for 100 min on average without clamping the

Figure 3 Free air (indicated by arrows) in abdominal X-ray after percutaneous endoscopic gastrostomy under steady pressure automatically controlled endoscopy.

downstream bowel in laparoscopic intragastric surgery (LIGS). The stomach was insufflated with a UHI-3 surgical insufflation unit connected to a transgastric port at an intragastric pressure of 6-8 mmHg. No adverse events were noted during LIGS, and no postoperative abdominal distention was observed. Nakajima *et al*^[28] have also reported esophageal ESD under SPACE using a standard endoscopic overtube and a detachable leak-proof valve with a luer-lock connection in an animal model. Moreover, Kato *et al*^[29] reported on the feasibility and safety of esophageal ESD under SPACE in a clinical study, and Yamada *et al*^[30] reported on the feasibility and safety of gastric ESD under SPACE in an animal model. In SPACE, endoscopic visualization is automatically obtained once the insufflation pressure and flow rate are set. Visualization after suction is automatically regained more quickly than with conventional endoscopy. The flow capacity of current surgical insufflators is higher than that of manual endoscopic insufflators and is considered responsible for the rapid regaining. UHI-3 can supply 35 L of CO₂ per minute and these flow rates are significantly higher than those of actual endoscopic flow with manual CO₂ insufflation (1.4 L/min). The insufflation process is automatic in SPACE. Air/water button manipulation is no longer necessary, leaving the endoscopist free to focus on the intervention itself. SPACE can prevent excessive CO₂ supply, which may result in gaseous regurgitation, vomiting, and abdominal bloating^[30].

In this study, CO₂ was successfully supplied through the endoscopic channel using a T-tube without an overtube. The intragastric pressure was kept from 5 to 8 mmHg throughout the procedure. PEG under SPACE had no negative effects such as vomiting or abdominal bloating and no impact on vital signs. Mild postprocedural free gas was observed in two patients and abdominal gas was slightly increased in another two patients. There were, however, no adverse events in any patients. Even if CO₂ is leaked into the abdominal cavity through the PEG site, CO₂ can be absorbed quickly *via* the peritoneal lining and abdominal distention will be resolved immediately. Nishiwaki *et al*^[20] reported that pneumoperitoneum was

not observed in the CO₂ insufflation group. In our study, pneumoperitoneum might have occurred because of the leakage of remnant air in the stomach. Nishiwaki *et al.*^[20] performed a pull method of the PEG procedure, while in our study, a modified introducer method was performed. After the dilator was withdrawn, the PEG tube was inserted during the modified introducer method, and it was possible that intragastric gas (air) might have leaked into the abdominal cavity at this time. Thus we hypothesized that postprocedural pneumoperitoneum might be caused by the difference of the PEG procedure. Yamada *et al.*^[30] reported the potential safety of pneumoperitoneum under SPACE, because intra-gastric pressure was regulated within the preset pressure range to prevent excessive transmural insufflation. Nakajima *et al.*^[28] have reported that the migration of CO₂ over the proximal jejunum does not occur because of a pinch-cock phenomenon and intestinal surface tension. In this pinch-cock phenomenon, the distended upstream bowel (stomach and duodenum) acts as a cock that compresses the downstream bowel, resulting in the prevention of massive gas migration. The surface tension in the collapsed gut lumen may work as another pressure barrier. The insufflated gas volume was sufficiently low in each SPACE, suggesting no major gas migration into the downstream bowel during SPACE. In fact, CO₂ outflow stopped automatically whenever the stomach was insufflated.

Although conscious sedation is necessary during PEG procedure, most patients who undergo PEG have cerebrovascular diseases and aspiration pneumonia, which means they are at high risk for developing respiratory dysfunction. CO₂ narcosis might develop in patients with chronic pulmonary diseases, so they were excluded from this study. There was a tendency to an elevated PaCO₂ median after PEG compared with before PEG, but CO₂ narcosis did not occur in any cases. This elevation might be caused by PEG under SPACE, but it could also be caused by the administration of sedative drugs that suppress the respiratory function.

There were several limitations in this study. First, as this was a pilot study, the sample size was very small. We need to accumulate more clinical data such as a randomized controlled trial between PEG under conventional manual air or CO₂ insufflation and that under SPACE system in near future. There was a tendency to an elevated median PaCO₂ after PEG compared with previous values, indicating that a randomized controlled trial to compare PEG under SPACE and under manual air insufflation is necessary. We examined PaCO₂ only twice: once before and once after PEG. Ideally we should examine the course of PCO₂ during PEG using the monitor of transcutaneous measurement of PCO₂. Most patients cannot complain of abdominal pain or distention because of comorbid diseases such as cerebrovascular disease, so the complaints of all patients cannot be detected. We have to examine the gas volume in the small intestine and the pneumoperitoneum in the abdominal X-ray and/or CT scan. The channel is free during a modified introducer

procedure of PEG, therefore, the SPACE system is available during PEG procedure. The introduction of snares or forceps through the channel affects the SPACE system.

In conclusion, PEG under SPACE might be feasible and safe. SPACE might enable standardized pneumostomach which leads to easier and safer PEG procedures.

COMMENTS

Background

"On-demand" insufflation using atmospheric air has been a gold standard in performing percutaneous endoscopic gastrostomy (PEG), not only for optimal visualization but also for maintaining pneumostomach to keep puncture sites stabilized. However, excessive air insufflation may result in gaseous regurgitation, vomiting, and abdominal bloating.

Research frontiers

PEG under steady pressure automatically controlled endoscopy (SPACE) using carbon dioxide (CO₂) has not been reported.

Innovations and breakthroughs

PEG under SPACE was feasible and safe.

Applications

SPACE enables standardized pneumostomach which leads to easier and safer PEG procedures.

Peer-review

The authors evaluated the safety of PEG under SPACE using CO₂. PEG was completed under stable pneumostomach in all nine patients. Further clinical trials in a randomized controlled study between PEG under conventional manual air or CO₂ insufflation and that under SPACE system will be necessary.

Abstract

Here we offer a review of the literature regarding endoscopic ultrasound-guided ethanol ablation for pancreatic neuroendocrine tumours and describe the case of a cystic tumour completely ablated after a multisession procedure. A total of 35 PubMed indexed cases of treated functioning and non-functioning pancreatic neuroendocrine tumours resulted from our search, 29 of which are well-documented and summarised. Endoscopic ultrasound-guided ethanol ablation appears as a local, minimally invasive treatment of pancreatic neuroendocrine tumours, suitable for selected patients. This technique appears feasible, relatively safe and efficient, especially when applied to symptom relief in functioning tumours, aiming at loss of endocrine secretion. For non-functioning tumours, where the goal is complete tissue ablation, endoscopic ultrasound-guided ethanol ablation can provide good results for patients who are unfit for surgery or for those who refuse surgical resection. Its role in "fit for surgery" patients requires assessment through further studies.

Key words: Endoscopic ultrasound; Pancreatic neuroendocrine tumour; Endoscopic ultrasound-guided injection; Ethanol; Tumour ablation

Core tip: We report a complete review of the literature about endoscopic ultrasound-guided ethanol ablation for pancreatic neuroendocrine tumours. The case of a cystic tumour completely ablated after a multisession procedure is described. On long term follow-up a durable

remission of the tumour was obtained; a complete image gallery showing the pre and post-treatment appearance is available. The technical aspects, clinical success and complication rates related to this kind of procedures are described.

Endoscopic ultrasound-guided ethanol ablation of pancreatic neuroendocrine tumours: A case study and literature review. *World J Gastrointest Endosc* 2016; 8(3): 192-197 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i3/192.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i3.192>

INTRODUCTION

In recent years the improvement of diagnostic and therapeutic technologies has led to less invasive treatments in any field of medicine with a shift from surgery to imaging guided treatments.

Endoscopic ultrasonography (EUS) has demonstrated excellent diagnostic accuracy for bilio-pancreatic district diseases and high safety and precision when applied for operative purposes. Along the years this peculiarity has made of EUS an optimal technique for imaging and cytological diagnosis, as well as for execution of more advanced procedures (*i.e.*, drainages and local treatments).

The current management of T1 and T2 pancreatic neuroendocrine tumours (pNETs) is somewhat similar to that of most pancreatic tumours (surgical resection), with a considerable economic burden and post-operative complications. However we are dealing with a pathology that offers a better prognosis and that is potentially responsive to local treatments^[1,2].

Neuroendocrine tumours arise from cells present in the diffuse endocrine system and can be found throughout the body. They are most commonly located in the gastrointestinal tract and lung but are also found in the pancreas^[3]. The 2010 World Health Organization (WHO) classification divides the pNETs in three grades (G1, G2 and G3) on the basis of Ki-67 nuclear antigen expression (< 2%; 2%-20% and > 20%) and mitotic rate (< 2; 2-20 and > 20). Biopsy is most commonly used to assess the grade of the tumour. According to the TNM, the tumour is classified as T1a (< 1 cm), T1b (1-2 cm) and T2 (larger than 2 cm); T3 and T4 are locally advanced tumours (Table 1).

Tumour grading and tumour stage are the main prognostic factors of pNETs. Well and moderately differentiated have a significantly better survival compared to poorly differentiated neuroendocrine carcinomas.

pNETs are also classified as functioning and non-functioning depending on the secretion of specific hormones. Functioning tumours are commonly associated with a specific hormonal syndrome directly related to a hormone secreted by the neoplasm such as insulinomas

Table 1 World Health Organization classification of pancreatic neuroendocrine tumors

Grade	Ki-67 index (%)	Mitotic count/10 HPF
G1	≤ 2	< 2
G2	3-20	2-20
G3	> 20	> 20
TNM	Size (cm)	Muscularis propria invasion
T1a	< 1	–
T1b	1-2	–
T2	> 2	+

Accordingly to the WHO classification 2010, the higher grade is assumed if the Ki-67 index and mitotic count differ; in the WHO 2010 TNM, the tumor is classified as T2 if it is larger than 2 cm in diameter or if it invades the muscularis propria. T3 and T4 tumors are locally aggressive tumors. WHO: World Health Organization; HPF: High-power field.

Figure 1 Abdominal magnetic resonance imaging demonstrating a round, well-demarcated nodule of the pancreatic tail. The 22 mm lesion (calipers) shows highly vascularised peripheral tissue.

with hypoglycemia, gastrinomas with Zollinger–Ellison or carcinoid syndrome. Most non-functioning tumours occur in the head of the pancreas and produce mass effect symptoms. When small, they are usually incidentally discovered due to the incremental use of high-level diagnostic imaging.

EUS is the optimal diagnostic modality and can provide a biopsy specimen for histological confirmation and differentiation grade. The EUS image is usually of a solid, ipoechoic, round and smooth nodule, sometimes with a cystic central component (bull's eye appearance).

To date, the management of pancreatic sporadic, small (< 2 cm), asymptomatic, low-grade (G1) NETs suggests a "wait and see" strategy. Surgical resection of non-functioning pNETs is actually recommended for large (> 2 cm) or G2-G3 lesions^[4]. For patients unfit for surgery due to high-risk comorbidity or for those who refuse resection, the EUS-guided ethanol ablation has been reported in a few cases^[5] as a local and minimally invasive therapy.

CASE REPORT

A 58-year-old man with essential hypertension and recent onset of glucose intolerance was referred for a

Figure 2 Endoscopic ultrasound appearances before (A) and after (B) treatment (white arrow).

Figure 3 Computed tomography scan showing thin residual hypervascular tissue (white arrow) two months after the first treatment.

transabdominal ultrasonography (US). Other laboratory test results including levels of carcinoembryonic antigen and carbohydrate antigen were all within normal ranges. The US session diagnosed a focal lesion on the pancreatic tail. An abdominal magnetic resonance image showed a 22 mm nodule with peripheral hypervascularization (Figure 1), and EUS confirmed a “bull’s-eye” appearance nodule with peripheral hypervascular pattern *via* power Doppler and a central cystic component. The EUS-guided FNA of the lesion confirmed the diagnosis of pNET. The Ki67 proliferative index was > 5% to yield a G2 grade. However, because the patient adamantly refused surgical resection, we decided to ablate the lesion *via* EUS-guided ethanol injection.

After aspiration of the cystic component, a mean volume of 1.7 mL of 95% ethanol per session was injected into the tumour and re-aspirated using a 25-gauge needle (Echo-tip ultra, Cook, Limerick, Ireland) through a linear array echoendoscope (Figure 2). Three treatment sessions over six months were performed to ablate the nodule (Figure 3).

The hospitalization time was 2 d for each session. The patient experienced mild pancreatitis in 2 out of 3 sessions - that resolved with standard-of-care. No major or late complications were observed. After 24 mo, we achieved a durable and complete remission of

the tumour as shown by CT and EUS morphological imaging (Figure 4).

DISCUSSION

Most diagnosed pNETs are non-functioning tumours (90.8%); the remaining 9% are malignant functioning tumours such as gastrinomas (4.2%), insulinomas (2.5%), glucagonomas (1.6%), and VIPomas (0.9%). Although commonly perceived to be indolent tumours, they exhibit a broad range of growth rates, malignant potential, and overall prognosis. Most patients with pNETs (60%-70%) present with metastatic disease at diagnosis. Following surgical resection, the 5-year cumulative survival for pNETs other than insulinomas is roughly 65% with a 10-year survival of 45%^[6].

Patients with incidental diagnosis of pNETs with a tumour size < 2 cm and low-grade (G1) dysplasia have a 5-year overall survival of 100% with a minimal risk of recurrence^[6]. In this setting, a “wait and see” policy is recommended.

On the contrary, surgical resection is the standard treatment for functioning and non-functioning G2-G3 pNETs. However, this is associated with a high risk of complications. Even when performed in high-volume centres, typical pancreatic resections (pancreaticoduodenectomy or distal pancreatectomy) have a mortality rate of about 5% with complications ranging from 40% to 50%^[7]. This is particularly common in the elderly or patients with comorbidities. Typical pancreatic resections are also associated with a high incidence of exocrine and endocrine insufficiency.

In an attempt to reduce complications and pancreatic impairment, new parenchyma-sparing resection techniques such as enucleation and middle pancreatectomy (resection of the central part of the gland) have been applied to small tumours^[8]. Although pancreatic head tumour enucleation resulted in decreased operative time and length of hospitalization, the 5-year survival and overall morbidity and mortality were comparable to standard surgical resection even for small pNETs^[9]. To date, no alternative treatment has been standardized for patients unfit for surgery or for those who refuse

Figure 4 Twenty-four months follow-up. A: Computed tomography scan showing absence of hypervascular tissue around a small hypodense area (white arrow); B: Endoscopic ultrasound scan of the pancreatic tail demonstrating poorly defined hyperechoic tissue (fibrosis) with posterior shadow (caliper).

Figure 5 Reported endoscopic ultrasound-guided ethanol ablation procedures over time. Literature review showed a progressive increase of performed procedures from 2006 to 2015. Cases described in abstract form by Paik *et al.*^[20] were not included in the final results analysis.

resection.

In the recent decades, EUS has evolved into a useful therapeutic tool for treating a broad range of tumours. EUS-guided injection has been applied both as a pancreatic cancer treatment aimed at controlling pain through nerve blockade as well as a solid tumour therapy for the introduction of brachytherapy seeds and viral vectors or as a tool for ablation therapy^[10,11]. The pNET EUS-guided ethanol ablation is a new, less invasive therapeutic option although it remains rare.

A PubMed literature review showed 26 patients affected by small pNETs (maximum diameter of 21 mm) who underwent EUS-guided ethanol ablation^[12-21] including 19 functioning and 10 non-functioning tumours (Table 2). The number of patients treated by this technique progressively increased from 2006 to 2015 (Figure 5).

Conscious sedation is generally reported during the procedure. A mean hospitalization time of 2 d/session is usually necessary even in the absence of complications.

Technical success is reported in 100% of cases; a 22 or 25 gauge needle was generally used to inject a small volume of ethanol with a range between 0.2 and 8 mL per session. The choice of ethanol volume is a

function of tumour size. For small (≤ 20 mm) tumours, Qin *et al.*^[19] suggested that the volume be calculated as follows. For round tumours, the volume of ethanol corresponds to half the tumour size; for oval or irregular tumours, the volume of ethanol is (major axis + minor axis of the tumour)/2. A 1.0 mL syringe should be used for precise injection.

In terms of therapeutic outcomes, differentiation of functioning and non-functioning tumours seems to be very important. For small functioning symptomatic G1 tumours, the aim of the ablation is the symptom relief. For non-functioning tumours, the treatment goal is complete ablation of the lesion as confirmed by imaging.

Including the case here described, this technique achieved clinical success (complete symptom resolution) in 100% of 19 functioning tumours with a mean follow-up of 13.6 mo (range 2-38). Ethanol ablation is less effective for non-functioning tumours with a reported success (complete radiological ablation) of 70% (7/10 tumours were ablated, one lost to follow-up) with a mean follow-up of 13.4 mo (range 3-24) (Table 2). The reason is unclear but it might be due to a "debulking" effect in functioning ones, resulting in loss of endocrine

secretion, although with persistent viable tissue, or to a more aggressive histological grading of non-functioning tumours. Unfortunately, lesion grading was not available in most of the reviewed cases.

Few early complications (within one week) are reported: 7 mild pancreatitis cases were observed (16.2%) out of 43 procedures. One (2.3%) major early complication was described^[13]: A pancreatic necrotic lesion that was likely caused by ethanol effusion. It was managed by laparoscopic necrosectomy.

Two (4.6%) late complications occurred: One hematoma and ulceration of the duodenal wall^[14] and main pancreatic duct stricture^[21]. These were managed by endoscopic retrograde cholangiopancreatography and stent placement (Table 3).

In our case, we achieved a diagnosis of a non-functioning pNET with moderate dysplasia, grade (G2), established on the basis of biopsy (Ki67 > 5%) in a 58-year-old male who refused surgery. We decided to

ablate based both on the grading and the age of the patient. Moreover it is worth noting that FNA cytology may underestimate the staging based on surgical specimens. Physicians should be very cautious in using FNA specimens to classify a tumour as low-grade^[22]. Consequently our treatment aimed at the complete ablation of the lesion while sparing the pancreatic parenchyma. The nodule we treated had a cystic central component, which has not yet been described in the literature for pNET EUS-guidance ablation. A technique similar to that described for cystic neoplasm ablation (ethanol injection and reaspiration) was used.

In conclusion, based on our case study and literature review, we find that this technique is feasible, relatively safe and efficient when applied to symptom relief in functioning tumours. However, the long-term outcomes remain unknown. For non-functioning tumours, it can provide good results for patients unfit for surgery or for those who refuse surgical resection. Its role in "fit for surgery" patients is still undefined and larger comparative studies with long-term follow-up are needed to assess its role.

COMMENTS

Case characteristics

The authors describe a procedure of eus guided ethanol ablation along three sessions for a cystic pancreatic neuroendocrine tumours (pNET).

Clinical diagnosis

Incidental focal lesion of the pancreatic tail with endoscopic ultrasound (EUS) "bull's eye appearance" and peripheral hypervascularization, suspicious for neuroendocrine tumour.

Differential diagnosis

Other focal lesions of the pancreas.

Laboratory diagnosis

No lab abnormality including levels of carcinoembryonic antigen and carbohydrate antigen, but recent onset of glucose intolerance.

Imaging diagnosis

Abdominal ultrasound, endoscopic ultrasound, magnetic resonance, EUS guided FNA.

Pathological diagnosis

Neuroendocrine tumor, G2, Ki67 proliferative index > 5%.

Treatment

The authors treated the patient by EUS-guided ethanol injection along three sessions.

Related reports

For patients unfit for surgery due to high-risk comorbidity or for those who refuse resection EUS-guided ethanol ablation has been reported in a few cases.

Term explanation

pNETS: Pancreatic neuroendocrine tumours; EUS: Endoscopic ultrasound.

Experiences and lessons

The authors find that EUS guided ethanol ablation is relatively safe and efficient

for the treatment of pNETs in patients unfit for surgery or for those who refuse surgical resection. Its role in "fit for surgery" patients is still undefined.

Peer-review

A well written paper having a clear endpoint and objectives. The review of the literature is complete and presented in an attractive way.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Erman Aytac, MD, Academic Fellow, Department of Colorectal Surgery, Cleveland Clinic, Digestive Disease Institute, Cleveland, OH 44106, United States

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Colorectal cancer is one of the commonly encountered cancers across the Western World. In United Kingdom, this constitutes third most common ranked cancer and second most common ranked cause of cancer related deaths. Its acute presentation as a malignant colonic obstruction imposes challenges in its management. Colonic stent has been used for many years to alleviate

acute obstruction in such cases allowing optimisation of patient's physiological status and adequate staging of cancer. In this review, current literature evidence regarding use of colonic stent in acute malignant colonic obstruction is critically appraised and recommendations on the use of colonic stent are advocated.

Key words: Colorectal; Cancer; Surgery; Emergency; Stent

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Although colonic stents have been used for years to treat acute malignant colonic obstructions, current evidence based on the systematic review and randomised controlled trials do raise concerns about its impact on the long term outcomes. Its use has not been recommended in acute suspected malignant colonic obstruction as a bridge to surgery due to evidence of its impact on recurrence rates; however there is enough evidence to suggest its use as a palliation. In patients with multiple co-morbidities with high American Society of Anaesthesiologists grades, colonic stent may be considered as an alternative option to emergency surgical procedure as a bridge.

Sagar J. Role of colonic stents in the management of colorectal cancers. *World J Gastrointest Endosc* 2016; 8(4): 198-204
Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i4/198.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i4.198>

BACKGROUND

Colorectal cancer is one of the commonly encountered cancers across the Western World. In United Kingdom, it constitutes third most common ranked cancer and second most common ranked cause of cancer

related deaths. Although surgical intervention remains the mainstay of treatment for colorectal cancers, radiotherapy and chemotherapy do have role especially in locally advanced and metastatic disease. With the implementation of colorectal screening programme, presentation at an early stage is expected with better outcome. However, about 8%-13% of patients with colorectal cancers presents with acute colonic obstruction^[1-3]. In elective settings, individual would undergo adequate staging of cancer before initiation of treatment in a controlled environment, but acutely presenting patients with colonic obstruction need immediate intervention to relieve the obstruction. Thus this group of patients represents challenges to the colorectal team as emergency surgery in these patients either in the form of defunctioning stoma or primary resection is related with significantly high complications and mortality and in some cases, inadequate treatment. The alternative approach would be to stent the obstructing lesion to alleviate the obstruction. This would allow adequate time to stage the disease, achieve best optimal health status of the patient and initiation of any neoadjuvant treatment. However, there have been controversies about the use of stent in the management of acute suspected malignant colonic obstruction. Recently, European Society of Gastrointestinal Endoscopy has published the guidelines regarding the use of colonic stent in acute malignant colorectal obstruction^[4].

ANATOMICAL LIMITATIONS

Although colonic stents can be placed in any part of colon, considering the alternative surgical approach in the form of primary resection and anastomosis, colonic stents are usually preferred in left sided colonic obstructions. Until recently, the reported randomised controlled studies (RCT) comparing stenting vs emergency surgery for malignant colonic obstruction omitted colonic lesions proximal to splenic flexure except one^[5]. Similarly, all published RCTs except one^[5] had excluded rectal cancers from their study population due to known higher failure rates and complication rates. Apart from colonic obstruction from colorectal pathology, extra colonic pathology including carcinomatosis peritonei can also cause colonic obstruction. In these cases, colonic stenting may be considered for palliative purposes but this is associated with lower technical and clinical success rates and higher complication rates^[6-8]. Regarding presence of inflammatory bowel disease (IBD) in conjunction with malignant colonic obstruction requiring colonic stent, there is no evidence as IBD would change approach to deal with malignant colonic obstruction as management of malignant obstruction would override the management of IBD, however one needs to be aware of existing disease in proximal or distal colon when considering surgical or stent option in these cases. This review mainly focused on the obstruction caused by primary colonic malignant pathology.

COLONIC STENT

Although there is much published regarding the use of colonic stents in suspected malignant colonic obstruction, there is no evidence of colonic stenting as prophylaxis in asymptomatic patients. Prophylactic stenting is not recommended due to potential risks associated with stenting. There have been reports suggesting less effectiveness of colonic stents in peritoneal carcinomatosis cases although there has not been any major study published looking at the role of colonic stenting in these cases. There are generally no contraindications for the colonic stenting except perforation of colon. The only absolute contraindication for colonic stenting is colonic perforation. Outcomes following stent placement are not affected by patient's age and American Society of Anaesthesiologists (ASA)/physiological status^[9-14] as they are the main two risk factors predicting mortality and morbidity with any procedure. Pre-stenting investigation in the form of computed tomography (CT) with contrast enhancement is the investigation of choice with a sensitivity of 96% and specificity of 93%. It also helps to define the aetiology in 81% of cases and level of stenosis in 94% of cases. There is an added advantage of local lymphovascular and distant staging of tumour. Flexible sigmoidoscopy may be added in dubious diagnosis on CT scans. Synchronous colonic tumours are present in around 3%-4% of patients with colonic cancers^[15-18]. Knowledge of these synchronous lesions may change the definitive treatment of colonic cancers. However, routine adequate imaging with CT colonography or visualisation with colonoscopy to detect these synchronous lesions is not feasible in acute presentations and is not recommended. If patient receives successful colonic stent, colonoscopy through stent or CT colonography can be considered as a safe procedure^[19-22] to look for any synchronous lesions. In cohort of patients diagnosed with suspected malignant colonic obstructions, there would be few patients with benign cause of their obstructions. In two RCTs, the benign obstructive lesion was found in 4.6%^[23] and 8.2%^[24] of patients suspected of malignant obstructions. As definitive pathological confirmation in acute situation is not feasible, if indicated, stenting should be performed in suspected malignant obstruction without waiting for pathological diagnosis. Brush cytology or tissue biopsy can be obtained during stent placement if possible, however if there is any risk of obscuring views due to bleeding following biopsy, it can be deferred for a later time. In contrast to malignant pathology, stenting should be avoided in suspected diverticular strictures or obstruction due to high risk of perforation^[25]. However, the risk of having underlying malignant lesion in patients with diagnosed diverticulitis on CT scan was quoted to be 2.1% in one systematic review^[26].

Bowel preparation is debatable before stent placement considering the obstructive nature of the disease and there are no published reports related with the use of bowel preparation in such cases. In most of these

patients, although colon distal to obstruction is usually empty due to peristaltic movements, an enema can be used to facilitate visualisation before stent procedure. Antibiotic prophylaxis during stent placement is not indicated due to very low incidence of clinical manifestation of bacteraemia^[13,27]. Colonic stent placement can be achieved either endoscopically or radiologically but combination of endoscopy and fluoroscopy is recommended. Retrospective studies have reported similar success rates following endoscopic and radiologically placed stents but have shown greater technical success rates with combination technique^[14,28-30]. There is also definitive learning curve for an endoscopist to perform colonic stents. Couple of noncomparative studies suggested performance of at least 20 procedures with increased technical success rate and reduction in the number of used stents by endoscopist^[31,32]. There is some suggestion that endoscopists experienced in therapeutic endoscopic retrograde cholangiopancreatography would benefit from translating skills in stent placement procedures^[13]. Dilatation of colonic obstructing stricture is not recommended due to high risk of perforation^[29,33,34] but this recommendation is based on retrospective studies only.

The available colonic stents can be divided broadly in to two groups, covered and bare or uncovered stents. The potential factors responsible for success of stent insertion also include length and diameter of stent. Two met analysis comparing covered stents against bare stents showed no difference in technical and clinical success and complication rates, however, bare stents had significantly higher tumour ingrowth rates but had lower migration rates^[35,36]. Smaller body diameter stents (< 24 mm) are associated with higher migration rates^[13,37-39]. Considering the shortening after stent deployment, it is recommended to use long enough stent, in addition to the length of obstruction, to cover at least 2 cm on either ends^[40]. There is evidence of no difference in outcomes among different stent designs^[41-46]. The other major factor that affects stent outcomes is stentability of the obstruction. There is evidence that success rates are high in short segment obstructions with higher technical and clinical failures in obstructions > 4 cm^[38,47]. Similarly, although the clinical and technical success rates were similar in complete and impending (subtotal) obstruction, complication rates, especially perforation were higher in complete obstruction^[48].

COLONIC STENTS AS A BRIDGE TO SURGERY

Although colonic stenting seems to be an apparent management option for acute large bowel obstruction in potentially curable and resectable cases, there has always been controversy about their use as a bridge to surgery. Due to an ability to convert an emergency condition to elective situation permitting opportunities for staging and optimisation of patient's condition, stent

seems a viable option, however current evidence failed to show its superiority over traditional surgical options. Eight systematic reviews^[49-56] and seven randomised controlled trials^[23,24,57-61] have been published in last few years comparing emergency surgery with pre-operative colonic stenting for acute suspected malignant colonic obstruction. Two of the randomised controlled trials were closed prematurely due to higher complication rate in the stent group^[23,24] while one was closed early due to high complication rate in the surgical patients^[60].

The most recently published systematic review performed meta-analysis of all published seven randomised controlled trials covering more than 180 patients in each group^[49]. Mean technical success rate of 76.9% was achieved following stent placement. There was no difference in post procedure/surgical mortality in either group but overall complication rate and permanent stoma rate were noted to be lower in the stent group. The primary anastomosis rate was also high in stent group. The outcomes regarding cost effectiveness of stents were unclear. From this systematic review, it is clear that colonic stenting in acute setting has some definitive advantages compared to emergency surgery. However, one needs to consider long term impact of colonic stent insertion in terms of oncological outcomes, especially in cases of curable and resectable cancers at presentation.

There has been some trepidation raised regarding the impaired oncological outcomes following placement of colonic stents in patient having potentially curable cancer. This concern increases more so with potential complication in the form of perforation. Three randomised controlled trials have compared the medium term oncological outcomes subsequent to stent placement till the surgery vs primary surgical resection^[58,60,62]. All of these trials were of small sample size and comparatively shorter follow-up periods. The Chinese study included 48 patients; 24 offered stents till the surgery and 24 offered emergency surgical procedure^[58]. In this study, two of 13 patients in surgery arm and 11 of 22 patients in stent arm who had curative resection developed recurrent disease. However there was wide gap in the median follow-up period; 32 mo in open surgery group and 65 mo in stent group, this difference did not reach statistical significance. The 5-year overall survival rate was 27% and 48% in open surgery and stent groups respectively although it was statistically insignificant. The Spanish study included 28 patients; 15 in stent arm and 13 in surgery arm^[60]. Although this study was closed prematurely due to high rate of complications in the form of anastomotic leak in the surgical group, the disease recurrence was noted in eight out of 15 cases in stent arm and two out of 13 cases in surgical group at mean follow-up of 37.6 mo but this was not statistically significant. The third study represents outcomes of Dutch stent in 2 trial^[62]. This included follow-up of patients who had only curative treatment. It had 32 patients in emergency surgery arm and 26 in stent arm. The median follow-up was 36 and 38 mo respectively. Five-

year overall recurrence rate was 25% (8 patients of 32) in surgery arm and was 42% (11 of 26) in stent group. Local recurrence rate was 9% (3 out of 32) in surgery group and was 19% (5 out of 26) in stent group. Although overall five-year recurrence rate was statistically significant, local recurrence rate failed to reach that. The cumulative overall recurrence rate was 83% in patients with clinical or subclinical stent related perforation and was statistically significantly higher compared to emergency surgery group and non-perforated stent group.

The above findings made one to rethink about the use of these stent in acute suspected malignant colonic obstruction as a bridge till surgery in cases with potentially resectable and treatable tumours. Although the above studies had small number of patients and the follow-up period was variable and not long, it seems obvious that placement of these stent is not without its potential adverse impact in form of higher local and overall recurrence rates. These findings were supported by another large comparative prospective study showing higher local recurrence rates in stented patients aged ≤ 75 years^[63]. Until we have results from large number of patients with adequately designed randomised controlled trial, the oncological outcomes of stents needs to be weighed against the outcomes following emergency surgical intervention. As published studies did not reveal any significant difference in postoperative mortality and morbidity in either group, colonic stent cannot be recommended as a bridge till surgery in acute suspected malignant colonic obstruction. However, if surgical risks outweighs the long term benefits as in patients with increasing age, multiple co-morbidities and increasing ASA, stents can be considered as an alternative option. If colonic stent is used as a bridge till surgery, optimal time interval of five to ten days should be considered between stent placement and resection surgery^[52]. This is based on the facts that this time would allow patient to recover his/her physical and nutritional status. If resection surgery is delayed longer, it would impose more challenges performing surgical resection due to maturing of scar tissues, especially when considering laparoscopic resections.

COLONIC STENT AS A PALLIATION

It is getting clearer from above discussion that although colonic stent is not recommended as a bridge to surgery, it obviously has a role in the palliation. Two published meta-analysis including randomised and non-randomised comparative studies compared the colonic stent and emergency surgery as palliation^[64,65]. The clear advantages of lower postoperative mortality, reduced intensive and overall hospital stay with earlier start of chemotherapy were evident in the stent arm but the clinical success rate was statistically significantly higher in surgery arm. There was no statistically significant difference in the post-operative complications; early complications were more common in surgery arm while late complications were reported more frequently in stent arm. Although the

technical success rate in stent arm was 88% to 100%, colonic perforation, stent migration and re-obstruction were reported complications. These findings favour colonic stents in a palliative setting in acutely presented suspected malignant large bowel obstruction.

Successful deployment of colonic stents in these cases allows the advantage of starting chemotherapy at an earlier stage. However, chemotherapy also raises the suspicion of increased complication rates of stent placement, especially of colonic perforation. Several retrospective studies have reported increased stent related colonic perforation in patients who were treated with bevacizumab^[13,38,66]. Single meta-analysis published significantly higher rate of colonic perforation in patients who were on bevacizumab in comparison to those who were on chemotherapy without bevacizumab or not on chemotherapy at all^[34]. As the newer anti-angiogenic drugs such as regorafenib and aflibercept work alike bevacizumab, colonic stenting is not recommended in patients who are considered for treatment with anti-angiogenic agents. Clinically, this may impose difficulty as presentation of acute large bowel obstruction may be patients' first clinical presentation and it would be difficult to assess their suitability for chemotherapy with antiangiogenic agents at that time. However, patients presenting as an acute large bowel obstruction with known colonic cancer and on anti-angiogenic agents are not recommended to have colonic stent. There is limited evidence of increased stent related complications in patients who are already on chemotherapy without anti-angiogenic agents before stent placement however tumour shrinkage leading to stent migration due to chemotherapy may be a concern. Apart from stent related perforation, stent failure, re-obstruction and stent migration, other common potential complications include pain, tenesmus, incontinence and fistula formation. When used as a palliation, re-stenting is a viable option in expert hands in cases of stent migration or obstruction.

CONCLUSION

Colonic stents are associated with lower mortality and morbidity compared to emergency surgery in cases of acute suspected malignant large bowel obstruction. However, current evidence does not recommend use of colonic stent as a bridge till surgery in these cases but it is a preferred treatment to relieve obstruction in palliative settings. In patients with multiple medical co-morbidities, poor performance status and increased ASA, colonic stent can be considered as an alternative option as a bridge till surgery but careful discussion with patients about potential adverse impact on long term oncological outcomes is recommended.

Abstract

New endoscopic techniques for hemostasis in nonvariceal bleeding were introduced and known methods further improved. Hemospray and Endoclot are two new compounds for topical treatment of bleeding. Initial

studies in this area have shown a good hemostatic effect, especially in active large scale oozing bleeding, *e.g.*, tumor bleedings. For further evaluation larger prospective studies comparing the substances with other methods of endoscopic hemostasis are needed. For localized active arterial bleeding primary injection therapy in the area of bleeding as well as in the four adjacent quadrants offers a good method to reduce bleeding activity. The injection is technically easy to learn and practicable. After bleeding activity is reduced the bleeding source can be localized more clearly for clip application. Today many different through-the-scope (TTS) clips are available. The ability to close and reopen a clip can aid towards good positioning at the bleeding site. Even more important is the rotatability of a clip before application. Often multiple TTS clips are required for secure closure of a bleeding vessel. One model has the ability to use three clips in series without changing the applicator. Severe arterial bleeding from vessels larger than 2 mm is often unmanageable with these conventional methods. Here is the over-the-scope-clip system another newly available method. It is similar to the ligation of esophageal varices and involves aspiration of tissue into a transparent cap before closure of the clip. Thus a greater vascular occlusion pressure can be achieved and larger vessels can be treated endoscopically. Patients with severe arterial bleeding from the upper gastrointestinal tract have a very high rate of recurrence after initial endoscopic treatment. These patients should always be managed in an interdisciplinary team of interventional radiologist and surgeons.

Key words: Gastrointestinal bleeding; Endoscopic treatment; Intestinal hemorrhage; Endoscopic clips; Topical hemostatic substances

Core tip: An increasing rate of patients who present

with nonvariceal hemorrhage present with an anticoagulative or antithrombotic medication. Often the patient suffers from concomitant disease. In the recent years new methods for flexible endoscopic treatment of hemorrhage have been developed. The following article discusses the current literature of the new endoscopic methods in the context of every day practice in endoscopic treatment for nonvariceal hemorrhage.

INTRODUCTION

Endoscopic hemostatic treatment is the gold standard for active gastrointestinal bleeding, as well as for recent bleeding with stigmata of a high recurrence rate. International treatment guidelines recommend an early risk stratification by immediate endoscopic diagnosis and treatment^[1]. Injection therapy, clip application and thermal hemostasis are well established methods of mono therapies. However a combination of two hemostatic methods have been found to be superior to an individual method alone and should therefore be preferred^[2]. Mechanical hemostasis with clips can be limited due to poor angulation and mobility of the endoscope, *e.g.*, in the duodenal bulb. Also some conventional clips cannot be reopened after closing even after poor placement.

In this review we highlight recent innovations in the field of endoscopic hemostasis in nonvariceal bleeding in the upper gastrointestinal tract with a focus on new topically applied substances (*e.g.*, Ankafer, Hemospray and EndoClot) and newly developed clips [instinct clip and over-the-scope-clip (OTSC)].

Before endoscopic treatment of a nonvariceal bleeding certain factors that correlate with a high rate of re-bleeding, should be considered. Interdisciplinary solutions should be evaluated at an early stage. Ogasawara *et al*^[3] described in a single center retrospective study the parameters: Age > 70 years, hemorrhagic shock on admission, hemoglobin < 8 mg/dL, serum albumin < 3.3 g/dL, vessels > 2 mm and Forrest I a and I b ulcers as negative predictors. The strongest predictors of failure of endoscopic therapy is a vessel diameter > 2 mm (OR = 4:38; 95%CI: 1.25-7.01) and the presence of hemorrhagic shock (OR = 5.26, 95%CI: 2.43-11.6)^[3].

The authors describe precisely the approach when initial hemostasis fails. From 2000-2010, *n* = 428 patients were treated with Forrest I a/ I b (F I a/F I b) and Forrest II a/b (F II a/F II b) lesions. The authors describe a standardized second-look endoscopy after 24 h in all patients. A recurrent bleeding occurred in 69 (16%) of the patients. Twelve percent of those

received surgery, 4% died. For the entire population of 428 patients with F I a/F I b and F II a/F II b bleeding endoscopic failure rate of 17/428 (4%).

The second endoscopic hemostasis was successful in 46/69 (66.7%). A third intervention was successful in 11/23 (47.8%) of the patients. With this approach, the authors were able to treat 57/69 (82%) recurrences during follow-up.

This work shows that by endoscopic hemostasis a large proportion of patients with upper nonvariceal gastrointestinal bleeding can be permanently treated with the first endoscopic hemostasis.

Attention should be paid to the special situation of a large visible vessel (> 2 mm). Especially arterial vessels on the posterior wall of the duodenal bulb should gain attention. Surprisingly, the proportion of intractable bleeding in the study of Ogasawara *et al*^[3] were more frequent in the duodenal bulb, but this did not reach statistical significance.

Another crucial parameter before starting any endoscopic therapy in the presence of bleeding is the fact that especially non-bleeding-related comorbidities cause the mortality of non variceal bleeding^[4]. The number of comorbidities and the probably of taking anticoagulative or antithrombotic drugs will affect decisively the prognosis in the individual cases.

NEW HEMOSTASIS METHODS - TOPICALLY APPLIED SUBSTANCES

Surface bleeding provides a problem for common hemostatic methods. Injections work better with localized active bleeding sources. Also, after injection of NaCl or diluted epinephrine solution a decongestion of the injected volume cause a reactivation of bleeding. Mechanical hemostatic methods can cannot easily be used for diffuse mucosal bleeding. Hemostasis with argon plasma coagulation would be the method of choice but a High Frequency (HF) Generator is required, which must be frequently initially activated in emergency examinations or on the intensive care unit.

Over the past 50 years, various substances for topical hemostasis were developed especially in open surgery. Bergel in 1909 described the application of fibrin to accelerate hemostasis. Other locally applied substances include thrombin clotting factors and sucralfate, which have been described with differing results in small case series^[5].

Currently the literature describes three substances, used for endoscopic hemostasis (Table 1). Hemospray (Cook Medical, Limerik, Ireland) and EndoClot (EPI, Santa Clara CA, United States) are eligible for endoscopic treatment of nonvariceal bleeding. The preparation of ankaferd [ankaferd blood stopper (ABS)] is not available for endoscopic hemostasis in Germany.

ABS

ABS is a preparation of Turkish medicine, specified by

Table 1 Overview on the commercially available substances for topical application^[5]

	Contains	Mechanism of action	Approved human application	Formulation
Ankaferd blood stopper	Herbal mixture	Forms protein networks, activates clotting cascade	Dental procedures, first aid services	Tampons, sprays, ampoules
Hemospray	Mineral powder	Absorbs H ₂ O, mechanical tamponade, activates clotting cascade	Nonvariceal GI bleeding	CO ₂ pressurized handheld canister (20 g)
EndoClot	Absorbable polymers	Absorbs H ₂ O and concentrate cells, activates clotting cascade	Adjuvant hemostatic therapy	Pressurized air compressor

GI: Gastrointestinal.

the manufacturer as a blend of vegetable ingredients. A preparation of 100 mL of ABS is composed of a standardized mixture of plants, including 5 mg *Thymus vulgaris* (dried grass extract), 9 mg *Glycyrrhiza glabra* (dried leaf extract), 8 mg *Vitis vinifera* (dried leaf extract), 7 mg *Alpinia officinarum* (dried leaf extract), and 6 mg *Urtica dioica* (dried root extract)^[6].

The endoscopic application of ABS is published in case reports and series for treatment of Mallory-Weiss tears, Dieulafoy ulcers, GAVE, anastomotic bleeding, post sphincterotomy and tumor bleeding^[7]. Prospective randomized trials comparing ABS to other endoscopic hemostasis procedures are lacking.

HEMOSPRAY TC-325

Hemospray (also named TC-325) is a mineral-based powder from Cook Medical Limerick Ireland. It was developed by the armed forces for control of bleeding in military operations. The powder is applied *via* a CO₂ pressurized handle. The powder is sprayed onto the source of bleeding and it is important for the application that an active bleeding is present. Only then the effect of the substance can occur.

In an animal model with an artificial arterial bleeding in the stomach, endoscopic hemostasis could successfully be achieved^[8]. There was no evidence for an embolic removal of the substance into the circulatory system or local reactions at the site of bleeding. Sung *et al*^[9] reported 2011 on the first application of hemostasis for $n = 20$ patients with peptic ulcer bleeding. The acute hemostasis rate was 95% (19/20). One patient with a F I a hemorrhage had to be embolized radiologically due to a pseudoaneurysm. Out of the patients with a successful initial treatment, 2/10 (11%) showed a recurrence of bleeding within 72 h, however these could again be treated endoscopically^[9].

In 2013, the results of the "Evaluate Survey of the Application of Hemospray in the luminal tract", a European database, were published^[10]. The authors report on $n = 30$ patients with peptic ulcers and $n = 33$ patients with other nonvariceal bleeding sources (e.g., post EMR, tumor bleeding, Dieulafoy ulcer). Monotherapy with Hemospray was carried out in 87%. The primary hemostasis rate was 85%. A rebleeding within 7 d occurred in 15% of all treated patients. In 8

cases Hemospray was applied adjuvantly after ineffective primary hemostasis with other methods. In all eight cases, treatment with Hemospray was successful, however, rebleeding occurred in 25%.

Another typical indication for Hemospray are large diffuse tumor bleedings. Chen *et al*^[11] described the successful treatment of $n = 5$ patients with different tumor bleedings. Binkau *et al*^[12] successfully treated two cases of an ulcerated carcinoma of the stomach and one case of small cell lung cancer, with bleeding from a metastasis in the stomach. The advantage of Hemospray is the contact-free application of the substance to a diffusely bleeding tumor surface. Upon blood contact, local hemostasis is accelerated (Figure 1).

ENDOCLOT

EndoClot contains absorbable polysaccharide particles, which are polysaccharides that absorb the blood fluid and form a gel to accelerate coagulation.

The substance is applied over a catheter with an air compressor. During application, the catheter tip has to be held at a distance from the bleeding source in order to prevent blockage of the catheter.

Müller-Gerbes *et al*^[13] report their experience of treating 22 patients either with EndoClot alone (17 patients) or in combination with other hemostatic methods (5 patients). Overall, hemostasis was successful in 21/22 patients. Out of these cases 8 involved diffuse tumor bleeding which could be stopped.

However, Holster *et al*^[14] could report sufficient hemostasis in patients with active arterial bleeding who were under anticoagulants.

Overall topically applied substances are particularly helpful for diffuse bleedings with low activity and without a clearly localized source. Also, patients taking anticoagulants or antithrombotic medication can well be treated with the new substances. Other indications such as arterial bleeding have shown less favorable results. In order to more firmly establish topically applied substances in the algorithm of endoscopic hemostatic therapy, larger studies comparing them to conventional methods are at need.

If positioning of the endoscope is adequate and the endoscopic team is clip-experienced, a mechanical method for hemostasis could be preferred. For this

Figure 1 Hemospray (Cook Medical, Ireland) with a CO₂ pressurized handle the mineral powder is applied with a catheter introduced through the working channel of the endoscope.

Figure 2 Over the scope clip (Oversco, Tübingen, Germany). The clip is preloaded on a transparent cap that can be fixed on the distal end of the endoscope. After suctioning of the bleeding source into the cap the clip is placed over the bleeding site.

Figure 4 Clip Master 3 (Medwork, Höchstädt/Aisch, Germany) is a through the scope clip with three consecutively preloaded clips. The clips can be applied without changing the device.

Figure 3 Different types of through the scope clips. A: Quick clip, (Olympus, Hamburg, Deutschland); B: Instinct clip (Cook Medical, Limerick, Ireland); C: Resolution clip (Boston Scientific Germany, Ratingen, Germany).

modality new clip models were presented in recent years.

CLIPS FOR MECHANICAL ENDOSCOPIC HEMOSTASIS

There are two groups of clips: Clips applied through the working channel of an endoscope [Through-the-

Scope (TTS)] and clips pre-loaded with a transparent detachable cap at the distal end of the endoscope (over the scope OTSC) (Figure 2).

The TTS clips are available from different manufacturers and with different opening lengths (Table 2, Figures 3 and 4). A clip with three branches (TriClip, Cook Medical, Ireland) is now no longer available. Prospective studies with the TriClip compared to the Quick Clip (Olympus, Hamburg, Germany) showed a slightly worse outcome for the TriClip. Another study showed more recurrent bleeding with the TriClip (15% vs 29%). The primary hemostasis rate was also significantly lower with the TriClip (94% vs 76%, $P = 0.01$)^[15].

Meanwhile the company has improved the clip model and offers a clip with two branches. It is called "instinct clip", opens at a very wide angle, can be rotated and reopened. However it is a single use clip, requiring a complete application set for each application. So far there are no published clinical trials. However, an *ex vivo* study showed a good application even in full inversion of the endoscope and a durable tissue closure (Figure 5)^[16].

The mechanical hemostasis is the only endoscopic procedure that offers a safe and permanent closure of larger vessels^[17]. However, the exact placement on the bleeding source and the durability of the clip until hemostasis has occurred are important.

Table 2 Currently available through the scope clips for endoscopic hemostasis

Clip	Manufacturer	Opening with	Special
Clipmaster 3	Medwork, Höchststadt/ Aisch, Germany	12 mm	3 clips in a row - no change of the applicator required
Quick clip 2	Olympus, Hamburg, Germany	9 mm	Multiple use applicator
Quick clip 2 long	Olympus, Hamburg, Germany	11 mm	Multiple use applicator
Resolution clip	Boston Scientific, Ratingen, Germany	11 mm	Reopenable after placement
Instinct clip	Cook Medical, Limerick, Ireland	16 mm	Reopenable after placement

With the clipmaster 3 clips can be applied with one applicator. The quick clip applicator is a multiple use device but every clip has to be separately loaded. The instinct and the resolution clip can be closed and reopened until a proper position could be achieved.

Figure 5 Instinct clip. A: Forrest Ib ulcer in the prepyloric antrum; B: After injection of diluted epinephrine solution and clearing of the blood clot a small feeding vessel is identified; C: The instinct clip (Cook Medical, Ireland) is positioned close to the lesion and then the branches are rotated to the desired angle; D: The clip is placed at the basis of the ulcer; E: The clip is closed in a proper position; F: The clip is released and a second clip is positioned on the opposite position.

Hepworth *et al.*^[18] compared the methods of endoscopic injection, heater probe thermal treatment, and clip application in an animal model on arterial vessels of different diameter. The injection could not achieve permanent hemostasis in any vessel diameter (1-3 mm). But even with the state of the art hemostasis clips, the authors were only able to achieve permanent hemostasis in 10%-15% of the cases. The attempt to achieve a higher hemostasis rate with an endoscopic suture or an endoloop achieved more durable vascular occlusion. Another *ex vivo* study was performed on the "Erlangen Active Simulator for Interventional Endoscopy" and measured the closing pressure after endoscopic application of different clip models. The maximum closure pressure of 200 mmHg was achieved in 59% with the OTSC system. The resolution clip (Boston Scientific, Ratingen, Germany) accomplished this in 10%, quick clip (Olympus, Hamburg, Germany) 3% and in TriClip

(Cook, Limerick, Ireland) in 10%. With injection alone, the maximum occlusion pressure has been reached in 5% of the tests. The authors conclude from their experimental results that arterial vessels greater than 2 mm can only be closed with the OTSC System^[19].

Another benefit of the OTSC System could be a circular grasp of the bleeding source and the surrounding tissue containing the supplying blood vessels. Kirschniak *et al.*^[20] reported the first clinical experience with the OTSC clip for hemostasis.

The clip was used for primary or postoperative bleeding in the gastrointestinal tract. In all seven patients in whom the clip was used for endoscopic hemostasis, the primary hemostasis was successful and there was no recurrent bleeding. Another series of 30 cases in which the conventional methods of endoscopic hemostasis had failed, use of the OTSC system achieved a success rate of 97% of primary hemostasis^[21]. In two cases there was

recurrent bleeding, which could be treated with repeated endoscopic treatment. In a recent case series, a technical success rate of 100% for hemostasis with the OTSC clip is reported. In two cases a rebleeding occurred, in one of which the source of bleeding was a multiply pretreated tumor^[22].

HEMOSTASIS STATE OF THE ART - NONVARICEAL BLEEDING

In recent years, new techniques for endoscopic hemostasis were introduced and known methods further improved.

With Hemospray and EndoClot two new compounds for topical treatment are available. Initial studies in this area have shown a good hemostatic effect, especially in active large scale oozing bleeding, *e.g.*, tumor bleedings. For further evaluation larger prospective studies comparing the substance with other methods of endoscopic hemostasis are needed.

For localized active arterial bleeding, primary injection therapy in the area of bleeding as well as in the four adjacent quadrants offers a good method to reduce bleeding activity. The injection is technically quite easy to learn and practicable. After bleeding activity is reduced the bleeding source can be localized more easily for clip application. Today many different TTS clips are available. The ability to close and reopen a clip can aid towards good positioning at the bleeding site. Even more important is the rotatability of a clip before application. Often multiple TTS clips are required for secure closure of a bleeding vessel. One model has the ability to use three clips in series without changing the applicator.

Severe arterial bleeding from vessels larger than 2 mm is often unmanageable with these conventional methods. Here the OTSC system is a newly available method. Its mechanism is similar to the ligation of esophageal varices and involves aspiration of tissue into a transparent cap before closure of the clip. Thus a greater vascular occlusion pressure can be achieved and larger vessels can be treated endoscopically. Patients with severe arterial bleeding from the upper gastrointestinal tract have a very high rate of recurrence after initial endoscopic treatment. These patients should always be managed in an interdisciplinary team of interventional radiologist and surgeons.

Abstract

Post-esophageal atresia anastomotic strictures and post-corrosive esophagitis are the most frequent types of cicatricial esophageal stricture. Congenital esophageal stenosis has been reported to be a rare but typical disease in children; other pediatric conditions are peptic, eosinophilic esophagitis and dystrophic recessive epidermolysis bullosa strictures. The conservative treatment of esophageal stenosis and strictures (ES) rather than surgery is a well-known strategy for children. Before planning esophageal dilation, the esophageal morphology should be assessed in detail for its length, aspect, number and level, and different conservative strategies should be chosen accordingly. Endoscopic dilators and techniques that involve different adjuvant treatment strategies have been reported and depend on the stricture's etiology, the availability of different tools and the operator's experience and preferences. Balloon and semirigid dilators are the most frequently used tools. No high-quality studies have reported on the differences in the efficacies and rates of complications associated with these two types of dilators. There is no consensus in the literature regarding the frequency of dilations or the diameter that should be achieved. The use of adjuvant treatments has been reported in cases of recalcitrant stenosis or strictures with evidence of dysphagic symptoms. Corticosteroids (either systemically or locally injected), the local application of mitomycin C, diathermy and laser ES sectioning have been reported. Some authors have suggested that stenting can reduce both the number of dilations and the treatment length. In many cases, this strategy is effective when either metallic or plastic stents are utilized. Treatment complications, such as esophageal perforations, can be conservatively managed, considering surgery only in cases with severe pleural cavity involvement. In cases of stricture relapse,

even if such relapses occur following the execution of well-conducted conservative strategies, surgical stricture resection and anastomosis or esophageal substitution are the only remaining options.

Key words: Esophageal stenosis; Esophageal stricture; Esophageal dilation; Esophageal stent; Caustic stricture

Core tip: The paper reviews the conservative treatment of esophageal stenosis and strictures (ES) in children. Different types of ES are discussed, including post-esophageal atresia anastomotic strictures, congenital esophageal stenosis and dystrophic recessive epidermolysis bullosa strictures. Endoscopic techniques are reviewed, including balloon and semirigid dilators, esophageal stents and different adjuvant treatment strategies, like corticosteroids (either systemically or locally injected), the local application of mitomycin C, and ES incision. Conservative management must be considered also for complications, such esophageal perforations, except for patients with severe pleural cavity involvement, who require surgery.

INTRODUCTION

The endoscopic treatment of esophageal strictures or stenosis (ES) has been reported to be the most frequently used strategy in children and adults. Improvements in endoscopes and accessories have supported an increase in the number of patients who are conservatively treated with endoscopic dilations (ED) rather than surgical treatment.

In the past, patients with severe cicatricial strictures, particularly cases that occurred following the ingestion of caustic agents, have generally undergone esophageal substitutions with or without esophagectomy. The conservative option was complicated by the difficulty of passing the bougie through the stricture without clear endoscopic control and without a guide wire. The mortality risks of these procedures was elevated because of high incidence of complicated esophageal perforations and consequently severe mediastinal infections.

Safe and effective ED performed with flexible endoscopes, guide wires with differing stiffnesses, balloon dilators or semirigid bougie dilators have drastically improved the outcomes and the quality of life of these

patients. Further, the rates of ES resolution with a stable esophageal caliber that is suitable for normal food intake without dysphagia are high.

Normal food intake is the only achievable target of conservative treatment because there are no treatments that can achieve a true normal esophagus with normal motility at the level of the cicatricial tissue.

ESOPHAGEAL DILATIONS

Conservative treatments of ES with ED utilizing different strategies have been reported, and the indications for each treatment depend on the operator's experience and preferences and the etiology of the ES.

General anesthesia represents a widespread strategy that is used in children both to reduce patient discomfort and to allow for proper airway protection during dilation maneuvers. In teenagers, repeated ED under conscious sedation can be used. In indwelling balloon dilation program, the patient requires neither sedation nor anesthesia^[1].

A guide wire that is inserted under endoscopic control through the stricture represents an important and effective tool for avoiding an incorrect path of the preferred dilator tip.

Different dilators are now available; for example, reusable dilators that are applied over the wire such as semirigid Savary-Giliard bougies and disposable balloon dilators have been used. Balloon dilators pass over a guide wire or through the channel of the endoscope. All of these dilators are available in different lengths and diameters.

There is no consensus regarding the use of balloon dilators or semirigid Savary-Giliard bougies. No prospective studies have directly compared the safety and efficacy of these types of dilators. However, retrospective studies have reported different results regarding perforation rates^[2,3].

Based on our more than thirty-five years of experience with thousands of dilations, we generally use balloon dilators in cases that involve inflammatory strictures, *e.g.*, in the early treatment of caustic, epidermolysis bullosa and peptic strictures.

Savary dilators are safer and more effective than balloon dilators in the treatment of consolidated and old cicatricial strictures and in cases of resistant esophageal narrowing due to, *e.g.*, congenital esophageal stenosis (CES) with cartilaginous remnants^[4].

The advantages of balloon dilators include the radial force that is applied to the ES and the avoidance of the application of axial force^[5]. Balloon dilators can be advanced through the endoscope channel and carefully pushed forward into and through the ES under direct vision. Balloon dilators may also be inserted, on the side of the endoscope itself or under fluoroscopic control, over a guide wire that has previously been inserted through the scope.

Inflating balloon devices allow for the application of a standard force (PSI or ATM) at a standard diameter

and with one specific pressure. The balloon filled with contrast medium allows for the verification of the disappearance of the hourglass image or the waist in the balloon caused by the stricture, under the fluoroscopic control^[5]. The persistence of a portion of the "waist" is an indication that the procedure was partially successful^[6].

There is no consensus regarding the duration, which can range from 10 to 120 s, that the balloon should remain inflated, and there are no published pediatric studies on this topic. An adult study^[7] revealed no difference in the outcomes of patient regardless of whether the balloon was dilated for 10 or 120 s.

Semirigid Savary-Giliard dilators require an expert operator to conduct progressive dilations and thus avoid esophageal perforation by carefully inserting the dilators without excessive force or hastiness.

The problem of the optimum dilator is difficult to solve, because of the different esophageal size during the pediatric age. The "tumble rule" was proposed, comparing the size of the thumb with the esophageal size. The most frequently used rule in children is to dilate no more than two sizes for each dilation session. Dilation can be repeated, with increasing diameter, after at least 3 d. Only the tissue damage after the previous dilation could represent a guide for the treatment. Personal experience plays a fundamental role in the choice of the optimal dilator size.

In patients operated for esophageal atresia (EA) the opportunity and the timing of the first endoscopic control of esophageal anastomosis is debated. Due to the absence of evidence of routine endoscopic control utility, the most used strategy is to evaluate with barium swallow or endoscopy only the patient that are not able to eat the normal food for the age. In case of dysphagia and stricture evidence the patient starts with a dilations program.

There is no consensus regarding the interval between repeated ED with either a balloon or a bougie. An average of two to three weeks is the most frequently reported interval^[2,3]. This interval should be individualized based on the stricture size, the resistance against the dilations, the post-dilation bleeding, the symptoms and the local or patient's logistical environment. Patients who require treatment in a level III endoscopic center may request a special dilation setting and an increased frequency of dilations to reduce difficult or expensive travel from the country of origin, if they are located far

from the level III center. In many cases the interval between ED can be progressively elongated, according with symptoms relapse, to reduce the patient's stress.

The steps to reduce the risk of esophageal perforation are listed in Table 1.

TYPE OF STRICTURES

Table 2 shows the most frequent ES in children listed in order of frequency.

In EA anastomotic strictures, there are no clear indications for dilations, as a routine post-operative procedures^[8]; indeed, the only indication is the presence of dysphagia symptoms.

This second strategy has been reported to be as effective as the first one and with fewer dilations^[9-11].

Due to the high risk of severe stricture that has reportedly been associated with long gaps EA with anastomotic tension^[12,13], patients with this condition require strict clinical follow-up to prevent sudden, full and potentially dramatic anastomotic occlusions that can only be dilated with special strategies. In very difficult situations that lack evidence of an anastomotic lumen, the simultaneous insertion of two endoscopes, one *via* the mouth and the second through a preexisting gastrostomy, could provide an opportunity to reestablish esophageal patency^[14].

In very thin anastomotic stricture it may be impossible to pass the guide wire through. Under fluoroscopy, using an ERCP cannula and strategy, filling water-soluble contrast medium it is possible to verify the correct way and then the correct wire passage through the cannula into the stricture.

In CES, different subtypes have been described. The two most important subtypes in terms of frequency are the fibromuscular (FMS CES) and tracheal cartilaginous remnant (TBR CES) subtypes.

The differential diagnosis, to rule out other esophageal narrowing etiologies, is necessary for selecting the correct therapeutic strategy. Miniprobe ultrasonography (MEUS) currently represents the only diagnostic tool that can provide an accurate evaluation of esophageal wall thickness and can differentiate the CES subtype^[4,15,16]. Different therapeutic options have been reported for CES. In case of TBR, some authors have suggested surgical stenosis resection and anastomosis^[15-17]. The conservative treatment with ED has been reported to be effective^[4] in a large series of 47 patients. An overall

success rate of 95% has also been reported in cases of TBR CES.

The reported incidences of perforation following stenosis dilation in CES are higher than those reported for other types of ES and range from 10%^[4] to 33%^[18] and 44%^[19]. These higher incidences are likely due to the high resistance of the stenosis and the risk of the sudden cracking of the stenosis during dilations, particularly with balloon dilators^[4]. In the reviews of Michaud *et al.*^[16] and Takamizawa *et al.*^[17], the authors reported many cases and studies of the surgical resection of TBR CES as the first option when diagnoses of TBR CES were obtained; but in many reported cases^[16] the TBR diagnosis was based only on post-operative histology and not preoperatively. Indeed, the surgical option has been reported to be the first option in surgical environments, whereas dilation options are more frequently employed in gastroenterological centers^[16]. The numbers of patients with diagnoses of cartilaginous remnants on endoscopic ultrasound with miniprbes that were reported in these two reviews were low, even if this tool is currently the only diagnostic tool that can identify cartilaginous remnants.

Romeo published results supporting conservative strategy as an effective treatment for CES, either FMS or TBR CES. Special care must be taken, in particular in previously MEUS detected TBR CES, to prevent esophageal perforation. Surgery should be reserved only for cases in which conservative treatment has been ineffective^[4].

In recessive dystrophic epidermolysis bullosa, the ES result from bullous lesions and tend to relapse. In these patients, it is important to reduce the esophageal trauma to avoid new blisters and the resultant risk of strictures^[20,21]. To minimize these risks, balloon dilation under only fluoroscopic control allows for ED without a high risk of blisters in non-stenotic esophageal areas^[21-23]. The first step is to pass a soft guide wire through the nostril, the pharynx and the esophageal stricture into the stomach. Under fluoroscopic control, the passage of the guide wire (0.032-0.035 mm hydrophilic wire) through the cricopharyngeal junction can occasionally be very difficult, but this difficulty can be resolved by using a thin tube, over-the-wire. In rare cases, the only option is endoscopic control. An over-the-wire-balloon dilator is then progressively introduced to reach the stomach. The balloon is partially filled with water and contrast medium and is slowly retracted to identify the stricture *via* the appearance of an "hourglass shape" that disappears with progressive balloon inflation. The balloon is then deflated and pulled back to identify any possible additional strictures. It is very important that the completely inflated balloon is not pulled back, to prevent the formation of blisters and new scars^[21-23]. Adjuvant treatment with dexamethasone (2 mg/kg per day for 3 d) reduces patient discomfort and can reduce the formation of scar tissue^[21].

Oral budesonide was recently reported in a short

series as adjuvant treatment in these special patients^[24].

In children during chemotherapy for leukemia or other hematologic diseases ES have been reported^[25,26], due to deep mucositis and esophageal wall damage. Conservative treatment with ED and stenting represents the first option but esophageal substitution could be necessary because of the stricture length and its recurrence. In our experience two, out three, ES resolved with stenting; the other underwent jejune esophageal substitution.

ADJUVANT TREATMENTS

Different adjuvant treatments have been proposed for cases of refractory or recurrent ES. These solutions can reduce fibroblastic activity in scar tissue production and reduce the damage to the injured esophageal wall due to acid gastro esophageal reflux. The role of these treatments is very important because they could give the chance to avoid a surgical procedure, with esophageal resection and anastomosis, a partial or total esophageal substitution or a gastric pull-up procedure. Before planning a surgical strategy in a refractory or relapsed ES a treatment with one or more combined adjuvant strategies is mandatory.

Proton pump inhibitors (PPI) are commonly used, although there are no studies of their efficacy in the prevention of stricture relapse. In one prospective study^[27], the authors reported no prophylactic effect of omeprazole (2 mg/kg) on post-esophageal atresia ES and no effect on reducing the number of ED.

In contrast, severe gastro esophageal reflux disease (GERD) is frequently observed in cases of severe ES due to corrosive esophagitis or long-gap esophageal atresia anastomosis strictures. Cicatricial shortening of the esophagus represents an important cause of GERD and consequent stricture worsening. In these patients, PPI treatment is very helpful to treat esophagitis and acid damage on the stricture wall; a correct evaluation is necessary for potential anti reflux surgery.

Mitomycin C is an antineoplastic antibiotic with *in vivo* and *in vitro* anti fibroblastic activities that has been described to exert inconsistent results at different drug concentrations. Good results in two patients with caustic ES and two patients with anastomotic ES who were treated with ED plus 1 mg/mL mitomycin C have been reported^[28]. The authors of one study reported results that were similar to those of an ED-only treated group in 11/21 anastomotic ES patients who were treated with ED plus mitomycin C (0.1 mg/mL)^[29]. In a review of 11 papers with 31 patients with ES, no direct or indirect side effects were reported. The mitomycin C concentrations varied from 0.1 mg/mL to 1 mg/mL. After a mean follow-up of 22 mo, good results in terms of symptom relief were reported for 21 children (67.7%), and 6 (19.4%) children experienced partial relief. In four children (12.9%), the mitomycin C treatment failed^[30].

In a recent prospective study, the authors described significant improvements in dysphagia in 18/30 corrosive ES patients who were treated with ED plus mitomycin C at 0.4 mg/mL^[31]. In two papers by El-Asmar *et al.*^[32,33], the authors described a significant effectiveness of 0.4 mg/mL of mitomycin C in caustic stricture.

No direct or indirect adverse effects were reported in any of these series.

Different techniques for the topical application of mitomycin C application have been reported. Cotton pledgets soaked in mitomycin C solution have generally been used. Other techniques, such as drug-eluting stents or, in our own experience, the local instillation of a mitomycin C solution at the stricture level with a cotton swab, have produced accurate solution aspiration and lavage after 4-5 min.

Until larger prospective studies are published, topical mitomycin C solutions (0.4 mg/mL) may help improve symptoms and reduces both the number of dilations and their frequency. There are no reports of direct or indirect adverse effects of the topical use of mitomycin C topical, but additional long-term follow-up studies are needed.

The use of corticosteroids, both systemically and intralesionally, has been described. In two ES patients, one post-anastomotic and one corrosive, who were previously treated with repeated intralesional dexamethasone injections, the systemic intravenous administration of prednisolone (2, 1, and 0.5 mg/kg daily for 1 wk each) improved the dysphagia in both patients^[34].

Adjuvant dexamethasone (2 mg/kg for 3 d, tapered over six additional days) has been used in the successful treatment of patients with "dynamic" custom plastic stents^[35,36].

Intralesional triamcinolone acetonide (TAC) injection has been described in adults and children. A prospective study of 60 adult patients with post-esophagectomy esophagogastric anastomotic strictures described non-significant improvement in the number of ED and the dysphagia-free period^[37]. Ten patients with intractable corrosive ES received 2 mL of TAC (40 mg/mL) injected in 3 or 4 quadrants and achieved symptom resolution^[38].

No direct or indirect adverse effects were reported in any of these series, and despite the lack of prospective pediatric studies, local TAC injections could aid the treatment of ES.

STENTING

Surgical ES resection and anastomosis with partial or total esophageal substitution may represent the only therapeutic option for refractory or recurrent ES.

Intra- and post-operative complications, anastomotic strictures, severe GERD, bronchopulmonary disease, chronic dysphagia due to esophageal motility disorders and frequent long-term low quality of life have prompted the use of more aggressive conservative strategies in the

treatment of ES with the goal of avoiding surgery and the goal to save the own patient's esophagus.

Two different strategies for stenting have been described. The metal and plastic stents press against the esophageal wall, with food and secretions that pass through the stent itself. The stents pressing against the cicatricial ES allow for the ES healing.

The second stenting strategy consists of a plastic or silicon tube, customized in different length and diameter according with the stricture size and level, affixed to a nasogastric tube. This type of stent allows the food and secretions to pass in the space between the ES and the stent itself. Such continuous passages seem to effectively maintaining lumen patency^[35,36,39-41]. In one review^[42], experiences with different stents were reported. There are three studies that have reported on second type PTFE or silicon custom stents and three that have reported on self-expanding metallic or plastic stents. Migration of the first type stent was the most commonly cited complication of metallic stents and occurred in 0% to 29% of the patients^[43,44]. The softening of the esophageal wall allowed for the distal displacement of the stent. Plastic stents affixed to nasogastric tubes are associated with a reduced risk of dislocation risks but are also associated with the increased discomfort of a nasal tube.

Results related to one of the second type of stent, the custom "dynamic stent", have been reported in two retrospective studies^[35,36] of patients with post-anastomotic (25 patients) and corrosive (55 patients) ES. The implantation of the stents was followed by high-dose dexamethasone therapy (2 mg/kg per day for 3 d tapered in 6 d more). This stenting strategy was reported to be effective in 88% of the patients. The authors underlined that this type of stent allows for continuous swallowing and food passage, which resulted in a type of gym for the esophageal wall. These dynamic custom stents might aid in stricture healing, but at a minimum, they aid in stricture shortening. This aspect has been reported to be important with respect to possible surgical resection and anastomosis. Indeed, total or long esophageal resection with partial or total esophageal substitution can be avoided^[35].

In a study of plastic and metallic stents^[45], the authors reported stent appositions in refractory ES and esophageal perforation of 23 and 14, respectively. These authors reported that the stents were effective in all patients with esophageal perforations. In the treatment of ES, the stents were effective in 6 of the 23 patients who did not receive further treatment following stent removal. The authors concluded that in anastomotic ES, self-expanding stents are very effective for treating post-dilation perforations and post-anastomotic leaks but are not effective in the treatment of ES with ES relapse after stent removal.

In a recent paper^[46], the authors reported on eleven patients with perforations or anastomotic strictures (7 and 4 patients, respectively) who were treated with

covered metal stents. No stent-related complications were observed during stent insertion or removal. Two patients underwent one additional ED. These authors concluded that stenting represents a safe and effective strategy for healing esophageal perforations.

Severe stent related complication has been described in esophageal atresia patients with post anastomotic ES. In three patients with stent (metallic and dynamic custom stent) massive bleeding from arterial-esophageal fistula has been reported. One patient with metallic stent had fatal outcome and two, with dynamic custom stent, needed thoracic surgery for subclavian anomaly^[47]. Because of the higher incidence of vascular anomalies in patients with post esophageal atresia, it is mandatory to rule out vascular anomalies with CT or MR angiography before implanting a stent.

Biodegradable esophageal stent use was described in children^[48]. The opportunity of progressive reduction of stent compression on the esophageal wall represents an important advantage of this special stent. The published inconstant results in children didn't show a significant advantage in the treatment of recalcitrant esophageal stricture. The most frequent described complications are the gastric dislocations and the mucosal overgrowth with consequent stent obstruction^[49].

ES incision has been reported in some case reports. In a recent retrospective paper, the authors reported on seven anastomotic ES patients.

In two patients ES relapsed and patients underwent one more successful incision. Three patients with ES longer than 1.5 cm underwent metallic stenting after the incision^[50].

This strategy, as the others above reported, should be performed only in III level referral centers in a pediatric medical-surgical setting, for individualized conservative strategy. Before planning surgery, in refractory or recurrent ES, all these conservative strategies must be considered.

ACKNOWLEDGMENTS

The medico-surgical endoscopic team thanks the patients, and their families, that, during the last thirty-five years, followed the difficult conservative strategy for their esophageal diseases. We thank all nurses that had a fundamental role in the treatment of these difficult patients.

Abstract

Benign biliary strictures comprise a heterogeneous group of diseases. The most common strictures amenable to endoscopic treatment are post-cholecystectomy, post-liver transplantation, related to primary sclerosing cholangitis and to chronic pancreatitis. Endoscopic treatment of benign biliary strictures is widely used as first line therapy, since it is effective, safe, noninvasive and repeatable. Endoscopic techniques currently used are dilation, multiple plastic stents insertion and fully covered self-expandable metal stents. The main indication for dilation alone is primary sclerosing cholangitis related strictures. In the vast majority of the remaining cases, temporary placement of multiple plastic stents with/without dilation is considered the treatment of choice. Although this approach is effective, it requires multiple endoscopic sessions due to the short duration of stent patency. Fully covered self-expandable metal stents appear as a good alternative to plastic stents, since they have an increased radial diameter, longer stent patency, easier insertion technique and similar efficacy. Recent advances in endoscopic technique and various devices have allowed successful treatment in most cases. The development of novel endoscopic techniques and devices is still ongoing.

Core tip: Endoscopic treatment of benign biliary strictures has been evolved in the last decades and is widely considered as first line therapy. Among endoscopic techniques, multiple plastic stents placement is an

effective method but requires multiple endoscopic sessions. Fully covered self-expandable metal stents appear as a reasonable alternative due to their larger lumen and longer patency. Emergent data proved their efficacy, their low complications rate and cost-effectiveness. We herein discuss the endoscopic management of benign biliary strictures and focus on the outcomes, advantages and disadvantages of each endoscopic technique.

INTRODUCTION

Endoscopic treatment for benign biliary strictures (BBS) has been evolving in the last decade. The vast majority of BBS are caused by postoperative biliary injuries [mainly post-cholecystectomy and orthotopic liver transplantation (OLT)] or chronic inflammatory disorders [such as chronic pancreatitis and primary sclerosing cholangitis (PSC)]. Less frequent causes of BBS include ischemia, trauma, autoimmune pancreatitis, radiation therapy, as listed in Table 1^[1-7].

Although BBS comprise a heterogeneous group of disorders with variable natural history, its etiology plays an important role in predicting endoscopic treatment success. Post-cholecystectomy BBS, whose incidence has increased 2-3 fold since the increment of laparoscopic cholecystectomy, are very responsive to endoscopic therapy^[8,9]. Bile duct strictures related to OLT can occur in 3% to 6% of patients. Among these, anastomotic strictures are more amenable to endoscopic treatment as compared to nonanastomotic strictures caused by ischemic injury^[5]. Approximately 10%-30% of patients with chronic pancreatitis will develop a symptomatic biliary stricture. However, these BBS are more resistant to endoscopic treatment with an overall lower success rate. On the other hand, BBS related to PSC showed a good response to endoscopic treatment^[5].

The diagnosis of BBS should lead to prompt treatment in order to avoid serious complications such as secondary biliary cirrhosis and end-stage liver failure^[3]. Treatment options for BBS include surgery, percutaneous approach, and endoscopic therapy. Endoscopic treatment is widely accepted as first line treatment option due to its efficacy and less invasiveness. The techniques currently used are dilation; single plastic stent; multiple large-bore plastic stents; and self-expandable metal stent (SEMS)^[1-3,5,6]. Recent advances in these endoscopic techniques and devices have allowed successful treatment of most BBS cases. When endoscopic treat-

ment fails, percutaneous and endoscopic combined approach may be attempted. Surgery is usually reserved for complete transections, prior endoscopic failure and refractory cases. Nevertheless, a consensus regarding the adequate management of BBS has not yet been established.

In this review, the authors will discuss the endoscopic management of BBS and focus on the outcomes, advantages and disadvantages of each endoscopic technique.

DIAGNOSIS

Diagnosis of BBS is usually based on the correlation between clinical, epidemiological, laboratorial data and imaging findings. Patients with biliary strictures can be completely asymptomatic or present with clinical and laboratory evidence of biliary obstruction, such as jaundice, abdominal pain, cholangitis and abnormal liver function tests^[10]. Clinical manifestations can also be related to the underlying cause of obstruction and its location. According to the distance from the stricture to the hepatic hilum, several classification systems for BBS have been proposed; most commonly used are Bismuth classification, which differs from malignant biliary strictures, and Strasberg classification (Table 2)^[11,12].

Abdominal ultrasound is typically the initial method for the evaluation of patients with biliary strictures. Accuracy levels over 90% in the detection of biliary dilation and the level of obstruction have been found. However, its accuracy for detecting the underlying cause is low and the results are operator dependent^[13].

Cross-sectional imaging modalities obtained both by computerized tomography and particularly magnetic resonance cholangiopancreatography (MRCP) can accurately delineate the biliary anatomy, location and length of the stricture. MRCP is therefore very useful before endoscopic retrograde cholangiopancreatography (ERCP) for treatment planning^[14]. Furthermore these imaging methods play a key role in differentiating benign from malignant biliary strictures and, in malignant disease, staging can be performed. Malignancy exclusion is indeed of utmost importance during the diagnostic evaluation of BBS and can be challenging. In a meta-analysis, including 4711 patients with suspected biliary obstruction, MRCP showed a sensitivity and specificity of 98% in determining the level of obstruction and 88% and 95%, respectively, in the detection of malignancy^[15]. Recent advances in magnetic resonance imaging (MRI), such as diffusion weighted MRI, have shown an improvement in the differentiation between benign and malignant lesions^[16].

The diagnostic role of ERCP in biliary obstruction evaluation has decreased with the wider availability of MRCP. However, unlike MRCP, ERCP enables tissue sampling, using biliary brushings or biopsies. A review of 16 studies including 1556 patients with biliary brushings and biopsies obtained during ERCP found an overall

Table 1 Etiology of benign biliary strictures

Post-operative injuries	Cholecystectomy Liver transplantation Hepatic resection Biliary anastomosis Biliary reconstruction Biliary enteric anastomosis
Inflammatory	Chronic pancreatitis Primary sclerosing cholangitis Autoimmune pancreatitis Choledocholithiasis Immunoglobulin G4 cholangiopathy Infections (recurrent bacterial cholangitis, tuberculosis, histoplasmosis, schistosomiasis, HIV, parasites) Postradiation therapy
Others	Ischemic (hypotension, hepatic artery thrombosis, portal biliopathy) Trauma Mirizzi syndrome Postbiliary sphincterotomy Endoscopic sclerotherapy for duodenal ulcer bleeding

HIV: Human immunodeficiency virus.

sensitivity of 41.6% and a negative predictive value of 58%^[17]. One of the reasons for this low sensitivity is the low cellularity of samples obtained; a recent study demonstrated that the identification of drunken honeycomb cells, loosely cohesive clusters of round cells and large atypical cells with foamy cytoplasm may significantly increase sensitivity^[18].

Endoscopic ultrasound (EUS) and intraductal ultrasonography (IDUS) have good accuracy in discriminating benign from malignant strictures in the extra-hepatic bile duct, but some strictures in the common duct and hilar region are difficult to identify. With the introduction of EUS guided fine needle aspiration (FNA) histological diagnosis is also possible. However, the sensitivity of EUS-FNA in distinguishing benign from malignant strictures is widely variable ranging from 43% to 86%^[19-22]. The possibility of peritoneal seeding during EUS-FNA is a limiting factor of this technique^[23].

Intraductal ultrasonography provides high-resolution images of the ductal wall and periductal structures. A review of 397 patients with indeterminate biliary strictures who performed ERCP with IDUS showed a sensitivity, specificity and accuracy of 97.6%, 98% and 92% respectively^[24].

Emerging technologies such as fluorescence *in-situ* hybridization (FISH), confocal laser endomicroscopy and direct cholangioscopy have yielded promising results in the differential diagnosis of biliary strictures. Furthermore measurement of volatile organic compounds in the bile duct fluid can help in the differentiation of benign vs malignant strictures^[25].

Fluorescence *in situ* hybridization uses fluorescently

Table 2 Classification for benign biliary strictures

Bismuth classification	
I	Low CHD stricture, > 2 cm distal to hilum
II	Proximal CHD stricture, < 2 cm distal to hilum
III	Hilar involvement up to proximal extent of CHD, but confluence preserved
IV	Confluence involved, no communication between left and right ducts
V	Type I, II or III plus stricture of an isolated (aberrant) right duct
Strasberg classification	
A	Small duct injury in continuity with biliary system, with cystic duct leak
B	Injury to sectoral duct with consequent obstruction
C	Injury to sectoral duct with consequent bile leak from a duct not in continuity with biliary system
D	Injury lateral to extrahepatic ducts
E1	Stricture located > 2 cm from bile duct confluence
E2	Stricture located < 2 cm from bile duct confluence
E3	Stricture located at bile duct confluence
E4	Stricture involving right and left bile ducts
E5	Complete occlusion of all bile ducts

CHD: Common hepatic duct.

labeled DNA probes to detect chromosomal abnormalities that can be indicative of tumor. One prospective study compared sensitivity and specificity of cytology with FISH in patients with cholangiocarcinoma and found that sensitivity of cytology was 15% compared to 34% for FISH and specificity was 91% and 98% respectively^[26]. The use of cholangioscopy-directed intraductal biopsies and FISH of brush cytology samples was shown to increase the diagnostic yield^[27,28].

Digital image analysis (DIA) uses Feulgen dye and spectrophotometric principles to quantify abnormalities in nuclear DNA that allow measuring ploidy within the cell. When FISH and DIA are used in combination a malignant diagnosis can be predicted in 67% of the cases compared with 62% and 14% for FISH and DIA when used separately^[29].

Cholangioscopy enables direct visualization and targeted biopsies. However, the sensitivity of its histologic biopsies was only 49% in the diagnosis of malignancy^[30].

Confocal laser endomicroscopy is a new diagnostic tool that uses an intravenous injected contrast agent like fluoresceine. It showed promising results in the diagnosis of biliary stenosis by using a catheter probe, which can be inserted through the working channel of an endoscope, or through a FNA needle. Several studies have shown that this new technique is rather useful in the differentiation between benign and malignant strictures of the bile duct with a high sensitivity of 73%-83%, but a low specificity of 33%-50%^[31-36].

Despite the development of these new diagnostic tools, the majority is still under evaluation in clinical trials.

ENDOSCOPIC THERAPY OF BBS

The objectives of BBS endoscopic treatment include biliary decompression with maintenance of the bile duct patency and prevention of recurrent stricture formation. This can be achieved by using expandable or graduating dilators; inserting single or multiple biliary plastic stents; inserting SEMS or, in some circumstances, by the combination of two modalities. Multiple endoscopic sessions are usually necessary before complete and sustained resolution is achieved. For those patients who may need surgery, endoscopic treatment can be considered as bridging therapy^[7].

During ERCP, there are three main technical decisions that should be made, namely the guide wire choice, the need for dilation and the stent choice. After endoscopic sphincterotomy, the crucial step is to overcome the stricture with a guide wire. The stricture can be negotiated only if there is no common bile duct complete transection. In postoperative stricture this step can be particularly difficult because the stenotic tract, even if short, can be asymmetric, angulated and rich in fibrous tissue. The choice for the adequate guide wire according to the morphology of the stricture is critical. Several types of ERCP guide wires are commercially available with different characteristics and wire tips (straight, tapered, J shaped or looped). Although there is a paucity of comparative studies, hydrophilic guide wires with a straight or J shaped tip are the preferred ones in this clinical setting^[1,37]. In a recent randomized trial involving 197 patients, a novel stiff-shaft flexible guide wire showed higher success rate in stricture cannulation (94% vs 79%, $P = 0.00041$) and lower procedure time (8.1 vs 11.2 min, $P < 0.0001$) when compared to a standard angle-tip hydrophilic wire in combination with a nitinol wire^[38]. Manipulation of guide wires demands patience, skill and optimal fluoroscopic imaging. The direction of the catheter and the wire should also be in the same axis as the stricture. Sometimes straightening the common bile duct by pulling an inflated stone extraction balloon just below the stricture or using the bending capabilities of the papilotome can be helpful. Other devices that can be used to overcome the stricture include tapered tip steerable catheters (3.9-4.9 Fr), a screw drill (7-8.5 Fr Soehendra stent extractor)^[39], angioplasty balloons mounted on 3 Fr catheters^[40], or a 6 Fr wire guided diathermic dilator^[41,42].

After overcoming the stricture with a guide wire, BBS dilation can be considered using either a balloon or bougie system. Although there is no head-to-head comparison between these two techniques, an elevated restenosis rate (up to 47%) has been consistently observed^[43-45]. Balloon dilation alone is therefore considered inappropriate in vast majority of cases. It should be performed only if necessary and during the first endoscopic procedure, because of the forceful disruption of the scar may add further traumatic damage to the tissue with subsequently development of a new

fibrotic reaction. Even so, the underlying cause of BBS should be taken into account in the final decision. According to retrospective studies, balloon dilation alone in BBS in the context of PSC can achieve a clinical and biochemical response in approximately 80% of non-cirrhotic patients^[46-49].

The next step, the choice of the stent, is currently the most contentious decision. Insertion of one plastic stent is easy to perform and cheap, but has short patency and a low rate of long-term success. A widely used alternative is a multiple plastic stent insertion method, where multiple large bore plastic stents (10 to 11.5 Fr) are inserted in the biliary tract at regular time intervals (every 3 to 6 mo) throughout one year^[50-52]. The rationale is that the gradual and continuous dilation of the stricture area may induce tissue remodeling and consolidation. Although it is a very effective technique, it requires multiple endoscopic procedures. SEMS due to its larger lumen and longer patency appear as a reasonable alternative. Bare SEMS, commonly used in malignant biliary obstruction, are not suitable for BBS since stent itself can create irreversible tissue hyperplasia and stent embedment, precluding its removal. With the evolution of stent design, partially covered and fully covered stents have been developed. These stents allow temporary placement and can therefore be used in BBS^[53].

These endoscopic techniques will be individually discussed, focusing on outcomes, advantages, disadvantages and complications.

Dilation

Dilation of BBS is mostly used as a complementary technique before stent placement and rarely as a single method. Actually, PSC is the main indication for dilation alone, when a dominant stricture (defined as a stenosis with < 1.5 mm in the main biliary duct or < 1 mm in the intra-hepatic duct) is present. Even so, the best endoscopic management is not yet defined.

In retrospective studies, dilation alone showed clinical and biochemical response in approximately 80% of non-cirrhotic PSC patients^[46-49]. There is no consensus on the method of dilation to be used, either rigid dilators or balloon dilators. If the stenosis is too tight some authors recommend rigid dilation from 5 Fr to 7 Fr followed by balloon dilators to obtain dilation up to 18 Fr to 24 Fr^[54]. In one prospective uncontrolled study involving 96 patients in which a total of 500 hundred dilations were performed over a 20-year period, the survival free of liver transplantation was 81% at 5 years and 52% after 10 years of follow-up^[55]. The use of stents in BBS related to PSC is still controversial since it was shown to be associated with increased complication rates when compared to balloon dilation. Previous studies with plastic stents showed a high risk of ascending cholangitis (up to 50%)^[56,57]. Although there are no prospective randomized controlled trials comparing dilation with dilation and stenting, a retrospective, single-center study compared endoscopic

balloon dilation with either percutaneous or endoscopic dilation with stent placement. Stent placement did not achieve any additional benefit and was associated with more infectious complications^[58].

Based on these studies most of authors prefer dilation to stenting in patients with PSC. Stent placement should be reserved for patients with cholangitis and in patients not responding to balloon dilation. Optimal endoscopic intervention is still unclear and results from randomized trials are necessary to answer these questions.

Plastic stents

By keeping the stricture open for a prolonged period of time, plastic stents placement may allow a continuous calibration of the stenosis diameter, with tissue remodeling around the stent and a more sustained stricture resolution.

Various stenting protocols (single stent, two or multiple stents) have been described with different short and long-term results^[1,52].

Single plastic stent placement usually does not achieve good results in terms of BBS resolution or long-term follow-up. Due to their limited stent diameter, single plastic stents have only short-term patency rates, and so multiple endoscopic sessions are required. Furthermore, most of the previous studies are retrospective and heterogeneous with different patient selection criteria, dilation methods, sent diameters, follow-up periods and success definitions. For these reasons, this technique has limited clinical applications^[59].

An aggressive multiple stent strategy described by Costamagna *et al*^[50,51] for the treatment of post-operative biliary strictures is associated with better results than the Amsterdam protocol described by Bergman *et al*^[60] and, thus, is the preferred approach. After the placement of one or two plastic 10 Fr stents at the initial ERCP the maximum number of 10 Fr plastic stents (up to six) are placed at the each subsequent ERCP with stent exchange being performed every 3-4

mo until complete stricture disappearance occurs usually 12-18 mo later^[50,51]. This maximal multiple stenting was also adapted for the treatment of chronic pancreatitis and post-cholecystectomy strictures.

The placement of multiple large bore plastic stents in BBS is achieved in over 90% of patients. However, the long-term patency varies according to BBS etiology. Table 3 summaries clinical trials reported the treatment of BBS with multiple plastic stents.

In post-cholecystectomy BBS, endoscopic treatment can be performed in patients in whom the bile duct has not been transected or ligated. The maximal stent insertion strategy (1 to 6, 10 Fr stents) with 3 monthly exchanges during one year or until complete morphologic disappearance of the stricture has consistently shown good long-term results with success rates over 90% in some series even after prolonged follow-up^[61]. A recurrence rate of 20%-30% within 2 years of stent removal has been reported^[5], but these patients can be successfully retreated endoscopically. The maximal multiple stent strategy is therefore often considered the first line treatment in most cases^[5,52,61,62]. Treatment of peri-hilar stricture are, in turn, more challenging, technically difficult, and with worse success rates than distal strictures (Bismuth III 25% vs 80% in Bismuth I / II)^[5,44,63].

Similarly, in post-OLT strictures multistenting technique is considered the first line treatment. Better results are seen in early anastomotic strictures with resolution achieved within 3 mo whereas those presenting later, usually associated with fibrosis, required longer stenting periods, up to 12 to 24 mo^[64]. Balloon dilation and maximal stent placement every 3 mo seems the most effective strategy with an 80% to 90% success rate. A recently published prospective study by Kaffes *et al*^[65] which compared plastic stents with fully covered self-expandable metal stents (FCSEMS) in anastomotic strictures showed similar stricture resolution between groups after a median follow-up of 23 mo (100% in

FCSEMS group vs 80% in plastic group, $P = \text{ns}$). On the other hand, in non-anastomotic strictures endoscopic treatment can be considered either as the first line treatment or as a bridge to retransplantation^[64]. These strictures, vascular in origin, are usually multiple, proximal and its endoscopic treatment associated with low long-term success rate (50%-75%), requiring retransplantation in up to 25%-50% of patients^[5,7,62,64].

Distal common bile duct strictures in chronic pancreatitis are, in turn, more resistant to endoscopic treatment. As many remain symptomless for years its true incidence is unknown. However, 10%-30% of patients with advanced chronic pancreatitis develop a symptomatic biliary stricture^[1]. Treatment is recommended when symptoms occur; in the presence of secondary biliary cirrhosis or bile duct stones; and for persistent (more than 1 mo) asymptomatic elevation of serum alkaline phosphatase (levels greater than twice the upper limit of normal values) and/or serum bilirubin^[66]. The long-term success of single biliary plastic stent strategies has been disappointing specially in the presence of pancreatic head calcifications^[67], whereas multiple stenting for 12 or more mo led to an overall success in 65.2% of patients (60%-92% of cases)^[5,68,69]. Recurrent stricture rates reaching 17% after stent removal have been reported during a mean follow-up period of 42 mo^[5] and can be retreated by ERCP. Recently, Haapamäki *et al.*^[70] published a prospective randomized multicenter study comparing the placement of multiple plastic stents with a FCSEMS. During a stenting period of 6 mo, either strategy showed good long-term relief of the stricture, with 2-year stricture-free success of 90% for plastic stent and 92% in the FCSEMS group and no difference in stent related complications. These results need to be followed-up and the results of upcoming trials (NCT01543256) are awaited especially in this population where non-compliance is of serious concern. Due to limited efficacy, need for repeated endoscopic therapy and risk of severe septic complications associated with non-compliance, the choice between endoscopic and surgical options should rely on patient co-morbidities, expected compliance and local expertise^[5,66].

Although some authors suggested that multistenting strategy has a low rate of premature symptomatic stent occlusion and a longer occlusion free survival^[71], these stenting strategies have shown some shortcomings. It is hindered by the need of patient compliance with multiple ERCP sessions over 1-year or more; its inherent costs; and its possible adverse events like cholangitis and other stent related complications. Fully covered SEMs are therefore gaining an increasing role in the treatment of BBS, but there is a lack of published head-to-head comparisons and the results of several on-going randomized trials are awaited.

SEMS

Among endoscopic treatments of BBS, stent placement

has emerged as a less invasive therapeutic option, with lower morbidity and mortality compared to surgery^[72].

In order to overcome major limitations of plastic stents, such as suboptimal stricture resolution and need for frequent ERCPs, SEMs appeared as a good alternative. Besides the initial enthusiasm with the use of partially covered SEMs (PCSEMS), further studies revealed high rates of stent migration (up to 23%), mucosal hyperplasia (up to 36%) and stent occlusion (up to 67%)^[73-80]. Like uncovered SEMs, the clinical use of PCSEMS has been therefore abandoned^[81].

The relative ease removal of FCSEMS triggered the attention of many investigators, leading to an increased use in benign biliary conditions. FCSEMS have, in fact, a covering membrane to prevent ingrowth and hyperplastic reaction, and to improve removability. FCSEMS do not embed into the mucosa, provided that the covering membrane remains intact^[82,83]. Other advantages include an increased radial diameter, longer stent patency, and easy insertion technique^[84-86]. Therefore, FCSEMS have emerged as a promising therapeutic option in the treatment of BBS, and have largely replaced their uncovered, partially covered counterparts, as well as plastic stents. Even so, before its use can be widely recommended the following questions need to be answered. Are FCSEMS-related outcomes significantly better than plastic multistenting procedures? What is the immediate, and long-term clinical success? Can FCSEMS be effectively removed at the end of treatment? Are FCSEMS complications serious enough to preclude their use? Several studies have been published trying to address all these issues.

FCSEMS efficiency in stricture resolution has been demonstrated in several studies that range from relatively small size with less than 10 patients^[83] to more recent and larger ones with over 100 patients^[72,79,87].

In a multicenter, prospective study of 133 patients, Kahaleh *et al.*^[72] found a high response rate of stricture resolution, ranging from 61% for anastomotic strictures to 91% for post-surgical strictures, and 81% for chronic pancreatitis related strictures. FCSEMS were removed after a mean time of 95.5 ± 48.7 d. Two predictors for stricture resolution were found, namely longer indwell time (OR = 4.3, 95%CI: 1.24-15.09) and absence of migration (OR = 5.4, 95%CI: 1.001-29.29).

Most recently, Devière *et al.*^[87] evaluated the ability to remove FCSEMS after extended indwell and the frequency and durability of stricture resolution. In this prospective, nonrandomized, multinational study of 187 patients stent removal was scheduled at 10-12 mo for patients with chronic pancreatitis or cholecystectomy related strictures, and at 4-6 mo for patients who received liver transplant. Stricture resolution occurred in 76.3% of patients (95%CI: 69.3%-82.3%). Removal success was accomplished in 74.6% (95%CI: 67.5%-80.8%) and it was more frequent in the chronic pancreatitis group (80.5%) than in the liver transplantation (63.4%) or cholecystectomy (61.1%) groups

($P = 0.017$). Endoscopic removal of FCSEMS was accomplished in all patients in whom this procedure was attempted. As such, in some types of BBS, FCSEMS can be left *in situ* for 1-year without compromising removability.

Although FCSEMS feasibility has been well established, comparative studies on the efficacy of multiple plastic stents are still lacking. To the best of our knowledge, only two prospective randomized trials comparing FCSEMS to plastic stents have been published. Kaffes *et al.*^[65], in a study of 32 patients with anastomotic post-liver transplant, showed that FCSEMS reduced the number of ERCPs needed to achieve stricture resolution (median 2 vs 4, $P = 0.0001$) with similar recurrence rates. There was no significant statistical difference between groups neither in stricture resolution (100% in FCSEMS group vs 80% in plastic group, $P = ns$), nor in complication rate (10% in FCSEMS group vs 50% in plastic group, $P = 0.051$). No cases of migration were observed in FCSEMS group. Cost analyses showed that FCSEMS was more cost effective. In the other multicenter, randomized trial, 60 patients with BBS caused by chronic pancreatitis were included. At 6 mo after randomization, all stents were removed and the patients were followed at 6 mo and 2 years after stent removal. The stricture-free success rate after 2 years was 90% (95%CI: 72%-97%) in the plastic group and 92% (95%CI: 70%-98%) in the FCSEMS group ($P = 0.405$). Stent migration was similar in both groups (10% in plastic group vs 7% in FCSEMS group, $P = 1$)^[70]. Recently a systematic review showed a tendency to successful use of FCSEMS in BBS related to chronic pancreatitis [77% (95%CI: 61%-94%) vs 33% (95%CI: 4%-63%), $P = 0.06$] with fewer endoscopic sessions (1.5 vs 3.9, $P = 0.0002$) and subsequently fewer complications. However, these results were not observed in other BBS etiologies other than chronic pancreatitis^[88].

Interestingly, in BBS related to chronic pancreatitis (particularly in calcified pancreatitis) the previous studies with multiple plastic stents showed inferior response to endoscopic therapy. On the contrary, as stated before, there is increasing evidence of a better success rate and lower recurrence rate with FCSEMS. It is thought that both the diameter of the FCSEMS and the duration of indwell may contribute to these findings^[82,87].

Among the available literature, stent duration is not homogeneous or standardized. Even so, it seems that a short stenting period might not be enough to allow for adequate tissue repair. Longer stenting duration should be therefore considered, as it has been independently associated with stricture resolution^[72,87,89].

The drawbacks of FCSEMS include stent migration, duodenal reflux and tissue hyperplasia^[2]. These issues should be addressed in the development of new stents in order to reinforce stent quality. Stent migration is, in fact, the major obstacle of FCSEMS. To minimize stent migration, the concept of flared ends (FE) and anchoring flaps has been introduced. Park *et al.*^[90], compared 2 stents, both with FE at the distal portion and with either

4 anchoring-fins (AF) or FE at the proximal end, in 43 BBS patients. Stents remained *in situ* for a median of 6 mo (interquartile range, 4 to 6) and no migrations were seen in the AF group, whereas a 33% migration was seen in the FE group ($P = 0.004$). Immediate stricture resolution was noted in 91% of patients with AF and 88% of those with FE. Recurrence during the median 4 mo follow-up period after stent removal occurred in 7 patients in total (16%) with no significant difference between the 2 groups. All nonmigrated stents were successfully removed without complications. The authors concluded that the AF design might be superior to the FE regarding antimigration effect for BBS. More recently, Walter *et al.*^[91] conducted a prospective, multicenter cohort study with a novel Niti-S biliary bumpy stent with bilateral FE and a high conformability at the middle part of the stent. In this study, involving 38 patients, the stent was removed after 3 mo. Despite the initial clinical success rate of 80%, the long-term clinical success rate was only 63% and stent migration occurred in 31% of patients. Regarding duodenal reflux issue, some studies using SEMS with antireflux valve have been conducted. However, only cases of malignant biliary obstruction were included^[92-94].

Besides stent migration, acute cholangitis, cholecystitis and pancreatitis have also been reported with FCSEMS placement^[65,70,87,88]. Even so, complications did not preclude its use in the treatment of BBS^[72,82].

After FCSEMS placement, clinical, laboratory and radiological follow-up has not yet been defined. Some authors advocate clinical follow-up for symptom recurrence and liver function tests every 3-6 mo for a minimum of 2 years after stent removal, then yearly with a baseline transabdominal ultrasound or MRCP^[79].

Based on these more recent data, FCSEMS might be recommended as the first line option for BBS, particularly in certain groups of patients, like chronic pancreatitis. Table 4 outlines the main prospective trials regarding FCSEMS use in BBS endoscopic treatment.

NEW AREAS OF RESEARCH

Bioabsorbable self-expandable stent is a growing area of interest in BBS treatment. This type of stent has a larger lumen than plastic stents, which allows better patency rate and reduced biofilm formation. Unlike FCSEMS, it does not require removal of stent and can reduce biliary mucosal hyperplasia. It is a braided structure of filaments made of absorbent polydioxanone or polylactide^[3]. After sent insertion, balloon dilation may be required to promote additional expansion of lumen, because of its radial force is weaker than FCSEMS. In animal models, biostents showed endoscopically deployment with success, expansion to full diameter, and maintenance of patency up to 9 mo^[95-97]. To the best of our knowledge, biodegradable stent have been currently experimented only in animal models^[95-97].

Recently, is has been published some early and

exciting work looking at intraductal radiofrequency ablation (RFA) in the treatment of BBS. In a pilot study, Hu *et al*^[98] performed intraductal bipolar radiofrequency at power 10W for 90 s/stricture, followed by balloon dilation with/without stent placement, in 9 BBS patients. Seven of them were refractory at endoscopic or percutaneous interventions. The treatment concept is aimed to using ablation power rather than using boogie effect to treat the structure. After RFA, stricture of all patients showed immediate improvement and five patients (55%) achieved stricture resolution during a follow-up of 12.6 mo. Three of the nine patients required no further stenting. Thus, RFA therapy is a new method that appears promising particularly in refractory cases.

CONCLUSION

Over the past 20 years, the progress and development of endoscopic devices and therapeutic options in the management of BBS have been really remarkable. Several prospective randomized trials have been recently published; including the most waited which compare FCSEMS with plastic stents.

Although multiple plastic stent insertion remains a very effective method in the vast majority of patients, there are emergent data suggesting that FCSEMS may be a reasonable alternative treatment option. The most recent studies support its efficacy, its relative low migration rate and low complications rate, and cost-effectiveness. However, data that clearly demonstrate the superiority of FCSEMS over plastic multistenting procedures are lacking. Thus, randomized, controlled trials assessing stent efficacy, complications, and cost-effectiveness are needed before a routine use of FCSEMS can be recommended. Also new functional SEMS are waited; the ideal stent characteristics have not been yet defined. In the near future, not only new techniques, like RFA, but also other therapies involving new devices will be available in clinical practice.

Abstract

AIM: To determine whether anaesthesiologist-administered sedation with propofol (AAP) or endoscopist-administered conscious sedation (EAC) with fentanyl/midazolam shortens colonoscopy duration/total room time.

METHODS: This is a prospective, non-randomized, comparative study that enrolled patients greater than 18 years of age undergoing colonoscopy in a single Canadian academic outpatient endoscopy unit over a three-month consecutive period. Colonoscopies in this unit are performed both with AAP and EAC. Patient demographics, procedure-related data and adverse events were documented. Additionally, the level of procedure difficulty, and whether a staff endoscopist, trainee with assistance, or independent trainee, performed the procedure were documented. A validated modified 4-question, 5-point Likert scale telephone survey was used to assess patient satisfaction with colonoscopy. The telephone patient satisfaction survey was conducted 24-72 h following the procedure.

RESULTS: Two hundred and thirty patients were

enrolled during the study period with 126 patients in the AAP group and 104 patients in the EAC group. Mean procedure time was 18.3 ± 10.1 min in the AAP group and 14.7 ± 7.1 min in the EAC group ($P = 0.002$). Mean total room time was 36.8 ± 13.7 with AAP and 30.1 ± 11 min with EAC ($P < 0.001$). Multivariate analysis revealed the use of AAP ($P = 0.002$), resident participation ($P < 0.001$), diagnostic interventions ($P = 0.033$), therapeutic interventions ($P < 0.001$), lower body mass index ($P = 0.008$) and American Society of Anaesthesiologist class ($P = 0.016$), to be predictors of longer total room time. Patient age and gender were not significant predictors. After excluding cases in which trainees were involved, there was no significant difference in procedure time between the two groups ($P = 0.941$), however total room time was still prolonged in the AAP group ($P = 0.019$). The amount of pain experienced was lower with AAP ($P = 0.02$), with a trend toward overall higher patient satisfaction ($P = 0.074$). There were 2 sedation-related adverse events, both in the AAP group involving a patient with aspiration requiring hospitalization and a patient with hypoxia managed with bronchodilators.

CONCLUSION: EAC results in reduced total room time compared to AAP. Resident participation doubles procedure time regardless of sedation type.

Core tip: There is little research examining sedation type in light of patient satisfaction and overall efficiency of colonoscopy. Our novel prospective study evaluated the total procedure room time and patient satisfaction in a high-volume endoscopy center, which performs colonoscopy using conventional sedation and propofol sedation. A statistically significant reduction in total room time with conventional sedation (midazolam/fentanyl) when compared to anaesthetist-administered propofol was demonstrated. Patients reported less procedure pain when receiving propofol sedation compared to conventional sedation. Special discussion emphasizes the need to further examine strategies to maximize endoscopy unit efficiency to respond to increasing patient demand, while maximizing patient satisfaction.

INTRODUCTION

Colorectal cancer is the leading cause of cancer related death among non-smokers in Canada and is the fourth leading cause of cancer death worldwide^[1]. Patients presenting with a high suspicion of colorectal cancer based on physical examination and imaging studies should receive a colonoscopy within two weeks of diagnostic suspicion^[2]. Furthermore, any patient referred for a screening colonoscopy should receive a colonoscopy within six months of referral^[2]. However, with an ever-increasing average population age, demand for colonoscopies is expected to increase by 5%-10% per annum over the coming decades^[3]. Presently, hospital endoscopy units are experiencing overwhelming demand for their service and as such it is imperative to examine methods to improve overall endoscopy unit efficiency^[4,5].

There has been growing interest in finding the ideal sedation for colonoscopy that is safe, easy to administer, provides adequate sedation and allows for rapid recovery. A combination of benzodiazepines and opiates (midazolam and fentanyl), the medications used most commonly by gastroenterologists for procedural sedation, provides adequate analgesia and sedation during colonoscopy^[6]. Propofol is an intravenously administered hypnotic drug used for induction and maintenance of general anaesthesia and is also used in procedural sedation. The perceived benefits of propofol sedation during colonoscopy include rapid post-procedure drug clearance, improved patient comfort and rapid recovery/discharge^[2]. Propofol administered by an anaesthesiologist has been extensively investigated and multiple randomized controlled trials have shown that using propofol sedation for colonoscopy in generally healthy individuals can lead to faster recovery and discharge times and increase patient satisfaction without an increase in side-effects^[7]. Furthermore, propofol sedation is preferred by some endoscopists for colonoscopy procedures compared to conventional sedation^[6].

The Canadian Association of Gastroenterology released a position statement on the use of propofol for sedation during endoscopic procedures indicating "propofol has advantages over standard agents used for conscious sedation"^[2]. The rate of cecal intubation (a marker of colonoscopy completion) is increased in procedures in which propofol-induced sedation has been used^[6]. However, the literature regarding the experience, overall efficacy and efficiency of using propofol in endoscopy units is limited.

The aim of this study was to determine whether anaesthesiologist-administered propofol sedation (AAP) results in a shorter duration of colonoscopy procedure time and total procedure room time in comparison to endoscopist-administered conventional sedation (EAC) with midazolam and fentanyl for colonoscopy. Secondary outcomes include a comparison of procedure times with

or without resident involvement, patient satisfaction and procedure related complications.

MATERIALS AND METHODS

Overview and patient selection

We performed a prospective, non-randomized, comparative study recruiting patients during a three-month (12 wk) consecutive period at a single high-volume Canadian academic outpatient endoscopy unit where both AAP and EAC are utilized. Bowel preparation protocols, colonoscopy indication, therapeutics performed and American Society of Anaesthesiologists (ASA) class are identical for patients receiving both AAP and EAC and patients do not select the type of sedation they receive. The Western University Ethics Review Board approved this study for patient recruitment. All patients 18 years of age and over undergoing colonoscopy either for symptomatic or screening purposes were approached for possible involvement in the study. Study enrolment involved an informed consenting process prior to the potential participant entering the procedure room. Verbal consent as well as written consent was obtained prior to enrolment in the study. Patients were provided a contact telephone number and electronic mail address of the study research assistant who was available to answer study questions and remove participants from the trial at their request at any point during the study period. A total of five patients declined participation in the study and no participants requested to be removed from the study after enrolment. Exclusion criteria included age less than 18 years, inability to read or write English and patients with major psychiatric or cognitive impairment. Six gastroenterologists participated in the study. All participating endoscopists in the study were experienced gastroenterologists with more than 200 colonoscopies performed per year.

Measurement tools and data collection

Following patient consent, a detailed list of parameters was documented for each patient during their colonoscopy. Patient demographics including age, sex, body mass index (BMI) and ASA class, and procedure related data including indication, pre-procedure time, procedure duration, the presence or absence of any intervention, procedure completion time and total procedure room time were all recorded. Additionally, the level of procedure difficulty, and whether a staff endoscopist, trainee with assistance, or independent trainee, performed the procedure were documented. The trainee included either a gastroenterology resident or second year general surgery resident. We also collected anaesthesia related data, including type of sedation used and total sedative dose/administration method.

A validated modified 4-question, 5-point Likert scale telephone survey was used to assess patient satisfaction with colonoscopy^[8]. Forty-eight hours post-procedure, enrolled patients were contacted regarding our post-

procedure patient satisfaction survey. If unable to reach the patient at this time, one additional follow-up call was made the following day (72 h post-procedure). To avoid recall biases and maximize group standardization, no participants were contacted prior to 48-h post-procedure, nor were participants contacted beyond the 72-h post-procedure time interval. Participant satisfaction data was combined according to the group represented by each participant (AAP or EAC). Patient satisfaction data was analyzed as a whole. Thus, stratification for difference between participants reached at the 48 h vs 72-h post-procedure time point was not performed.

Throughout the study, a research assistant (PT) was available to answer participants' questions. The study research assistant was not involved in any direct care of study participants and was responsible for collecting patient written consent, recording study measurable and contacting patients post-procedure for the patient satisfaction survey.

Statistical analysis

For the purposes of statistical analysis, statistical significance was understood to be achieved when *P*-value was less than 0.05. χ^2 analysis and unpaired *t*-test were used to compare differences between the two patient groups (AAP vs EAC). χ^2 analysis and Wilcoxon 2 sample test were used to analyze the patient satisfaction survey responses. Study endpoints were analyzed with unpaired *t*-tests, Fischer exact tests and analysis of covariance were adjusted for gender where appropriate. Height discrepancies were correlated to gender differences. This approach was justified by performing a logistic regression of height and gender as independent variables with respective group as an endpoint and it was noted that only gender was a significant variable, height was not. Multivariate analysis was utilized to normalize the collected data set. Adjustments were made for a non-normally distributed total room and total procedure time and between-group statistical tests are based on the log-transformed data. All database management and statistical analysis was conducted and reviewed by the department's staff biomedical statistician, Larry Stitt, from Western University Department of Epidemiology and Biostatistics.

RESULTS

A total of 230 patients were enrolled in our study. A total of 126 (55%) patients received AAP, while 104 (45%) patients received EAC. The cecum was intubated in all patients and confirmed by standard cecal landmarks and in most instances by intubation of the ileum and direct visualization of intestinal villi. Patient demographics are outlined in Table 1.

Mean procedure time (time measured from scope insertion to scope removal) was 18.3 ± 10.1 min in the AAP group and 14.7 ± 7.1 min in the EAC group (*P* = 0.002). Mean total procedure room time (time measured

AAP: Anaesthesiologist-administered sedation with propofol; BMI: Body mass index; ASA: American Society of Anaesthesiologists.

from the moment the patient entered the room until the moment the patient was wheeled to recovery) was 36.8 ± 13.7 min with AAP and 30.1 ± 11 min with EAC ($P < 0.001$). Trainee involvement was 51/126 (40%) in the AAP group and 15/104 (14%) in the EAC group ($P < 0.001$). Multivariate analysis revealed the use of AAP ($P = 0.002$), resident participation ($P < 0.001$), diagnostic interventions ($P = 0.033$), therapeutic interventions ($P < 0.001$), lower BMI ($P = 0.008$) and ASA class ($P = 0.016$), to be predictors of longer total procedure room time, as detailed in Table 2. There were two sedation related adverse events in the AAP group. One case involved a patient who aspirated during procedure, which subsequently required hospitalization. The second adverse event involved a post-procedure, recovery room incidence of hypoxia, which was resolved by bronchodilators.

Log transformation of procedure time and total procedure room time was performed to normalize data for height and gender. With removal of trainee presence, there was no significant difference in procedure time between the two groups ($P = 0.941$) (Table 3). However, the total procedure room time was still prolonged in the AAP group ($P = 0.019$) relative to the EAC group

Table 3 Procedure time and total procedure room time with removal of trainee presence (staff endoscopist data only) for endoscopist-administered sedation and anaesthesiologist-administered sedation with propofol groups

	EAC (<i>n</i> = 89)	AAP (<i>n</i> = 75)	<i>P</i> -value

Mean \pm SD	13.0 \pm 4.9 min	12.9 \pm 4.8 min	0.941
Total room time			
Mean \pm SD	28.1 \pm 9.3 min	31.1 \pm 10.1 min	0.019

EAC: Endoscopist-administered conscious sedation; AAP: Anaesthesiologist-administered sedation with propofol.

(Table 3). With respect to the post-procedure patient satisfaction surveys, 74/104 (71%) of participants from the EAC and 80/126 (64%) of participants from the AAP group completed the telephone survey (Table 4). There was a trend toward overall higher patient satisfaction with AAP 72/80 (90%) in comparison to EAC 59/74 (80%) ($P = 0.074$). However there were no differences between the two groups with regard to statement 2, "I would strongly recommend this procedure to friends who qualify for it" ["strongly agree": EAC 55/74 (74%) and AAP 61/80 (76%)] and statement 3, "I would be willing to repeat this examination in the future if necessary" ["strongly agree": EAC 64/74 (87%) and AAP 67/80 (84%)] ($P = 0.882$ and 0.667 respectively). When examining pain experienced during procedures and patient satisfaction, the amount of pain experienced was lower with AAP 78/80 (98%) than EAC 64/74 (87%) ($P = 0.02$).

When examining the effect of resident participation on the efficiency of colonoscopy, we found that the mean procedure time was 12.9 ± 4.8 min in the staff endoscopist alone group (SE) and 26 ± 10.2 min in the resident participation (RP) group ($P < 0.001$). Mean total room time was 29.5 ± 9.8 min in the SE group and 44.4 ± 13.7 in the RP group ($P < 0.001$) (Table 5). Using multivariate analysis, the use of AAP was still a predictor of longer total procedure room time ($P = 0.002$).

DISCUSSION

As endoscopy units continue to receive increasing pressures to maximize efficiency, mechanisms to reduce cost of colonoscopy, while increasing overall number of colonoscopies performed annually must be examined. Propofol vs conventional sedation in colonoscopy has been extensively investigated and compared in multiple previous studies^[9]. Common outcomes studied include procedure time, recovery time, discharge time, cecal intubation rate, patient satisfaction, endoscopist satisfaction, level of sedation, pain control and complications. There is little literature comparing AAP to EAC with regard to total procedure room time and overall endoscopy unit efficiency.

This investigation has demonstrated that at a single-centre high-volume endoscopy unit, and after

Table 4 Results of the telephone patient satisfaction survey for endoscopist-administered sedation and anaesthesiologist-administered sedation with propofol groups *n* (%)

	EAC (<i>n</i> = 104)	AAP (<i>n</i> = 126)	<i>P</i> -value

EAC: Endoscopist-administered conscious sedation; AAP: Anaesthesiologist-administered sedation with propofol.

Table 5 Study endpoints - comparing staff endoscopists only with cases involving resident participation

	Resident involved (<i>n</i> = 66)	Staff endoscopist only (<i>n</i> = 164)	<i>P</i> -value
Total procedure time			< 0.001
Mean ± SD	26.0 ± 10.2	12.9 ± 4.8	< 0.001
Total room time			< 0.001
Mean ± SD	44.4 ± 13.7	29.5 ± 9.8	< 0.001

removal of trainee presence, there was no difference in procedure time with AAP or EAC but there was a significant difference in total procedure room time. There was however a trend toward overall greater patient satisfaction with AAP sedation. This raises important questions requiring further elucidation of how best to maximize patient satisfaction and efficiency in delivery of colonoscopy to the masses.

A previously reported model indicated that practice efficiency gains from rapid recovery agents (*i.e.*, propofol) could offset higher operating costs^[10]. There are multiple steps in the flow of a patient through the endoscopy unit affecting efficiency. Our findings suggest that the time saved in the recovery room with the use of propofol may be offset by increased time within the procedure room, thus not improving overall unit efficiency. Our study between EAC and AAP with respect to total procedure room time demonstrates a difference of 3 min per colonoscopy on average. This has implications when cumulatively added over the course of a full endoscopy day, with the potential for 1 full additional colonoscopy performed per day with EAC compared to AAP sedation (assuming a standard eight hour endoscopy procedure day).

Previous concerns regarding the cost prohibitive

nature of AAP have been raised and addressed in the literature^[11]. The cost of anaesthesia consultation and anaesthesiologist reimbursement for colonoscopy may represent limiting factors in AAP use over EAC. In a questionnaire conducted in the United States addressing 451 gastroenterologist and 460 endoscopy nurses it was demonstrated that 53% of gastroenterologists and 70% of endoscopy nurses preferred AAP to EAC if they were to have screening colonoscopy. When they were asked how much extra they were willing to pay out of pocket to have AAP, 60% and 63% (respectively) were unwilling to pay more than \$200, significantly less than is currently charged to patients in the United States^[12]. The administration of propofol by non-anaesthesiologists has been endorsed by several gastroenterology societies and there is growing evidence to suggest that propofol can be safely administered by a trained gastroenterologist or registered nurse particularly in low-risk patients in a screening setting^[13,14]. However, this is controversial and likely would not suit all endoscopists or endoscopy units. Similarly, the impact of endoscopist-directed propofol sedation on unit efficiency is unknown.

Our study was too small to demonstrate significant differences in safety between AAP and EAC. Korman *et al*^[15] previously outlined some of the implications of propofol sedation for colonoscopy. One such implication indicated that endoscopists are more likely to apply more forces during colonoscope insertion and push through loops and angulated segments as a result of deep sedation^[15]. Whether this can be linked to significant adverse event is unknown. In a retrospective study by Adeyemo *et al*^[16] among patients having a therapeutic colonoscopy, propofol use was independently and significantly associated with an increased perforation

risk, with adjusted odds ratios of 1.32. Additionally, there are implications to trainees learning colonoscopy techniques on patients under propofol sedation given that patient feedback is greatly reduced and thus reduction techniques are different and potentially dangerous^[15]. The significant difference between trainees involved in AAP vs EAC cases in our study is cause for reflection and evaluation of the number of AAP and EAC cases to which our trainees are exposed.

Our study has shown a significant difference in the pain/discomfort experienced during colonoscopy favouring AAP when compared with EAC ($P = 0.021$). However, 86.5% of patients in the EAC group either "agreed" or "strongly agreed" with the telephone survey statement: "I did not experience too much pain/discomfort during the procedure" which correlate with the result of the recent meta-analysis that showed little to no difference in pain scores for patients receiving propofol vs conventional sedation^[7]. Patients were also equally likely to have the procedure repeated which is important for surveillance. One important limitation of the current investigation.

Consistent with previous studies, trainee involvement in colonoscopy (either EAC or AAP) doubles procedure time and significantly increased total procedure room time^[17]. Colonoscopy training is the corner stone of any accredited gastroenterology fellowship program and adequate training is essential to ensure all future endoscopists are competent in conducting colonoscopy independently and delivering the best standard of care to their patients. Given the fixed costs associated with endoscopy units, it will be important to consider the impact of resident training in academic centers if colonoscopy funding changes to a cost per case model. Standard guidelines on teaching techniques may also improve efficiency.

Its worth mentioning that some other factors that could potentially improve overall colonoscopy performance and patient experience - particularly for inexperienced endoscopists - such as cap-assisted colonoscopy, magnetic endoscopic imaging system and anti-spasmodic medication were not investigated in our study^[18,19].

In conclusion, the principal results of this study suggest that AAP sedation is associated with increased total procedure room time relative to EAC. However, no significant difference in procedure time between EAC and AAP groups was observed. Given that the difference in total room time is not manifested in a difference in procedure time itself, it is likely that the additional time comes from either pre-procedure consultation required by the anaesthesiology team or post-procedure management prior to transfer out of the room to the recovery area. Strategies to reduce the need for in-room anaesthesiologist assessment may help improve overall unit efficiency. Future investigations should include overall cost-effectiveness analysis for EAC vs AAP and

direct comparison between AAP and EAC in terms of safety and efficiency.

We would like to thank Larry Stitt (Western University, Department of Epidemiology) for his help with statistical analysis.

COMMENTS

Background

Colorectal cancer is the leading cause of cancer-related death among non-smokers in Canada and the fourth leading cause of cancer-related death worldwide. As the gold standard procedure for treatment and diagnosis of conditions of the colon, colonoscopies are an important screening measure. Additionally, with increased emphasis on colon cancer screening programs among the aging population of many nations, the number of colonoscopies performed globally will continue to increase drastically in the near future.

Research frontiers

A main factor known to increase patient satisfaction and willingness to return for a repeat colonoscopy is the organization of the clinic and its efficiency (*i.e.*, reduced patient anxiety and increased patient satisfaction with colonoscopy is associated with a reduced wait time before procedure). The research hotspot is to pursue a novel measurement of colonoscopy unit efficiency (total procedure room time), which has direct implications for overall unit efficiency, with emphasis on assessing patient satisfaction with different sedation types for colonoscopy, a highly controversial topic in current colonoscopy literature.

Innovations and breakthroughs

Much emphasis in currently focuses on decreasing the length of the colonoscopy procedure as a means to increase unit efficiency. In this study, the authors analyze the differences in total procedure room time between two differing sedation types for colonoscopy. The results demonstrate that currently administration of propofol-based sedation is better tolerated by patients and efforts to improve efficiency must be pursued as this modality is currently significantly slower in terms of total procedure room time than conventional sedation techniques for colonoscopy, which carries implications for responding to the rising demand for colonoscopy globally.

Applications

The results of this study suggest that anaesthesiologist-administered sedation with propofol leads to increased patient satisfaction with colonoscopy. However, this sedation type was found to lead to a significantly increased total procedure room time, without a difference in procedure time, which has important implications for efficiency of colonoscopy units.

Terminology

Throughout this article, the following terms are used frequently: Anaesthesiologist-administered propofol sedation (AAP) and endoscopist-administered conscious sedation (EAC). AAP refers to anaesthesiologist-administered sedation with propofol, whereby deeper sedation occurs with propofol during the colonoscopy procedure under the guidance of a trained anaesthesiologist. EAC refers to endoscopist-administered conscious sedation, a conventional sedation type commonly used for colonoscopies throughout Canada, whereby sedation is administered by the endoscopist (a trained gastroenterologist in the case of this study) in the form of a combination of midazolam and fentanyl, titrated to maximize patient comfort and ensure procedural safety.

Peer-review

Available papers concerning total procedure room time for colonoscopy are highly limited. This study includes important results on a controversial issue about colonoscopy sedation procedures and contributes to the ongoing discussion on the mode and delivery of sedation for colonoscopy.

Abstract

AIM: To investigate the techniques and efficacy of peroral endoscopic reduction of dilated gastrojejunal anastomosis after bariatric surgery.

METHODS: An extensive English language literature search was conducted using PubMed, MEDLINE, Medscape and Google to identify peer-reviewed original and review articles using the keywords "bariatric endoscopic suturing", "overstitch bariatric surgery", "endoscopic anastomotic reduction", "bariatric surgery", "gastric bypass", "obesity", "weight loss". We identified articles describing technical feasibility, safety, efficacy, and adverse outcomes of overstitch endoscopic suturing system for transoral outlet reduction in patients with weight regain following Roux-en-Y gastric bypass (RYGB). All studies that contained material applicable to the topic were considered. Retrieved peer-reviewed original and review articles were reviewed by the authors and the data extracted using a standardized collection tool. Data were analyzed using statistical analysis as percentages of the event.

RESULTS: Four original published articles which met our search criteria were pooled. The total number cases were fifty-nine with a mean age of 46.75 years (34-63 years). Eight of the patients included in those studies were males (13.6%) and fifty-one were females (86.4%). The mean time elapsed since the primary bypass surgery was 5.75 years. The average pre-endoscopic procedure body mass index (BMI) was 38.68 (27.5-48.5). Mean body weight regained post-RYGB surgery was 13.4 kg from their post-RYGB nadir. The average pouch length at the initial upper endoscopy was 5.75 cm (2-14 cm). The pre-intervention anastomotic diameter was averaged at 24.85 mm (8-40 mm). Average procedure time was 74 min (50-164 min). Mean post endoscopic intervention anastomotic diameter was 8 mm (3-15 mm). Weight reduction at 3 to 4 mo post revision noted to be an

average of 10.1 kg. Average overall post revision BMI was recorded at 37.7. The combined technical and clinical success rate was 94.9% (56/59) among studied participants.

CONCLUSION: Endoscopic suturing can be technically feasible, effective and safe for transoral outlet reduction in patients with weight regain following RYGB.

Key words: Endoscopic anastomosis reduction; Bariatric surgery; Endoscopic suturing; EndoCinch; Overstitch bariatric surgery

Core tip: Roux-en-Y gastric bypass is one of the most effective bariatric surgical procedures, but is associated with 5% weight regain during 1 to 3 years post procedure. Such weight regain has been attributed to a dilated gastrojejunal anastomosis (GJA). However given the increased perioperative risk of mortality, surgical revision is not generally considered. Endoscopic suturing system has shown potential in reducing the dilated GJA.

INTRODUCTION

Obesity is an epidemic and persists as one of the world's leading chronic diseases with increasing prevalence, morbidity and mortality. According to the National Health and Nutrition Examination surveys conducted in 2009-2010, 35.7% of American adults were obese [body mass index (BMI) > 30] with 6.3% considered to have severe obesity (BMI > 40 kg/m²)^[1]. Obesity is associated with increased mortality and risk of developing comorbid conditions such as type 2 diabetes mellitus, hypertension, dyslipidemia, coronary heart disease, obstructive sleep apnea and obesity hypoventilation syndrome^[2,3]. Treatment options available for obesity include lifestyle and behavioral modifications, pharmacological, and surgical interventions.

Surgery has proven to be the best option for significant weight reduction with low rates of weight regain^[4]. Bariatric procedures work mainly to achieve and maintain weight loss *via* two main modalities; they function to restrict food accommodation in the stomach thereby causing early satiety and reducing caloric intake and or cause intestinal malabsorption^[5]. Four main types of bariatric procedures exist, namely laparoscopic adjustable gastric banding, sleeve gastrectomy,

biliopancreatic diversion with duodenal switch, and Roux-en-Y gastric bypass (RYGB).

RYGB as a bariatric procedure is considered the best and as a result the most popularly performed in the United States^[6]. RYGB is achieved by creating a small gastric pouch which is connected to a Roux limb of the jejunum^[7]. Its mechanism of weight loss reduction is mainly three folds: Food intake restriction by the small gastric pouch, dumping syndrome caused by the gastrojejunal anastomosis causing diarrhea and abdominal pain which act as negative reinforcement against high sugar diets, and the selective malabsorption due to the decreased length of Roux limb^[8]. Additionally, the reduction of Ghrelin levels due to the bypass of the stomach and duodenum in RYGB is reported to cause decreased stimulation of appetite leading to decreased food intake^[9].

Many studies on RYGB have reported weight reduction averages of 65% and more than 85% of patients losing and maintaining 50% of initial excess weight loss. However, studies have noted significant weight regain in patients beyond 18-24 mo after the initial weight loss surgery. Sugerman *et al*^[10] reported a 5% weight regain noted in bariatric surgical patients during a follow-up evaluation at 1 to 3 years. Powers *et al*^[11] also noted an average of 40 lb excess weight regain in bariatric surgery patients during a 2-year follow-up duration. Many factors have been suggested to contribute to such weight regain in patients who undergo weight loss surgery. Mechanical dehiscence of staple lines has been cited by many studies as a major contributing factor to weight regain^[12-14]. Additionally, dilation of the gastrojejunal anastomosis has been suggested as another possible mechanism of weight regain resulting in decreased distension of the gastric pouch and hence a reduction in satiety stimulation.

Fixation of such gastrojejunal dilation is however controversial as it carries significant surgical risks and often times the degree of weight regain does not justify surgical revision. Linner *et al*^[15] in their study of revision procedures noted a doubling of perioperative morbidity (15%) and mortality (0.7%) rates when compared to morbidity (8%) and mortality (0.3%) associated with the primary bariatric surgeries. Many different open revision surgeries have been suggested to restrict the dilated gastrojejunal anastomosis; however most of the patients did not achieve significant weight reduction, and suffered major procedural complications^[14,16].

Technological advancement in endoscopy has led to a novel approach of endoscopic fixation of gastrojejunal dilation in bariatric patients with weight regain after RYGB. This article discussed the endoscopic devices and their success in transoral gastric pouch outlet reduction to treat weight gain after RYGB.

MATERIALS AND METHODS

An extensive English language literature search was conducted using PubMed, MEDLINE, Medscape and Google to identify peer-reviewed original and review

articles using the keywords “bariatric endoscopic suturing”, “overstitch bariatric surgery”, “endoscopic anastomotic reduction”, “bariatric surgery”, “gastric bypass”, “obesity”, “weight loss”. Studies involving human models were selected. The references of pertinent studies were manually searched to identify additional relevant studies. The technical feasibility, safety, efficacy, and adverse outcomes of overstitch endoscopic suturing system for transoral outlet reduction in patients with weight regain following RYGB were considered as inclusion criteria for evaluation. Search results yielded mostly small sample sized studies including case reports and case series.

RESULTS

Four original published articles were considered suitable for inclusion in this review article. All studies were performed in Boston, Massachusetts, United States. All the four articles were case series on human subjects. The total number cases were fifty-nine with a mean age of 46.75 years (range, 34-63 years). Eight of the patients included in those studies were males (13.6%) and fifty-one were females (86.4%). All cases are summarized in Table 1.

Time since primary bypass surgery

The mean time elapsed since the primary bypass surgery in the studied population was 5.75 years with a range from 2 to 10 years^[17-19]. Fernández-Esparrach *et al*^[20] did not report the number of years after the primary bariatric surgery for their study patients.

Average pre-procedure BMI

The average pre-endoscopic procedure BMI among the study participants was 38.68 with range between 27.5-48.5^[17-20].

Average weight regain post RYGB nadir

The mean body weight regained post RYGB surgery was 13.4 kg from their post-RYGB nadir with a range between 0.9-53.6 kg^[17-20]. Fernández-Esparrach *et al*^[20] did not report the average weight gained post RYGB for their study patients.

Average pre-intervention pouch length and anastomotic diameter

The average pouch length at the initial upper endoscopy was 5.75 cm; ranging between 2-14 cm. The pre-intervention anastomotic diameter was also averaged at 24.85 mm; ranging from 8-40 mm^[17-20].

Endoscopic equipment used

Studies have described use of EndoCinch suturing system (CR Bard, Murray Hill, NJ), EndoSurgical Operating System (EOS) (USGI Medical San Clemente, Calif) and Overstitch Endoscopic Suturing System (Apollo Endosurgery) without any differences in outcome.

The Overstitch Endoscopic Suturing System (Apollo

Endosurgery) was connected to a two channel endoscope (GIF-2T160; Olympus America, Central Valley, Pennsylvania, United States). With a curved suture arm on one channel, and the anchor exchange on the other channel, stitches were placed through the tissue when the handle was closed. The tissue was released upon opening of the handle and a new stitch placed when the suture arm was returned to the anchor^[19]. Mullady *et al*^[18] used the EOS (USGI Medical San Clemente, Calif), which has a main component of the TransPort, The TransPort has 4 large channels accepting a 4.9-mm endoscope (GIF-N180; Olympus America, Inc, Center Valley Pa) and flexible equipments. With a 4 way tip, the TransPort uses a shapelock system in suturing, where a tissue approximator (g-Prox; USGI Medical), a tissue grasper and a needle catheter were advanced through the TransPort channels. The tissue grasper grasps the tissue and pulls into the approximator, which then closes onto the tissue. The needle catheter is then passed through the tissue and a self-expanding tissue anchor passed through the catheter is deployed. The approximator is opened and then the tissue anchor released. A stitch connecting the 2 anchors was then tightened, bringing together the 2 anchors^[18].

EndoCinch suturing system (CR Bard, Murray Hill, NJ) by Thompson *et al*^[17] was passed through the gastrojejunostomy site where tissue at the anastomosis site was pulled into the device and the stitch placed by activation of the handle. The Bard device was then removed and reloaded for a second bite and stitch placement. The process was repeated to attain one to three interrupted sutures around that anastomosis rim. Suture were tightened to plicate the tissue^[17,20].

Average number of interrupted stitches applied and procedure time

The average procedure time was charted at 74 min, ranging from 50-164 min^[17-20]. The number of interrupted stitches applied at the gastrojejunal anastomosis and the gastric pouch is averaged at 3.8 (range, 0-7)^[17-20].

Average post intervention anastomotic diameter

The mean post endoscopic intervention anastomotic diameter was 8 mm with a range between 3-15 mm^[17-20]. Overall the average anastomotic diameter reduction was 16.85 mm; a 67.8% reduction.

Average weight loss at 3-4 mo after revision

Weight reduction at 3-4 mo post revision was observed at an average of 10.1 kg (range, 1.4-19.5 kg)^[17-20].

Overall post procedure BMI

The average overall post revision BMI was recorded at 37.7^[9]. The remaining three articles did not report the post revision BMI^[18-20].

Major complications and limitations

The use of EndoCinch as an overstitch endoscopic suturing system for transoral outlet reduction in patients

GJA: Gastrojejunal anastomosis; EOS: EndoSurgical Operating System; F: Female; M: Male; BMI: Body mass index; RYGB: Roux-en-Y gastric bypass.

with weight regain following RYGB has been associated with no reported significant procedure-related complications. Minor complications reported have included postprocedural nausea and vomiting, sore throat, mild transient abdominal pain, diarrhea and constipation^[17,20]. Jirapinyo *et al*^[19] reported three intra-procedural complications including a small esophageal abrasion which was remedied with fibrin glue and two patients who had arterial bleeding after the stitch placement, resolved with tissue plication.

Technical and clinical success rates

The combined technical and clinical success rate of EndoCinch as an endoscopic suturing system for outlet reduction in post RYGB patients with weight regain was 94.9% (56/59) among studied participants.

DISCUSSION

The reported findings on the use of endoscopic suturing devices are promising and appear to be safe in practice. Outlet reduction appears to be effective in decreasing the gastrojejunal anastomosis diameter and the gastric pouch length, ultimately leading to significant weight reduction and addressing the problem of weight regain in RYGB patients. The cases discussed above have some limitations however. The main limitation is the small number of subjects studied. Also the number of male participants in these studies was disproportionately low (8/59; 13.6%). More studies with larger sample size, are needed to study the long-term efficacy of endoscopic suturing systems in treatment of weight regain in post RYGB.

COMMENTS

Background

Obesity is an epidemic and persists as one of the world's leading chronic diseases. Many treatment options for obesity exist, but surgery has proven to be the best for significant weight reduction with low rates of weight regain. Roux-en-Y gastric bypass (RYGB) is one of the most effective bariatric surgical procedures, but is associated with 5% weight regain during 1 to 3 years post procedure. Such weight regain has been attributed to a dilated gastrojejunal anastomosis (GJA). However given the increased perioperative risk of mortality, surgical revision is not generally considered. Endoscopic suturing system has shown potential in reducing the dilated GJA. The aim of this review is to verify the techniques and efficacy of peroral endoscopic reduction of dilated gastrojejunal anastomosis after RYGB.

Research frontiers

The endoscopic suturing system was first used in 1996, in the treatment of gastroesophageal reflux disease. Sutures were placed at the gastric cardia to plicate and ultimately tighten the gastroesophageal junction. In its application for the treatment of dilated GJA, the endoscopic suturing system is attached to the endoscope via channels and advanced to the gastrojejunal anastomosis. By opening and closing of the handle of endoscopic suturing system, endoscopic stitches are applied to plicate the tissues resulting in a tightening of the GJA.

Innovations and breakthroughs

Peroral endoscopic reduction of dilated gastrojejunal anastomosis post RYGB has been successfully performed in various clinical studies. The retrieved manuscripts were reviewed by the authors, and the data were extracted using a standardized collection tool.

Applications

This review suggests that peroral endoscopic reduction *via* the endoscopic suturing system is an efficacious method in reducing dilated gastrojejunal anastomosis, thereby curbing the problem of weight regain post RYGB.

Terminology

The peroral endoscopic reduction technique is a novel modality employed in addressing the problem of dilated gastrojejunal anastomosis in RYGB as the cause of weight regain. The endoscopic suturing system is attached to the endoscope *via* its channels and advanced to the gastrojejunal anastomosis. Stitches are then applied through the tissue with opening and closing of the handle of endoscopic suturing system.

Peer-review

Overall, this is an interesting review of transoral endoscopic fixation of gastrojejunal dilation.

Abstract

Gastric adenocarcinoma of fundic gland type (GA-FG) with chief cell differentiation was recently proposed as an extremely rare type of gastric adenocarcinoma. Here, we report 4 cases of GA-FG with chief cell differentiation. Endoscopic features included a submucosal tumor shape or a flat shape, whitish discoloration and dilated vessels on the surface. The tumors were located in the upper or middle third of the stomach. All cases were preoperatively diagnosed as GA-FG by biopsy, and endoscopic submucosal dissection was performed. Resected specimens revealed well-differentiated adenocarcinomas resembling chief cells. Tumor cells were diffusely positive for pepsinogen- I , but partially positive for H⁺/K⁺-ATPase in scattered locations around the tumor margin. Despite the presence of minimal invasion of the carcinoma into the submucosal layer, which was observed in two cases, neither lymphatic nor venous invasion was detected in any of the cases. Finally, all cases showed less aggressive clinical behavior with low grade malignancy.

Key words: Early gastric cancer; Low grade malignancy; Fundic gland type; Chief cells; Endoscopic submucosal dissection

Core tip: Gastric adenocarcinoma of fundic gland type (GA-FG) with chief cell differentiation is a new and extremely rare type of gastric adenocarcinoma, and the clinicopathological features of GA-FG have thus not yet been elucidated. In the present study, we discuss 4 cases of GA-FG that displayed low grade malignancy, slow-growth and less aggressive clinical behavior. Endoscopic submucosal dissection was performed and

complete tumor resection was confirmed pathologically. None of the patients showed any signs of recurrence during the follow-up periods. We decided to report these rare cases because of their distinct endoscopic and clinicopathological features and unique biological behaviors.

Gastric adenocarcinoma of fundic gland type: Endoscopic and clinicopathological features. *World J Gastrointest Endosc* 2016; 8(4): 244-251 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i4/244.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i4.244>

INTRODUCTION

Gastric carcinoma has been histologically classified into differentiated and undifferentiated types^[1]. Following the advent of recent advanced techniques such as mucin histochemistry and immunohistochemistry, gastric adenocarcinomas can be classified as having either a gastric or an intestinal phenotype^[2,3], irrespective of their histological features. Among the types of differentiated adenocarcinomas with gastric phenotypes, tumors of both the foveolar type and the pyloric gland type have been reported. However, gastric adenocarcinomas of fundic gland type (GA-FG) have been considered extremely rare. After several cases of GA-FG with a parietal cell phenotype were reported^[4-9], a GA-FG with a chief cell differentiation was reported^[10] and was proposed as a new entity of gastric adenocarcinoma^[11]. Since this proposal, several cases of GA-FG have been reported^[12-20], but it is still considered an extremely rare type of gastric cancer. In the present study, we describe 4 cases of GA-FG with a chief cell differentiation, and evaluate their endoscopic findings, clinicopathological features and biological behaviors.

CASE REPORT

Between October 2010 and September 2014, among the 30182 patients who underwent upper gastrointestinal endoscopy as part of a yearly check-up, 4 patients were diagnosed with GA-FG. The clinicopathological findings are summarized in Table 1. The two male and two female patients were between 42 and 62 years of age. Concerning the gastric mucosa, atrophic changes with *Helicobacter pylori* (*H. pylori*) infection were observed in two of the 4 cases. The tumors were located in the upper or middle third of the stomach, and some appeared as either submucosal tumor (SMT)-like elevated lesions, whereas others had a flat shape. Faded or whitish discoloration and dilated vessels on the surface were also observed by conventional endoscopy (Figure 1). Neither irregular microvascular architecture nor an irregular microsurface pattern was detected by magnifying endoscopy with narrow band imaging. All

of the tumors were smaller than 5 mm in diameter. Histological examination of the biopsy specimens showed well-differentiated adenocarcinomas composed of chief cell-like cells. No evidence of metastasis was observed on computed tomography. After a preoperative diagnosis of GA-FG, endoscopic submucosal dissection (ESD) was performed.

According to the hematoxylin and eosin staining, the tumors were primarily composed of well-differentiated adenocarcinoma with columnar cells that mimicked fundic gland cells (Figure 2). Irregularly anastomosing glands with mildly enlarged and hyperchromatic nuclei were also observed. Histologically, in all cases, the tumors arose within the deeper zone of the gastric mucosa and were covered with a non-neoplastic epithelium. Despite the small sizes of the tumors, minimal invasion of the submucosal layer by tumor cells was observed in 2 cases. However, none of the cases demonstrated lymphatic or venous invasion. Moreover, none of the endoscopically resected specimens showed atrophic changes or intestinal metaplasia in the surrounding mucosa.

Cell differentiation according to the expression of Mucin 2 (MUC2) (a marker of goblet cells), MUC5AC (a marker of gastric foveolar epithelium), MUC6 (a marker of mucous neck cells and pyloric glands), CD10 (a marker of the brush border), pepsinogen-I (a marker of chief cells), H⁺/K⁺-ATPase (a marker of parietal cells) was evaluated immunohistochemically (Table 2). The tumor cells were classified as the gastric mucin phenotype based on diffuse positive staining for MUC6 and negativity for MUC2 and CD10. Immunohistochemical staining showed diffuse positive staining for pepsinogen-I and limited positivity for H⁺/K⁺-ATPase in scattered locations around the tumor margin (Figures 3 and 4). Finally, all 4 cases were diagnosed as GA-FG with chief cell differentiation. Cell proliferation, which was based on the Ki-67 (MIB-1) labeling index, was lower than 5% in all cases. Complete tumor resection was confirmed pathologically without further treatment. No complications associated with ESD were observed. None of the patients showed any signs of recurrence during the follow-up periods.

DISCUSSION

Histologically, GA-FG is typically classified into a chief cell-predominant type, a parietal cell-predominant type, or a mixed type. GA-FG with chief cell differentiation has been considered extremely rare and has been proposed as a new entity and pathologic subtype of gastric adenocarcinoma^[11]. GA-FG is associated with distinct clinicopathological characteristics, tumor location (they arise within a deeper zone of the gastric mucosa), and histological features (high-frequency of submucosal invasion independent of tumor size) as well as mucin expression (stomach type), and low-grade malignancy (mild atypism, lack of lymphovascular invasion and low proliferative activity). Moreover, GA-FG is not associated with *H. pylori* infection^[11]. In the present study, we describe 4 cases of GA-FG with chief cell differentiation.

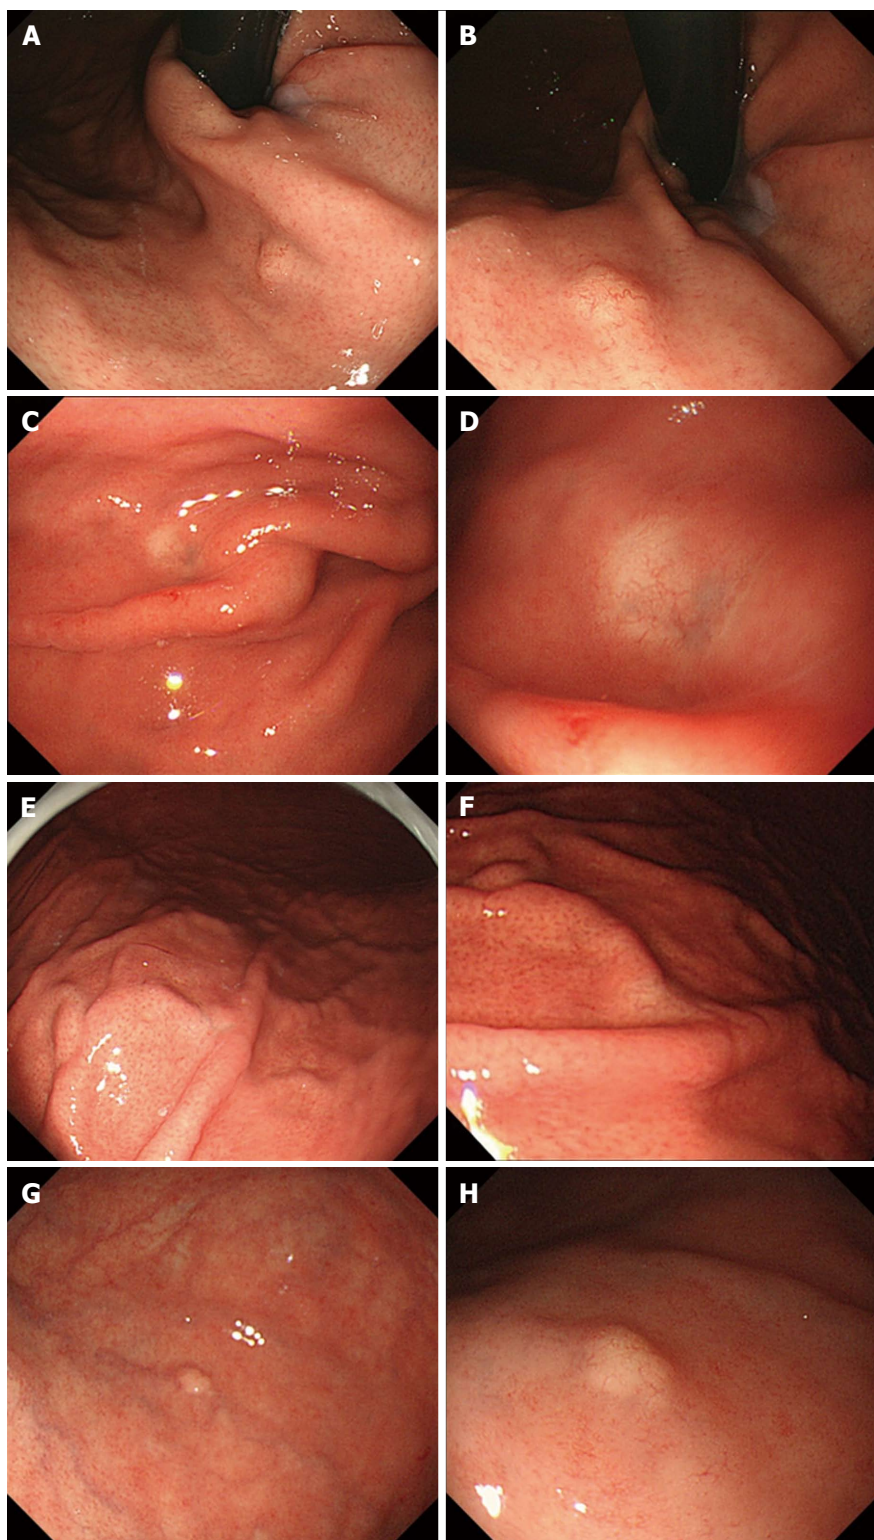

Figure 1 Endoscopic findings: Case 1 (A, B), case 2 (C, D), case 3 (E, F) and case 4 (G, H). Conventional endoscopy on white-light imaging showed flat lesions with whitish discoloration (C-F) or yellowish submucosal tumor shapes (A, B, G, H). Dilated vessels were shown on the surface of tumors (B, D, F, H).

During the diagnostic process of GA-FG, endoscopic features should be taken into consideration. According to previous reports^[11,18], GA-FG has distinct endoscopic features, such as an SMT shape or a flat/depressed shape, a faded/whitish color and dilated vessels on the surface, which can provide valuable information in

the diagnostic process. In the present study, 2 cases revealed an SMT-like morphology on endoscopy. For these cases, we would have to consider the possibility of sporadic carcinoid tumors that may also have been centered in the deeper zone of the gastric mucosa. The other 2 cases featured a flat mucosa with faded/

Figure 2 Histological findings (hematoxylin and eosin staining): Case 1 (A, E, F), case 2 (B), case 3 (C) and case 4 (D). Well-differentiated adenocarcinomas with columnar cells that mimicked fundic gland cells were observed. Tumors histologically arose in the deeper zone of gastric mucosa (A-D). Irregularly anastomosing glandular structures with mildly enlarged and hyperchromatic nuclei were observed (E, F). Minimum carcinoma invasion of the submucosal layer was detected (C, D). Neither lymphatic nor vascular invasion was observed. Magnification: A-D (low-power view $\times 100$), E (high-power view $\times 200$), F (high-power view $\times 400$).

whitish discoloration. For these cases, undifferentiated adenocarcinoma, mucosa-associated lymphoid tissue lymphoma, and normal gastric mucosa with focal atrophy would have to be considered as the differential diagnoses. Although distinct endoscopic features might be helpful in the diagnosis of GA-FG, it may still be difficult to discriminate among the differential diagnoses by endoscopic findings.

In the process of a histological diagnosis of GA-FG, dysplasia and adenocarcinoma in the fundic gland polyps (FGPs) have to be considered as the differential diagnoses. According to previous reports^[21,22], dysplasia and adenocarcinoma in the FGPs usually arise from the foveolar epithelium, which is different from the epithelium of the fundic glands. Therefore, these diseases can be distinguished from GA-FG. Cases of FGPs with chief cell hyperplasia and morphologic atypia have also been

reported^[23,24]. In these reports, structural and nuclear atypia in chief cell hyperplastic lesions were detected, but they were not diagnosed as adenocarcinoma due to a low Ki-67 labeling index. However, it is possible that such cases may become carcinomas because they are similar to the tumors of GA-FG chief cell-predominant type.

In the present study, all cases of GA-FG were discovered in the early stages. Neither lymphatic nor venous invasion was observed despite the presence of minimal tumor invasion into the submucosal layer. A high Ki-67 labeling index is considered to be related to a poor prognosis of gastric adenocarcinoma^[25,26]. In our study, all cases show a low proliferative index in regards to Ki-67 expression. No signs of recurrence or metastasis were observed during the follow-up periods. Patients with GA-FG are considered to have a favorable prognosis^[11,16-18]. In the current report, long-term follow-up of patients with

changes that were barely detectable^[17]. In our study, a 50-year-old woman who was diagnosed with GA-FG underwent follow-up endoscopy every 8 mo. However, no detectable changes in the tumor were observed, and ESD was performed after three years of observation. Minimal invasion by the cancer cells into the submucosa

Figure 4 Immunohistochemical staining: **Case 3.** Tumor cells were diffusely positive for MUC6 (C) and pepsinogen-I (E), partially positive for H⁺/K⁺-ATPase in scattered locations around the tumor margin (F), negative staining for MUC2 (A), MUC5AC (B) and CD10 (D). was observed, but no lymphovascular invasion was noted. Our cases also suggest that GA-FG displays slow-growth and less aggressive clinical behavior compared with typical gastric adenocarcinomas.

Base on the less aggressive biological behavior of GA-FG, a reclassification of GA-FG as a benign, oxyntic gland polyp/adenoma was proposed^[16]. However, advanced stage GA-FG with unusual clinicopathological features has since been reported^[19]. It has also been reported that GA-FG shows a favorable prognosis with less aggressive clinical behavior but that some cases of GA-FG might transform into high-grade malignancies during tumor progression^[11,19]. A recent study clarified that the molecular pathway of GA-FG is different from that of conventional type gastric adenocarcinomas^[27-29]. Because only a few case reports of early stage GA-FG have been published, the pathogenesis of GA-FG has not yet been elucidated. Further research is needed to analyze the

molecular mechanism of GA-FG and to evaluate the clinicopathological features including those of tumor development.

In conclusion, we reported 4 cases of well-differentiated adenocarcinoma of GA-FG with chief cell differentiation. GA-FG is extremely rare and has distinct characteristics that distinguish it from the more common types of gastric adenocarcinoma. Future studies will be expected to analyze the clinical behavior of GA-FG.

COMMENTS

Case characteristics

Four middle-aged patients without symptom underwent upper gastrointestinal endoscopy as a yearly check-up, and diagnosed as gastric adenocarcinoma of fundic gland type (GA-FG) with chief cell differentiation.

Clinical diagnosis

Upon physical examination, no significant physical findings were observed.

Differential diagnosis

Carcinoid tumors, undifferentiated adenocarcinoma, mucosa-associated lymphoid tissue lymphoma, normal gastric mucosa with focal atrophy, and adenocarcinoma in the fundic gland polyps were considered as differential diagnoses.

Laboratory diagnosis

All laboratory data were within normal limits.

Imaging diagnosis

In the upper or middle third of the stomach, a submucosal tumor-like elevated lesions or a flat shape with faded/whitish discoloration and dilated vessels on the surface were observed by upper gastrointestinal endoscopy.

Pathological diagnosis

The tumors were primarily composed of well-differentiated adenocarcinoma resembling fundic gland cells, and diagnosed as GA-FG with chief cell differentiation by immunohistochemical staining.

Treatment

In all cases, endoscopic submucosal dissection was performed and complete tumor resection was confirmed pathologically.

Related reports

GA-FG is a novel diagnostic entity with getting more reported cases worldwide. GA-FG usually shows low grade malignancy and less aggressive clinical behavior. Future studies will be expected to analyze the long-term prognosis of GA-FG.

Term explanation

GA-FG is a new diagnostic entity of gastric adenocarcinoma. Endoscopic treatment is often performed because of its low grade malignancy and less aggressive clinical behavior.

Experiences and lessons

GA-FG has been reported as a new entity and pathologic subtype of gastric adenocarcinoma. Recognizing the endoscopic and clinicopathological features of GA-FG can prevent misdiagnosis and provide adequate treatment.

Peer-review

GA-FG has been recently reported as a novel diagnostic entity of gastric adenocarcinoma. There is little information about GA-FG. In this study, the clinicopathologic findings of GA-FG are summarized. It is worthwhile for the readers because of its rarity or being less noticed.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Yong-Liang Zhu, PhD, Assistant Professor, Second Affiliated Hospital of College of Medicine, Zhejiang University, Hangzhou 310009, Zhejiang Province, China

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Colorectal cancer (CRC) is the 2nd most common cancer in women and 3rd most common cancer in men worldwide. Most CRCs develop from adenomatous polyps arising from glandular epithelium. Tumor growth is

initiated by mutation of the tumor suppressor gene *APC* and involves other genetic mutations in a stepwise process over years. Both hereditary and environmental factors contribute to the development of CRC. Screening has been proven to reduce the incidence of CRC. Screening has also contributed to the decrease in CRC mortality in the United States. However, CRC incidence and/or mortality remain on the rise in some parts of the world (Eastern Europe, Asia, and South America), likely due to factors including westernized diet, lifestyle, and lack of healthcare infrastructure. Multiple screening options are available, ranging from direct radiologic or endoscopic visualization tests that primarily detect premalignant or malignant lesions such as flexible sigmoidoscopy, optical colonoscopy, colon capsule endoscopy, computed tomographic colonography, and double contrast barium enema - to stool based tests which primarily detect cancers, including fecal DNA, fecal immunochemical test, and fecal occult blood test. The availability of some of these tests is limited to areas with high economic resources. This article will discuss CRC epidemiology, pathogenesis, risk factors, and screening modalities with a particular focus on new technologies.

Key words: Colorectal neoplasm; Prevention and control; Guidelines; Epidemiology; Colonoscopy; Capsule endoscopy; Computed tomographic colonography; Occult blood

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Multiple societies have issued screening guidelines for colorectal cancer (CRC). However, global CRC screening implementation can be challenging due to wide variability in healthcare infrastructure and resources in different countries. The practical implementation of CRC screening in a given area depends mainly upon availability of endoscopic resources. In areas with the greatest healthcare resources, colonoscopy remains the gold standard, although technological advances have provided alternative screening methods including

computed tomographic colonography, fecal DNA testing, and colon capsule endoscopy. In areas with fewer healthcare resources, guaiac-based fecal occult blood testing is the predominant screening modality.

El Zoghbi M, Cummings LC. New era of colorectal cancer screening. *World J Gastrointest Endosc* 2016; 8(5): 252-258 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i5/252.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i5.252>

INTRODUCTION

Colorectal cancer (CRC) is the second most common cancer in women and third most common cancer in men worldwide^[1]. Globally, there is marked variation in CRC incidence and mortality^[1,2]. Some countries in Eastern Europe and Asia have demonstrated increasing incidence rates (Slovakia, Czech Republic, Singapore, and Japan) which have been attributed to behavioral risk factors related to westernization of diet and lifestyle^[3]. In addition, some countries (Brazil, Mexico, and Romania) have experienced increasing CRC mortality rates from CRC purportedly due to limited healthcare resources^[4]. In the United States, CRC is the third leading cause of cancer death and accounts for approximately 7% and 9% of overall cancer deaths in females and males, respectively^[5]. CRC incidence and mortality rates have been declining in the United States secondary to increased screening mainly *via* colonoscopy, which enables primary prevention and early detection^[6,7]. In recent years, technological advances have led to the development of new, less invasive screening modalities including fecal immunochemical testing, computed tomographic colonography (CTC), stool DNA testing, and colon capsule endoscopy. This article will discuss CRC pathogenesis, risk factors, and screening with a particular focus on new screening methods.

PATHOGENESIS

Most colorectal carcinomas develop from adenomatous polyp arising from the glandular epithelium of the intestine^[8]. Adenomas are initiated by somatic mutation of the tumor suppressor gene *APC*^[9]. Additional genetic alterations of oncogenes and tumor suppressor genes are involved in a stepwise growth process that occurs over years^[10-12]. The accumulation of genetic mutations in accordance with chromosomal instability, shifts the normal intestinal lining to an adenomatous polyp, then high-grade adenoma and finally to a carcinoma^[13,14]. CRC can also arise from nonpolypoid and depressed lesions. Although these lesions are less common than that of the polypoid adenoma, they manifest more aggressive behavior and more rapid growth, and they are more difficult to diagnose^[15,16].

SCREENING TESTS

Available tests for CRC screening are divided into 2 major types, stool-based tests or endoscopic and radiologic tests. The stool-based tests include the guaiac-based fecal occult blood test (gFOBT), fecal immunochemical test (FIT), and fecal DNA testing. These tests detect cell debris and blood shed by vascularized polyps, adenomas and cancers^[17]. The endoscopic and radiologic examinations include optical colonoscopy, flexible sigmoidoscopy (FS or FSIG), double-contrast barium enema (DCBE), capsule endoscopy, and CTC and are based on direct or radiographic visualization of the polyp or cancer.

STOOL-BASED TESTS

gFOBT

gFOBT detects the presence of blood in feces through a chemical reaction dependent upon the peroxidase activity of heme. It is an inexpensive test that can be mailed to patients. Annual or biennial gFOBT have shown to decrease CRC mortality rates by 15%-33%^[18-20]. In the Minnesota Colon Cancer Control Study, a 30-year follow-up of patients randomly assigned to annual/or biennial gFOBT vs usual care showed a 32% decrease in CRC mortality. Furthermore, mortality reduction was more pronounced in men compared to women^[21].

A disadvantage of gFOBT is the requirement for 3 different stool samples^[22]. This makes collection more cumbersome to the patient, which results in lowered adherence and thus decreases its effectiveness as a screening test^[23,24]. gFOBT endorses a risk of false-positive results if patients ingest animal products or vegetables prior to testing, or if the patient is on anticoagulants or antiplatelet agents^[25]. On the other hand, a risk of false negative test arises if patient is on ascorbic acid or any other form of antioxidants^[26].

FIT

FIT is an antibody-based test that detects and binds to the globin component of hemoglobin. The FIT sampling technique is simpler and easier to collect compared to that of gFOBT. Only one or two fecal samples are required and no dietary or medication restrictions are needed prior to the test. The overall accuracy of FIT for detection of CRC was 95% with 79% sensitivity and 94% specificity as been shown in systematic review and meta-analysis including 19 qualified studies performed by Lee *et al*^[27]. FIT has been shown to have a greater sensitivity in detecting advanced adenomas and CRC than gFOBT^[28-31].

A disadvantage of FIT is its more expensive cost compared to FOBT. Although FIT is easier to collect, its sensitivity decreases with any delay in mailing or processing of the sample. Furthermore, similar to other non-invasive tests, if the test is positive, a follow-up colonoscopy would be needed.

Fecal DNA testing

Fecal DNA testing, or Cologuard (Exact Sciences), is a non-invasive, easy to perform test based on a single stool sample, and does not require dietary or medication restriction. It is a composite test that includes an immunochemical assay similar to the one used in FIT, methylated markers and molecular mutations markers associated with CRC. In 2014, this test was approved by the United States Food and Drug Administration as a screening test for CRC.

One multicenter study on 9989 patients comparing fecal DNA test to FIT using colonoscopy as the gold standard showed that the fecal DNA test had a higher sensitivity than FIT for detecting CRC, (92% vs 74%), adenomas with high-grade dysplasia (69% vs 46%), and serrated sessile polyps (42% vs 5%). However, specificity was lower with fecal DNA test at 87%-90% compared to FIT at 95%-96%^[32].

In a large multicenter case-control study, automated fecal DNA testing accurately detected CRC regardless of the site or the stage of the lesion with an overall sensitivity of more than 98%. Sensitivity for precancerous lesions increased in proportion to lesion size from 57% for lesions > 1 cm to 83% for those > 3 cm^[33].

Disadvantages of fecal DNA testing include its expensive cost; the inconvenience stool sampling and shipment to the lab; and the need for colonoscopy if the test is positive.

ENDOSCOPIC AND RADIOLOGIC TESTS**DCBE**

DCBE is a non-invasive radiological test, which provides a complete evaluation of the large intestine. The sensitivity and specificity of barium enema for polyps of any size is 38% and 86%, respectively^[34]. One study comparing barium enema to CT colonography and colonoscopy showed that DCBE has the lowest sensitivity and specificity with sensitivity of 41% for lesions ≥ 6 mm and sensitivity and specificity of 48% and 90% respectively for lesions ≥ 10 mm^[35]. These results are consistent with a meta-analysis comparing the performance of barium enema to that of CTC showing CTC is more sensitive and more specific than barium enema for large polyps (≥ 10 mm) and small polyps (6-9 mm) in average-risk and high-risk populations^[36]. In the United States, CT colonography has largely replaced DCBE as a radiographic option for CRC screening. A disadvantage of DCBE is that the test must be followed by colonoscopy if abnormalities are found.

Colonoscopy

Optical colonoscopy entails direct visualization of the colonic mucosa from the cecum to the rectum with a flexible endoscope. Insufflation, irrigation, and suction facilitate careful inspection of the mucosa. Colonoscopy allows both detection and removal of polyps, which can be submitted for histopathological examination.

Colonoscopy is routinely performed in some countries with sedation, whereas in others sedation is rarely used. Colonoscopy requires a bowel preparation with a laxative and clear liquid diet prior to the procedure. Split-dose protocols, in which patients ingest half the bowel preparation the day of the procedure, may encourage compliance and are now recommended for optimal bowel cleansing^[37]. Procedural risks include cardiopulmonary complications due to sedation, the possibility of missed lesions, bleeding, and a 0.08% rate of perforation, which is typically related to polypectomy^[38]. Although traditionally colonoscopy has been considered to be the gold standard for CRC screening, the miss rate for adenomas ≥ 1 cm was 6% in a tandem colonoscopy study^[39]. Moreover, colonoscopy is less effective at reducing proximal compared with distal CRCs^[40-43]. This finding may result from a combination of factors including inadequate bowel preparation, which is more likely to affect the right colon; incomplete colonoscopy; and a higher prevalence in the proximal colon of non-polypoid colorectal neoplasms, which are often more difficult to detect than traditional polypoid neoplasms^[44]. Based on pooled data from several large North American studies, 0.6% of patients with adenomas developed CRC within an average of 4 years after clearing colonoscopy^[45]. Fifty-two percent of these cancers were felt to be missed lesions, 19% were thought to be potentially incompletely resected lesions, and 24% were thought to be new lesions. These statistics reflect the fact that colonoscopy is operator dependent. Indeed, the development of interval cancers within 3 years after colonoscopy has been associated with performance of colonoscopy by non-gastroenterologists^[46].

FS

FS is used to visualize the left-sided or descending colon and the rectum where approximately 60% of all CRCs develop. Compared to colonoscopy, FS is safer, faster, and more easily tolerated procedure. Sedation is not required, and self-administered enemas are usually used in bowel preparation^[47,48].

Screening with FS decreases the incidence and overall mortality of CRC^[48,49]. A large randomized control trial involving 34272 participants between the ages of 55 and 64 years with a median follow-up of around 11 years showed a 31% decrease in the incidence of CRC and a 38% decrease in CRC mortality after one-time screening with FS, compared with no screening^[49].

A disadvantage of FS is that follow-up colonoscopy is required given that about 3%-5% of patients with CRC in the distal colon will have lesions in the proximal colon^[50]. In the United States, colonoscopy has largely replaced FS for CRC screening.

Colon capsule endoscopy

With capsule endoscopy (Pillcam COLON, Given Imaging Ltd, Yoqneam, Israel) the patient swallows a capsule which records digital images on 2 camera heads at a rate ranging from 4 to 35 frames per second for appro-

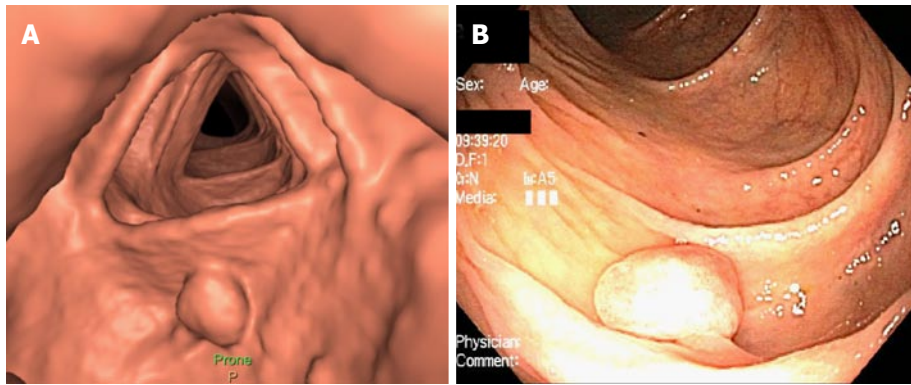

Figure 1 Visualization of a colonic polyp by computed tomographic colonography and optical colonoscopy. A: Three dimensional view of a splenic flexure colonic polyp on computed tomographic colonography; B: View of the same polyp on optical colonoscopy.

ximately 10 h. These images are then transmitted wirelessly to a recording device carried by the patient. The data are transferred from the device to a computer that uses a software (RAPID) to compile the video to be analyzed then by an experienced gastroenterologist^[51]. Indications for colon capsule endoscopy have not been standardized; the use of CE is recommended in cases of colonoscopy contraindication, colonoscopy failure, or in patients unwilling to perform colonoscopy. In the United States, the Food and Drug Administration has approved Pillcam COLON 2 (second generation) for patients who have had an incomplete colonoscopy.

A recent prospective study conducted by Doug Rex on 884 patients comparing accuracy of PillCam COLON 2 to that of optical colonoscopy demonstrated 88% sensitivity and 82% specificity in detecting adenoma \geq 6 mm in average risk screening population^[52].

An advantage of capsule endoscopy compared to other non-invasive methods is the lack of radiation exposure. Disadvantages of capsule endoscopy include the need for a complex bowel preparation regimen and the risk, albeit low, of capsule retention, which may necessitate surgical removal.

CTC

CTC, or virtual colonoscopy, is a radiographic imaging test in which two-dimensional or three-dimensional images of the colon and rectum are generated using specialized computer software and abdominal computed tomography scanning. It is offered to the patient if colonoscopy is incomplete or in the event of patients' refusal or has additional risk factors. CT colonography every 5 years is a screening option according to some CRC screening guidelines (see below). Multiple steps are involved in completing CTC. The first step is the bowel preparation, which includes a fiber-free diet and ingestion of a laxative and contrast medium prior to the test. The second step is colonic insufflation, which is done by insufflation of CO₂ *via* a rectal catheter and bulb in a gradual manner with a controlled pressure to prevent perforation. The third step is acquisition of the

radiographic images. An adjusted scout-view is obtained so that the entire colon is covered. Images are obtained in 2 positions, supine and prone; decubitus lateral positions are performed if patient is overweight.

The final step is interpretation of images; two dimensional interpretation identifies any lesion that is larger than a centimeter. The infracentimetric lesions are identified *via* three dimensional interpretation. After identification of a polyp-like lesion, its density should be determined. The lipoma or an inverted tumor is fatty, fecal residue is dense, and tumor tissue's density is similar to that of the colonic wall. Each lesion is then classified by C-RAD, which specifies the site, the shape, type of density, and the largest diameter of the head of the polyp. A colonoscopy is indicated for lesions that are \geq 10 mm or more than 3 lesions $>$ 5 mm^[53]. Figure 1 displays a polyp visualized on CT colonography and subsequent colonoscopy.

A multicenter trial enrolling 845 patients who underwent screening with CTC followed by colonoscopy showed 69% sensitivity and 91% specificity in detecting polyps $>$ 6 mm^[54]. CTC was found to accurately detect 90% of lesions $>$ 10 mm in diameter^[55]. The detection rate for advanced neoplasm was found to be similar for patients undergoing CTC compared to colonoscopy, while the rate of polypectomies and complications was considerably smaller in the CTC group compared to that of colonoscopy^[56]. Radiation exposure is one of disadvantage of CTC^[57]. In addition, perforation is still a risk, although it is less than that with colonoscopy^[36].

SCREENING GUIDELINES

In the United States, the two major guidelines for CRC screening are: (1) joint guidelines from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology; and (2) the US Preventive Services Task Force (USPSTF) guidelines. Other organizations have issued their own guidelines as well, such as the American College of Gastroenterology and the American College of Physicians. Table 1 summarizes the varying

Table 1 Summary of colorectal cancer screening guidelines from various organizations in the United States

	Joint guidelines	USPSTF	ACG	ACP
Flexible sigmoidoscopy	Every 5 yr	Every 5 yr, with high sensitivity FOBT every 3 yr	Every 5-10 yr	Every 5 yr
Colonoscopy	Every 10 yr	Every 10 yr	Every 10 yr	Every 10 yr
Barium enema	Every 5 yr	Not recommended	Not recommended	Every 5 yr
CT colonography	Every 5 yr	Insufficient evidence to recommend	Every 5 yr	Every 5 yr
gFOBT	Annual	Annual	Annual	Annual
FIT	Annual	Every year	Annual	Annual
sDNA	Uncertain	Insufficient evidence to recommend	Every 3 yr	Uncertain

USPSTF: United States Preventive Services Task Force; ACG: American College of Gastroenterology; ACP: American College of Physicians; FOBT: Fecal occult blood testing; CT: Computed tomographic; gFOBT: Guaiac-based fecal occult blood testing; FIT: Fecal immunochemical test; sDNA: Stool deoxyribonucleic acid.

recommendations from these different sets of guidelines for average risk individuals. USPSTF guidelines were issued in 2008 and are in the process of being updated. On a global level, CRC screening can be challenging to implement due to wide variability in healthcare infrastructure and resources in different countries. The World Gastroenterology Organization practice guidelines on CRC screening provide differing recommendations for average risk screening depending upon the availability of endoscopic resources^[58]. In areas with the lowest access to FS and colonoscopy, for example, biennial gFOBT or FIT is recommended, while colonoscopy every 10 years is recommended in areas with greater healthcare and endoscopic resources.

CONCLUSION

CRC screening is associated with decreased CRC incidence and mortality. CRC screening modalities include radiographic or endoscopic methods (colonoscopy, FS, CT colonography, double contrast barium enema, colon capsule endoscopy) and stool-based tests (fecal DNA test, gFOBT, and FIT). Options for screening also depend upon the healthcare infrastructure of the country including the availability of endoscopic resources. In offering CRC screening, the physician should discuss with the patient the advantages and disadvantages of each test and ascertain the patient's preferences for better adherence.

ACKNOWLEDGMENTS

We thank Luis Landeras, MD, for providing the CT

colonographic image.

Abstract

The incidence of esophageal adenocarcinoma (EAC) has dramatically increased in the United States as

well as Western European countries. The majority of esophageal adenocarcinomas arise from a backdrop of Barrett's esophagus (BE), a premalignant lesion that can lead to dysplasia and cancer. Because of the increased risk of EAC, GI society guidelines recommend endoscopic surveillance of patients with BE. The emphasis on early detection of dysplasia in BE through surveillance endoscopy has led to the development of advanced endoscopic imaging technologies. These techniques have the potential to both improve mucosal visualization and characterization and to detect small mucosal abnormalities which are difficult to identify with standard endoscopy. This review summarizes the advanced imaging technologies used in evaluation of BE.

Key words: Esophageal adenocarcinoma; Barrett's esophagus; Dysplasia; Intestinal metaplasia; Advanced endoscopic imaging; Narrow band imaging; Confocal laser endomicroscopy

INTRODUCTION

The incidence of esophageal adenocarcinoma (EAC) has been steadily rising over the last three decades, with population-based cohort studies suggestive of a 300%-500% increase during this time^[1]. The majority of esophageal adenocarcinomas arise from a backdrop of Barrett's esophagus (BE), a premalignant lesion which progresses through several stages of dysplasia to cancer. The prevalence and incidence of BE have increased over time, parallel to the increase in frequency of EAC^[2]. There are various estimates (ranging from 0.1%-2.0%) of the annual rate of progression from BE to cancer, with higher rates of progression to cancer reported for patients with low grade dysplasia (0.54% to 1.8% per year) and high grade dysplasia (6.6% per year)^[3-6]. Because of the increased risk of EAC, GI society guidelines recommend that patients with BE undergo endoscopic surveillance^[7-10]. The aim of endoscopic surveillance is to identify areas of dysplasia which can subsequently be treated with endoscopic eradication therapy before progression to cancer. In patients with BE undergoing surveillance, biopsies are collected from areas with visible mucosal abnormalities and at random in four quadrants every 1-2 cm along the BE segment^[11]. This protocol, however, is labor intensive and can still miss neoplasia despite multiple biopsies.

The emphasis on early detection of pre-cancerous lesions has led to the development of advanced imaging technologies to improve care of patients with BE. These techniques have the potential to improve mucosal visualization and detection of abnormal tissue, such as with high-definition white light endoscopy (HD-WLE), while other techniques such as dye-based or electronic chromoendoscopy enhance and adjust the color of the endoscopic images to improve lesion detection and tissue characterization. There are also techniques that allow histological evaluation such as confocal laser endoscopy (CLE). This review summarizes the currently available advanced imaging technologies used in evaluation of BE.

CONVENTIONAL (WHITE LIGHT) ENDOSCOPY

HD-WLE

Over the past decade, high resolution endoscopes using high definition (HD) systems have largely replaced the original low-resolution or standard definition (SD) white light video-endoscopes in most if not all endoscopic units. Capable of producing images with higher magnification and an image resolution of more than 1 million pixels (compared to the 100000-400000 pixels of standard-definition endoscopes), HD-WLE has enhanced

the endoscopists' ability to inspect and visualize subtle mucosal abnormalities^[12,13]. Many research studies using HD-WLE combine it with another advanced endoscopic imaging technique, such as narrow band imaging (NBI) or chromoendoscopy^[14,15]. There are few studies comparing standard endoscopy with HD-WLE, but one study did show improved detection of dysplasia using HD-WLE^[16]. In some studies, addition of additional imaging techniques does not significantly improve detection of BE and neoplasia above HD-WLE alone on a per-patient basis, although additional lesions may be detected and fewer biopsies may be acquired^[17-19]. Though high resolution endoscopes have higher sensitivity for detection of neoplasia than standard endoscopes, targeted biopsies using high resolution endoscopy (HRE) alone may still miss dysplasia that is found using random biopsies^[15].

Magnification endoscopy

Magnifying or zoom endoscopes permit better visualization of mucosal details by enabling the images to be magnified from 1.5 times to 150 times without loss of resolution^[20]. While magnification endoscopy alone allows for visualization of mucosal surface patterns and vessels, this technique has most often been studied in combination with chromoendoscopy. In one study, magnification chromoendoscopy improved the detection of intestinal metaplasia (IM) and HGD in patients BE compared to standard endoscopy^[21]. Magnification endoscopy is not widely used for patients with BE and some studies have shown a high level of inter-observer variability in identifying dysplastic lesions^[22].

ENHANCING COLOR DURING ENDOSCOPY

Chromoendoscopy

Chromoendoscopy involves endoscopic evaluation of gastrointestinal mucosa following the topical application of dyes or contrast agents. The goal of chromoendoscopy is to improve the detection and characterization of abnormalities and facilitate targeted biopsy sampling of suspicious areas. While it can be used with standard endoscopy, chromoendoscopy is most often performed with another advanced imaging modality, such as HD-WLE, magnification endoscopy, or confocal endomicroscopy. There are several types of chromoendoscopy agents, some of which are absorbed by cells, while others highlight the mucosal surface. Absorptive stains, such as methylene blue (MB) and Lugol's iodine, are absorbed across cell membranes while contrast agents such as indigo carmine are not absorbed by the mucosa but highlight the surface topography and mucosal irregularities.

Methylene blue has been used in several studies of patients undergoing chromoendoscopy for evaluation of BE and BE-associated neoplasia. Several studies suggested that MB could discern areas of IM

and dysplasia with high accuracy and with fewer biopsies compared to traditional surveillance techniques^[23-26]. However, other studies have found that chromoendoscopy was not better than conventional four quadrant random biopsies for detection of BE and neoplasia^[27,28]. Further limiting the widespread use of methylene blue chromoendoscopy is the potential risk of DNA damage and carcinogenesis^[29].

Indigo carmine has been used in conjunction with magnification endoscopy to identify the mucosal pit patterns within segments of BE^[21,30]. The presence of villiform pit patterns and irregular mucosal patterns have been shown to correlate with presence of IM and dysplasia^[30].

Acetic acid chromoendoscopy has been used in several recent studies for evaluation of patients with BE. Targeted biopsies following staining with acetic acid has been associated with increased yield for detecting BE as well as dysplasia and early cancer within an area of BE^[31]. One retrospective cohort study evaluated the yield for neoplasia in patients with BE, comparing acetic acid chromoendoscopy and a standard random biopsy protocol. Acetic acid chromoendoscopy detected more neoplasia than conventional protocol-guided mapping biopsies and required significantly fewer biopsies per neoplasia detected^[32]. Another randomized crossover study of acetic acid magnification endoscopy found a higher yield for detection of BE (78%) compared to standard endoscopy with biopsy (57%)^[33].

In comparison to other endoscopic imaging modalities, chromoendoscopy is relatively inexpensive, requiring only a spray catheter and contrast agent, many of which are readily available. On the other hand, chromoendoscopy can be cumbersome requiring a significant increase in endoscopy time and image interpretation is operator dependent, with high inter-observer variability reported in some studies^[22]. These factors and the mixed results of research studies have limited the widespread use of chromoendoscopy in patients with BE.

Electronic chromoendoscopy: Narrow band imaging

First described in 2004 by Gono *et al*^[34], NBI enhances the resolution of the mucosal surface and is the most-investigated image-enhanced endoscopy technique^[34,35]. NBI restricts the wavelengths of light used for endoscopic imaging. Shorter wavelength blue light (440-460 nm) highlights the superficial capillary network, while longer wavelength green light (540 nm) highlights the sub-epithelial vessels, allowing identification of subtle mucosal abnormalities. Furthermore, as blue light is absorbed by hemoglobin, the alterations in vascular patterns associated with neoplasia may be detected.

NBI has shown promise in the detection of BE-associated dysplasia^[36,37]. In a recent meta-analysis of eight studies including 446 patients and 2194 lesions, NBI demonstrated a pooled sensitivity and specificity of 95% and 65%, respectively, for the detection of

BE. The sensitivity and specificity of NBI in detecting HGD was 96% and 94%^[38]. Additional studies have demonstrated NBI's superiority in identifying higher grades of dysplasia in comparison to WLE using significantly fewer biopsies per patient^[14,17,37]. However, not all studies have shown an improvement in detection of neoplasia using NBI. Kara *et al*^[15] found no difference in the detection of HGD and intra-mucosal cancer (IMC) in a tandem study comparing HD-WLE and NBI, although NBI did detect additional lesions in some patients who had neoplasia identified by HD-WLE.

Several studies have focused on the specific mucosal patterns, or pit patterns, associated with BE and BE-associated neoplasia. Hamamoto *et al*^[39] described the use of NBI and a pit pattern classification system in BE and reported superior results when magnifying endoscopy was combined with NBI. Several studies of NBI combined with magnification endoscopy have identified irregular microvascular and microstructural patterns with a high sensitivity, specificity and positive predictive value for identification of HGD and cancer^[36,37,40]. Singh *et al*^[41] demonstrated that presence of a villous or ridged with regular microvasculature was suggestive of IM, while a distorted pit pattern and irregular microvasculature was highly suggestive of dysplasia. A meta-analysis of the various NBI pit pattern classification schemes for BE found a high sensitivity (96%) and specificity (94%) for detection of BE neoplasia when irregular pit patterns and/or microvasculature were identified using NBI with magnification^[38].

The advantages of NBI include the ability to study both mucosal and vascular patterns, the ease of use, and integration into standard endoscopic equipment. Limiting the widespread implementation of NBI-targeted biopsies has been the lack of a universal classification system for the mucosal and vascular patterns observed and some studies have shown only moderate interobserver agreement with interpretation of NBI images^[40,42].

Electronic chromoendoscopy: Flexible intelligent chromoendoscopy and i-scan

Similar to the principle behind NBI, Flexible Intelligent Chromoendoscopy (FICE) and i-scan are electronic chromoendoscopy techniques that manipulate the red, green, and blue components of light to create an image that enhances the superficial mucosal and vascular structures. FICE has been used in several studies, including one that showed FICE was able to clearly demarcate the junction between Barrett's mucosa and gastric mucosa^[43]. In one study comparing FICE and acetic acid chromoendoscopy, FICE was found to have comparable sensitivity to acetic acid chromoendoscopy for detection of BE neoplasia^[44]. I-scan has also been used in patient with BE, most recently in a randomized trial comparing the efficacy of endoscopy with 4-quadrant random biopsies and targeted biopsies using i-scan or acetic acid chromoendoscopy^[45]. Use of i-scan or acetic acid-guided biopsies produced a significantly

higher diagnostic yield for IM compared to endoscopy with random biopsies. Acetic acid and i-scan showed comparable results for diagnosis of BE.

Autofluorescence imaging

Endogenous tissue fluorophores are biological substances in mucosa that emit fluorescent light when exposed to a light of a shorter wavelength. Autofluorescence imaging (AFI) is based on the principle that different tissue types differ in their fluorescence emission, with normal mucosa appearing green under fluorescence excitation, while dysplasia and neoplasia appears magenta or purple^[46]. Differences in fluorescence emission can be examined using a fluorescence-detecting endoscope and these differences in fluorescence can be used for lesion detection and characterization.

AFI is a sensitive but poorly specific tool for the detection HGD and early cancer in BE^[47-49]. Studies comparing AFI to white light endoscopy (WLE) found that AFI increased the detection of HGD and IMC compared with WLE, but was associated with a high false positive rate^[49]. Subsequent studies have attempted to reduce this false positive rate by combining AFI with NBI, with improvement in one study of patients with BE and suspected neoplasia from false positive rate of 40% to 10% using NBI^[48]. The combination of high resolution WLE, AFI and NBI is known as endoscopic trimodal imaging (ETMI), and is not currently available in the United States. An international multicenter study by Curvers *et al*^[50] compared ETMI with standard video endoscopy and demonstrated that addition of AFI to HRE increased detection rate of HGD and IMC compared to WLE alone (90% vs 53%), but did so at the expense of a high false-positive rate of 81%, which was reduced to 26% with the addition of NBI. Two subsequent large randomized studies from the same group comparing ETMI and WLE failed to show superiority of ETMI over endoscopy with a 4 quadrant random biopsy protocol^[19,51]. Furthermore, in these studies random four quadrant biopsies with WLE identified more areas of high grade dysplasia (HGD) and EAC than targeted biopsies after ETMI inspection. The addition of NBI to AFI and HRE reduced the false positive rate in one of the studies, although 17% of dysplastic lesions were re-classified as being normal^[51]. While AFI may be useful as an adjunctive technique to WLE, due to its decreased sensitivity and high false positive rate, AFI as a solo method of detection is not suitable to replace the standard BE surveillance biopsy protocol.

MICROSCOPIC ENDOSCOPY

Several advanced endoscopic imaging techniques are available for *in vivo* histological evaluation of the esophageal mucosa, and are used in conjunction with WLE and other advanced endoscopic imaging techniques to identify suspicious lesions that require

further evaluation.

Confocal laser endomicroscopy

Confocal laser endomicroscopy (CLE) magnifies the mucosa up to 1000-fold and up to 250 μ m below the mucosal surface allowing for real-time histological assessment of the GI mucosa during endoscopy. When evaluating patients with BE, this level of magnification allows for visualization of the specialized IM and goblet cells. Two endomicroscopy platforms have been used for most of the CLE studies of BE, an endoscope based confocal system (eCLE) in which a confocal microscope is integrated into the tip of a standard endoscope and a probe-based system (pCLE), in which a probe is passed through the accessory channel of the endoscope. Both systems use blue laser light and require administration of either topical or intravenous fluorescent contrast agents.

The initial study of eCLE found that BE and BE-associated neoplasia could be identified with a sensitivity of 98.1% and 92.9% and a specificity of 94.1% and 98.4%, respectively^[52]. A subsequent prospective randomized controlled crossover trial of eCLE found that CLE with targeted biopsies almost doubled the diagnostic yield for neoplasia compared to a standard biopsy protocol for BE (33% vs 17%), with a significant reduction in the number of mucosal biopsies needed for diagnosis. Two thirds of patients in this study undergoing routine surveillance of BE were able to avoid any mucosal biopsies during their CLE procedures^[53]. In a subsequent multicenter randomized, controlled trial of eCLE, 192 patients with BE were randomized to either HD-WLE with random biopsies or HD-WLE and CLE with targeted biopsies. In this study, CLE with targeted biopsies outperformed HD-WLE with standard biopsies for detection of neoplasia (22% vs 6%) and impacted clinical decision-making (such as the decision to perform endoscopic mucosal resection) in almost 1/3 of patients^[54]. Multiple studies have evaluated use of pCLE in patients with BE with promising results. Bertani *et al*^[55] found the use of pCLE in addition to WLE enhanced the detection of dysplasia compared with WLE alone (28% vs 10%). A multi-center study of 101 patients found the addition of pCLE to HD-WLE improved the diagnostic yield and detection of neoplasia^[56]. This study examined the pCLE for *in vivo* prediction of HGD and EAC and found that the addition of pCLE to WLE and NBI increased sensitivity for neoplasia from 45% to 76% and allowed for a reduction in number of biopsies needed for diagnosis^[56]. The advantages of CLE, such as the potential for real-time histological diagnosis during an endoscopic procedure, may be offset by the increased procedure length, equipment costs, and the training necessary to interpret the images.

Endocytoscopy

Endocytoscopy allows for real time microscopic imaging of the mucosa using white light and special lenses for

magnification. Images are acquired on the surface of the mucosa after application of a contrast agent, most commonly methylene blue. Surface magnification during endocytoscopy is up to 1400-fold, depending on the endocytoscopy system used and has been used in several studies of squamous esophageal cancer and squamous dysplasia^[57]. Studies have reported variable accuracy of endocytoscopy for the detection of neoplasia in a backdrop of BE and the technique has been limited in BE patients by inadequate image quality. In one study evaluating patients undergoing surveillance for BE, image quality was found to be inadequate in 49% of sites imaged at 450-fold magnification and inadequate in 22% of images using 1125-fold magnification^[58]. Another study has examined *ex vivo* EMR specimens with endocytoscopy to develop a classification system which showed good accuracy and interobserver agreement. At this time, endocytoscopy is not widely used in management of patients with BE^[59].

OTHER LIGHT-BASED TECHNIQUES

Optical coherence tomography

Optical coherence tomography (OCT) is similar to ultrasound in acquiring tissue images but uses light waves rather than acoustic waves to generate cross-sectional images of epithelial and sub-epithelial tissues based on differences in optical scattering of the tissue structures. OCT does not require tissue contact and images are obtained *via* a catheter introduced through a standard endoscope. One prospective clinical study assessed the presence of dysplasia in BE in 55 patients using 177 biopsy correlated images and found that OCT could detect HGD and EAC with 83% sensitivity and 75% specificity^[60]. Several other studies have evaluated a variety of OCT systems and found variable sensitivity, specificity, and accuracy for detection of dysplasia in Barrett's esophagus^[61-63].

Optical frequency domain imaging and volumetric laser endomicroscopy

Optical frequency domain imaging (OFDI), also known as volumetric laser endomicroscopy (VLE), allows for high resolution, high-speed acquisition of larger areas of the luminal surface than standard OCT. Preliminary studies with both OFDI/VLE have suggested that differences between normal squamous mucosa, BE, and BE neoplasia can be identified using this technique^[64,65]. Recent studies of VLE have focused on interobserver agreement with image interpretation and correlation of VLE images with histology findings^[66,67].

Spectroscopy

Spectroscopy uses variation in scattered light across a full spectrum to obtain information about nuclear size, crowding, vascularity and tissue structure and organization. Several types of spectroscopy have been used to study BE, including light-scattering, reflectance and Raman spectroscopy. Light-scattering spectroscopy

provides information about cell nuclei characteristics and has demonstrated the ability to detect dysplasia in patients with BE^[68,69]. Reflectance spectroscopy measures the color and intensity of reflected light after tissue illumination to help differentiate normal from neoplastic tissue and has also been used in studies of BE^[70,71]. Raman spectroscopy detects scattered light that has been changed in wavelength (termed inelastic scattering) and results in characteristic peaks and bands that are correspond with normal vs abnormal mucosa. One study reported an accuracy of 96% when using Raman spectroscopy for detecting EAC^[72]. In a large study of 373 BE patients, Raman spectroscopy was used for real-time detection of BE and neoplasia with good success^[73]. At this time, spectroscopy remains an interesting research technique for patients with BE.

CONCLUSION

In the last decade there have been many advances in the field of endoscopic imaging for the detection of early dysplastic changes and neoplasia in patients with BE. While many of these modalities have demonstrated high sensitivity and specificity in detecting dysplasia and EAC, some limitations to widespread adoption exist. The need for training in image interpretation, inter-observer variability in image interpretation, expensive equipment, and potential increases in procedure length have limited use of these technologies. Technological improvements could make several of these novel endoscopic imaging techniques easier to use, and in time endoscopists may become more comfortable with advanced endoscopic imaging options. In the future, advanced endoscopic imaging techniques could improve care for patients with BE and BE-associated neoplasia by providing more accurate detection of dysplasia and providing real-time histology.

Abstract

Clear visualization of the gastrointestinal mucosal surface is essential for thorough endoscopy. An unobstructed assessment can reduce the need for additional time-consuming manipulations such as frequent washing and suction, which tend to prolong total procedure time. However, mucus, foam, and bubbles often hinder clear visibility during endoscopy. Premedication with pronase, a compound of mixed proteolytic enzymes, has been studied in order to improve mucosal visibility during endoscopy. Although its effects differ according to the location in the stomach, premedication with pronase 10 to 20 min before endoscopy significantly improves mucosal visibility without affecting the accuracy of *Helicobacter pylori* identification. The effects of pronase as premedication also extend to chromoendoscopy, narrow-band imaging, magnifying endoscopy, and endoscopic ultrasonography. In addition, endoscopic flushing with pronase during endoscopy may improve the quantity and the quality of a biopsy to some degree. Although improved mucosal visibility does not necessarily improve clinical outcomes, premedication with pronase may be helpful for increasing the detection rate of early cancers.

Key words: Endoscopy; Premedication; Pronase

INTRODUCTION

Esophagogastroduodenoscopy (EGD) is commonly performed to diagnose and treat benign and malignant diseases, especially early gastric cancer in the upper gastrointestinal tract. Clear visualization of the gastrointestinal mucosal surface is essential for thorough EGD, particularly when using advanced endoscopic methods such as narrow-band imaging (NBI) or magnifying endoscopy (ME). Furthermore, clear visualization can decrease the need for additional time-consuming manipulations such as frequent washing and suction, which may prolong the total procedure time. In other words, proper premedication before EGD is important to obtain satisfactory visualization of the gastrointestinal mucosa. However, mucus, foam, and bubbles often hinder clear visibility during EGD^[1]. To overcome these problems, mucolytic and defoaming agents have been applied in EGD.

In most endoscopic centers, simethicone or dimethylpolysiloxane (DMPS) is commonly used to eliminate bubbles and foam during EGD^[1,2]. Simethicone is a mixture of polydimethylsiloxanes that reduces the surface tension of air bubbles and results in the coalescence of small bubbles into larger ones, which may then pass more easily with belching or flatulence^[3]. DMPS, which is similar to simethicone, also has the effect of eliminating foam and bubbles. Several studies have shown that simethicone is a suitable premedication to improve the endoscopic view of EGD^[4,5]. However, despite premedication with these defoaming agents, great deal of mucus can still be encountered during EGD^[6].

Pronase, a compound of mixed proteolytic enzymes, was isolated from the culture filtrate of *Streptomyces griseus* in 1962, and has been used as a base material in the preparation of anti-inflammatory and digestive enzymes^[7]. Because of its mucolytic effects^[8], pronase was used to remove gastric mucus for roentgenographic

examination in 1964^[9]. It has also been applied as a premedication for endoscopy since 1991^[10]. However, the effectiveness of premedication with pronase for improving mucosal visibility during EGD has been the subject of a few clinical trials. Similarly, a limited number of systematic reviews have been performed to address its efficacy in improving mucosal visibility during advanced endoscopy such as NBI or ME as well as conventional endoscopy. Therefore, the aim of this review is to evaluate the role of pronase in increasing imaging quality of various endoscopic examinations based on the published literature.

METHODS TO IDENTIFY STUDIES

Two reviewers (Kim GH and Chung IK) performed a literature search using PubMed and Embase databases. Key words included pronase, premedication, and endoscopy. Relevant review articles were also investigated and additional studies were identified by searching the bibliography of published articles. We focused on studies that described premedication with pronase to increase imaging quality during endoscopy.

THE EFFECTS OF PRONASE ON MUCOSAL VISIBILITY DURING CONVENTIONAL ENDOSCOPY

Table 1 summarizes studies of the effects of pronase as premedication for conventional endoscopy. In most studies, the mucosal visibility score was classified from 1 to 4 (1, no adherent mucus; 2, mild mucus, but not obscuring vision; 3, large amount of mucus obscuring vision; and 4, heavy adherent mucus). All studies showed the superior effects of pronase for improving mucosal visibility in the stomach, but this effect differed according to the location in the stomach. In a recent meta-analysis that included three studies until 2012^[11], significant improvement in mucosal visibility was noted only with pronase use in the antrum and fundus. Mucosal visibility in the greater curvature of the upper body did not improve despite pronase premedication, which suggests that this area needs to be cautiously observed^[12,13]. In our study, even though the grade of mucosal visibility in the upper body and fundus was high compared to other sites, a significant difference in mucosal visibility grade during EGD was observed in the fundus and upper body of the stomach^[7].

Improving visibility can also lead to reduce the need of additional manipulation for washing to clear the surface of the gastrointestinal mucosa, which results in shortening the total EGD procedure time^[8,10,13]. However, pronase only induces mucolysis, but itself does not have a defoaming effect. Therefore, if a defoaming agent is used simultaneously as premedication in addition to pronase, it is expected that mucosal visibility will be improved vs using pronase alone. In fact, many studies have reported a combination of pronase

Table 1 Summary of studies about premedication with pronase for visualization of the mucosa during conventional endoscopy

DMPS: Dimethylpolysiloxane; SB: Sodium bicarbonate.

with defoaming agents such as DMPS significantly improves visibility during conventional endoscopy or chromoendoscopy^[6,8,10]. Therefore, when pronase is used to improve visibility during EGD, we recommend the concurrent use of a defoaming agent.

THE EFFECTS OF PRONASE ON MUCOSAL VISIBILITY DURING ADVANCED ENDOSCOPY

Table 2 summarizes studies that explored the effects of pronase as premedication for advanced endoscopy.

Chromoendoscopy

Chromoendoscopy requires a clear field in order for the dye to bind to the targeted mucosa rather than the overlying mucus^[14,15]. Gastric mucus prevents the dye from spraying onto the gastric mucosa and is a frequent source of artifacts during endoscopic imaging. The mucolytic effect of pronase during conventional endoscopy is sustained during chromoendoscopy. In a randomized controlled trial of chromoendoscopy with methylene blue, premedication with pronase came to significantly improve the visibility of the gastric wall both before and after methylene blue spraying and also to significantly shorten the time of the chromoendoscopic examination^[8].

NBI and ME

Recently, NBI has been reported to improve the visibility of mucosal structure and the accuracy of detection for

precancerous conditions^[16]. Like conventional endoscopy, the presence of foam, bubbles, or mucus on the gastric mucosa can obstruct mucosal visualization during NBI endoscopy. Therefore, a premedication with defoaming and mucolytic agents can be an effective method to improve visibility and possibly the diagnostic performance of NBI endoscopy. In our study comparing the visibility score and diagnostic performance of NBI endoscopy for patients with precancerous conditions with or without pronase premedication, a combination of pronase with simethicone significantly improved visibility during NBI endoscopy in the proximal part of the stomach, and it also improved the negative predictive value of NBI endoscopy compared with that of white light endoscopy^[17].

ME with NBI (ME-NBI) is reported to have high accuracy for diagnosing corpus gastritis, intestinal metaplasia and early gastric cancer^[18-21]. In particular, the microvascular and microsurface patterns observed during ME-NBI are clinically helpful for distinguishing cancerous from noncancerous lesions. As mucosal visibility during EGD is essential in finding subtle mucosal abnormalities associated with early neoplasia, mucosal visibility is especially important during ME-NBI in that this procedure has time-consuming and complicated nature. In a randomized study, we showed that premedication with pronase improved mucosal visibility during ME-NBI of the stomach and reduced the frequency of water flushing needed to clear the mucosa^[7].

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) plays an important

Table 2 Summary of studies about premedication with pronase for visualization of the mucosa during advanced endoscopy

Examination	Ref.	Year	Study design	Premedication group (n)	Mucosal visibility
Chromoendoscopy	Fujii <i>et al</i> ^[8]	1998	Prospective	A: DMPS (34) B: DMPS + SB (32) C: DMPS + SB + pronase (34)	C > A, B
NBI endoscopy	Cha <i>et al</i> ^[17]	2014	Prospective	A: Pronase + SB (28) B: Simethicone (27)	A > B

NBI: Narrow-band imaging; ME-NBI: Magnifying endoscopy with narrow-band imaging; EUS: Endoscopic ultrasonography; DMPS: Dimethylpolysiloxane; SB: Sodium bicarbonate.

role in assessing benign and malignant gastrointestinal diseases. It is especially useful for diagnosing subepithelial lesions and the staging of early gastric cancer^[22,23]. However, artifacts caused by gastric mucus can potentially affect visibility during EUS, which inhibits the ability to evaluate superficial mucosal lesions. Reducing gastric cavity and mucosal surface artifacts caused by mucus may be helpful in improving EUS performance. A randomized study evaluating the effect of pronase in improving EUS images showed that premedication with pronase reduced artifacts during EUS *via* a mucolytic effect that disrupts the surface mucus gel layer of the stomach^[24]. In another similar randomized controlled study, premedication with pronase decreased the number of gastric wall and lumen hyperechoic artifacts observed in patients given either saline solution or pronase/simethicone^[25]. Unlike pronase, the use of simethicone led to turbidity and echogenicity, which did not improve visibility during EUS. Although a more accurate diagnosis is not necessarily gleaned from better-quality images, obtaining good EUS images through premedication with pronase may lead to improve the diagnostic accuracy for superficial mucosal lesions during EUS.

CONSIDERATIONS IN USING PRONASE AS PREMEDICATION

To improve the effect of pronase on removing gastric mucus, several factors must be considered^[10]. First is intragastric pH. Mucolysis by pronase is found to be maximal at pH 6 to 8. Therefore, it is necessary to neutralize the acidity of the gastric juice with a neutralizer such as sodium bicarbonate and to prevent subsequent hypersecretion of gastric juice with an anticholinergic agents such as scopolamine butylbromide^[8]. The second consideration is the amount of pronase and the volume of oral solution. Based on previous findings^[6,8,10,13], 2000 units or more (usually 20000 units) of pronase and 80 mL to 100 mL of oral solution are needed to achieve

adequate effects. The third consideration relates to position change of the patient. Rotation from supine, left or right lateral, to prone position several times is helpful for completely removing gastric mucus^[8]. However, in two recent studies, similar effects of pronase were shown without position changes before EGD^[12,13]. The argument for not changing position before EGD stems from the fact that the ingested solution flows into the gastric fundus, then gradually into the gastric antrum by the way of the gastric body after premedication with pronase.

When is the optimal time for taking pronase to maximize its mucolytic effect before EGD? In previous studies, premedication with pronase was administered 10 to 20 min before EGD^[8,12]. In a recent study comparing premedication times of 10 min and 20 min before EGD, mucosal visibility score did not differ between the two groups^[13]. In another recent study evaluating the optimal time of medication with pronase, administration of pronase within 30 min before EGD significantly improved endoscopic visualization compared to administration at 30 min before EGD^[26]. These results suggest that if pronase is given within 30 min before EGD, the duration of premedication does not play a significant role in satisfactory mucosa visualization.

OTHER ADDITIVE EFFECTS OF PRONASE

Effect of pronase on Helicobacter pylori

Because *Helicobacter pylori* (*H. pylori*) strains reside in the surface mucous gel layer as well as on the surface of gastric epithelial cells, premedication with pronase could reduce the accuracy of *H. pylori* identification in biopsy specimens *via* its mucolytic effect. However, the use of pronase seems not to influence the identification of *H. pylori* by culture and rapid urease test of biopsy specimens in many studies^[6,8,12].

Pronase can disrupt gastric mucus and so reduce the thickness of the surface mucous gel layer, which enhances drug delivery to improve the eradication

rate of *H. pylori*^[6,27,28]. Therefore, it is assumed that supplements of pronase in addition to anti-*H. pylori* regimen could increase the eradication rate of *H. pylori*. Earlier randomized controlled studies showed the additive effect of pronase in improvement of *H. pylori* eradication rates^[27,28], but a recent randomized controlled study did not confirm this effect^[29].

Effect of pronase on gastric biopsy

Although pronase improves visibility, a patient's positioning may prevent it from reaching some portions of the stomach in sufficient quantity. In these situations, the endoscopist aid distribution to the target lesion through endoscopic flushing of pronase. Although endoscopic flushing is not able to provide equivalent improvements in mucosal visibility during EGD when compared with the oral administration of pronase^[30], it can be helpful for improving the visibility of a target lesion. Furthermore, patients receiving endoscopic flushing with pronase in a limited area exhibited decrease in thickness of mucus, increase in depth of biopsy, improved anatomical orientation, and improved overall diagnostic assessment of the second biopsy specimens compared with a control group^[31]. Therefore, endoscopic flushing with pronase during EGD can be recommended in order to improve the quantity and quality of endoscopic biopsies.

CONCLUSION

During EGD, foam, bubbles, and mucus often obstruct visibility. Premedication is therefore usually administered prior to an endoscopic procedure in order to remove foam and mucus. Satisfactory visibility achieved through premedication with proper agents can reduce the need to carry out flushing during the procedure, thus shortening the duration of an endoscopy. The use of pronase as premedication improves mucosal visualization in advanced endoscopy as well as in conventional endoscopy without affecting the accuracy of *H. pylori* identification. Although the use of pronase does not necessarily result in a higher detection rate of early cancers or improve clinical outcomes, improved mucosal visibility may be helpful for increasing the detection rate of early cancers. Large randomized clinical trials will be needed to confirm the utility of pronase for identifying early cancers.

Abstract

Raman spectroscopy is a spectroscopic technique based on the inelastic scattering of monochromatic light that represents the molecular composition of the interrogated volume to provide a direct molecular fingerprint. Several investigations have revealed that confocal Raman spectroscopy can differentiate non-dysplastic Barrett's esophagus from esophageal high-grade dysplasia and adenocarcinoma with high sensitivity and specificity. An automated on-line Raman spectral diagnostic system has made it possible to use Raman spectroscopy to guide accurate target biopsy instead of multiple random forceps-biopsies, this novel system is expected to improve *in vivo* precancerous diagnosis and tissue characterization of Barrett's esophagus.

INTRODUCTION

Confirmed by the presence of intestinal metaplasia with or without goblet cells from a squamous to a columnar-lined esophageal epithelium^[1,2], Barrett's esophagus is a metaplastic precursor of esophageal adenocarcinoma. Given the poor prognosis that has remained relatively constant, with current 5-year survival rates of only 8% to 15%^[3], early identification of Barrett's esophagus associated with high-grade dysplasia followed by targeted endoscopic resection is the most critical measure to prevent progression to invasive esophageal malignancy^[4]. According to the current diagnostic guidelines, patients with Barrett's esophagus are recommended to undergo strict biopsy samplings (typically 4-quadrant random samplings) for every 2 cm of Barrett's mucosa during endoscopic surveys at intervals of 3 to 5 years. This approach may produce a large number of negative biopsies and increase the risk of bleeding. Considering the elevated incidence of esophageal adenocarcinoma, the need for new advanced endoscopic technologies that can transition standard Barrett's esophagus surveillance from random biopsies to a real-time "optical biopsy" is imperative.

Optical spectroscopy is a technique that utilizes microstructural information contained in light-tissue interactions to enhance suspicious tissue recognition during standard endoscopy^[5], including fluorescence, elastic scattering, and inelastic (Raman) scattering.

Principle of raman spectroscopy

Raman spectroscopy represents a unique optical vibrational technique based on the inelastic scattering of a monochromatic laser light source. Inelastic scattering is a phenomenon in which the frequency of the scattered photon is shifted up or down with respect to the incident excitation light depending on the specific vibrational motions of the molecules in the tissue being interrogated, which is called the Raman effect. This shift of frequency provides unique information on the scattering molecules.

Taking the unique advantage of the ability of Raman spectroscopy to harvest a wealth of direct molecular fingerprint information from inter and/or intracellular components such as proteins, lipids, carbohydrates and DNA in cells and tissue, Raman spectroscopy has shown great promise for histo-pathologic assessments at the biochemical and molecular levels^[6]. Because the progression from non-dysplastic Barrett's esophagus to esophagus adenocarcinoma manifests a progressive series of molecular and biochemical changes, Raman spectroscopy may provide the capability to analyze the carcinogenesis process. Furthermore, the majority of biological molecules are Raman active, each with its own unique fingerprint. As a result, Raman spectroscopy is a very sensitive tool to detect subtle biochemical and molecular changes, which is crucial for differentiating nondysplastic from high-grade dysplastic Barrett's esophagus.

Overall configuration of the raman spectroscopy system

Briefly, the Raman spectroscopy system consists of four major components^[6]: A light generator (near-infrared diode laser); light collection optics; a wavelength selector (filter or spectrophotometer); and a detector (photodiode array, charge coupled device or photomultiplier tube). Compared with an ultraviolet ray illumination source, near infrared excitation not only minimizes spectral disruption from tissue fluorescence but also produces reduced mutagenic effects and deeper penetration capability.

The combination of Raman spectroscopy and an endoscopic system is realized by a Raman probe, which is coupled to an optical cable containing the excitation and collection fibers, with an outer diameter enabling easy passage through the instrument channel of an endoscope. Currently, the two novel confocal Raman probes^[3,4] have the following advantages: They ensure the precise interrogation of the epithelium (with a volume of $< 0.02 \text{ mm}^3$), which is closely related to early onset of Barrett's carcinogenesis, because the ratio of the epithelium to stromal Raman photons collected is 19-fold higher than that collected using previous volume-type Raman probes; and they provide the capacity for reproducible and objective Raman measurements achieved in a direct contact mode.

Clinical application

Water molecules, the predominant constituents of living tissue, have a negligible influence on Raman signals due to the limited change in the polarity of the -OH bond, which enables Raman spectroscopic analysis of fresh, unprepared tissue, both *ex vivo* and *in vivo*.

Robles^[5] summarized some clinical research on Raman spectroscopic technology for classification of malignant changes in Barrett's esophagus, carried out by two groups, from Gloucestershire Royal Hospital^[3], United Kingdom and the National University of Singapore^[4], Singapore. The latter demonstrated for the first time that confocal Raman spectroscopy can be used to target dysplasia identification and subsequent biopsy in Barrett's esophagus in real-time, which has also been used to diagnose gastric^[7] and colorectal^[8] lesions. The characteristics of the two abovementioned confocal probes were compared and listed in Table 1.

At present, most biomedical Raman research on pre-cancer and early cancer diagnosis remain focused on the fingerprint (FP) Raman spectra, which contain rich biochemical information regarding the tissue; however, some extremely weak tissue Raman signals in certain organ sites may be overwhelmed by the tissue autofluorescence (AF) background. Because the high-wavenumber (HW) Raman spectral range exhibits stronger tissue Raman signals with less AF interference, it has been integrated with the FP Raman spectra to improve the real-time *in vivo* diagnosis of esophageal squamous cell carcinoma (ESCC) during endoscopic examination, resulting in a predictive diagnostic sensitivity of 92.7% and specificity of 93.6% for ESCC

Table 1 Comparison of two endoscopic confocal raman spectroscopic systems

Technical parameters	Developed by Almond <i>et al.</i> ^[3]	Developed by Bergholt <i>et al.</i> ^[4]
λex	830 nm	785 nm
Diameter of probe	2.7 mm	1.8 mm
Range of Raman spectra	400-1850 cm ⁻¹	800-1800 cm ⁻¹
Acquisition times	1 s	0.2 s
Classification model	Principal component fed linear discriminant analysis	Partial least-squares discriminant analysis ^[9]
Diagnostic way	<i>Ex vivo</i>	Real-time <i>in vivo</i>
Sensitivity and specificity for detecting HGD in BE	86% and 88%	87.0% and 84.7%

HGD: High grade dysplasia; BE: Barrett's esophagus.

identification^[10].

CONCLUSION

Despite some limitations, such as only identifying molecular features, susceptibility to interference of fluorescence from impurities or from the sample itself, and thermal damage to tissues, confocal Raman spectroscopy uncovers the biochemical and molecular changes occurring in the epithelium during Barrett's carcinogenesis. This technique is expected to improve *in vivo* precancerous diagnosis and tissue characterization of Barrett's esophagus with increased accuracy based upon updated algorithms and the on-line real time automatic analysis system.

Abstract

AIM: To evaluate risk factors for local recurrence after endoscopic mucosal resection of colorectal adenomas > 20 mm.

METHODS: Retrospective data analysis of 216 endoscopic mucosal resections for colorectal adenomas > 20 mm in 179 patients (40.3% female; median age 68 years; range 35-91 years). All patients had at least 1 follow-up endoscopy with a minimum control interval of 2 mo (mean follow-up 6 mo/2.0-43.4 mo). Possible factors associated with local recurrence were analyzed by univariate and multivariate analysis.

RESULTS: Median size of the lesions was 30 mm (20-70 mm), 69.0% were localized in the right-sided (cecum, ascending and transverse) colon. Most of the lesions (85.6%) showed a non-pedunculated morphology and the majority of resections was in piecemeal technique (78.7%). Histology showed carcinoma or high-grade intraepithelial neoplasia in 51/216 (23.6%) lesions including 4 low risk carcinomas (pT1a, L0, V0, R0 - G1/G2). Histologically proven recurrence was observed in 33/216 patients (15.3%). Patient age > 65 years, polyp size > 30 mm, non-

pedunculated morphology, localization in the right-sided colon, piecemeal resection and tubular-villous histology were found as associated factors in univariate analysis. On multivariate analysis, only localization in the right-sided colon (HR = 6.842/95%CI: 1.540-30.394; $P = 0.011$), tubular-villous histology (HR = 3.713/95%CI: 1.617-8.528; $P = 0.002$) and polyp size > 30 mm (HR = 2.563/95%CI: 1.179-5.570; $P = 0.017$) were significantly associated risk factors for adenoma recurrence.

CONCLUSION: Meticulous endoscopic follow-up is warranted after endoscopic mucosal resection of adenomas localized in the right-sided colon larger than > 30 mm, with tubular-villous histology.

Key words: Colorectal adenoma; Endoscopic mucosal resection; Piecemeal resection; Local recurrence rate; Tubular-villous adenoma

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Endoscopic mucosal resection of larger adenomas is burdened with relatively high rates of local recurrence. In this retrospective analysis, size > 30 mm, non-pedunculated morphology, right-sided localization, piecemeal resection and histology were all associated with local recurrence. In addition, right-sided localization, tubular-villous histology and size > 30 mm were independently associated with local recurrence. These findings emphasize the necessity of meticulous endoscopic follow-up, they might also argue in favor of *en bloc* resection of larger colorectal lesions, in particular in the right-sided colon.

Briedigkeit A, Sultanie O, Sido B, Dumoulin FL. Endoscopic mucosal resection of colorectal adenomas > 20 mm: Risk factors for recurrence. *World J Gastrointest Endosc* 2016; 8(5): 276-281 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i5/276.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i5.276>

INTRODUCTION

Screening colonoscopy and removal of detected adenomas is now recognized as an effective measure to prevent colorectal cancer^[1-3]. However, efficacy of screening endoscopy is hampered not only by a low adenoma detection rate but also by incomplete removal of advanced adenomas^[4].

Endoscopic mucosal resection (EMR) is the current standard for the treatment of colorectal adenomas in Western countries^[5-7]. While widely used, EMR is burdened by incomplete adenoma resections even for smaller lesions up to 20 mm^[8]. The technique is also used for lesions > 20 mm where it is performed in piecemeal technique, *i.e.*, the adenoma is removed in fragments. As a consequence of fragmentation it is impossible to histologically confirm the completeness of

resection. Endoscopic control is therefore recommended after 2-6 mo by current guidelines^[9-12]. Reported recurrence rates during endoscopic follow-up vary from 5%-27% in retrospective studies^[13-23]. In a recently published well-conducted prospective study the recurrence rate was 32%^[24]. Since the majority of colorectal lesions harbors only low-grade intraepithelial neoplasia, local recurrence is usually not viewed as a treatment failure^[22,25]. Nevertheless, all patients need close endoscopic observation and those with recurrences often need several EMR interventions during follow-up^[26]. Moreover, there is a concern about late local recurrences and even subsequent cancer after a negative first control endoscopy^[13,22,24,27]. Many of these problems could be overcome by the use of endoscopic submucosal dissection (ESD) - which allows *en bloc* resection of larger adenomas, but colorectal ESD is still largely considered an experimental therapy in the Western world^[11].

Several risk factors for local recurrence after EMR (*e.g.*, lesion size, localization, morphology, resection in piecemeal technique, histological features) have been reported in retrospective studies^[18,22,28-30]. The purpose of this study was to analyze risk factors in a cohort of larger colorectal adenomas with preferentially right-sided localization. The results of this study should have an impact on the choice of the resection strategy (*e.g.*, EMR vs ESD vs laparoscopic surgery) as well as on the intensity of endoscopic follow-up.

MATERIALS AND METHODS

Patients and data collection

A single experienced interventional endoscopist (FLD) performed 688 EMRs over a five-year period (03/2008-03/2013). Of these, 216 EMRs in 179 patients, 87 female (40.3%) and 129 male (59.7%), with a median age of 68 years (35-91) met the inclusion criteria of polyp size > 20 mm, at least one endoscopic control 2-6 mo after EMR and sufficient data of follow-up examinations. The median follow-up time was 6 mo (range: 2-43.4 mo).

EMR procedure

EMRs were carried out under conscious sedation with propofol (B Braun Melsungen, Melsungen, German) and occasionally midazolam (Roche Pharma AG, Basel, Switzerland) using standard endoscopes (GIF 1-TQ160, CF-H180 AL, PCF 180 AL; Olympus Europe, Hamburg Germany). After detailed endoscopic inspection, lesions were classified according to the Paris classification^[31] and the size of the lesion was estimated by comparison to an opened snare. Submucosal injection of normal saline with 0.01% indigo carmine (Novaplus, Lake Forrest, IL, United States) was performed with a small bore injector needle (25G, Olympus Europe, Hamburg, Germany). EMR was then carried out with different snare types according to the size and shape of the lesions (Snaremaster®, Olympus Europe, Hamburg,

Table 1 Characteristics of the resected lesions *n* (%)

No. of polyps	<i>n</i> = 216
Size (median/range)	30 mm (20.0-70.0)
Localization	
Right-sided colon (cecum, ascending, transverse)	149 (69.0)
Left-sided colon (descending, sigmoid) or rectum	67 (31.0)
Morphology of polyps (Paris classification ^[31])	
Pedunculated (0-Ip)	31 (14.4)

Resection in piecemeal technique	170 (78.7)
Final histology	
Low-risk invasive adeno-carcinoma	4 (1.9)
Tubular-villous adenoma	102 (47.2)
Tubular adenoma	65 (30.1)
Serrated adenoma	45 (20.8)

Germany; Acusnare®, Cook Medical Germany, Mönchengladbach, Germany) using standard power settings on an Erbe VAI0 200S electrosurgical unit (Erbe Elektromedizin, Tübingen, Germany). Careful APC coagulation of resection bed or margins was performed if deemed necessary. Resected specimens were retrieved and fixed in phosphate buffered formaldehyde solution for histopathology. To prevent delayed bleeding hemoclips (EZ clip; Olympus Europe, Hamburg, Germany) were used in most procedures.

Endoscopic follow-up after EMR

According to the German S3 guideline on colorectal carcinoma^[11] control endoscopies were done 2-6 mo after EMR. If longer follow-up endoscopies without signs of recurrence were available the longest follow-up interval was counted.

Statistical analysis

Univariate (Kaplan Meier) analysis was carried out to describe the distributions of baseline variables. Cox regression analysis was then used to evaluate various combinations and interactions of prognostic variables in a multivariate manner. Data analysis was done using the SPSS package (student's edition; SPSS Inc. Somers, NY, United States). A *P* value < 0.05 was considered statistically significant.

RESULTS

A total of 216 adenomas with a median size of 30 mm (range 20-70 mm) were resected. Most adenomas were localized in the right-sided colon (69%), had a flat or sessile morphology (85.6%) and were resected in piecemeal technique (78.7%). Histological analysis revealed tubular adenoma (30.1%), tubular-villous adenoma (47.2%), serrated adenoma (20.8%) and invasive cancer in four lesions (1.9%). High-grade intraepithelial neoplasia was detected in 47 lesions (21.8%). While piecemeal fragments did show lateral margins with adenoma tissue, positive vertical margins were not detected. All four colorectal cancers were low risk (pT1a, L0, V0, R0 - G1/G2) and did not recur

Table 2 Histology by localization of the lesions *n* (%)

Histology	Right-sided colon (<i>n</i> = 149)	Left-sided colon (<i>n</i> = 67)

Serrated adenoma	43 (28.9)	2 (3.0)

during follow-up (Tables 1 and 2).

After a median follow-up interval of 6 mo (range 2-43.4) a total number of 33 recurrences were detected, resulting in a local recurrence rate of 15.3%. All recurrences showed the same histology as the initially resected lesion and by the time of writing all patients with recurrences had been treated endoscopically by EMR and/or argon plasma coagulation. Univariate (Kaplan-Meier) analysis (Table 3) detected significant differences in the recurrence rates for age group (< 65 years: 11.4%/> 65 years: 19.2%), adenoma size (< 30 mm: 12.4%/> 30 mm: 22.2%), localization (left-sided colon: 3.0%/right-sided colon: 20.8%), morphology (pedunculated: 0%/non-pedunculated: 17.8%), resection technique (*en bloc*: 6.5%/piecemeal: 17.6%) and histology (tubular, serrated, carcinoma: 7.1%/ tubular-villous 24.3%) but not for time interval of follow-up or histology of serrated adenoma. On multivariate (Cox regression) analysis only localization in the right-sided colon (HR = 6.842), histology of tubular-villous adenoma (HR = 3.713) and size > 30 mm (HR = 2.563) were independently associated with local recurrence. We did not detect an association of recurrence with high-grade intraepithelial neoplasia (OR = 0.549/95%CI: 0.193-1.562; *P* = 0.279) (Table 4).

DISCUSSION

In this retrospective analysis of EMRs for 216 large colorectal adenomas (median size 30 mm) with preferential proximal localization (69% right-sided colon) we observed a recurrence rate of 15.3% after a median follow-up of 6 mo. Univariate analysis showed significantly higher recurrence rates for patient age > 65 years, adenoma size > 30 mm, proximal localization, non-pedunculated morphology, resection in piecemeal technique and tubular-villous histology. Multivariate analysis revealed only adenoma size > 30 mm, right-sided localization and tubular-villous histology as risk factors independently associated with local recurrence.

Many of the above mentioned factors have been described in the literature (Table 5). Interestingly, and in contrast to most other reports, the strongest risk factor for adenoma recurrence identified in this study was a right-sided localization (HR = 6.842). These findings are in line with data from Cipolletta *et al.*^[30] who reported a similar association for lesions with predominantly right-sided localization. In the present study, 69% of the lesions were located in the right-sided colon and the

Table 3 Risk factors for recurrence (univariate analysis)¹

Variable	Recurrence (fraction/%)	OR (95%CI)	P value ²
Age			
< 65 yr	10/96 (11.4%)	2.492	0.011
> 65 yr	23/120 (19.2%)	(1.182-5.252)	
Size			
< 30 mm	19/153 (12.4%)	2.472	0.005
> 30 mm	14/63 (22.2%)	(1.233-4.957)	
Morphology			
Paris 0-Ip (pedunculated)	0/31 (0%)	26.386	0.018

Localization			
Right-sided colon	31/149 (20.8%)	7.475	0.002
Left-sided colon or rectum	2/67 (3.0%)	(1.787-31.264)	
Resection technique			
Piecemeal (fragmented)	30/170 (17.6%)	3.741	0.01
<i>En bloc</i>	3/46 (6.5%)	(1.139-12.292)	
Histology			
Tubular-villous adenoma	25/103 (24.3%)	3.417	0.002
Tubular, serrated, carcinoma	8/113 (7.1%)	(1.533-7.614)	

¹The overall recurrence rate was 33/216 (15.3%); ²As calculated with the Kaplan-Meier method.

recurrence rate was 20.9% (vs 3.0% for localization in left-sided colon or rectum). Our interpretation is, that this association is driven by the higher technical difficulty for the treatment of right-sided lesions, resulting in lower complete resection rates, in particular since all pedunculated lesions were localized in the left-sided colon. Since relatively high recurrence rates have been reported after resection of serrated lesions^[8] it is tempting to speculate on a correlation of a serrated histology with local recurrence rates but in the current study we did not find any statistically significant association. Interestingly, contradictory findings with higher recurrence rates for left-sided rather than right-sided localization have been reported from a retrospective study with predominantly left-sided adenomas^[28]. Thus, the diverging findings most probably reflect a difference in the study population, in particular with respect to adenoma characteristics (size, localization, morphology, *en bloc* resection rate), rather than true differences.

In addition, a larger size of the lesion^[14,22,23,30] and resection in piecemeal technique^[19,23,29,30] or a resection in more than 5 fragments^[18] have been reported as risk factors for recurrence. Our findings of a significant association of piecemeal resection (univariate analysis only) and of adenoma size > 30 mm (multivariate) with local recurrence after EMR are in complete agreement with the aforementioned studies.

Finally, we identified tubular-villous histology as a risk factor for local recurrence. Since tubular-villous adenoma represents a more advanced neoplastic lesion these data are in line with Lim *et al.*^[28] who reported an association of recurrence with high-grade intraepithelial neoplasia (not significantly associated in our dataset). Such associations could reflect biological

Table 4 Risk factors for recurrence (multivariate analysis)¹

Variable	HR (95%CI)	P value
Size > 30 mm	2.563 (1.179-5.570)	0.017
Localization right-sided colon	6.842 (1.540-30.394)	0.011
Histology tubular-villous adenoma	3.713 (1.617-8.528)	0.002

¹The factors age, morphology, resection technique were not significant in multivariate analysis.

Moss <i>et al.</i> ^[22]	799	> 40 mm		
Oka <i>et al.</i> ^[23]	1029	> 40 mm		Yes
Briedigkeit <i>et al.</i> (this study)	216	> 30 mm	Right-sided	Yes
				(univariate only)

differences between the different types of histology (serrated vs tubular vs tubular-villous) but the study size was probably too small to definitively address such differences in greater detail. The same holds true for age, morphology and resection technique with significant associations only on univariate but not on multivariate analysis.

The presented study has several limits. In particular, the retrospective design and the relatively short follow up interval (which results from the current guideline in our country^[11]) might have underestimated the true recurrence rate. In addition, the relatively low number of adenoma recurrences could have reduced the probability of correctly identifying associated risk factors. Nevertheless, the data underscore the necessity of meticulous endoscopic follow-up, in particular after EMR of larger adenomas with right-sided localization and tubular-villous histology, and probably also for adenomas resected in piecemeal technique. In these situations alternative procedures with higher *en bloc* resection rates such as colorectal ESD^[23,32] or laparoscopic surgery should be considered.

ACKNOWLEDGMENTS

We are indebted to Mrs. Jennifer Nadal (Institute for Medical Biometrics, Informatics and Epidemiology, University of Bonn, Germany) who reviewed the statistics reported in this study. In addition, we gratefully acknowledge the following colleagues for referring patients and for providing follow-up data: Bockelmann N, Bönninghausen G, Fehring C, Gille K, Klassen PM, Lindstaedt H, May P, Mayershofer R, Nordhoff S, Oeyen

M, Rosenhauer von Deimling K, Plaßmann D, Robertz-Vaupel GM, Respondek A, Schmidt C, Schulte-Witte H, Vogt M, Zumfelde P.

COMMENTS

Background

Endoscopic mucosal resection of colorectal adenomas is the standard treatment in the Western world. However, the effectiveness for endoscopic mucosal resection (EMR) is limited for larger adenomas with reported recurrence rates of more than 30%.

Research frontiers

The identification of risk factors associated with local adenoma recurrence may be useful to identify patients in need for a more intensive follow-up and - possibly - to guide treatment methods.

Innovations and breakthroughs

This study shows an increased risk for recurrence after EMR of adenomas with proximal localization, larger size (> 30 mm) and tubular-villous histology.

Applications

The results can be used to determine the follow-up strategy, which should be more stringent for adenomas with the above-mentioned criteria. Moreover, resection strategy for colorectal adenomas with particular high recurrence risk should preferably be an *en bloc* resection (either by endoscopic submucosal dissection or laparoscopic surgery).

Peer-review

The study is a well written paper, addressing an important issue regarding treatment of these borderline lesions.

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Periampullary diverticulum (PAD) is duodenal outpouching defined as herniation of the mucosa or submucosa that occurs *via* a defect in the muscle layer within an area of 2 to 3 cm around the papilla. Although PAD is

usually asymptomatic and discovered incidentally during endoscopic retrograde cholangiopancreatography (ERCP), it is associated with different pathological conditions such as common bile duct obstruction, pancreatitis, perforation, bleeding, and rarely carcinoma. ERCP has a low rate of success in patients with PAD, suggesting that this condition may complicate the technical application of the ERCP procedure. Moreover, cannulation of PAD can be challenging, time consuming, and require the higher level of skill of more experienced endoscopists. A large portion of the failures of cannulation in patients with PAD can be attributed to inability of the endoscopist to detect the papilla. In cases where the papilla is identified but does not point in a suitable direction for cannulation, different techniques have been described. Endoscopists must be aware of papilla identification in the presence of PAD and of different cannulation techniques, including their technical feasibility and safety, to allow for an informed decision and ensure the best outcome. Herein, we review the literature on this practical topic and propose an algorithm to increase the success rate of biliary cannulation.

Key words: Periampullary diverticulum; Cannulation techniques; Tips; Endoscopic ultrasound; Endoscopic retrograde cholangiopancreatography

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Presence of periampullary diverticulum (PAD) is thought to complicate the application of endoscopic retrograde cholangiopancreatography, which is already a technically difficult procedure. To improve success rates, different techniques have been developed to achieve successful biliary cannulation in patients with PAD. For patients with PAD, endoscopists must be aware of papilla identification and the different available cannulation techniques, as well as the technical feasibility and safety of each.

Altonbary AY, Bahgat MH. Endoscopic retrograde cholangiopancreatography in periampullary diverticulum: The challenge of cannulation. *World J Gastrointest Endosc* 2016; 8(6): 282-287 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i6/282.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i6.282>

INTRODUCTION

Periampullary diverticulum (PAD) is duodenal outpunching defined as herniation of the mucosa or submucosa that occurs *via* a defect in the muscle layer within an area of 2 to 3 cm around the papilla. Prevalence of PAD increases with age, and overall prevalence among the elderly is reportedly 65%^[1]. The formation of PAD is related to progression of duodenal motility disorders. Furthermore, increased intraduodenal pressure and progressive weakening of intestinal smooth muscles are known as the main underlying etiologies for this defect^[2]. PAD is sub-classified into two categories according to the location of the papilla with respect to the diverticulum. In type I, or peri-diverticular papilla, the papilla is located at the edge of the diverticulum or within a radius of 2 cm from the diverticular edge. In type II, or intra-diverticular papilla (IDP), the papilla is located inside the diverticulum or lying between two adjacent diverticula^[3].

Although PAD is usually asymptomatic and discovered incidentally in patients during endoscopic retrograde cholangiopancreatography (ERCP), it is associated with different pathological conditions such as common bile duct (CBD) obstruction, pancreatitis, perforation, bleeding, and rarely carcinoma^[4-7]. Several hypotheses have been put forth to explain the observed higher incidence of biliary stone formation in the presence of PAD. First, it was proposed that dysfunction in the sphincter of Oddi, which in turn causes reflux of pancreatic fluid and intestinal content, can lead to biliary stone formation^[8]. Second, it was proposed that diverticula cause spasm of the sphincter, thereby increasing biliary tract pressure that may in turn produce jaundice and cholangitis as well as predispose for choledocholithiasis^[9]. Finally, it was proposed that PAD may compress the distal part of the CBD to cause functional biliary stasis, and this hypothesis was supported by the observation of increased incidence of pigment biliary stones^[10,11].

Reported success rates of cannulation in patients with PAD have varied from 61% to 95.4%, a range that is significantly lower than that observed in patients without PAD^[12]. In recent years, new techniques and new devices for successful biliary cannulation have been developed to improve rates of success in patients with PAD. For patients with PAD, endoscopists must be aware of papilla identification and the different cannulation techniques available, including the technical feasibility and safety of each, in order to make an informed decision and ensure the best outcome. Herein, we review the literature on this practical topic that was

obtained through an electronic search of the literature databases of Google Scholar and PubMed using the following terms alone or in combination: ERCP, difficult cannulation, cannulation techniques, and periampullary diverticulum.

TIPS FOR PAPILLARY ORIENTATION AND CANNULATION

The presence of PAD is thought to complicate the application of ERCP, an already technically difficult procedure^[2]. Cannulation of IDP can be challenging, time consuming and require the higher level of skill of more experienced endoscopists. A large portion of the failures of cannulation in patients with PAD has been attributed to inability of the endoscopist to detect the papilla^[6]. However, in some studies, the finding of PAD during an ERCP was suggested as an indicator of an easier cannulation attempt, with a reported success rate of 94.9% compared to that of 94.8% in non-PAD patients after exclusion of cases with undetectable papillas that were considered to be likely IDPs^[7]. In ERCP, identification of the papilla is the first major obstacle, especially in the presence of large diverticula. Thus, it is extremely helpful to know the following tips^[13]: (1) in most cases, the papilla is located on the lower edge of the diverticulum or just inside, somewhere between the positions of 4 o'clock and 8 o'clock; (2) large diverticula are usually divided from proximal to distal by a ridge-like septum. This mostly involves the bile duct, with the ridge terminating at the papilla; (3) a catheter can be used to straighten and evert the folds to identify a hidden papilla within the diverticulum; (4) cannulation with the tip of the duodenoscope within the sac is also possible, but care must be taken to avoid perforation; and (5) in contrast to the usual papillary anatomy, the presence of PAD alters the biliary direction. It is often not acutely angulated superiorly, but runs more directly. Thus, acute angulation of the sphincterotome is not necessary.

TECHNIQUES FOR DIFFICULT CANNULATION

To address cases where the papilla is identified but does not point in a suitable direction for cannulation, the below-described techniques are available for consideration (Table 1).

Two-devices in one-channel method

A biopsy forceps is used to pull the duodenal mucosa adjacent to the papilla, bringing the papillary orifice out of the diverticulum. Another instrument, either a cannula or sphincterotome, is then inserted into the working channel of the endoscope together with the biopsy forceps. With coordination of the two instruments, biliary cannulation can be attempted (Figure 1A). A report of this technique applied to two PAD cases showed successful cannulation for both and with no complications in either (success rate

100%)^[14].

Reversed guidewire method

A second guidewire is advanced in reverse (stiff end forward) through the working channel of the duo-

denoscope, alongside the sphincterotome. This wire is then used to push the mucosa adjacent to the papilla toward the lumen of the duodenum and to straighten the folds, anchoring the papilla in a better configuration and creating a suitable direction for cannulation. A report of this technique applied to one PAD case showed successful cannulation with no complication (success rate 100%)^[15].

Double endoscope method

A forward-viewing gastroscope is inserted inside the diverticulum for better visualization of the papilla. A foreign body forceps is used to grasp the tissue just beside the papilla in order to bring it into a better orientation. The gastroscope holding the papilla is left in place, to avoid backsliding after opening of the forceps. A side-viewing duodenoscope is inserted alongside the gastroscope. With both endoscopes positioned simu-

Itaneously in the duodenum, the CBD can be cannulated (Figure 1B). A report of this technique applied to one PAD case showed successful cannulation with no complication (success rate 100%)^[16].

Balloon dilation of the narrow diverticular neck

In narrow-necked papillary diverticula with the papilla located in the fundus of the diverticulum, endoscopic balloon dilation of the narrow diverticular neck, using a 15-mm stone retrieval balloon, can be done safely, bringing the papillary orifice into view. Cannulation of the bile duct can be attempted without any complications (Figure 1C). A report of this technique applied to three PAD cases showed successful cannulation and no complications (success rate 100%)^[17].

Endoclip-assisted cannulation

One or more endoclips can be used to rotate the IDP externally and to fix it on the outside rim of the diverticulum. This manipulation can successfully evert and fix the papilla on the diverticular margin in a better position, resulting in successful biliary cannulation (Figure 1D). A report of this technique applied to two PAD cases showed successful cannulation with no complications (success rate 100%)^[18].

Cap-assisted cannulation

A transparent cap is attached to the tip of a forward-viewing endoscope. At first, selective biliary cannulation can be attempted through the papillary orifice. If selective biliary cannulation fails, endoscopic fistulotomy can be attempted. Fistulotomy is performed between the lower two-thirds and the upper one-third of the papillary roof. To gain biliary access after the fistulotomy, needle puncture is made and a soft-tipped guidewire is advanced (Figure 1E). A report of this technique applied to twelve PAD cases showed successful cannulation in all cases (success rate 100%) and a minor complication (bleeding at the site of fistulotomy) in two patients (complications rate 16.5%); primary hemostasis was achieved by hemoclippping in one patient and by saline-epinephrine mixture spray in the other^[19].

Pancreatic duct stent placement followed by pre-cut biliary sphincterotomy

In the case of pancreatic duct cannulation, placement of a main pancreatic duct stent keeps the papilla out of the diverticulum, thereby facilitating pre-cut needle knife sphincterotomy and selective cannulation of the CBD (Figure 1F). A report of this technique applied to eight cases showed successful cannulation in seven of the patients (success rate 87.5%), with two of those requiring a second ERCP for success. In addition, two patients developed post-ERCP pancreatitis (complication rate 25%)^[20].

Percutaneous ultrasound-guided rendezvous technique

After the percutaneous ultrasound-guided transhepatic biliary puncture is performed a sterile guidewire is

inserted into the CBD, then into the papilla. A snare or forceps is then used to grasp the guidewire and pull it back through the working channel of the duodenoscope for subsequent over-the-wire cannulation (Figure 1G)^[21]. However, it is sometimes difficult to grasp the guidewire, which may be damaged or kinked, during the withdrawal through the working channel of the duodenoscope; thus, passing a catheter over it is difficult or sometimes impossible^[22]. A study on the percutaneous-ultrasound guided rendezvous technique applied to a total of fourteen patients showed success in 13 (success rate 93%) with complication (retroperitoneal perforation) experienced in only 1 (complication rate 7%)^[21].

Endoscopic ultrasound-guided rendezvous technique

When the echoendoscope is positioned in the stomach or duodenum, and the bile ducts can be visualized by the endoscopic ultrasound (EUS), a 19-gauge or 22-gauge needle are used to puncture the bile ducts. After aspiration of bile, contrast is injected through the EUS needle to facilitate display the intra- and extra-hepatic bile ducts. After confirmation of bile duct puncture, a guidewire is advanced distally through the CBD and across the papilla under fluoroscopic guidance. The endoscope exchange is performed after passage of the guidewire through the papilla into the duodenum. In this process, the echoendoscope is removed, leaving the guidewire in place, after which a duodenoscope is passed up to the papilla alongside the EUS-placed guidewire. Finally, a snare or forceps is used to grasp the guidewire and pull it back out of the working channel of the duodenoscope for subsequent over-the-wire cannulation. After access to the CBD is achieved, a standard ERCP can be performed (Figure 1H). A study on the EUS-guided rendezvous technique applied to a total of 45 patients showed success in 36 (success rate 80%) with complications (bile leakage and pneumoperitoneum) experienced in only 2 (complication rate 4%)^[23].

PROPOSED ALGORITHM

We propose an algorithm based on the previous techniques to increase the success rate of cannulation (Figure 2). It is important to note, however, that this algorithm has several limitations. First, it is based on a small number of published cases for most of the techniques. Second, the success rates are comparable in most of the techniques and the choice depends on the endoscopist's preference and experience. Finally, percutaneous ultrasound-guided and EUS-guided rendezvous techniques are not available in all centers.

Feasibility and safety of therapeutic maneuvers

When therapeutic maneuvers are performed in patients with PAD the potential risks of complications are a concern, primarily because of the thin mucosa and the absence of sphincter muscle present in the ampullary area^[24]. Currently, endoscopic papillary large balloon dilation (EPLBD) combined with limited endoscopic

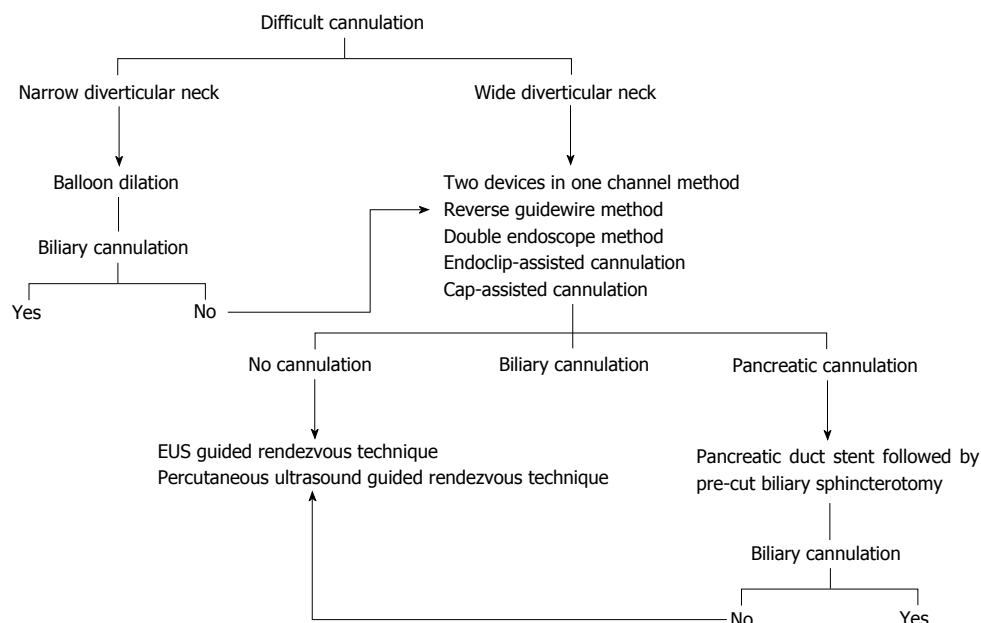

Figure 2 Proposed algorithm to ensure the best outcome. EUS: Endoscopic ultrasound.

sphincterotomy (ES) (EPLBD + ES) is regarded as an effective maneuver for treating difficult CBD stones. It has been reported that perforation and hemorrhage are less frequent in cases treated with EPLBD + ES than in those treated with standard ES alone^[25,26]. The tendency toward a shorter ballooning time in patients with PAD can be explained by the lack of sphincter muscle and the ease of ampullary widening facilitated by EPLBD, which suggest that EPLBD is a safe method for retrieval of CBD stones in patients with PAD^[24]. Moreover, the complication rates of ERCP are similar in patients with or without PAD and the therapeutic outcome is not affected by the presence of PAD^[3,7].

CONCLUSION

PAD represents a technical barrier to the successful application of ERCP. Cannulation of IDP can be challenging, time consuming and require the skill of more experienced endoscopists. In cases where the papilla is identified but does not point in a suitable direction for cannulation, a number of feasible techniques are available for consideration. Moreover, complication rates of ERCP are similar in patients with and without PAD, and therapeutic outcome is not affected by the presence of PAD.

Abstract

AIM: To identify the cut-off value for predicting the ability of elderly patients with dysphagia to swallow pureed diets using a new endoscopy scoring method.

METHODS: Endoscopic swallowing evaluation of pureed diets were done in patients ≥ 65 years with dysphagia. The Hyodo-Komagane score for endoscopic swallowing evaluation is expressed as the sum (0-12) of four degrees (0-3) with four parameters: (1) salivary pooling in the vallecula and piriform sinuses; (2) the response of glottal closure reflex induced by touching the epiglottis with the endoscope; (3) the location of the bolus at the time of swallow onset assessed by "white-out" following swallowing of test jelly; and (4) pharyngeal clearance after swallowing of test jelly. We used receiver operating characteristic (ROC) curve analysis to retrospectively analyze the association between the total score and successful oral intake of pureed diets.

RESULTS: One hundred and seventy-eight patients were enrolled including 113 men (63%), mean age 83 years (range, 66-98). One hundred and twenty-six patients (71%) were able to eat pureed diets during the observation period (mean \pm SD, 19 \pm 14 d). In ROC analysis, the cut-off value of the score for eating the pureed diets was 7 (sensitivity = 0.98; specificity = 0.91).

CONCLUSION: The Hyodo-Komagane endoscopic score is useful to predict the ability to eat pureed diets in elderly patients with dysphagia.

Key words: Dysphagia; Endoscopy; Pureed diets; Percutaneous endoscopic gastrostomy

Core tip: Predicting successful oral intake in elderly patients with dysphagia remains a challenge. The scoring method for endoscopic swallowing evaluation was based on final score (from 0 to 12) using four parameters; (1) the salivary pooling in the vallecula and piriform sinuses; (2) the response of glottal closure reflex induced by touching the epiglottis with the endoscope; (3) the location of the bolus at the time of swallow onset assessed by "white-out" after the swallowing of test jelly; and (4) the extent of pharyngeal clearance after test jelly is swallowed. A total score of 7 or less during endoscopic swallowing evaluation reliably predicted the ability to eat pureed diets.

INTRODUCTION

With aging of the population, dysphagia is becoming an important medical and social issue^[1]. Pneumonia is the fourth most common cause of mortality in the elderly in Japan; the majority of cases in hospital-acquired pneumonia are reported to be related to aspiration^[2]. Pureed diets are often used as an initial dysphagia diet for patients with moderate to severe dysphagia because, if the dysphagic patients can fulfill their nutritional requirements by eating pureed diets, they can avoid enteral feeding using a percutaneous endoscopic gastrostomy (PEG) tube. Wilkinson *et al*^[3] previously reported PEG should be considered for people unable to tolerate a pureed diet 14 d after their stroke despite the fact that half will recover sufficiently to manage oral intake. They suggested that the texture of the pureed diet is likely to be most useful factor predictive of the need for PEG. No methods for predicting successful oral intake of pureed diets in elderly patients with dysphagia have been established.

Endoscopic and videofluoroscopic examinations are often used to evaluate swallowing and to quantify the risk of aspiration^[4-7]. Our facility uses a team approach that includes a gastroenterologist and a speech therapist. Swallowing is evaluated by endoscopy using an

endoscope normally used for transnasal esophagogastroduodenoscopy. We previously used this approach to study factors that influenced swallowing of pureed diets^[8]. Saliva pooling and pharyngeal residues of pureed foods were shown to predict impaired swallowing of pureed foods. However, endoscopic determination of whether patients could swallow pureed diets was not always reproducible or safe especially for severely dysphagic patients. Irreproducibility was possibly related to variability in the texture and physical characteristics of the pureed diet despite being prepared in the same facility.

We previously developed a scoring system for endoscopic swallowing evaluation using blue-dyed water^[9]. We modified the test meal to contain a test jelly instead of blue-dyed water so that elderly patients with severe dysphagia could undergo endoscopic examination of swallowing safely even unable to swallow pureed diets and the data would be reproducible. The aim of this study was to validate the revised scoring system to predict the ability to eat pureed diets in elderly patients with dysphagia.

MATERIALS AND METHODS

Patients

From January 2012 to November 2014, 205 hospitalized patients who underwent endoscopic swallowing evaluation at Showa Inan General Hospital, a municipal local hospital, were consecutively enrolled. We included dysphagia patients able to sit in a chair or up in bed with assistance and whose oral intake had been observed at least for 5 d after endoscopic swallowing evaluation. Subjects were included irrespective of whether oral intake of dysphagic diets was successful or unsuccessful. Exclusion criteria included an age less than 65 years old or the presence of an acute infection.

Study design

Verbal and written informed consent for the endoscopic examination of swallowing was obtained from all patients. Gastroenterologists, who were experienced in transnasal esophagogastroduodenoscopy and PEG, performed the endoscopic swallowing evaluation along with a speech therapist. Results of endoscopic swallowing examination including the new scoring system (Hyodo-Komagane score) were recorded in the endoscopic database. Determination of the validity of the proposed endoscopic swallowing score was based on a retrospective review of the patients' charts with special attention to the Hyodo-Komagane score and the status of oral intake of diets. This retrospective analysis was approved by the ethics committee of Showa Inan General Hospital.

Procedure

Participants underwent the endoscopic swallowing evaluation while sitting in a chair or sitting up in bed. Two minutes prior to inserting the endoscope, 0.2-0.5

Table 1 Hyodo-Komagane score

A: Salivary pooling in vallecula and piriform sinuses
0 No pooling
1 Pooling at the only vallecula
2 Pooling in vallecula and piriform sinuses and no penetration ¹ into larynx
3 Pooling in vallecula and piriform sinuses and penetration into larynx
B: The response of glottal closure reflex induced by touching the epiglottis with the endoscope
0 Marked reflex by one touching
1 Slow and/or weak reflex by one touching
2 Reflex by two or three touchings
3 No reflex despite three touchings
C: The location of the bolus at the time of swallow onset assessed by "white-out" ² following swallowing of test jelly
0 Pharyngeal
1 Vallecula
2 Piriform sinuses
3 No swallowing
D: The extent of pharyngeal clearance after swallowing of test jelly
0 No residues
1 Pharyngeal residues remain, but are absent after swallowing is attempted two or three times
2 Pharyngeal residues remain, but do not penetrate into larynx
3 Pharyngeal residues remain and penetrate into larynx

¹When saliva or test jelly enters the glottis (opening to the trachea) and moves as far as the vestibule above the true vocal folds, this is termed as "penetration"; ²"white-out" is defined as the period when the videoendoscopic image is obscured owing to pharyngeal closure. Total score (A + B + C + D) = 0-12.

mL of 4% lidocaine was applied to the nasal cavities of each participant using a nasal spray. An endoscope (GIF-XP260N, Olympus, Tokyo, Japan) was used for endoscopic swallowing evaluations. This is a forward-viewing upper gastrointestinal videoscope with an ultra-miniature, resolution charged-coupled device with a 120 degree field of view. The insertion diameter is 5.5 mm and the videoscope has a tip deflection capability of 210/120 up/down in a single plane. The lubricated endoscope was passed transnasally, typically on the floor of the nose, to obtain a superior view of the hypopharynx. The endoscope was moved throughout the study between swallowing and post-swallow positions to collect the data as described previously^[8]. Images of the oropharynx, hypopharynx and larynx were displayed on a monitor and recorded on the digital video recorder (Sony EVO-550H, Tokyo, Japan).

Hyodo-Komagane scoring method

All patients underwent endoscopic swallowing evaluation at least once prior to starting oral intake. First, salivary pooling in the vallecula and piriform sinuses was evaluated. The response of the glottal closure reflex was also evaluated by touching the epiglottis with the tip of endoscope. When glottal closure reflex was not elicited by touching the epiglottis, the result was confirmed by attempting to touch the epiglottis with the endoscope at least three times before absence of glottal closure reflex was declared. The swallowing trial was then performed following ingestion of a 3 mL of test diet contained in a spoon. The interior larynx and airway were examined before and after each swallow for the presence of food within the laryngeal vestibule and/or aspiration of test materials below the true vocal folds. Silent aspiration, defined as lack of cough or gag reflex when the test

materials passed into the trachea, was also noted.

This scoring system was based on our previously clinic-based scoring for endoscopic swallowing evaluation using a blue-dyed water test meal^[9]. Table 1 shows the modified scoring method that consists of four parameters: (1) salivary pooling in the vallecula and piriform sinuses (Figure 1); (2) the response of glottal closure reflex induced by touching the epiglottis with the tip of the endoscope; (3) the location of the bolus at the time of swallow onset assessed by "white-out" following swallowing of test jelly; and (4) the extent of pharyngeal clearance after swallowing of test jelly. The four parameters above are scored using a 4 point scale of 0 to 3 (Table 1). The final Hyodo-Komagane score is expressed as the total score (0 to 12) of the four parameters. All patients for whom the endoscopic swallowing evaluation was performed during the time period of the study had the score recorded in the clinical chart.

Test diets

Test jelly, that is gelatin jelly (Isotonic jelly[®], Nutri Co., Ltd., Yokkaichi, Japan) is shown in Figure 2. The characteristics were as follows: Hardness, 5000 N/m²; cohesiveness, 0.4; adhesiveness, 89 J/m³. The swallowing of test jelly was attempted for all subjects who underwent endoscopic swallowing evaluation. When the test jelly was absent from pharyngeal cavity after swallowing was attempted two or three times, swallowing of test jelly was regarded as successful. If swallowing of the test jelly was successful, swallowing of a semi-solid diet (Elental[®] jelly, Ajinomoto Pharmaceutical Co., Tokyo, Japan) and pureed diets was attempted.

The semi-solid diet (Elental[®] jelly) was made by adding a thickening agent (Jelly mix[®], Ajinomoto

Figure 1 Endoscopic images of Hyodo-Komagane score. Salivary pooling in vallecule and piriform sinuses. A: A-0 no pooling; B: A-1 pooling at the only vallecule; C: A-2 pooling in vallecule and piriform sinuses and no penetration into larynx; D: A-3 pooling in vallecule and piriform sinuses and penetration into larynx.

Figure 2 Test jelly used in this study (Isotonic jelly®, Nutri Co., Ltd., Yokkaichi, Japan).

Pharmaceutical Co.) which contained 11.7% agar, sugar, stabilizer, and other ingredients to an elemental diet, Elental®. The thickening agent (5.8 g) was dissolved with 150 mL of hot water, and 80 g of Elental® was added to the solution which was then cooled to harden. The texture characteristics were: Hardness, $17000 \pm 640 \text{ N/m}^2$; cohesiveness, 0.14 ± 0.0066 ; adhesiveness, $150 \pm 49 \text{ J/m}^3$.

Assessment of oral intake of pureed diets

Except for patients in whom pureed diet was noted to penetrate into the larynx after swallowing the pureed diet, feeding of pureed diets was attempted and assessed once each day by a speech therapist throughout the subjects' hospitalization, irrespective of

Hyodo-Komagane score. When patients were able to eat sufficient pureed diet to meet their daily nutritional requirements for at least 5 d, they were judged to be able to be managed with pureed diets. Dysphagia diets at next higher level were then attempted at the discretion of the speech therapist. The status of oral intake of dysphagia diets was noted.

Statistical analysis

Sensitivity and specificity of variables were based on receiver operating characteristic (ROC) curve analysis. In a ROC curve the true positive rate (sensitivity) is plotted in function of the false positive rate ($100 - \text{specificity}$) for different cut-off points of a parameter. Each point on the ROC curve represents a sensitivity/specificity pair corresponding to a particular decision threshold. The area under the ROC curve is a measure of how well a parameter can distinguish between two groups (successful/unsuccessful). Statistical analysis was performed by using JMP® 9.0.2 version software (SAS Institute, Inc., Japan).

RESULTS

One hundred and seventy-eight dysphagic subjects were included in this study. Their demographic and clinical data are shown in Table 2. There were 113 men (63%) with a mean age of 83 years (range: 66-98). Approximately 70% (124 patients) were 80 years and over. Severe comorbid diseases such as cerebrovascular disease (38%), aspiration pneumonia (32%), and

Figure 3 Endoscopic image of Hyodo-Komagane score. A: Before swallowing of test jelly; B: D-3 pharyngeal residues remain and penetrate into larynx after swallowing of test jelly.

neuromuscular disease (20%) were common. Patients who had developed new cerebrovascular disease, myocardial infarction, and aspiration pneumonia within two weeks were not included. Fifty-two patients had remaining pharyngeal residue seen to penetrate into the larynx after swallowing the test jelly (D-3) (Figure 3). In nine of these patients the pureed diet also penetrated into larynx. With these patients feeding trials were not attempted to avoid aspiration pneumonia. In the remaining 169 patients, swallowing trials of the pureed diet were attempted. Overall, 126 (71%) of 178 patients were able to eat pureed diets or a higher level of dysphagia diet that fulfilled their daily nutritional needs [the observation period: Mean \pm SD (range), 19 \pm 14 d (5-58 d)]. The remaining 43 patients were judged to fail the subsequent pureed food tests because the amount they ate was less than their daily nutritional needs.

Figure 4 shows the distribution of Hyodo-Komagane scores among the 178 patients who underwent endoscopic swallowing evaluation (lower scores are better). Using ROC curve analysis of the Hyodo-Komagane scores, the area under the curve was 98.3% (95%CI: 0.097-0.996) (Figure 5). The optimal cut-off value of successful oral intake of pureed diets was a score of 7 (sensitivity = 0.98; specificity = 0.91). In 115 patients

Figure 4 Distribution of a new scoring (Hyodo-Komagane score) in 178 patients undergoing endoscopic evaluation of swallowing.

with Hyodo-Komagane scores of 7 or less only one patient was not able to maintain adequate nutritional status with pureed diets (his Hyodo-Komagane score was 6). Ten (53%) of the 19 patients whose scores were 8 were able to eat pureed diets after a rehabilitation using the semi-solid diet made from an elemental diet. Oral intake of pureed diets was unsuccessful for those with scores of 9 or higher on the Hyodo-Komagane score (Table 3). For patients who could not eat pureed diets, enteral feeding was employed.

Adverse events

No adverse events such as cardiopulmonary events or aspiration pneumonia occurred in included subjects of this study.

DISCUSSION

The aim of this study was to obtain a cut-off value of the Hyodo-Komagane score that reliably predicted the ability to eat pureed diets in elderly patients with dysphagia. The Hyodo-Komagane scoring system differs from the original Hyodo score^[9] with regard to the assessment of salivary pooling in that it uses a test jelly instead of blue-dyed water as the test meal. Jelly was used because it is very difficult for severe dysphagic patients to swallow water. In addition, we previously demonstrated a low agreement in judging the presence or absence of glottal closure response as whether the

Table 3 Association between Hyodo-Komagane score and oral intake of pureed diets

Score	Oral intake of pureed diets
0-7	Successful 100%
8 ¹	Successful in some cases
9-12	Unsuccessful

¹Some patients were able to eat pureed diets after a rehabilitation.

reflex was elicited depended on how and whether the endoscopists actually touched the epiglottis^[9]. Because it is difficult to be confident that the tip of the endoscope touches the epiglottis, we attempted to touch the epiglottis with the endoscope at least three times prior to scoring the reflex of glottal closure as absent. We speculate that this increased the reliability of making that determination and thus the Hyodo-Komagane modification of the scoring system improved both the validity and reliability of Hyodo score.

Dysphasia diets vary considerably from facility to facility. Dysphagia diets are designed to adjust food/liquid intake in terms of amount, consistency, and timing of the meal to achieve maximal nutritional intake and minimize swallowing difficulty. Traditional oral dysphagia diets typically involve a stepwise progression of bolus consistencies. A pureed diet is the basic level of swallowing for severe dysphagia patients. When dysphagia patients can swallow pureed diets, they generally do not require enteral nutrition including PEG^[3,8]. The aim of this study was to develop methods to prospectively assess whether elderly patients with severe dysphagia could eat pureed diets. ROC analysis of this study suggested that the cut-off value of the Hyodo-Komagane score for eating the pureed diets is 7 (sensitivity = 0.98; specificity = 0.91) for predicting successful oral intake of pureed diets in elderly patients with dysphagia.

In the Hyodo-Komagane score the extent of pharyngeal clearance after swallowing of test jelly was regarded as important. Pharyngeal residue has consistently been identified to be greater using endoscopic evaluation of swallowing than when using videofluoroscopy^[10] and penetration/aspiration was also perceived to be more severe with endoscopic evaluation of swallowing compared to videofluoroscopy images^[11]. Penetration/aspiration is thought to be a clinically important variable in patients with swallowing dysfunction and is likely to be associated with an increased risk of aspiration/pneumonia. However, the agreement between the gastroenterologists regarding the presence of penetration/aspiration was found to be poor in our previous study^[8]. Here, we scored penetration/aspiration only when penetration of saliva or the pharyngeal residues of test jelly into the larynx occurred. These phenomena were adopted as A-3 or D-3 in Hyodo-Komagane score.

In addition, the response of glottal closure reflex induced by touching the epiglottis with the endoscope was examined to assess the relationship between the

Figure 5 Receiver operating characteristic curve to evaluate the prediction capability of the Hyodo-Komagane score for successful oral intake of pureed diets.

sensory and motor components of the swallow. The relationship between laryngopharyngeal sensation and motor function has been well documented^[12] and patients with impaired pharyngeal squeeze at different levels of sensory deficits are at significantly greater risk for aspiration of pureed foods compared with those with normal squeeze^[13]. While the use of 0.5 mL of 4% lidocaine during endoscopic swallowing evaluation has been reported to impair swallowing ability in patients with dysphagia, this result did not achieve statistical significance and was associated with a reduction in subjective pain and discomfort^[14]. A recent study confirmed that 0.2 mL of 4% lidocaine improved examination tolerability and did not impair the swallowing activity in dysphagic patients during endoscopic swallowing evaluation^[15]. Therefore, we speculated that the amount (0.2-0.5 mL) of lidocaine used in this study had minimal effects on testing the sensory aspects of swallowing.

Our study has some limitations. This study was retrospective and comparative data using established competitive techniques are absent in part because there was no gold standard for detection of failure to swallow. Comparison with the other commonly used method such as with a videofluoroscopic swallowing study may provide useful comparative data in subsequent studies. Finally, all subjects were older than 65 years. It is unknown whether the prediction based on the Hyodo-Komagane endoscopic score are applicable to those less than 65 years old.

In conclusion, the modified scoring method for endoscopic swallowing evaluation was based on final score (from 0 to 12) using four parameters: (1) the salivary pooling in the vallecula and piriform sinuses; (2) the response of glottal closure reflex induced by touching the epiglottis with the endoscope; (3) the location of the bolus at the time of swallow onset assessed by "white-out" after the swallowing of test jelly; and (4) the extent of pharyngeal clearance after test jelly is swallowed. A total score of 7 or less during endoscopic swallowing evaluation reliably predicted the ability to eat pureed

diets. The use of the modified scoring system appears to be a reliable method to decide whether the elderly patients can eat pureed diets or requires enteral feeding.

The authors thank David Y Graham, MD for helping with preparation of the manuscript in English.

COMMENTS

Background

Pureed diets are often used as an initial dysphagia diet for patients with moderate to severe dysphagia because, if the dysphagic patients can fulfill their nutritional requirements by eating pureed diets, they can avoid enteral feeding using a percutaneous endoscopic gastrostomy tube. However, no methods for predicting successful oral intake of pureed diets in elderly patients with dysphagia have been established.

Research frontiers

The authors' group pioneered a scoring system for endoscopic swallowing evaluation in elderly patients with dysphagia; the authors think that the method for predicting successful oral intake of pureed diets in elderly patients with dysphagia should be established and they provide support to their hypothesis with this paper, reporting that the Hyodo-Komagane endoscopic score is useful to predict the ability to eat pureed diets in elderly patients with dysphagia.

Innovations and breakthroughs

Endoscopic and videofluoroscopic examinations have been used to evaluate swallowing and to quantify the risk of aspiration. However, endoscopic determination of whether patients could swallow pureed diets was not always reproducible or safe especially for severely dysphagic patients. Irreproducibility was possibly related to variability in the texture and physical characteristics of the pureed diet despite being prepared in the same facility. This paper shows a new scoring system for endoscopic swallowing evaluation using a test jelly so that elderly patients with severe dysphagia can undergo endoscopic examination of swallowing safely even unable to swallow pureed diets; in addition, the cut-off value of the score for eating the pureed diets was defined as 7 (sensitivity = 0.98; specificity = 0.91).

Applications

Elderly patients with dysphagia will benefit from the use of Hyodo-Komagane endoscopic score which is useful to predict the ability to eat pureed diets. If evaluated with this scoring system, avoiding unfavorable enteral feeding.

Terminology

When saliva or test jelly enters the glottis (opening to the trachea) and moves as far as the vestibule above the true vocal folds, this is termed as penetration; aspiration is defined when the test materials passed into the trachea below the true vocal folds. White-out is defined as the period when the videoendoscopic image is obscured owing to pharyngeal closure.

Peer-review

This is a nice study, well-conceived and written.

Abstract

AIM: To evaluate the effectiveness of automated irrigation pumps (AIPs) in improving the quality of the bowel preparation and the yield of colonoscopy.

METHODS: A retrospective observational study was conducted at a single medical center. Outpatient colonoscopies performed during a 4-mo time period when AIPs were not in use, were compared to colonoscopies performed during control period. The main outcomes measured were quality of bowel preparation, procedures aborted due to poor preparation, recommendations to repeat at short interval due to sub-optimal bowel preparation and adenoma detection rates.

RESULTS: One thousand and thirty-seven colonoscopies were included. A higher proportion of cases did not achieve a satisfactory bowel preparation when AIPs were not used (24.4% *vs* 10.3%, $P < 0.01$). The number of procedures aborted due to inadequate preparation was not significantly different, however a repeat procedure at a short interval was recommended in a higher proportion of cases when AIPs were not used (21.3% *vs* 6.9%, $P < 0.01$). Good or excellent preparation was 2.91 (95%CI: 2.04-4.15) times more likely when AIPs were used. Detection of polyps and adenomas was not significantly different.

CONCLUSION: AIP use during colonoscopy results in a higher proportion of colonic preparation rated as satisfactory, although polyp detection rate is not significantly affected. Recommendations for repeat colonoscopy at shorter interval significantly decrease with the use of AIPs. This study supports the use of the irrigation pumps in endoscopy units to improve the quality of colonoscopy.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer deaths in the United States^[1,2]. Colonoscopy is used for screening to detect early cancer, and may also prevent CRC by detection and removal of the CRC neoplastic precursor, the adenomatous polyp^[3-5]. Improving the yield of colonoscopy has attracted much attention in recent years^[6]. In the past, manual irrigation using water-filled syringes, was used to clean any retained fecal matter or colonic contents, in order to allow for a detailed examination of the colonic mucosa and therefore to improve the yield of colonoscopy^[7,8]. Automated irrigation pumps (AIPs), which are operated by a foot pedal and connect to the auxiliary channel of newer generation endoscopes have largely replaced the manual irrigation method, as they are much more efficient and

convenient. It is, however, not known whether the AIPs increase the detection of polyps during colonoscopy when compared to the manual method. Moreover, the efficacy of these AIPs in decreasing the rate of procedures prematurely repeated due to inadequate bowel preparation has also never been studied. The aim of this study is to evaluate the effectiveness of AIPs in improving the quality of the bowel preparation, improving the yield of colonoscopy and decreasing the rate of repeat colonoscopy for inadequate bowel preparation.

MATERIALS AND METHODS

Study design

The study was conducted at the John D. Dingell Veterans Affairs Medical Center (JDDVAMC) in Detroit, Michigan. It was approved by the Wayne State University Institutional Review Board and the JDDVAMC Research Committee.

A retrospective chart review was performed for colonoscopies completed during the study periods. The use of AIPs was suspended at the endoscopy unit of the JDDVAMC for a period of 4 mo in 2009 for administrative reasons; therefore patients who underwent colonoscopy during this period constituted the main study group. For these procedures, manual irrigation was performed at the request of endoscopist, when retained fecal or bilious material was encountered. It was done by a technician using syringes filled with 60 mL of sterile water through the suction channel of the endoscope. Patients who underwent colonoscopy in an eight-month period in 2008 and 2009 constituted the control groups. They were selected to match the level of training of the gastroenterology fellows involved and the calendar year of the study group. Standard bowel preparation for both groups consisted of conventional dosing of a 4-L polyethylene glycol solution and 15 mg of Bisacodyl the evening prior to endoscopy. Colonoscopies that were aborted due to reasons other than poor colonic preparations, procedures repeated at a short interval (such as for follow-up after piecemeal polypectomy), colonoscopies performed on hospitalized patients, and those performed by non-gastroenterologists were excluded from the study.

Information was collected by review of the medical records about each patient's demographics, indication for the procedure, history of prior adenomatous polyps or cancer, involvement of a gastroenterology fellow, use of the AIPs, quality of the colonic preparation, detection of polyps and adenomas, with all associated details, and if the procedure was aborted due to sub-optimal preparation or if it was advised to repeat the procedure sooner than recommended by guidelines due to the quality of the preparation.

Colonoscopy was performed using Olympus Q160 and Q180 endoscopes (Olympus America Inc., Center Valley, PA). Some procedures were performed by an

attending physician alone (board-certified in Gastroenterology), while, in other cases, the attending physician directly supervised a gastroenterology fellow. Attending physicians involved in the procedures were the same during the different study periods. AIPs (OPF, Olympus America Inc., Center Valley, PA) were available in every procedure room and routinely connected to the endoscope during the control period. Indications for colonoscopy were classified into either screening or diagnosis. The bowel preparation was determined by the attending physician for every case and reported in the endoscopy report using the Aronchick scale^[9], as excellent, good, fair or poor. For our study, we considered the bowel preparation to be satisfactory if the procedure report described it as either good or excellent, no retained fecal material was mentioned in the findings and no recommendation for repeat at short interval for sub-optimal bowel preparation was made.

The primary outcomes were quality of the bowel preparation and the number of procedures aborted or repeated early due to sub-optimal preparation. The secondary outcomes evaluated were detection rates for polyps and adenomas.

Statistical analysis

SAS version 9.3 (SAS Institute, Cary, NC) was used for statistical analyses. For the preliminary descriptive analyses, χ^2 test was used for the description of categorical variables and a two-sided *t*-test was used for continuous variables for the comparison of means. Multivariable logistic regression model was used to compare the outcomes between the groups. Odds ratio was considered to be statistically significant if the *P* value was less than 0.05.

RESULTS

Information was collected for a total of 1037 colono-

scopies. AIPs were used for 709 procedures. Mean age of the group was 60.23 years. Majority was male (93.5%). The study group included 535 (51.6%) African-Americans and 487 (47%) Caucasians. Five hundred and sixty-four colonoscopies were performed for screening or surveillance (54.4%), while 473 (45.6%) were performed for diagnostic purposes. Two hundred and seventy-two (26.2%) of the patients had a prior history of polyps/CRC. The two groups were not significantly different in the demographic factors, endoscopist, indication for the procedure or history of polyps or CRC (Table 1).

A significantly higher proportion of cases did not achieve a satisfactory bowel preparation when manual flushes were used as compared to when AIPs were used (24.4% vs 10.3%, *P* < 0.01) (Table 2). Although the number of procedures aborted due to poor preparation was slightly higher in the group with manual flushes, this was not statistically different (*P* = 0.10). However a repeat procedure at a short interval was recommended in a significantly higher proportion of cases when manual flushes were used (21.3% vs 6.9%, *P* < 0.01). On multivariate logistic regression analysis, after adjusting for indication, history of polyps or CRC, sex, age and race, odds of calling bowel preparation satisfactory was 2.91 (95%CI: 2.04-4.15) times more likely when AIPs were used in comparison to manual flushes. When adjusted for the same variables, the detection of polyps and adenomas was not significantly different between the two groups.

DISCUSSION

Colonoscopy is a cost-effective (USD 11900 per year of life gained)^[10] tool for screening and prevention of CRC through the detection and removal of pre-cancerous, adenomatous polyps. However sub-optimal bowel preparation limits the effectiveness of colonoscopy as it

Table 2 Colonoscopy results stratified by the use of the automated irrigation pumps

No	134 (40.8)	302 (42.6)	
Adenoma detection, <i>n</i> (%)			0.99 (0.75-1.31) <i>P</i> = 0.65
Yes	133 (40.6)	298 (42.0)	
No	195 (59.4)	411 (58.0)	

can result in a higher than usual rate of missed polyps, which can lead to interval cancers^[11]. Studies have shown that endoscopists do not always follow guidelines and frequently recommend repeat colonoscopy at a shorter interval than suggested by those guidelines^[12,13]. This makes colonoscopy less cost-effective as a CRC screening modality. The reasons for such recommendations are not well known^[12], however the fear of missed lesions when bowel preparation is sub-optimal is probably a major factor^[14].

For all these reasons, a lot of attention has been paid in recent years towards improving the quality of bowel preparation, such as multiple studies comparing different types and brands of laxatives used for bowel preparation, as well as the recommended changes in the timing of those laxatives to "split dose"^[15].

However, there has not been much research to evaluate the effectiveness of AIPs in enhancing the adenoma detection rate, improving the quality of bowel preparation or decreasing the rate of procedures prematurely aborted and repeated due to inadequate bowel preparation. Our study supports the hypothesis that the use of AIPs during colonoscopy results in a significantly higher proportion of colonic preparation being rated as satisfactory with a corresponding decline in the odds of recommending a repeat procedure at a shorter than usual interval.

Our study results are in concurrence with other studies evaluating the relationship between quality of the bowel prep and the recommendation from the endoscopist about the timing of the repeat procedure^[16-18]. As colonoscopy is usually aborted when the bowel preparation is very poor and unlikely to be improved with any type of irrigation, manual or automated, there was no difference in the rate of procedures aborted for poor

preparation in our study.

Although studies have shown an increase in adenoma and polyp detection rate with improvement in the quality of bowel prep^[16,19-21], we did not find an increased rate of adenoma or polyp detection with the use of AIPs, despite the improvement in the quality of the bowel preparation. We believe this could possibly be from the heightened vigilance of the endoscopist when the use of AIPs was suspended for a limited period of time in our unit, and the results might have been different if the AIPs were introduced for the first time during the study.

The study has a few limitations. The retrospective design has some inherent limitations. The determination of the quality of preparation was based on each individual endoscopist's interpretation on the Aronchick scale. Withdrawal time was not routinely recorded in our endoscopy unit at the time of the study. The influence of cleaning using manual flushes or AIPs on total procedure as well as on withdrawal times, which might be different depending on the quality of the bowel preparation, could not be determined. The total volume of water used in either group was not recorded. Although the devices were routinely connected to the endoscope for every single case in the AIPs group, while they were not available in the other group, we could not determine if irrigation by either method was indeed used in every case. Some of the information that could influence adenoma detection rate such as lifestyle and dietary habits could not be evaluated. The sample in itself included both diagnostic and screening colonoscopies. We attempted to alleviate the bias by adjusting for indication of colonoscopy. In addition, our study population was from a Veterans Affairs medical center with a majority of African-American males. This

might limit the generalizability of the results of the study. The suspension of the use of AIPs for a period of time might by itself have led to results that could be different if AIPs were being introduced to an endoscopy unit for the first time. As we used the conventional bowel preparation regimen in our endoscopy unit at the time of the study, we could not evaluate the usefulness of AIPs with split dose bowel regimen.

In conclusion, our study provides evidence that AIPs improve the endoscopist assessment of the quality of the bowel preparation and reduce the number of repeat procedures due to sub-optimal preparation. This supports the widespread use of these devices in endoscopy units to improve the quality of colonoscopy.

COMMENTS

Background

Colonoscopy is used for screening to detect early cancer, and may also prevent colorectal cancer (CRC) by detection and removal of the CRC neoplastic precursor, the adenomatous polyp. Automated irrigation pumps (AIPs), which are operated by a foot pedal and connect to the auxiliary channel of newer generation endoscopes have largely replaced the manual irrigation method, as they are much more efficient and convenient. It is, however, not known whether the AIPs increase the detection of polyps during colonoscopy when compared to the manual method. Moreover, the efficacy of these AIPs in decreasing the rate of procedures prematurely repeated due to inadequate bowel preparation has also never been studied.

Research frontiers

AIPs, which are operated by a foot pedal and connect to the auxiliary channel of newer generation endoscopes have largely replaced the manual irrigation method, as they are much more efficient and convenient.

Innovations and breakthroughs

The aim of this study is to evaluate the effectiveness of AIPs in improving the quality of the bowel preparation, improving the yield of colonoscopy and decreasing the rate of repeat colonoscopy for inadequate bowel preparation.

Applications

This study provides evidence that AIPs improve the endoscopist assessment of the quality of the bowel preparation and reduce the number of repeat procedures due to sub-optimal preparation. This supports the widespread use of these devices in endoscopy units to improve the quality of colonoscopy.

Peer-review

This manuscript by Ravi *et al* describes a retrospective evaluation of patients receiving colonoscopy performed with manual irrigation or an automatic irrigation device. The manuscript is certainly relevant to modern endoscopic practices.

Abstract

AIM: To identify characteristic endoscopic findings and risk factors for cytomegalovirus (CMV)-associated colitis in patients with active ulcerative colitis (UC).

METHODS: A total of 149 UC patients admitted to the Department of Gastroenterology, Nagoya University Hospital, from January 2004 to December 2013 with exacerbation of UC symptoms were enrolled in this retrospective study. All medical records, including colonoscopy results, were reviewed. CMV infection was determined by the presence of CMV antigen, CMV inclusion bodies in biopsy specimens, or positive specific immunohistochemical staining for CMV. Multivariate analysis was used to identify independent risk factors for CMV colitis.

RESULTS: Multivariate analysis indicated independent associations with the extent of disease (pancolitis) and

use of > 400 mg corticosteroids for the previous 4 wk. In contrast, no association was seen with sex, age at UC diagnosis, immunomodulator use, or infliximab use. Punched-out ulceration was also significantly associated with CMV infection in patients with active UC (odds ratio = 12.672, 95%CI: 4.210-38.143).

CONCLUSION: Identification of a total corticosteroid dose > 400 mg for 4 wk, extensive colitis and a specific endoscopic finding of punched-out ulcer might facilitate the more rapid diagnosis and timely initiation of antiviral therapy for CMV-associated colitis in patients with active UC.

Key words: Colonoscopy; Risk factor; Ulcerative colitis; Antigenemia; Cytomegalovirus

Core tip: It has been reported that cytomegalovirus (CMV) infection can be associated with steroid resistance and be an exacerbating factor in ulcerative colitis (UC). This paper provides important information regarding characteristic endoscopic findings and risk factors for CMV-associated colitis in patients with active UC. A total corticosteroid dose > 400 mg for 4 wk and extensive colitis are associated with an increased risk of CMV-associated colitis. In addition, punched-out ulceration appears predictive of CMV-associated colitis in active UC.

INTRODUCTION

Cytomegalovirus (CMV), a member of the double-stranded DNA human herpes virus family, is reported to infect between 40% and 100% of the general population^[1]. Primary CMV infection is asymptomatic or minimally symptomatic, and is followed by a latent state, similar to other herpes virus infections^[2,3]. Most cases of symptomatic CMV infection are therefore caused by reactivation of latent virus^[1-3].

Although active CMV infection can occur in immunocompetent individuals, it occurs most frequently in immunocompromised patients, such as those with acquired immunodeficiency syndrome, leukemia patients during chemotherapy, and patients on high-dose immunosuppressants (e.g., recipients of solid organ or bone marrow transplants)^[1,4-7].

Powell *et al*^[8] reported that CMV infection in patients

with ulcerative colitis (UC) was associated with exacerbation of symptoms, while one early retrospective study reported the presence of CMV in surgical specimens of patients who underwent colectomy for the treatment of toxic megacolon or steroid-resistant UC^[9]. However, the significance of CMV infection in inflammatory bowel disease (IBD) is still controversial, and the pathogenic role of CMV infection in IBD is debated: Some authors believe that CMV is only an "innocent bystander" and does not significantly impact outcome, whereas many other studies have reported a significant association between CMV infection and IBD^[10-13].

Active CMV infection has been observed in UC patients receiving high-dose corticosteroid therapy^[13-17]. From 27% to 100% of patients with steroid-refractory UC have been found to harbor CMV, and steroid resistance is one of the central characteristics of CMV infection in UC patients^[9,16,18-21]. Moreover, multiple studies have concluded that CMV infection can be an exacerbating factor in UC patients and that UC prognosis is generally poor in patients with CMV if anti-viral therapy is not started at an early stage^[2,3,13-15,21-23].

Thus, CMV infection may exacerbate UC and may even cause death if appropriate treatment is not given. Although the development of ganciclovir (GCV) antiviral therapy has improved outcomes of CMV-associated colitis^[5,17,20], CMV infection must still be diagnosed early in corticosteroid-resistant UC patients so that antiviral therapy can be initiated as soon as possible. However, it is difficult to distinguish exacerbation of UC by CMV infection from exacerbation not associated with CMV on the basis of symptoms and signs alone. In such cases, UC symptoms, signs, and severity in patients at risk of CMV-associated colitis are routinely evaluated by endoscopy. While a few such studies have reported the absence of any characteristic endoscopic findings in patients with UC complicated by CMV infection^[24], others have reported characteristic endoscopic features, including the absence of large single ulcers and the presence of longitudinal ulcers, microerosions, deep ulcers, pseudotumors, punched-out ulcers, mucosal defects, geographic ulcers, and irregular ulcers^[1,25-30]. These studies have methodological differences, however, and no consensus on unique endoscopic features that can be used to facilitate early diagnosis of CMV-associated colitis in UC has yet been obtained.

Against this background, we conducted a retrospective review of all clinical and endoscopic findings in a large cohort of patients with moderate to severe UC with symptom exacerbation to identify risk factors and characteristic endoscopic findings of CMV-associated colitis.

MATERIALS AND METHODS

Patients

This study was a retrospective analysis of medical charts and endoscopic images obtained from patients diagnosed with moderate to severe (active) UC. From

Figure 1 Clinical course of cytomegalovirus-associated colitis in patients with moderate to severe ulcerative colitis. Flow chart of the 171 patients admitted to our department with active UC. ¹Seven patients with a history of CMV-associated colitis or anti-CMV treatment were excluded; ²Fifteen patients who had not undergone colonoscopy and examination using the CMV antigenemia assay were also excluded; ³Out of 34 UC patients with CMV-associated colitis, 26 received GCV antiviral therapy. After GCV therapy, 13 patients achieved remission, but 13 required colectomy. Eight patients did not receive GCV antiviral therapy, 4 of whom underwent colectomy; ⁴The remaining 115 UC patients not diagnosed with CMV-associated colitis received treatment for active UC, of which 81 achieved remission. Of the remaining patients, some improved but did not fulfill remission criteria, while others required a second treatment, hospitalization, or colectomy. CMV: Cytomegalovirus; UC: Ulcerative colitis; Ag: Antigenemia; GCV: Ganciclovir.

January 2004 to December 2013, a total of 171 UC patients were admitted to the Department of Gastroenterology, Nagoya University Hospital, with exacerbation of UC symptoms (Figure 1). The diagnosis of UC was based on clinical, endoscopic, radiological, and pathological criteria, and the severity of UC was assessed according to Stange *et al.*^[31], Truelove *et al.*^[32] and Dignass *et al.*^[33]. We routinely examine CMV antigenemia in such patients, and almost all undergo colonoscopy or sigmoidoscopy at admission^[34-36]. Of the present 171 patients, we excluded 7 patients with a previous history of CMV-associated colitis or anti-CMV treatment, as well as 15 patients who had not undergone colonoscopy or examination using the antigenemia assay. Finally, 149 patients who received both a blood test for CMV antigenemia and endoscopic examination at admission were included in the analysis.

The following demographic and clinical data were obtained at the time of admission and classified according to the Montreal Classification^[31,33]: Age at admission, age at diagnosis, sex, familial or spontaneous disease (familial disease was considered when at least one first- or second-degree relative was diagnosed with IBD), and disease localization (proctitis, left sided colitis, or pancolitis) as revealed by colonoscopy.

Endoscopic findings

Disease severity was assessed by colonoscopy. If ulcers were present, the shape and depth were described, and biopsies were obtained at the margin and base

for histologic investigation. If no ulcers were detected, biopsies were obtained in the areas with the most severe inflammation. Colonic biopsy specimens were fixed, paraffinized, and stained with hematoxylin and eosin (HE) and specific immunohistochemical (IHC) staining with monoclonal antibody against CMV immediate early antigen^[6,37]. Specimens were also evaluated for the presence of characteristic CMV inclusion bodies by experienced pathologists.

Diagnosis of CMV infection/CMV-associated colitis

CMV infection was defined by a positive CMV antigenemia assay, the presence of inclusion bodies in HE stained sections, or positive specific IHC staining for CMV. Diagnosis of CMV-associated colitis in patients with active UC was determined by active UC complicated by CMV infection.

Ethical considerations

The study protocol was approved by the institutional review board of Nagoya University Graduate School of Medicine.

Statistical analysis

Data are presented as mean \pm SD or number (%) as appropriate. Categorical data were compared between groups using the χ^2 or Fisher's exact test. Continuous variables were compared using the Mann-Whitney *U* test. To identify candidate risk factors and characteristic endoscopic features for CMV-associated colitis, univariate analyses were conducted using Fisher's exact test. All factors which were significant on univariate analysis were entered into multivariate logistic regression models constructed to identify significant independent risk factors and characteristic endoscopic features of CMV-associated colitis. For continuous variables, we found the best cut-off value with plotting the area under the receiver operating characteristic curve. The results are expressed as odds ratios (ORs) with 95% CIs. *P*-values less than 0.05 were considered statistically significant for all tests. All statistical analyses were performed using SPSS Statistics 21.0 (SPSS Inc., Chicago, IL).

RESULTS

Patient characteristics

A total of 149 UC patients presenting with UC symptom exacerbation between January 2004 and December 2013 were included in the study. Of these, 34 (22.8%) tested positive on CMV antigenemia assay or had biopsy specimens with indicative of CMV infection. The clinical and demographical parameters of CMV-positive and CMV-negative patients are presented in Table 1. Univariate analysis revealed statistically significant group differences in age at UC diagnosis, age at admission, extent of disease (pancolitis), serum albumin level, systemic steroid dose on the day of admission, total systemic steroid dose for the week before admission, and total systemic steroid dose for 4 wk before admi-

Values presented as mean ± SD or number (%) as appropriate. CMV: Cytomegalovirus; CRP: C-reactive protein; WBC: White blood count; BMI: Body mass index; 5-ASA: 5-aminosalicylate acid; SASP: Salicylazosulfapyridine; AZA: Azathioprine; 6-MP: 6-mercaptopurine; IBD: Inflammatory bowel disease; UC: Ulcerative colitis; PSC: Primary sclerosing cholangitis.

Table 2 Risk factors for cytomegalovirus-associated colitis among the 149 patients with active ulcerative colitis (multivariate analysis)

	Odds ratio	95%CI	<i>P</i> value
Age at UC diagnosis > 30 yr	2.764	0.581-13.152	0.202
Age at admission > 35 yr	1.433	0.295-6.951	0.655
Pancolitis	3.419	1.077-10.856	0.037
Albumin < 3.0 g/dL	1.402	0.480-4.098	0.537
Total systemic steroid dose for 4 wk before admission > 400 mg	26.697	5.848-121.868	< 0.001

UC: Ulcerative colitis; CMV: Cytomegalovirus.

ssion. There were no significant group differences in sex ratio, disease duration, clinical course, total lifetime systemic steroid dose, immunomodulator use, infliximab

use, or laboratory data at admission other than serum albumin level.

For multivariate analysis, we selected a total systemic steroid dose for 4 wk before admission as the most important factor among factors regarding steroid dose. This multivariate analysis using a logistic regression model identified pancolitis and a total systemic steroid dose > 400 mg for 4 wk before admission as significant independent risk factors for CMV infection (Table 2). Patients treated with more than 400 mg corticosteroid for UC exacerbation over the 4 wk prior to admission had a 27-fold greater risk of CMV-associated colitis and patients with extensive UC (pancolitis) had about a 3-fold greater risk. The other factors tested (age at UC diagnosis, age at admission, and serum albumin) were not significant risk factors by multivariate analysis.

Table 3 Endoscopic findings in patients with active ulcerative colitis (*n* = 149)

	CMV (+) <i>n</i> = 34	CMV (-) <i>n</i> = 115	Accuracy (%)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	<i>P</i> value

Table 4 Characteristic endoscopic findings for cytomegalovirus-associated colitis in patients with active ulcerative colitis (multivariate analysis)

	Odds ratio	95%CI	<i>P</i> value
Deep ulcer	2.128	0.678-6.680	0.196
Punched-out ulcer	12.672	4.210-38.143	< 0.001
Geographical ulcer	1.919	0.664-5.542	0.229
Spontaneous bleeding	2.106	0.735-6.036	0.166

Endoscopic findings

To identify endoscopic findings characteristic of CMV-associated colitis in patients with active UC, we analyzed ulcerative features (*e.g.*, deep ulcer, punched-out ulcer, geographical ulcer, longitudinal ulcer, and mucosal defect) and mucosal features (*e.g.*, mucopurulent exudate, spontaneous bleeding, cobblestone-like appearance, and post inflammatory polyp). Characteristic colonoscopic features of CMV-associated colitis included deep ulcer, punched-out ulcer, geographical ulcer, longitudinal ulcer, and mucosal defect (Figure 2). We defined endoscopic findings according to published reports^[28,38]. Deep ulcer was defined as deep excavated ulceration near or beyond muscularis propria with or without slightly raised edges. Punched-out ulcer was defined as ulceration with an almost round shape and clear demarcation. Geographical ulcer was defined as ulceration with an irregular pattern and a branched shape. Longitudinal ulcer was defined as ulceration with a longitudinal spread along the lumen of the colon. Mucosal defect was defined as a wide area of defect with a longitudinal and/or transverse spread, indicating that more than one-fourth of the mucosa in the endoscopic field was defective. The accuracy, sensitivity, specificity, positive predictive value, and negative predictive value for each of these features were determined. Univariate analysis revealed that deep ulcer, punched-out ulcer, geographical ulcer, and spontaneous bleeding were more frequent in CMV-positive patients than in CMV-negative patients (Table 3).

Multivariate analysis showed that only punched-out ulcer was a significant independent predictor of CMV colitis (OR = 12.672, 95%CI: 4.210-38.143) (Table 4).

Patient outcomes

In the CMV-positive (CMV-associated colitis) group, 26 of the 34 patients (76.5%) received antiviral therapy with GCV. After GCV therapy, 13 of these patients achieved remission, while 13 required colectomy because of severe and refractory UC. Of the remaining 8 patients who did not receive GCV antiviral therapy, 4 underwent colectomy because of severe UC.

Among the CMV-negative group, 81 patients (70.4%) achieved remission with anti-inflammatory therapy (including relapse cases), while 37 (32.2%) eventually underwent colectomy during the course of follow-up. Among these 37 patients, 4 underwent colectomy for cancer or dysplasia.

DISCUSSION

In this retrospective study of 149 UC patients presenting with exacerbation of symptoms, we identified extensive UC (pancolitis) and 4 wk of high-dose steroid treatment as independent risk factors for CMV-associated colitis in active UC. The only endoscopic finding indicative of CMV-associated colitis by multivariate analysis was punched-out ulcer. To our knowledge, this is the first study to identify both risk factors and characteristic endoscopic findings for CMV-associated colitis in patients with moderate to severe UC. These factors may help facilitate both the timely diagnosis and treatment of UC complicated by CMV infection.

We evaluated total systemic steroid dose over the patient's lifetime, as well as dose over the 4 wk before admission, over the previous week before admission, and on the day of admission. Between CMV-positive and CMV-negative patients, total systemic steroid dose over the 4 wk prior to admission (total dose > 400 mg) was an independent risk factor for CMV-associated colitis in active UC patients. Furthermore, neither immunomodulator nor infliximab use was associated with CMV-associated colitis. However, this study included only a few cases treated by immunomodulators or infliximab, and additional studies are required to confirm these results. Nonetheless, the finding that immunomodulator and infliximab use did not alter the risk of CMV-associated colitis is important, because it suggests an alternative

Figure 2 Endoscopic images of cytomegalovirus-associated colitis in patients with active ulcerative colitis. A-C: Deep ulcer; D-G: Punched-out ulcer; H-J: Geographical ulcer; K: Longitudinal ulcer; L: Mucosal defect.

treatment regimen for patients with moderate to severe UC rather than using high-dose corticosteroids for corticosteroid-refractory cases or corticosteroid-resistant cases. Given that tumor necrosis factor (TNF)- α from monocytes and dendritic cells plays an important role in the reactivation of CMV and that infliximab is a potent blocker of TNF- α , we consider that this combination therapy may be particularly effective^[7,39]. However, the efficacy of infliximab for UC patients with concomitant CMV infection remains controversial, as there have been few case reports and no controlled clinical trials.

Pancolitis was significantly associated with CMV infection in active UC, consistent with the theory that CMV is prone to proliferate in granulation tissue^[9]. Some studies reported that CMV was readily found in granulation tissue and tissue from deep ulcers, suggesting that CMV can penetrate inflamed mucosa *via* mononuclear cells and then proliferate in the mucosa^[2,9,40,41]. It is thus possible that a more extensive UC lesion may lead to wider CMV infection.

In general, there is no clear consensus on the diagnostic criteria for CMV infection in active UC. There are several methods of detecting CMV infection, including histology with IHC, serology, CMV culture, polymerase chain reaction (PCR) detection of the CMV genome, and CMV antigenemia^[6,34-37,42]. Each method offers advantages and disadvantages in the precise diagnosis of CMV infection. For example, histological examination is a relatively easy method, but its sensitivity is lower (10%-87%) than PCR. In contrast, PCR for CMV genes is highly sensitive, but the method is time-consuming and its selectivity is low given the ubiquity of CMV infection. CMV culture is too slow. In contrast, CMV antigenemia is relatively sensitive (60%-100%) and easy to measure within a short period, and has also been used to monitor CMV infection in heart transplant recipients and for the early diagnosis of CMV infection in renal transplant recipients^[43]. Moreover, results of CMV antigenemia are good indication for antiviral therapy^[44,45].

Accordingly, we adopted CMV antigenemia and histology, including IHC for CMV, to detect CMV infection in our analysis. Results showed that 33 of the 34 CMV-associated colitis patients (97.1%) were positive for CMV

antigenemia. Histology including IHC is considered the objective standard for the diagnosis of CMV infection. In our study, however, among the 34 patients with CMV-associated colitis whose biopsy specimens were stained with HE and a CMV antibody, only 8 patients were positive by histology. Only 7 were positive by both CMV antigenemia and histology. We therefore suggest that our combination of CMV antigenemia and histology including IHC for CMV is an appropriate strategy for diagnosis of CMV infection/CMV-associated colitis in active UC patients.

Colonoscopy is usually performed in patients with exacerbation of UC symptoms because direct observation of the colonic mucosa provides detailed information on disease status and is useful for judging disease severity and treatment efficacy. The rapid and accurate diagnosis of CMV-associated colitis in UC patients is critical, because its treatment strategy differs markedly from that for UC exacerbation not associated with CMV infection. A few reports have documented the endoscopic findings of CMV-associated colitis, but several failed to find features able to rapidly distinguish CMV-associated colitis from unrelated active UC. Endoscopic findings of UC concomitant with CMV infection can range from normal appearing mucosa to mucosal erosion or ulceration, which can be difficult to distinguish from active UC unrelated to CMV infection. In our study, punched-out ulceration was significantly more frequent in UC patients with CMV infection, consistent with reports that CMV tends to localize to the colon mucosa and granulation tissue in deep ulcers^[2,9,40,41]. Regardless of etiology, we suggest that a finding of punched-out ulceration may facilitate the rapid and accurate diagnosis of CMV-associated colitis in UC patients.

The limitations of this study include its retrospective nature and evaluation of patients at a single institution. This study also involved a relatively small number of patients, which limits its statistical power.

In conclusion, this study suggests that a total corticosteroid dose > 400 mg for 4 wk and extensive colitis are associated with an increased risk of CMV-associated colitis in patients with moderate to severe UC. In addition, punched-out ulceration appears predictive of

CMV-associated colitis associated with UC. These clinical predictors and specific endoscopic findings may facilitate rapid diagnosis and antiviral treatment.

COMMENTS

Background

Although it has been reported that cytomegalovirus (CMV) infection can be associated with steroid resistance and be an exacerbating factor in ulcerative colitis (UC), the relationship between CMV and UC is not well studied.

Research frontiers

The aim of this study was to identify characteristic endoscopic findings and risk factors for CMV-associated colitis in patients with active UC.

Innovations and breakthroughs

This is one of a few retrospective studies focused on important information regarding characteristic endoscopic findings and risk factors for CMV-associated colitis in patients with active UC.

Applications

This study suggests that a total corticosteroid dose > 400 mg for 4 wk and extensive colitis are associated with an increased risk of CMV-associated colitis in patients with moderate to severe UC. In addition, punched-out ulceration appears predictive of CMV-associated colitis associated with UC. These clinical predictors and specific endoscopic findings may facilitate rapid diagnosis and antiviral treatment.

Peer-review

An interesting article dealing with clinically relevant subject of risk factors in ulcerative colitis. There is a solid number of patients and good experimental and clinical design. Data are good and discussion is a good representation of the problem.

Abstract

AIM: To perform a systematic review comparing the outcomes of endoscopic, percutaneous and surgical pancreatic pseudocyst drainage.

METHODS: Comparative studies published between January 1980 and May 2014 were identified on PubMed, Embase and the Cochrane controlled trials register and assessed for suitability of inclusion. The primary outcome was the treatment success rate. Secondary outcomes included were the recurrence rates, re-interventions, length of hospital stay, adverse events and mortalities.

RESULTS: Ten comparative studies were identified and 3 were randomized controlled trials. Four studies reported on the outcomes of percutaneous and surgical drainage. Based on a large-scale national study, surgical drainage appeared to reduce mortality and adverse events rate as compared to the percutaneous approach. Three studies reported on the outcomes of endoscopic ultrasound (EUS) and surgical drainage. Clinical success and adverse events rates appeared to be comparable but the EUS approach reduced hospital stay, cost and improved quality of life. Three other studies compared

EUS and esophagogastroduodenoscopy-guided drainage. Both approaches were feasible for pseudocyst drainage but the success rate of the EUS approach was better for non-bulging cyst and the approach conferred additional safety benefits.

CONCLUSION: In patients with unfavorable anatomy, surgical cystojejunostomy or percutaneous drainage could be considered. Large randomized studies with current definitions of pseudocysts and longer-term follow-up are needed to assess the efficacy of the various modalities.

Core tip: Pancreatic pseudocysts are traditionally managed by open surgical internal drainage. With continued improvements in medical technology, the uses of percutaneous, endoscopic and laparoscopic drainage were increasingly reported. Nevertheless, trials comparing these different approaches are lacking. In this systematic review, endoscopic ultrasound-guided drainage appeared to be advantageous in drainage of pancreatic pseudocysts located adjacent to the stomach or duodenum. In patients with unfavorable anatomy, surgical cystojejunostomy or percutaneous drainage could be considered. Large randomized studies with current definitions of pseudocysts and longer-term follow-up are needed to assess the efficacy of the various modalities.

INTRODUCTION

Pancreatic pseudocysts are amylase rich fluid collections in the peri-pancreatic tissues surrounded by a well-defined wall^[1]. There should be absence of necrosis or solid component in the collections. The relative proportion of acute and chronic pseudocyst varies between reports and depends on how the pseudocysts are being defined^[2]. The incidence is higher in patients suffering from chronic pancreatitis. Pancreatic pseudocysts are traditionally managed by open surgical internal drainage. With continued improvements in medical technology, less invasive options including percutaneous, endoscopic and laparoscopic drainage were increasingly reported. Nevertheless, trials comparing these different approaches

are lacking and there is an absence in consensus on the best approach for management of this condition. Thus, the aim of the current systematic review was to evaluate the outcomes of comparative studies on endoscopic, percutaneous and surgical pancreatic pseudocyst drainage and to summarize the findings of available data.

MATERIALS AND METHODS

Inclusion criteria

Eligible studies were comparative studies on endoscopic, percutaneous or surgical methods of pancreatic pseudocyst drainage. The definition of pseudocyst was according to the revised Atlanta's classification^[1] (Table 1). In brief, pseudocyst referred to a fluid collection in the peri-pancreatic tissues persisting for more than 4 wk on computed tomography, surrounded by a well-defined wall and contained no solid material. Studies describing the results of pancreatic necrosis or abscesses were excluded. The indications for treatment of pancreatic pseudocyst was if they persisted for more than 4 to 6 wk and are ≥ 6 cm in size, causing symptoms or complications^[3,4].

Search strategy and trial identification

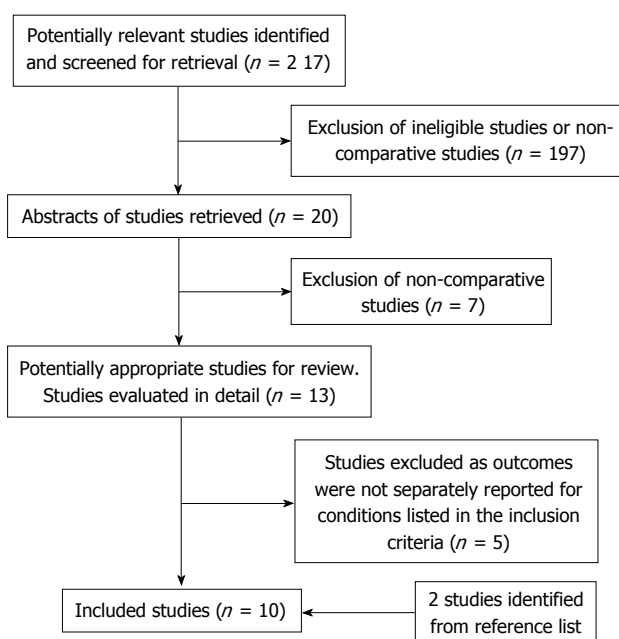

A computerized systematic literature review from January 1980 to May 2014 on PubMed, Embase and the Cochrane controlled trials register was performed. Articles were selected using MeSH headings and text words related to pancreatic pseudocyst, pseudocyst drainage, cystogastrostomy, cystojejunostomy, transmural pseudocyst drainage, transpapillary pseudocyst drainage and percutaneous pseudocyst drainage. Only English comparative studies involving the concerned treatment approaches were included. Reference lists from eligible trials were checked to locate missing publications. The titles of the articles and abstracts located were evaluated (Anthony Yuen Bun, TEOH1 and Vinay DHIR2). Where the article fulfilled the selection criterion, a copy of the full manuscript was obtained. Full manuscripts were then reviewed and a final decision was made about the inclusion. Studies published only in abstract form, conference abstracts, symposium proceedings and case reports were not eligible for inclusion. Any disagreements were resolved by consensus.

Data extraction and outcomes

Data were extracted using a standard extraction form. Parameters included were study methodology (including randomization and blinding), inclusion criteria, demographics, the indications of treatment and types of pancreatic fluid collection. Procedural data including the technical approaches, methods of anastomosis, catheters and stents used were also recorded. The primary outcome was the treatment success rate. Secondary outcomes included were the recurrence rates, re-interventions, lengths of hospital stay, adverse events and mortalities. Treatment success was defined

Table 1 Definition of peri-pancreatic fluid collections according to the revised Atlanta's classification

Name of the collection	Definition
Onset < 4 wk after initial attack	
Acute peripancreatic fluid collection	Fluid collections that develop in the early phase of pancreatitis. They do not have a well-defined wall, are homogeneous, are confined by normal fascial planes in the retroperitoneum
Acute necrotic collection	A collection containing variable amounts of fluid and necrotic tissue without a well-defined wall
Onset ≥ 4 wk after initial attack	
Pancreatic pseudocyst	A collection of fluid in the peripancreatic tissues surrounded by a well-defined wall and contains no solid material
Walled-off pancreatic necrosis	A mature, encapsulated collection of pancreatic and/or peripancreatic necrosis and has a well-defined inflammatory
Any time after initial attack	
Infected necrosis	Presence of superimposed infection of the necrotic pancreas. May be indicated by presence of gas in the collection

**Figure 1** Flow chart showing selection of included studies.

as radiographic cyst resolution after the index intervention. Re-intervention was defined as the need for repeat interventions owing to persistent symptoms in association with a residual pseudocyst. Adverse events were defined according to the individual study criteria.

Assessment of methodological quality and risk of bias of the included studies. Assessment of risk of bias were performed by AT and VD according to principles of the Cochrane Handbook for systemic reviews of interventions version 5.1^[5]. For randomized trials, the assessment focused on sequence generation, allocation concealment, blinding, incomplete outcome data, follow-up losses, intention to treat method of analysis and selective reporting. For non-randomized comparative trials, quality assessments were according to the Newcastle-Ottawa scale and the studies were scored on 3 domains including: Case selection, comparability of cases and controls and outcome assessments^[6]. The results of this study were reported according to the PRISMA guidelines^[7].

RESULTS

The search identified 217 potentially relevant publications and 20 articles were selected for reviewing of the abstracts. Seven studies were rejected as they were not comparative studies and the full manuscripts of the remaining 13 publications were reviewed. Two studies were further excluded as the outcomes for pseudocyst drainage were not separately reported and in 3 studies the outcomes of the different techniques were not reported individually. Two further articles were identified from the reference list of the included studies (Figure 1)^[8-17]. Since there was significant heterogeneity amongst the study interventions, recruitment and outcome measurements, statistical pooling of the results was not performed.

Description of the techniques

Surgical drainage procedures: Cystogastrostomy, cystoduodenostomy and cystojejunostomy:

Surgical drainage of pseudocysts is traditionally performed by the open approach^[18,19]. However in recent years, laparoscopic pseudocyst drainage is increasingly reported^[9,20]. For the open approach, midline or bilateral subcostal incisions were employed. The type of surgical drainage depended on the location of the cysts and whether it was adherent to the stomach or duodenum. When adhered to the posterior wall of the stomach, a cystogastrostomy were performed. If the cyst were not adhered to the stomach or duodenum, then a Roux-en Y cystojejunostomy would be fashioned. It is acknowledged that resectional procedures are sometimes required for patients with concomitant pancreatic ductal pathologies or complicated pseudocyst. However, resectional procedures do not have comparable endoscopic counterparts and these are not considered in this review.

In laparoscopic drainage procedures, various techniques have been described to replicate their open equivalents^[9,20]. These include intragastric, transgastric or exogastric approaches and they differ in the method of accessing the posterior wall of the stomach to create a cystogastrostomy. The anastomosis is usually created with a laparoscopic stapler and the enterostomy closed

by laparoscopic suturing. Laparoscopic cystojejunostomy is also possible for pseudocysts that protrude into the infracolic compartment and this is usually drained by a Roux-en Y jejunal loop.

Percutaneous drainage

Percutaneous drainage can be performed by ultrasound or computed tomography (CT) guidance and this can be achieved by the retroperitoneal route or transperitoneally^[15-17]. The appropriate drainage site is first identified, followed by progressive track dilation and insertion of a 7 to 12 Fr drainage catheter into the pseudocyst. In patients that received transperitoneal drainage, a transgastric needle puncture can be performed and the passage through the stomach could allow subsequent exchange of a double pigtail stent and internalization into the stomach. In patients with retroperitoneal drainage, the pigtail stents would be connected to an external bag for free drainage.

Endoscopic drainage

Endoscopic drainage can be performed transpapillary or transmurally^[21]. Transpapillary drainage can be performed if the pseudocyst communicates with the pancreatic duct on endoscopic retrograde cholangiopancreatography (ERCP) and a transpapillary stent is passed through the pancreatic duct into the pseudocyst. In patients with pancreatic ductal leak or ductal stricture, the stent may also serve to bridge the leak or stricture site^[22].

Endoscopic transmural drainage can be performed with or without endoscopic ultrasound (EUS) guidance^[11-13]. A prerequisite is that the pseudocyst is in direct apposition with the gastric or duodenal wall. When performed under esophagogastroduodenoscopy (EGD) guidance, the location of the pseudocyst is usually identified by the presence of bulging on the stomach wall. This is then confirmed by needle puncture, aspiration of the fluid and injection of contrast. A catheter and guide-wire is then passed into the pseudocyst. The fistula track is dilated with a balloon catheter and 1 or 2 plastic stents would be inserted. When performed under EUS guidance, the puncture site of the pseudocyst is chosen away from intervening vessels or structures. The pseudocyst is then punctured with a 19-gauge needle and a guide-wire passed to form 2 or more loops. The needle tract is dilated and plastic stents would be inserted. Recently, the use of metallic stents for draining pseudocyst has also been described but results from comparative studies are lacking^[23,24]. All the studies included in the current review used plastic stents.

Description of the studies

The identified studies covered a heterogeneous group of patients and mostly included small numbers from a single center (Table 2). In only one study, the outcomes of percutaneous drainage were compared to surgical drainage on a national level. Amongst the 10 included

studies, 3 were randomized controlled trials^[8,10,12]. One compared EUS drainage with open cystogastrostomy and 2 compared EGD vs EUS guided-drainage. The remaining seven studies were non-randomized trials, 1 compared laparoscopic, endoscopic and open cystogastrostomies^[9], 1 study compared EUS drainage with open cystogastrostomy^[10], 1 study compared EGD and EUS-guided drainage and 4 studies compared percutaneous and open surgical drainage^[13-17]. The definition of pseudocyst was clearly stated in all the randomized studies and in 6 out of 7 non-randomized studies. The indications for intervention were defined in all the randomized studies and 2 non-randomized studies.

Assessment of risk of bias of the included studies

The risks of bias in the randomized trials were assessed according to the principles of the Cochrane Handbook for systemic reviews of interventions (Table 3). None of the studies blinded the assessor of the outcomes. In one study comparing EGD versus EUS drainage^[11], the patients randomized to the EGD arm also received EUS when the pseudocyst could not be located. This resulted in a hybrid technique and may contaminate the data in the EGD arm resulting in contamination bias. The risks of bias in non-randomized trials were assessed using the Newcastle-Ottawa scale (Table 4). Most studies were of moderate quality and scored between 4 to 7 stars out of 10.

Assessment of outcomes by the different approaches of pseudocyst drainage

Percutaneous vs surgical drainage: Four retrospective studies were included (Table 5). The largest United States study included more than 14000 patients (Percutaneous: 8121 and surgical: 6409) that were identified using a US national database^[14]. Significant differences in background demographics between the groups were noted, including the cause of pseudocyst, the percentage of patients that received CT or ERCP and the proportion of patients that were treated in a teaching hospital. After adjusting for these confounding variables, a reduction in mortality was still observed in the surgical drainage arm (OR = 1.37, 95%CI: 1.12-1.68). Both emergency admission and acute pancreatitis increased the odds of in-patient mortality (OR = 2.45, 95%CI: 1.87-2.30 and OR = 2.36, 95%CI: 1.89-2.96, respectively) and the use of ERCP yielded a protective effect (OR = 0.68, 95%CI: 0.51-0.9). This study was the largest and most statistically robust amongst all the included studies. Yet, there is also a risk of selection biases, as the patients who were poor candidates for surgery tended to receive percutaneous drainage.

Heider *et al.*^[15] compared the results of expectant treatment with percutaneous and open surgical drainage. No statistical analysis of the results was performed (no *P*-values given). The patients that were treated by percutaneous drainage had a re-intervention rate of

Quality assessment was according to the Newcastle-Ottawa scale for non-randomized trials. +: High quality of the studies.

50%, adverse events rate of 67% and mortality rate of 9.1% and the results were worse than surgery. On the contrary, two smaller studies favored the percutaneous

approach. Adams noted higher risk of mortalities, morbidities and re-interventions in patients that were treated with surgical drainage^[16]. Whilst in another study, similar risks of mortalities and adverse events were observed in both groups but the patients that underwent surgery required more subsequent re-interventions^[17].

It is worthwhile to note that the definition of pseudocyst in some of the older studies may not be according to the Atlanta's classification and thus, the study population could include some patients with pancreatic necrosis and the results of these may need to be interpreted with caution. Based on the results of the national study, surgical drainage appeared to reduce mortality and adverse events risk as compared to the percutaneous approach. The lack of an external catheter also reduced risk developing pancreatic fistula and wound site infection. However, the validity of these results in the current era needs to be confirmed by a

modernized randomized trial with updated definitions.

EUS vs surgical drainage: One randomized trial and two retrospective studies were included (Table 6). Varadarajulu *et al*^[10] first published a retrospective case-matched study comparing EUS and open cystogastrostomy. No differences in treatment success, adverse events or re-interventions were noted between the groups. The same author then followed-up with the first randomized study, comparing 20 patients that received EUS drainage with an equal number receiving open cystogastrostomy^[8]. The time to pseudocyst recurrence was used as the main outcome measurement. However, none of the patients in the EUS group developed recurrence, thus raising the issue of an underpowered study. Nevertheless, similar rates of clinical success, mortalities and morbidities were observed between the two groups. In addition, the EUS group was associated with significantly lower hospital costs (mean difference of -\$8040 USD) and better quality of life scores (physical component scores and mental component scores). Hence, favoring the EUS approach over open cystogastrostomy.

In another study comparing EUS, laparoscopic and open cystogastrostomy, a significantly higher rate of clinical success was observed in the surgery arm. However, the rate of clinical success in the EUS group was unusually low at 51.1% and grade 2 or above complications occurred in up to 15.6% of the patients. Three patients required urgent laparotomy and 2 experienced a gastric perforation. These results reflect that

the endoscopist performing the procedures may still be overcoming their learning curves and the difference in outcomes may not be truly representative of the techniques. Nevertheless, this study was the only comparative study that incorporated the results of laparoscopic cystogastrostomy.

EUS vs EGD drainage: Two randomized trials and 1 retrospective comparison were included (Table 7)^[11-13]. Kahaleh performed a retrospective comparison of patients that underwent EUS or EGD drainage^[13]. Those with bulging pseudocyst underwent EGD drainage whilst patients with non-bulging cyst or those at risk of bleeding underwent EUS drainage. No difference in clinical success and adverse event rates were observed between the two groups. In a Korean randomized study, EUS was compared to a modified EGD approach^[11]. In patients with bulging cyst, a blind EGD puncture was performed. Whilst in patients with the absence of bulging, radial EUS was employed to mark the site of puncture. This resulted in hybrid EUS-EGD approach in some of the patients. The trial found a significant difference in technical success rates in favor of the EUS approach (94% vs 72%, $P = 0.039$). The patients with failed EGD approach then crossed over to EUS drainage and this was successful in all patients. No differences in adverse events were observed in both arms. The third study was also a randomized study comparing EUS with pure EGD drainage of pseudocyst^[12]. The EUS approach was shown to have significantly higher success rate as compared to the pure EGD technique (100% vs 33.3%,

Table 7 Endoscopic ultrasound vs esophagogastroduodenoscopy drainage of pancreatic pseudocysts

Ref.	Sample size	Size (cm) ¹	Clinical success	Hospital stay (d)	Reintervention	Mortalities	Adverse events	Bleeding	Intra-abdominal infection

	EGD: 53	9.5 (3-20) ³	91%	-	9.4%	0	18.9%	1.9%	7.5%

¹Values in mean \pm SD; ²Values in mean (interquartile range); ³Values in mean (range); ⁴Values in median (range) except otherwise indicated; ⁵Indicates significant differences between the 2 groups. EUS: Endoscopic ultrasound drainage; EGD: Esophagogastroduodenoscopy drainage.

$P < 0.001$) and all patients with failed EGD drainage were successfully drained with the EUS technique. However, of more concern was that 2 patients in the EGD arm suffered from severe bleeding after drainage. One patient died within 4 h after the procedure due to massive bleeding into the cyst and another required endoscopic hemostasis and blood transfusion.

Hence, the results of these studies suggest that although a blind EGD pseudocyst drainage is technically feasible, it may result in life-threatening adverse events. The success rate of the EUS approach was better for non-bulging cyst and the approach conferred additional safety benefits by allowing visualization of extraluminal structures.

DISCUSSION

Although the current review has established a strict criterion for inclusion, the included studies incorporated a heterogeneous group of patients that were treated with a number of different approaches. Thus, the results were not directly comparable and statistical analysis in a form of meta-analysis was inappropriate. Nevertheless, a number of conclusions could still be made. EUS-guided drainage has similar efficacy to surgery but the EUS approach may reduce hospital stay, costs of the procedure and improve quality of life. EGD and EUS-guided drainages are both feasible but the success rate of the EUS approach is better for non-bulging cyst and it may offer additional safety benefit. Whether surgical internal drainage of pancreatic pseudocyst is preferred over percutaneous drainage needs to be validated, as no results from a modern study are available. However, surgical cystogastrostomy may still be preferred it avoids the need of an external catheter and reduces the risk developing an external pancreatic fistula. Consequently, the EUS approach is preferred when anatomy of the pseudocyst allows for direct drainage into the stomach or duodenum. However, if the pseudocyst is located away from the stomach or duodenum, surgical cystojejunostomy or percutaneous drainage could be considered. In addition, it is acknowledged that laparoscopic drainage is the modern minimally invasive approach for surgical drainage. However, results from comparative studies were lacking and the long-term outcomes of the treatment approaches could not be made.

The current study is the only systematic review comparing percutaneous, endoscopic and surgical drainage of pseudocyst. A prior systematic review compared endoscopic and laparoscopic internal drainage by summarizing the results from cohort studies without direct statistical comparison^[20]. No randomized or comparative studies were available. The review concluded that both approaches were safe and the laparoscopic approach appeared to have a higher success rate, lower morbidity and recurrence. In a meta-analysis comparing EGD and EUS-guided drainage, 2 randomized studies and 2 prospective studies were included^[25]. Technical success was higher for EUS drainage (RR = 12.38, 95%CI: 1.39-110.22) and adverse events were similar between the two techniques. The review concluded that for bulging pseudocysts, both approaches could be selected whereas for non-bulging pseudocyst, portal hypertension or coagulopathy, EUS drainage is the preferred modality.

There were some limitations to the current study. Firstly, the numbers of high quality comparative studies assessing the 3 approaches were lacking. Hence, the robustness of the results generated in this review is limited by the quality of the original studies. Furthermore, with regards to the available randomized trials, all were single center studies with small sample sizes and they were not designed to detect differences in recurrence rates or adverse event rates between the modalities. Thus, the results were prone to type II error. In addition, the literature search failed to identify any comparative studies involving endoscopic transpapillary drainage and laparoscopic internal drainage. Therefore, conclusions regarding these approaches could not be made. Furthermore, it was observed that many of the studies did not report on the follow-up time or only reported a very short follow-up period. This may not be adequate to detect longer-term recurrence. Lastly, the definitions of pseudocyst has changed over time and may be different for each study, thus of the patients included in the current review may not be suffering from the modern definition of pseudocyst and the outcomes of treatment may be affected by the definition.

Currently, there is a lack of consensus in the best practice for pseudocyst drainage. A number of professional bodies have attempted to establish guidelines regarding the management of complications of acute pancreatitis including infected pseudocyst and pancreatic

necrosis^[26]. However, none of these guidelines have received widespread acceptance. In a systemic review of 16 guidelines published by profession bodies, it was observed that the guidelines lacked consensus and few were graded according to the strength of evidence. In addition, there were wide variations in the recommendations regarding the role of percutaneous and endoscopic drainage of pancreatic fluid collections. For infected pseudocyst, percutaneous drainage was recommended by 6 guidelines, 1 did not recommend its use and for endoscopic drainage, the approach was recommended by 7 guidelines. A recent guideline published by the International Association of Pancreatology and the American Association of Pancreateology, represented the best evidenced-based recommendations concerning key aspects the management of acute pancreatitis^[27]. However, the optimal management of pseudocysts were not discussed and there is still a pressing need for more randomized studies to establish the best approach for management of this condition.

In conclusion, significant heterogeneity was present in the included studies and a clear conclusion could not be made. However, EUS-guided drainage appeared to be advantageous in drainage of pancreatic pseudocysts located adjacent to the stomach or duodenum. In patients with unfavorable anatomy, surgical cystogastrostomy or percutaneous drainage could be considered. Large randomized studies with current definitions of pseudocysts and longer-term follow-up are needed to assess the efficacy of the various modalities.

ACKNOWLEDGMENTS

The authors would like to extend the deepest gratitude to all Asian EUS group members for their support to the group. We would also like to thank Mr. Steven Chan and his team in their excellent support during all AEG related activities.

COMMENTS

Background

Pancreatic pseudocysts are traditionally managed by open surgical internal drainage. With continued improvements in medical technology, the uses of percutaneous, endoscopic and laparoscopic drainage were increasingly reported. Nevertheless, trials comparing these different approaches are lacking. Thus, the aim of this study is to perform a systematic review comparing the outcomes of endoscopic, percutaneous and surgical pancreatic pseudocyst drainage.

Research frontiers

Currently, there is a lack of consensus in the best practice for pseudocyst drainage. A number of professional bodies have attempted to establish guidelines regarding the management of complications of acute pancreatitis including infected pseudocyst and pancreatic necrosis. However, the guidelines lacked consensus and few were graded according to the strength of evidence.

Innovations and breakthroughs

Endoscopic ultrasound (EUS)-guided pseudocyst drainage is an endoscopic approach for establishing internal transmural drainage of a pseudocyst. The approach allows visualization of extra-mural structures to allow precise

placement of internal stents.

Applications

In the current study, the authors conclude that EUS-guided drainage appeared to be advantageous in drainage of pancreatic pseudocysts located adjacent to the stomach or duodenum. In patients with unfavorable anatomy, surgical cystojejunostomy or percutaneous drainage could be considered. Large randomized studies with current definitions of pseudocysts and longer-term follow-up are needed to assess the efficacy of the various modalities.

Terminology

Pseudocyst are fluid collections in the peri-pancreatic tissues persisting for more than 4 wk on computed tomography, surrounded by a well-defined wall and contained no solid material after an attack of pancreatitis.

Peer-review

The manuscript gives an overview of publications on outcome of endoscopic drainage of pancreatic pseudocysts, compared with percutaneous and/or surgical drainage.

World Journal of *Gastrointestinal Endoscopy*

World J Gastrointest Endosc 2016 April 10; 8(7): 319-356

Editorial Board

2014-2017

The *World Journal of Gastrointestinal Endoscopy* Editorial Board consists of 330 members, representing a team of worldwide experts in gastrointestinal endoscopy. They are from 40 countries, including Australia (3), Austria (3), Brazil (6), Canada (3), China (62), Croatia (1), Czech Republic (1), Denmark (1), Ecuador (1), Egypt (3), France (1), Germany (8), Greece (10), Hungary (2), India (11), Indonesia (1), Iran (6), Iraq (1), Ireland (2), Israel (1), Italy (37), Japan (43), Lebanon (1), Lithuania (1), Malaysia (1), Mexico (4), Netherlands (1), Norway (2), Poland (4), Portugal (5), Romania (1), Singapore (3), Slovenia (2), South Korea (19), Spain (9), Thailand (2), Turkey (11), United Arab Emirates (1), United Kingdom (14), and United States (43).

REVIEW

- 319 What are the current and potential future roles for endoscopic ultrasound in the treatment of pancreatic cancer?

Oh SY, Irani S, Kozarek RA

ORIGINAL ARTICLE

Retrospective Cohort Study

- 330 Risk factors for local recurrence after *en bloc* endoscopic submucosal dissection for early gastric cancer

Lee JY, Cho KB, Kim ES, Park KS, Lee YJ, Lee YS, Jang BK, Chung WJ, Hwang JS

Retrospective Study

- 338 Stent type used does not impact complication rate or placement time but can decrease treatment cost for benign and malignant esophageal lesions

McGaw C, Alkaddour A, Vega KJ, Munoz JC

- 344 What is the impact of capsule endoscopy in the long term period?

Ormeci A, Akyuz F, Baran B, Gokturk S, Ormeci T, Pinarbasi B, Soyer OM, Evirgen S, Akyuz U, Karaca C, Demir K, Kaymakoglu S, Besisik F

- 349 Risk factors for postoperative bleeding after gastric endoscopic submucosal dissection in patients under antithrombotics

Shindo Y, Matsumoto S, Miyatani H, Yoshida Y, Mashima H

World Journal of Gastrointestinal Endoscopy
Volume 8 Number 7 April 10, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Bo Yu, MD, Professor, Department of General Surgery, Beijing Military Command General Hospital, Beijing 100700, China

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Pancreatic adenocarcinoma is the fourth leading cause of cancer-related death in the United States. Due to the aggressive tumor biology and late manifestations of the disease, long-term survival is extremely uncommon and the current 5-year survival rate is 7%. Over the last two decades, endoscopic ultrasound (EUS) has evolved from a diagnostic modality to a minimally invasive therapeutic alternative to radiologic procedures and surgery for pancreatic diseases. EUS-guided celiac plexus intervention is a useful adjunct to conventional analgesia for patients with pancreatic cancer. EUS-guided biliary drainage has emerged as a viable option in patients who have failed endoscopic retrograde cholangiopancreatography. Recently, the use of lumen-apposing metal stent to create gastrojejunal anastomosis under EUS and fluoroscopic guidance in patients with malignant gastric outlet obstruction has been reported. On the other hand, anti-tumor therapies delivered by EUS, such as the injection of anti-tumor agents, brachytherapy and ablations are still in the experimental stage without clear survival benefit. In this article, we provide updates on well-established EUS-guided interventions as well as novel techniques relevant to pancreatic cancer.

Key words: Endoscopic ultrasound; Pancreatic cancer; Palliation; Endoscopic ultrasound-guided celiac plexus neurolysis and block; Endoscopic ultrasound-guided biliary drainage; Endoscopic ultrasound-guided gastrojejunal anastomosis; Endoscopic ultrasound-guided anti-tumor therapy; Endoscopic ultrasound-guided fiducial placement; Endoscopic ultrasound-guided ablation

Core tip: Endoscopic ultrasound (EUS) is an indis-

pensable tool in pancreatic cancer not only for tissue diagnosis and disease staging but also for therapeutic purposes. Although some EUS-guided therapies such as celiac plexus interventions and biliary drainage in the setting of unsuccessful endoscopic retrograde cholangiopancreatography (in expert tertiary referral centers) have become widely accepted interventions for patients with pancreatic cancer, other techniques have yet to evolve. Given the lack of effective systemic treatment for pancreatic cancer at present, further research in therapeutic EUS is warranted.

Oh SY, Irani S, Kozarek RA. What are the current and potential future roles for endoscopic ultrasound in the treatment of pancreatic cancer? *World J Gastrointest Endosc* 2016; 8(7): 319-329 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i7/319.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i7.319>

INTRODUCTION

Pancreatic adenocarcinoma is the fourth leading cause of cancer-related death in the United States^[1]. Only 20% of patients at diagnosis are amenable to surgical resection^[2], which offers the best chance of long-term survival. As a result, the majority of patients are treated with palliative chemotherapy or best supportive care. From a histological standpoint, one of the defining features of pancreatic ductal adenocarcinoma is extensive desmoplastic stroma with fibrotic reaction around the tumor. The fibrotic stroma promotes tumor growth^[3], induces resistance to chemotherapy and radiotherapy^[4], and constitutes a barrier to the delivery of therapeutic agents^[5]. Due to the aggressive tumor biology and late manifestations of the disease, long-term survival is extremely uncommon and the current 5-year survival rate is 7%^[6].

Over the last two decades, endoscopic ultrasound (EUS) has evolved from a diagnostic modality to a minimally invasive therapeutic alternative to radiologic procedures and surgery for pancreatic diseases. EUS-guided celiac plexus neurolysis (CPN)/block are widely accepted techniques for pain management in patients with pancreatic cancer. Recently, EUS-guided biliary access in both malignant and non-malignant biliary obstruction has been increasingly utilized. As EUS offers dynamic images, unparalleled access to the pancreas and Doppler to avoid vascular structures, it has a theoretical advantage of targeting the tumor directly through the desmoplastic stroma while minimizing complications. This, coupled with the lack of effective systemic chemotherapies for pancreatic cancer, has prompted researchers to investigate local EUS-guided delivery of anti-tumor agents and ablative therapies over the last decade.

In this article, we provide updates on well-established EUS-guided interventions as well as novel techniques that are in the development for the treat-

ment of pancreatic cancer.

PALLIATIVE/SYMPTOMATIC THERAPIES

EUS-guided celiac plexus interventions

CPN refers to permanent chemical ablation of the celiac plexus and is performed by injecting alcohol or phenol into or around the celiac plexus or ganglion. Celiac plexus block denotes inhibition of pain transmission *via* the celiac plexus by injecting a combination of a corticosteroid and a long acting local anesthetic. Injections can be delivered *via* a percutaneous, surgical or EUS-guided approach. EUS provides access to the celiac plexus which is located adjacent to the proximal gastric wall. The main advantage of this route over a percutaneous one is the ability to avoid vessels with Doppler, in addition to being able to undertake concomitantly at the time of another intervention such as an endoscopic retrograde cholangiopancreatography (ERCP) or fine needle aspiration of the primary mass.

Since the first report of EUS-CPN in 30 patients with intra-abdominal malignancy (25 with pancreatic cancer) showing significant improvement in pain scores^[7], multiple randomized controlled and meta-analyses^[8-12] have demonstrated that EUS-CPN provided effective pain relief in patients with pancreatic cancer compared with conventional analgesia. There is also evidence that CPN reduces analgesia use. Two meta-analyses showed that CPN (either EUS or percutaneous approach) was associated with a significant reduction in narcotic use^[8,11]. Additionally, a randomized controlled trial involving 96 patients with advanced pancreatic cancer reported that morphine consumption was lower at 3 mo in the EUS-CPN group compared to placebo^[11]. Nonetheless, approximately 15% of patients may see no reduction in their use of narcotics, and in this group, a repeat EUS-CPN has not been shown to be effective. A study of 24 patients with pancreatic cancer undergoing repeat EUS-CPN showed that repeat CPN was not as effective as index procedure in pain control (67% after the initial CPN vs 29% at 1 mo follow-up)^[13].

EUS-guided injection can be given centrally into the space between the aorta and the origin of the coeliac trunk, or bilaterally on either side of the coeliac axis. To date, one randomized trial comparing the two techniques demonstrated no difference in the duration of pain relief (11 wk vs 14 wk), complete pain relief (2/29 patients vs 2/21 patients) or reduction in pain medication (9/29 patients vs 7/21 patients)^[14]. The decision to inject centrally or bilaterally often depends on the personal preference and experience of an endosonographer and further prospective studies are needed to determine which approach is superior. On the other hand, a Japanese group investigated the efficacy of broad plexus neurolysis (BPN) extending over the superior mesenteric artery with the aim of delivering a larger amount of neurolytic agents^[15]. The study found that EUS-BPN patients had significantly greater reductions at days 7 and 30 on the visual analog pain

Figure 1 Endoscopic ultrasound-guided injection into the celiac ganglion. A: Celiac ganglion visualized by linear endoscopic ultrasound as a hypoechoic structure anterior to the aorta (arrow); B: 19-gauge needle puncture into the celiac ganglia for neurolysis.

scale scores compared with EUS-CPN group. This technique, however, is yet to be validated in a large, prospective trial.

There has been an interest in direct celiac ganglia injection to improve the efficacy of CPN (Figure 1). Celiac ganglia appear as an oval, hypo to isoechoic structures around the celiac axis and are visible in upwards of 80% of the general population^[16,17]. A recent study randomized 34 patients to EUS-ceeliac ganglia neurolysis vs EUS-CPN showed that celiac ganglion neurolysis was associated with more effective pain relief compared with CPN (73.5% vs 45.5%, respectively; $P = 0.026$) with a smaller volume of alcohol needed for the ablation^[18].

Contraindications to celiac plexus interventions include coagulopathy (international normalized ratio > 1.5), thrombocytopenia (platelets $< 50000/L$), and hemodynamic or respiratory instability prohibiting adequate sedation. Otherwise, EUS-guided celiac plexus intervention is generally safe. Diarrhea, abdominal pain and hypotension due to the disruption of the autonomic nervous system are usually self-limiting. A paradoxical increase in pain has been shown to occur in 9% of cases but generally resolves spontaneously^[19]. Serious adverse events including paralysis from anterior spinal cord infection^[20,21], necrotic gastric perforation^[22], and celiac artery thrombosis causing infarction^[23,24] are rare.

EUS-guided biliary drainage

ERCP for biliary access and drainage is successful in 90% to 95% of cases and is the preferred method of stenting the bile duct in obstructive jaundice from pancreatic cancer. In cases of unsuccessful ERCP due to difficult cannulation or altered anatomy, the alternatives have been precut papillotomy, percutaneous transhepatic biliary drainage (PTBD) and surgical bypass. Recently, EUS-guided biliary drainage has emerged as an alternative to these options. EUS-guided approach spares patients the discomfort of an external drain, and can be performed at the time of an unsuccessful ERCP, reducing the need for additional percutaneous interventions.

Three main approaches for EUS-guided biliary

drainage have been described. Rendezvous technique is where a guidewire is placed into the intra or extrahepatic bile duct and passed through the papilla for retrieval by duodenoscopy for retrograde biliary intervention. Direct transgastric (hepaticogastrostomy) or transduodenal (choledochoduodenostomy) route involves the dilation of the tract followed by stenting for transmural biliary drainage (Figure 2). This obviates biliary access *via* the papilla. A third, less frequently performed intervention, involves the antegrade placement of a stent across the papilla *via* a transduodenal approach^[25,26]. The transduodenal approach requires at least an intact duodenal bulb^[27] and can sometimes be performed after placement of a duodenal stent for gastric outlet obstruction. In patients with obstruction at the level of the pylorus, the transgastric approach almost always requires a dilated intrahepatic biliary system^[28].

Available evidence suggests excellent technical and clinical success with EUS-guided biliary drainage in 87% of cases, however, adverse events up to 10%-20% have been reported^[29-40]. One of the major shortcomings of the rendezvous technique is a failure rate of 25%, and this can be associated with prolonged procedure times and higher risk of bile leak^[31,36,37,40,41]. In contrast, transluminal stenting can be complicated by stent migration or occlusion, bile leak and biliary peritonitis, cholangitis, hemobilia and pneumoperitoneum^[27,33-35].

Alternatively, EUS-guided gallbladder drainage may be an option when the previously mentioned approaches are not feasible. As the gallbladder presents a large target in close proximity to the gastric antrum and duodenal bulb, this technique can be performed more easily. However, it would not be beneficial in a non-dilated gallbladder suggesting cystic duct invasion by tumor^[42]. Excellent technical success, clinical success and safety profiles with EUS-guided gallbladder drainage in patients with acute cholecystitis have been demonstrated in a randomized controlled trial^[43] and its use in the setting of malignancy has been described in case reports and small series^[44,45].

At present, experts recommend that EUS-guided biliary drainage should be performed by an advanced

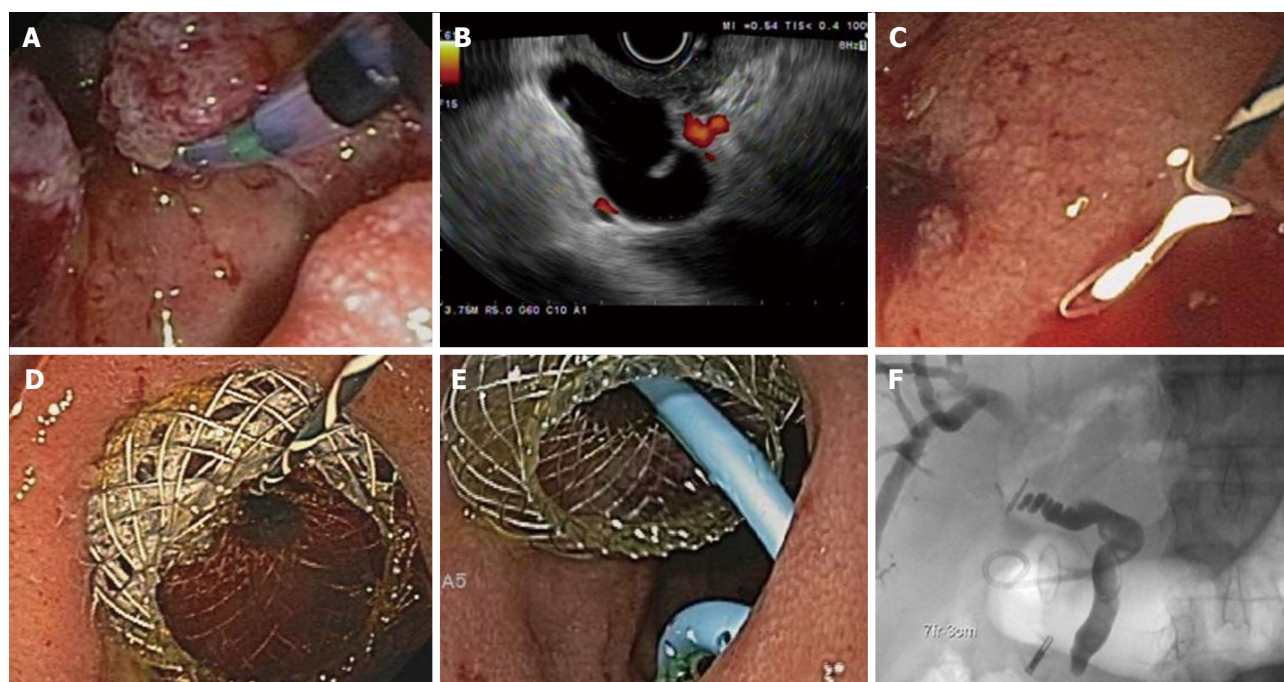

Figure 2 A 84 years old male with duodenal adenocarcinoma causing biliary obstruction underwent endoscopic ultrasound-guided choledochoduodenostomy following unsuccessful endoscopic retrograde cholangiopancreatography. endoscopist with expertise in both ERCP and EUS in a tertiary center, where surgery and radiology unit can provide support to manage adverse events if they arise^[46,47].

EUS-guided anastomosis

Gastric outlet obstruction is a common late manifestation of cancer in the head of the pancreas. When endoscopic gastroduodenal stent placement is unsuccessful in relieving obstruction, bypass surgery can be performed to accomplish the anastomosis between the stomach and jejunum. However, in poor surgical candidates, the EUS-guided approach may offer a minimally invasive means of establishing an anastomosis. In this technique, a gastrojejunal fistula is created by obtaining an access to the jejunum *via* EUS-guided needle, placing a guidewire through the needle and dilating the tract over the wire using a dilator catheter, balloon and/or electrical cautery needle. Subsequently, a lumen-apposing stent is placed across the fistula (Figure 3). This has been described in 2 recent case reports^[48,49]. EUS-guided gastrojejunostomy using a double-balloon enteric tube to distend the jejunum between the two balloons at the EUS-guided needle puncture has also been reported^[50,51].

The use of magnetic compression devices through oral, percutaneous, and surgical introduction of magnets to create gastroenterostomy and cholecystoenteric anastomosis in animal models has been reported^[52,53] (Figure 4). Encouraged by the favorable outcomes of the experimental studies, two human trials of endoscopic gastroenteric anastomosis have been performed. The

first study evaluated 15 patients with malignant obstruction undergoing gastroenteric anastomosis using magnetic compression devices and a yoyo stent and found that the procedure was successful in 13 (87%) patients^[54]. One perforation occurred and was attributed to manipulation of the recently formed fistula. Three stents migrated (2 distal and 1 proximal) and no mortality was reported. Subsequently, a prospective multicenter study evaluated 18 patients who had gastroenteric anastomosis using magnetic compression device and self-expandable stent^[55]. The procedure was successful in 12 (67%) patients but the study was terminated after inclusion of 18 patients due to a fatal perforation in 1 patient. Three (25%) patients experienced stent migration. This technique is usually performed by forward-viewing endoscope but can also be performed under the guidance of EUS combined with fluoroscopy. Creation of magnetic biliary anastomoses using endoscopic and radiologic techniques has also been described in case reports^[56,57] but there are no large trials to date.

Through-the-scope device for EUS-guided suturing and tissue approximation between two organs has been tested in porcine models^[58,59]. A suturing device was developed for suturing under EUS guidance to the desired depth. The device allowed multiple sutures to be placed without withdrawing the echoendoscope. Stitching, knot tying, and thread cutting were achieved through an accessory channel in the echoendoscope. Traction for the insertion of stents and other devices was provided through the lumen of both organs. With-

in 4 to 7 d, anastomoses had formed between the small intestine and the stomach, and between the gallbladder and the stomach. The initial diameter of the anastomoses ranged from 3 to 9 mm, and no adverse events were reported.

ANTI-TUMOR THERAPIES

EUS-fine needle injection of anti-tumor agents

Cytoimplant: An allogenic mixed lymphocyte culture (Cytoimplant) induces cytokine production and activates the host immune effector mechanism. EUS-fine needle injection (EUS-FNI) of Cytoimplant was examined in a phase I trial of 8 patients with advanced pancreatic cancer^[60]. The median survival was 13.2 mo, with 2 partial responses (> 50% reduction in tumor size

measured on imaging) and 1 minor response (tumor size reduction of < 50%). The technique was feasible and no major complications were seen.

Immunotherapy/dendritic cells: Immature dendritic cells can stimulate primary T-cell response against tumor antigens. To date, 2 pilot trials have been conducted on EUS-FNI of dendritics for the treatment of unresectable pancreatic cancer. The use of EUS-FNI of immature dendritic cells was reported in a study of 7 patients with advanced pancreatic cancer who previously failed gemcitabine. Injections of 10 billion or more dendritic cells at two to three sites were performed. There was 1 complete response, 3 partial responses and 2 patients had stable disease with a median survival of 9.9 mo. No adverse events were seen^[61]. Later, the

use of combined systemic gemcitabine and EUS-FNI of OK432-pulsed dendritic cells, followed by intravenous lymphokine-activated killer cells was reported in 5 patients with unresectable pancreatic cancer. One patient showed a partial response and 2 patients had stable disease over 6 mo^[62].

Tumor necrosis factor erade: Tumor necrosis factor (TNF)erade is a replication-deficient adenovirus vector that expresses human TNF- α gene regulated by promoter Egr-1, which is inducible by chemotherapy and radiation. Preliminary results from a phase I / II trial of intratumoral TNFerade injection (either EUS or percutaneous approach) in combination with systemic 5-fluorouracil and radiotherapy in 50 patients with locally advanced pancreatic cancer demonstrated encouraging results^[63]. One complete response, 3 partial responses and 12 stable disease with a median survival of 297 d was noted. Interestingly, seven patients had surgical resection, 6 with negative margins, 1 with complete pathologic response and 3 surviving more than 2 years. However, a subsequent large randomized multicenter trial involving 304 patients with locally advanced pancreatic cancer showed no survival benefit of combining intratumoral TNFerade injection with 5-fluorouracil and radiotherapy compared with chemoradiation alone^[64]. In addition, the study used either EUS-guided or a percutaneous approach for the injection of TNFerade and found that EUS-FNI was associated with inferior progression-free survival. This was thought to be the operator-dependent nature of EUS-FNI.

ONYX-015: ONYX-015 is a modified adenovirus (deletion in the E1B gene) which preferentially replicates in tumor cells leading to cell death. In a phase I / II trial using EUS-FNI of ONYX-015 in 21 patients with locally advanced pancreatic cancer, patients received 8 injections and the last injection was administered with systemic gemcitabine^[65]. The mean survival was 7.5 mo. Serious adverse events included duodenal perforations and sepsis in 2 patients each, raising concerns over its safety.

BC-819: BC-819 is a DNA plasmid that targets the expression of diphtheria-toxin gene under the control of H19 regulatory sequences and has the potential to treat pancreatic cancer that overexpresses the *H19* gene. In a phase I / II a trial, EUS or computed tomography (CT)-guided FNI of BC-819 was performed in 9 patients with advanced pancreatic cancer treated with concurrent chemoradiation^[66]. Three patients achieved partial response and 2 were successfully downstaged for surgery. No serious adverse events were reported.

Radiotherapy and EUS

EUS-guided brachytherapy: Brachytherapy involves the insertion of a radioactive seed directly into the tumor for local destruction. Iodine-125 (125I) is the most common radioactive seed used and has a half-life of

59.7 d and tissue penetration of 1.7 cm^[67]. EUS-guided implantation of 125I into pancreatic tumor was first reported in a pilot study of 15 patients with unresectable pancreatic cancer^[68]. The study showed partial response in 27%, minimal response in 20% and stable disease in 33%. Reduction in pain was noted in 30% but the effect was short-lived. Two further studies examined the efficacy of combined EUS-brachytherapy and systemic gemcitabine-based chemotherapy in patients with advanced pancreatic cancer, both demonstrating no significant survival benefit but improvement in pain was again noted^[69,70].

Stereotactic body radiotherapy and fiducial placement: The main benefit of stereotactic body radiotherapy (SBRT) is that it limits the field of radiation to the organ of interest thereby minimizing irradiation of adjacent normal tissue^[71]. One prospective^[71] and two retrospective studies^[72,73] showed that local tumor control and overall survival following SBRT were comparable with the outcomes of external beam radiotherapy.

Placement of fiducial markers prior to SBRT acts as a landmark and enables precise tumor targeting. Fiducial markers are available in different forms, including radiopaque spheres, coils or seeds and were traditionally placed in or near the tumor using surgical or radiological techniques (Figure 5^[74]). However, two recent prospective studies have demonstrated that EUS-guided placement of fiducial markers in pancreatic tumors had excellent technical success rates (88% to 90%) and safety^[74,75]. EUS-guided placement is performed by passing fiducials through a 19G or 22G needle and deploying them by using stylet or injecting sterile water into the needle after the needle is punctured to the desired depth^[76]. Different types of fiducial markers have also been studied. Khashab *et al*^[77] evaluated the EUS-placement of traditional vs coiled fiducials in a study of 39 patients with locally advanced pancreatic cancer. Visibility score was significantly better for traditional compared with coil fiducials but no difference in migration rate, number of fiducials placed, technical success or complication rate were seen. The authors recommended the placement of traditional fiducials whenever possible.

EUS-guided ablative techniques

Radiofrequency ablation: Radiofrequency ablation (RFA) works by passing electrical current in the range of radio waves between a needle electrode positioned in the tumor, and grounding pads placed on the patient's skin. Radiofrequency current produces a high level of heat within the tumor leading to protein desaturation and loss of fluids (coagulative necrosis)^[78]. Several studies have demonstrated the feasibility of RFA *via* open, percutaneous and laparoscopic approaches in patients with locally advanced pancreatic cancer^[79,80].

The application of EUS-guided RFA in porcine models was shown to be effective in destroying pancreatic tissue^[78,81,82]. Complications included pancreatitis^[81], intestinal wall adhesion^[82], and retroperitoneal fibrosis

Figure 5 Images courtesy of Sanders *et al*^[74]. A: Fiducial loaded into 19-gauge needle with sterile forceps; B: Fiducial within tip of needle; C: Sealing fiducial with sterile bonewax; D: Loaded fiducial ready for advancement down operating channel; E and F: Needle delivering fiducial into pancreatic mass (arrow).

in an adjacent organ^[83]. To date, there is only one study that reported the use of EUS-RFA in humans. The study used a cryothermal probe which is a large bore flexible bipolar device that combines radiofrequency with cryogenic cooling in the same session. The probe was successfully applied under EUS guidance in 73% (16/22) of patients with locally advanced pancreatic cancer and the procedure was well tolerated in all patients. In 6/16 patients, reduction in tumor size was noted on follow-up CT^[83].

Photodynamic therapy: Photodynamic therapy (PDT) is a technique where a specific wavelength of light is delivered *via* optical fibers threaded through a needle placed in the target tissue^[84]. Wavelength light is then activated by a photosensitizing agent which is usually administered intravenously. Photosensitizer is also present in pancreatic cancer at a sevenfold greater concentration compared with normal tissue^[85]. The combination of a photosensitizing agent and wavelength light in the presence of oxygen leads to the generation of reactive oxygen species that can damage cellular constituents leading to cell death^[86]. Unlike RFA, PDT is collagen sparing and preserves normal tissue architecture^[87].

Promising results of PDT on cholangiocarcinoma have been reported including survival benefit^[88-94] however its use in pancreatic cancer is still at an experimental stage. Three pilot trials of PDT in patients with locally advanced pancreatic cancer have demonstrated its feasibility and safety^[86,95,96].

CONCLUSION

EUS-guided celiac plexus intervention is a useful adjunct

to conventional analgesia for pain management in patients with pancreatic cancer. Direct injection into the celiac ganglia may result in a better response.

EUS-guided biliary drainage has emerged as a viable alternative to PTBD in patients who have failed ERCP. However, it should be performed by an interventional endoscopist with expertise in both ERCP and EUS at a tertiary center where surgery and radiology can provide support in case of adverse events.

EUS-guided anastomosis is in the preliminary stage of development and the majority of studies are limited to animal models. Major advancements in technique and prospective human trials are needed before it becomes a feasible alternative to surgery in patients at high risk of operative complications.

Results of trials with EUS-guided anti-tumor injection therapy have been disappointing. The lack of effective anti-tumor agents is a significant barrier to the development in this field.

EUS-guided brachytherapy and fiducial placement can be performed safely and easily. However, there is no available data to suggest clear survival benefit, although clinical benefit from pain relief has been noted in some studies.

The use of EUS-guided ablative therapies is still at an experimental stage. Further human trials are needed to determine its clinical benefit.

To summarize, EUS is an indispensable tool in pancreatic cancer not only for tissue diagnosis and disease staging but also for therapeutic purposes. Although some EUS-guided therapies have become widely accepted interventions for patients with pancreatic cancer, others have yet to evolve. Given the lack of effective systemic treatment for pancreatic cancer at present, further research in this field is warranted.

Abstract

AIM: To investigate factors related to recurrence following *en bloc* resection using endoscopic submucosal dissection (ESD) in patients with early gastric cancer (EGC).

METHODS: A total of 1121 patients (1215 lesions) who had undergone ESD for gastric neoplasia between April 2003 and May 2010 were retrospectively reviewed. Data from 401 patients (415 lesions) were analyzed, following the exclusion of those who underwent piecemeal resection, with deep resection margin invasion or lateral margin infiltration, and diagnosed with benign lesions.

RESULTS: Local recurrence after *en bloc* ESD was found in 36 cases (8.7%). Unclear resection margins, long procedure times, and narrow safety margins were identified as risk factors for recurrence. Lesions located in the upper third of the stomach showed a higher rate of recurrence than those located in the lower third of the stomach (OR = 2.9, $P = 0.03$). The probability of no recurrence for up to 24 mo was 79.9% in those with a safety resection margin ≤ 1 mm and 89.5% in those with a margin > 1 mm (log-rank test, $P = 0.03$).

CONCLUSION: Even in cases in which *en bloc* ESD is performed for EGC, local recurrence still occurs. To reduce local recurrences, more careful assessment will be needed prior to the implementation of ESD in cases

in which the tumor is located in the upper third of the stomach. In addition, clear identification of tumor boundaries as well as the securing of sufficient safety resection margins will be important.

Key words: Early gastric cancer; Endoscopic mucosal resection; Recurrence; *En bloc* resection; Endoscopic submucosal dissection

INTRODUCTION

As regular national gastric cancer screening *via* endoscopy is being implemented in South Korea with an increased interest in health, findings of early gastric cancer (EGC) and precancerous lesions are increasing rapidly^[1,2]. In addition, due to advances in the development of endoscopy-related tools and equipment and improvements in the procedural skills of doctors, performing endoscopic treatment for EGC is getting easier^[3]. As a result, existing endoscopic mucosal resection (EMR) has led to significant progress in endoscopic submucosal dissection (ESD), in terms of resection techniques, and regardless of the size of the lesions, *en bloc* resection has become possible^[4].

The classic EMR method is a simple procedure, but it has limitations in that the ratio of *en bloc* resection to complete resection decreases depending on the size of the lesion^[5,6]. In the contrast, the ESD method is a relatively complex procedure with a high level of difficulty, but it has a higher rate of *en bloc* resection than the EMR method, with the capacity to perform accurate post-resection pathological assessment, and it has recently become widely available as a treatment

for EGC^[5-8]. In endoscopic resection, accomplishing reconstruction of dissected tissues when the resection is performed in a piecemeal fashion and determining whether complete resection of the lesion has been achieved is difficult, and this results in higher rates of local recurrence. Therefore, *en bloc* resection is being suggested as the standard method of ESD as it increases the accuracy of pathological assessment of complete resection and lowers the rate of local recurrence^[9]. Incomplete resection procedures have been identified as an independent factor that increases the risk of local recurrence^[10], but although *en bloc* resection has been practiced, there have been very few studies on the risk factors associated with local recurrence after *en bloc* resection. To that end, the aim of the current study was to investigate factors related to local recurrence in patients with EGC who underwent *en bloc* resection *via* ESD.

MATERIALS AND METHODS

Study subjects

The medical records of 1121 patients (1215 lesions) who had undergone ESD for the treatment of gastric neoplasia between April 2003 and May 2010 at Keimyung University Dongsan Hospital (Daegu, South Korea) were retrospectively reviewed. Because we aimed to evaluate the risk factors for local recurrence after *en bloc* resection only and to analyze the risk factors depending on the safety resection margin, patients who underwent partial resection, with deep resection margin invasion or lateral margin infiltration, and diagnosed with benign lesions were excluded. Finally, data from 401 patients (415 lesions) were analyzed (Figure 1). Written informed consent was obtained from all patients. This study was approved by the Institutional Review Board of the Keimyung University Dongsan Medical Center, South Korea (DSMC 2015-10-047).

ESD methods

The ESD procedure was performed following a standard method. First the boundaries of the lesions were clarified using a solution of indigo carmine diluted to 10 times its volume, and the margins were marked with a 5 mm space from the boundaries of the lesions using an argon plasma laser connected to an ERBE VIO 300D electrosurgical unit (ERBE United States, Marietta, GA, United States). For submucosal injection, a solution was used consisting of hypertonic saline solution 100 mL, 1:1000 epinephrine 1 mL, and indigo carmine 1 mL. The incision knife was connected to the ERBE VIO 300D electrosurgical unit, a flex knife (Olympus, Tokyo, Japan) was used in mucosal incision, and the IT-2 knife (Olympus, Tokyo, Japan) was used for most submucosal dissection, but in some cases, a hook knife (Olympus, Tokyo, Japan) was used as well. Most procedures were carried out in Endocut I mode (Effect 2), and in some portions containing blood vessels, forced coagulation

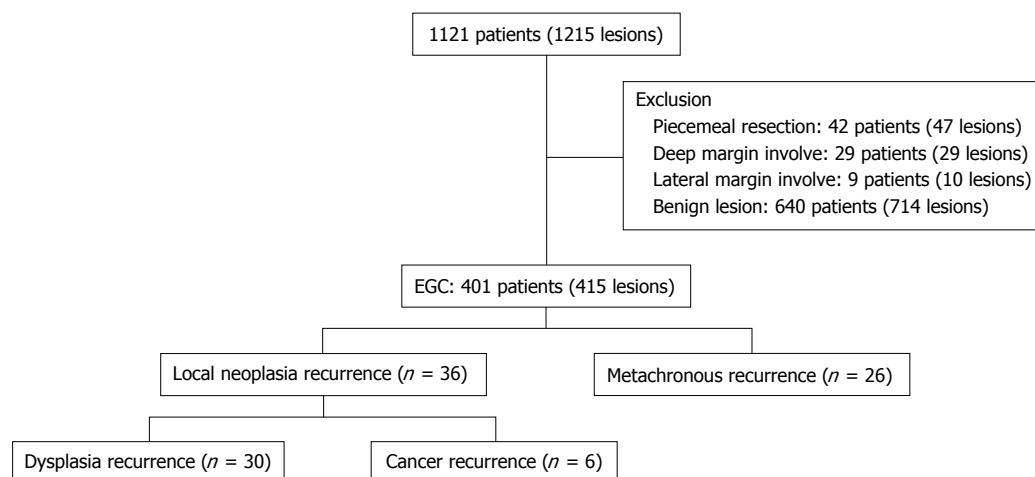

Figure 1 Flow chart of the patients. EGC: Early gastric cancer.

mode (Effect 1) was utilized.

Histopathological evaluation

For histopathological examination, resected specimens were sectioned perpendicularly at 2-mm intervals. The EGC location was classified into upper third, middle third, and lower third according to the location of the center point. The gross type of EGC was classified into type I (protruded type), type II (superficial type), and type III (excavated type) in accordance with the classification methods of the Japan Gastroenterological Endoscopy Society, and type II was subdivided again into type IIa (superficial elevated), type IIb (flat type), and type IIc (superficial depressed type)^[11]. In cases in which various shapes were mixed in one lesion, it was recorded as the mixed type. Based on the histological findings, tissues of the lesion were classified into differentiated type adenocarcinoma (well or moderately differentiated adenocarcinoma) and undifferentiated type adenocarcinoma (poorly differentiated or signet ring cell adenocarcinoma). Tumor involvement in the lateral and deep margins, lymphatic and vascular involvement, and the presence of submucosal invasion was assessed. In cases of submucosal infiltration, invasion depth was measured and quantified.

Evaluation of outcomes

The following clinical variables were investigated: Patient age, sex, gross tumor type, *en bloc* resection rate, location, size, histology, procedure time, safety margin, local neoplasia recurrence rate, and local cancer recurrence rate.

En bloc resection was defined as a resection in a single piece, whereas piecemeal resection was conducted in multiple pieces. Complete resection was defined as complete reconstruction of the lesion with negative deep and lateral margins with no lymphovascular involvement. The sizes of lesions were categorized into less than 20 mm, 21–30 mm, 31–40 mm, and over 40 mm. When malignant cells were found from the resection site within

3 mo after endoscopic removal of gastric carcinoma, the case was defined as incomplete resection, and when malignant cells or dysplastic cells (low grade, high grade) were found from the resection site during follow-up examinations after 3 mo, the case was defined as local recurrence of neoplasia. When only malignant cells were found from the resection site, the case was defined as local cancer recurrence. In addition, when neoplasia (dysplasia or malignant) was found from a site other than the resection site during follow-up observation, the case was defined as metachronous recurrence. Procedure time was defined as the time from the start of marking to complete removal of the tumor. Safety margins were defined as the distance between the lesion and the edges of the cuts around the resected specimen.

Follow-up observation

Patients were followed up with endoscopic examinations and biopsy at 3, 6, 12 and 24 mo after ESD. To detect local recurrence or metachronous cancer, biopsy was performed at the treatment-related scar in the case of any suspicious abnormalities. The cumulative neoplasia recurrence-free rate was estimated.

Statistical analysis

SPSS software version 18.0 for Windows (SPSS, Inc., Chicago, IL, United States) was used for statistical analysis. For comparison of continuous variables between two groups, the independent samples t-test was used, while for comparison of frequency variables, the χ^2 test was used through cross analysis. Continuous variables were presented as means \pm SD, and count variables were presented in the forms of frequency and percentage. Multivariate analysis was performed using binary logistic regression methods. Cumulative recurrence rates and recurrence times were calculated by the Kaplan-Meier method, and they were compared with each other using a log-rank test. A *P* value less than 0.05 was considered statistically significant. The statistical methods of this study were reviewed by Lee YJ and Lee YS.

Follow-up period, mo (mean ± SD)	19.7 ± 17.5

RESULTS

Characteristics of patients and lesions

The mean age of patients was 64.2 ± 9.8 years and 291 (70.1) patients were men. For the gross type of tumor, 146 (35.2%) cases were type II a and this was the most frequent type. Regarding the location of lesions, 271 (65.0%) patients had lesions in the lower third of the stomach, representing the highest frequency, followed by 129 (30.9%) patients with lesions in the mid-third of the stomach, and 15 (3.6%) patients with lesions in the upper third of stomach. Regarding the size of tumors removed by ESD, tumors ≤ 20 mm were found in 110 (28.0%) cases, tumors 21-30 mm were found in 77 (18.8%) cases, tumors 31-40 mm were found in 122 (29.4%) cases, and tumors over 40 mm were found in 100 (24.1%) cases. Histologically, well differentiated adenocarcinoma and moderately differentiated adenocarcinoma were observed in 195 (47.0%) and 180 (43.4%) cases, respectively, constituting ≥ 90%. The mean follow-up period for these patients was 19.7 mo (Table 1).

Comparison of the recurrence group and the non-recurrence group

Local neoplasia recurrence was observed in 36 (8.7%) cases, but there was no significant difference in age at the time of diagnosis, sex, tumor size, location, or degree of differentiation when compared to the non-

recurrence group (Table 2). However, there were many recurrences in cases in which tumors had ill-defined margins (33.3% vs 17.4%, $P = 0.02$), long procedure times (63.5 min vs 48.8 min, $P = 0.02$), and narrow safety resection margins (3.1 mm vs 4.2 mm, $P = 0.03$) (Table 2). The performance of multivariate analysis revealed that ill-defined tumor margin was the element factor that related to local neoplasia recurrence ($P = 0.03$) (Table 2).

Factors related to sufficient safety resection margins

When 1 mm was used as the reference value, 63 (15.2%) cases were found to have safety resection margins ≤ 1 mm. There was no difference in age at the time of diagnosis, sex, tumor size, location, or degree of differentiation between the two groups. Nevertheless, the group with safety resection margins ≤ 1 mm was found to have more lesions located in the upper third and mid-third of the stomach ($P < 0.0001$) and had longer operation times ($P = 0.04$) (Table 3). Multivariate analysis revealed that the patients with lesions located in the upper third of the stomach demonstrated more recurrences than those with lesions located in the lower third of the stomach (OR = 2.900, 95%CI: 1.110-7.579, $P = 0.03$) (Table 4). Designating 1 mm as the safety resection margin, there was no difference in recurrence of neoplasia, but there was more frequent recurrence of cancer ($P = 0.006$) (Table 5).

Follow-up observation and cumulative local recurrence rate

During the entire follow-up observation period, 6 cases (6/415, 1.4%) were observed of the recurrence of malignancy at the same site, and 26 cases (26/415, 6.3%) were observed of metachronous gastric carcinoma (Figure 1). In addition, the probability of no recurrence for up to 24 mo was 79.9% in those with safety resection margin ≤ 1 mm and 89.5% in those with margins that exceeded 1 mm, indicating that the local recurrence of neoplasia was observed more frequently in those with safety resection margins ≤ 1 mm, and the difference between the two groups was significant ($P = 0.03$) (Figure 2).

DISCUSSION

In cases of lesions larger than 20 mm, ESD offers far superior *en bloc* resection rates and very low local recurrence rates when compared with EMR^[12]. In general, the results of ESD for lesions larger than 20 mm have demonstrated an *en bloc* resection rate of over 90% with little local recurrence, while EMR has demonstrated very low *en bloc* resection rates of about 60% in cases of lesions sized about 10 mm and 14%-40% for lesions sized about 20-30 mm, and the local recurrence rate is about 10%^[13,14]. Regarding the *en bloc* resection rate, following the resection, determining complete resection with histological accuracy and thereby significantly reducing the occurrence of any situations that require

unnecessary additional treatment, re-treatment, or

surgical treatment due to local recurrence is possible. Due to these advantages, ESD is being used as a major treatment method for EGC.

The current study investigated the factors related to recurrence in patients with EGC who had undergone *en bloc* resection using ESD. Even in cases in which *en bloc* resection was performed, local recurrence of neoplasia was observed in 36 patients (8.7%). When a comparison was performed between the recurrence group and the non-recurrence group, the identified risk factors for recurrence included unclear resection margins, long procedure times, and narrow safety margins, whereas

Table 5 Neoplasia recurrence and cancer recurrence by safety margin 1 mm *n* (%)

	Safety margin ≤ 1 mm <i>n</i> = 63	Safety margin > 1 mm <i>n</i> = 352	<i>P</i> value

Cancer recurrence	4 (6.3)	2 (0.6)	0.006

Figure 2 Cumulative neoplasia recurrence free rate according to period after endoscopic submucosal dissection. The probability of no recurrence up to 24 mo was 79.9% in those with the safety resection margin ≤ 1 mm and 89.5% in those exceeded 1 mm.

among the factors related to sufficient safety resection margins, it was found that the location of the tumor was an important factor. In particular, tumor location in the upper third of stomach was identified as having the greatest association with recurrence.

The visual tumor boundaries and safety resection margins of tumors had been identified as the risk factors for local recurrence. The introduction of ESD has increased the rates of *en bloc* resection and complete resection, but incomplete resection, in which resection margins are found to be positive in the post-ESD pathological testing, remains problematic. This results in cases in which the degree of horizontal invasion at the lesion is not assessed accurately and there is a failure to secure sufficient safety resection margins prior to performing the procedure^[15-17]. In the current study as well, the group with visually unclear tumor margins showed a higher rate of post-ESD recurrences (33.3% vs 17.4%, $P = 0.03$), and more incidences of recurrent tumors were found among those with safety resection margins ≤ 1 mm. Thus, good visual observation of the boundaries of lesions and the securing of sufficient safety resection margins before performing the procedures would be helpful in reducing local recurrence. However, since it is better to attempt minimal incision in order to minimize the procedure time and complications, as possible, accurate diagnosis is required before performing ESD. There have been reports suggesting that in cases in which the boundaries of the tumor are unclear, a preoperative biopsy on the ambient area of the lesion could be useful^[18,19], and the horizontal degree of invasion of the tumor could be assessed *via* chromoendoscopy^[20]

or narrow-band imaging magnifying endoscopy^[21].

The most important factor that has effects on local recurrence following the implementation of EMR or ESD is whether complete resection is performed. Ono *et al.*^[22] reported that the rate of local recurrence was 2% in cases of complete resection, while in contrast, recurrence was found in 18% of 85 patients either who had incomplete resection or in whom it was impossible to make assessments. Isomoto *et al.*^[23] also reported that while only 0.2% of patients who underwent complete resection had experienced local recurrence, 10.3% of patients who had incomplete resection had been found to have local recurrence, indicating that the complete resection group had a statistically significant lower rate of local recurrence in comparison to the incomplete resection group. Takenaka *et al.*^[6] presented a study on factors affecting local recurrence following ESD. They reported no cases of local recurrence among lesions that had been completely resected, but patients who underwent incomplete resection had local recurrences. Statistical analysis had confirmed that incomplete resection and local recurrence had a very high level of correlation. The authors analyzed the factors that cause incomplete resection and identified tumor size ≥ 30 mm, tumor location in the mid-third or upper third, and any ulcer or ulcerative scar on the lesion as the risk factors that can cause incomplete resection. Imagawa *et al.*^[24] also reported that tumor location (upper third, 74% vs mid-third, 77% vs lower third, 91%, $P < 0.05$) and tumor size (> 20 mm, 59% vs < 20 mm, 89%, $P < 0.0001$) were important elements of complete resection. In our study, it was confirmed that the more lesions were located in the upper third, the more frequent local recurrences were. However, according to the results of our study, tumor size was identified as having no significant correlation with recurrence, and it was considered that the procedures were implemented after securing sufficient safety resection margins considering the risk of recurrence as the tumor sizes increased. The underlying causes of more frequent local recurrences when lesions are located in the upper third of the stomach are, first, when the tumor is located nearer to the upper third, the endoscopic approach becomes difficult, resulting in difficult setting of accurate boundaries; second, this region has unclear boundaries of the mucosa in many cases; and third, this area has a larger distribution of blood vessels than any other site, which causes frequent bleeding during the procedure^[25]. The use of side-view endoscopes or multi-bending endoscopes can offer easy access to these sites, which is very helpful in performing the procedures^[26].

A molecular pathological epidemiology approach, which analyzes tumor molecular pathology of resected tumors, can predict recurrence after ESD. Semba *et al.*^[27] reported that EGC demonstrating intestinal claudin-positive phenotype has a high risk of synchronous and metachronous gastric neoplasia. Hasuo *et al.*^[28] investigated the correlation between microsatellite instability (MSI) status and the incidence of metachronous recurrence after initial ESD. They demonstrated that patients with the MSI-type tumors showed a high incidence of metachronous recurrence within a 3-year observation period after initial ESD. These molecular approaches are expected to be of value for decisions regarding therapy and surveillance after ESD.

The advantage of the current study is that it was conducted in patients who underwent *en bloc* resection only, and those patients with deep and lateral resection margin invasion were excluded, so that we could analyze the risk factors depending on the safety resection margins. However, the study also has limitations in that the follow-up periods were different, as it was a retrospective study, and there were differences in the number of biopsies during the follow-up endoscopy.

In conclusion, even in cases in which *en bloc* resection using ESD is performed for EGC, local recurrence occurs. In terms of risk factors related to local recurrence, tumor location and the visual boundaries of the tumor are important. In order to reduce post-ESD local recurrences, more careful assessment will be needed prior to the implementation of ESD in cases in which the tumor is located in the upper third of the stomach. In addition, clear identification of tumor boundaries as well as the securing of sufficient safety resection margins will be important.

COMMENTS

Background

En bloc resection is suggested as the standard method of endoscopic submucosal dissection (ESD) as it increases the accuracy of pathological assessment of complete resection and lowers the ratio of local recurrence. However, although *en bloc* resection has been practiced, there are few studies regarding the risk factors associated with local recurrence after *en bloc* resection.

Research frontiers

The authors aimed to investigate factors related to recurrence in patients who had undergone *en bloc* resection using ESD for early gastric cancer (EGC).

Innovations and breakthroughs

Unclear resection margins, long procedure times, and narrow safety margins were identified as risk factors for recurrence lesions located in the upper third of the stomach demonstrated more recurrences than those located in the lower third of the stomach.

Applications

Even in cases in which *en bloc* resection for ESD is performed, local recurrence occurs. Regarding risk factors related to local recurrence, tumor location and the visual boundaries of the tumor are important. In order to reduce post-ESD local recurrences, more careful assessment will be needed prior to the implementation of ESD in cases in which the tumor is located in the upper third of the stomach. In addition, clear identification of tumor boundaries as well as

the securing of sufficient safety resection margins will be important as well.

Terminology

EGC is defined as malignant tumor confined to the mucosa or the submucosa regardless of lymph node metastases. ESD is an endoscopic technique for the treatment of early gastrointestinal neoplasms allowing direct dissection of the submucosal layer of the lesion with *en bloc* resection.

Peer-review

This is a large retrospective study on risk factor for local recurrence after ESD of early gastric cancer. The topic is important and interesting.

Abstract

AIM: To evaluate if differences exist between self-expanding esophageal metal stents (SEMS) and self-expanding esophageal plastic stents (SEPS) when used for benign or malignant esophageal disorders with regard to safety, efficacy, clinical outcomes, placement ease and cost.

METHODS: A retrospective analysis was performed to evaluate outcome in patients having SEPS/SEMS placed for malignant or benign esophageal conditions from January 2005 to April 2012. Inclusion criteria was completed SEMS/SEPS placement. Outcomes assessed included technical success of and time required for stent placement, procedure-related complications, need for repeat intervention, hospital stay, mortality and costs.

RESULTS: Forty-three patients underwent stent placement for either benign/malignant esophageal

disease during the study period. Thirty patients had SEMS (25 male, mean age 59.6 years old) and 13 patients had SEPS (10 male, mean age 61.7 years old). Placement outcome as well as complication rate (SEPS 23.1%, SEMS 25.2%) and in-hospital mortality (SEPS 7.7%, SEMS 6.7%) after placement did not differ between stent types. Migration was the most frequent complication reported occurring equally between types (SEPS 66.7%, SEMS 57.1%). SEPS was less costly than SEMS, decreasing institutional cost by \$255/stent.

CONCLUSION: SEPS and SEMS have similar outcomes when used for benign or malignant esophageal conditions. However, SEPS use results in decreased costs without impacting care.

Core tip: Self-expanding esophageal metal stents (SEMS) are preferable to self-expanding esophageal plastic stents (SEPS) for treatment of malignant or benign esophageal conditions, due to decreased technical difficulties. Comparative studies between stent types evaluating differences between SEMS and SEPS for these conditions with regard to safety, efficacy, clinical outcomes, placement ease and cost are lacking. Retrospective analysis indicated placement outcome, complication rate, most frequent complication and in-hospital mortality after placement was equivalent between stent types. SEPS was less costly than SEMS. SEPS and SEMS have similar outcomes when used for malignant/benign esophageal conditions but SEPS results in decreased costs without impacting care.

McGaw C, Alkaddour A, Vega KJ, Munoz JC. Stent type used does not impact complication rate or placement time but can decrease treatment cost for benign and malignant esophageal lesions. *World J Gastrointest Endosc* 2016; 8(7): 338-343 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i7/338.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i7.338>

INTRODUCTION

Placement of an esophageal stent is a minimally invasive procedure regularly used in both malignant and benign disease. Since the initial description in 1976, treatment using esophageal stents has advanced into a commonly accepted therapeutic technique for malignant esophageal strictures, fistulas and other complications^[1-3]. The aim of esophageal stenting is to restore luminal patency and thereby nutritional intake, improving patient quality of life^[2,4,5]. In addition, esophageal stent use has expanded to various inoperable malignancies localized in the esophagus, gastroesophageal

junction and cardia as well as benign conditions including benign refractory strictures, anastomotic leaks, perforations, and trachea-esophageal fistulas^[2-7].

Presently, the two most common types of self-expandable esophageal stents are the self-expandable esophageal plastic stent (SEPS), made from durable polymers and multiple self-expandable esophageal metal stent (SEMS), made from metal alloy compounds (Table 1)^[3,7]. SEMS are considered preferable to SEPS for treatment of malignant or benign esophageal conditions, due to decreased technical difficulties at or following placement^[8,9]. However, comparative studies of between stent types used for either benign or malignant esophageal conditions are limited with inconsistent results reported regarding technical outcome and migration^[10-12]. The aim of the present investigation was to evaluate if differences exist between SEMS and SEPS placed for benign or malignant esophageal disorders with regard to safety, efficacy, clinical outcomes, placement ease and cost.

MATERIALS AND METHODS

A retrospective analysis was performed at the University of Florida Health Science Center-Jacksonville to evaluate the outcomes of patients undergoing endoscopic SEPS placement compared to endoscopic SEMS placement for malignant or benign esophageal conditions. Inclusion criteria were the following: Endoscopic esophageal stent placement between January 1, 2005 to April 30, 2012, presence of adenocarcinoma or squamous cell carcinoma of the esophagus, recurrent fistula caused by malignant tumor, benign esophageal strictures, and esophageal perforation or leak. Exclusion criteria were tumor above 2 cm from the upper esophageal sphincter. Clinical data obtained and assessed included technical success of stent placement, procedure-related complications, need for subsequent re-intervention, hospital stay, and mortality. Demographic and clinical data were collected from the local electronic medical record. Stent type selected for use was based on endoscopist and referring physician preference. Stent length was determined according to the size and localization of the tumor. All endoscopic treatments occurred under conscious sedation, monitored anesthesia, or general anesthesia. Initial evaluation occurred using standard esophagogastroduodenoscopy (EGD). If dilation was required, this was performed by means of fluoroscopic guidance prior to stent placement. Proximal and distal ends of the lesion to be stented was determined during EGD and hemoclips were used as markers to delineate both ends. A 0.35 mm tracer metro direct wire or Savary guide wire was used to assist placement. All stents used in the present investigation were from Boston Scientific, Marlborough, MA. The SEMS used was WallFlex fully covered with an institutional cost of \$2650 and patient insurance cost of \$4500. The SEPS used was Polyflex with an institutional cost of \$2395 and patient insurance cost of \$4090. All SEMS were placed under dual vision (fluoroscopy and endoscopy) while

Table 2 Overall demographics in patients having self-expanding esophageal metal stents/self-expanding esophageal plastic stents placed for malignant or benign esophageal conditions from January 2005 to April 2012

	Overall (<i>n</i> = 43)	nHw (<i>n</i> = 25)	AA (<i>n</i> = 15)	Other (<i>n</i> = 3)
Mean age (yr)	60.2	57.7	60.4	80 ¹
% male	85.1	80	80	100

¹Compared to nHw ($P < 0.01$) and AA ($P < 0.03$). nHw: Non-Hispanic White; AA: African American.

SEPS were placed under fluoroscopy vision only due to the delivery system. Appropriate placement of the SEPS was confirmed by direct visualization using EGD to verify positioning. A contrast esophagogram was performed postoperatively at the discretion of the endoscopist. This study was approved by the University of Florida Health Science Center-Jacksonville Institutional Review Board.

Statistical analysis

Continuous data were described as mean \pm SD and compared using two sided student *t* tests. Categorical data were presented as numbers or percentages and analyzed using appropriate χ^2 testing. Results were analyzed in relation to stent type placed (SEMS or SEPS). A *P* value of less than 0.05 was considered statistically significant. Data analysis was performed using the GraphPad Prism statistical analysis program (Kenneth J Vega, version 6, La Jolla, CA).

RESULTS

Patient characteristics

Forty-three patients underwent stent placement for either benign (8 patients) or malignant (35 patients) esophageal disease during the study period. Patients

with benign esophageal disease had the following diagnosis: 3 with esophageal fistulas, 2 with extrinsic compression and 1 each with esophageal stricture, perforation or iatrogenic tear. Of the 35 patients with malignant esophageal disease, 14 patients had squamous cell carcinoma, 16 patients had adenocarcinoma and 5 patients had mixed malignant histology. Mean patient age of the overall group was 60.2 years (SD 13.5 years) and 81.4% were male (Table 2). Ethnicity was distributed as follows, 25 non-Hispanic Whites (nHw), 15 African Americans (AA) and 3 from other groups (2 Asian Americans and 1 Hispanic American). Compared to both nHw and AA, the other group was older [80 (other) vs 57.7 (nHw), $P < 0.01$ or 60.4 (AA) years, $P < 0.03$]. No significant difference was seen in the number of males in each ethnic group.

Stent groups

SEMS were placed in 30 patients and SEPS used in 13 patients. Patient characteristics of both stent groups are seen in Table 3. Mean age, percentage of male patients and ethnic distribution was equivalent in the SEMS and SEPS groups (Table 3). Both stent groups also were similar with regard to esophageal lesion location, percentage of malignant esophageal lesions and comorbid diseases (Table 3).

Stent placement, outcome and cost

Successful stent placement occurred in all SEMS and SEPS patients. No patient in either stent group required more than 1 stent initially. Table 4 illustrates placement and outcome comparisons between SEMS and SEPS. Dilation was more frequent in the SEPS group compared to SEMS ($P = 0.023$). No significant difference was seen between stent groups in initial placement time, complication rate, time to first complication, in hospital mortality, repeat intervention required frequency, length

Table 3 Patient characteristics based on stent type placed

	SEMS (<i>n</i> = 30)	SEPS (<i>n</i> = 13)	<i>P</i> value

SEMS: Self-expanding esophageal metal stents; SEPS: Self-expanding esophageal plastic stents.

of stay and 30 d survival (Table 4). Stent migration was the most frequent complication, occurring in 4 SEMS and 2 SEPS patients. Interestingly, SEMS resulted in increased costs than SEPS with an average cost savings of \$255-410 for each SEPS used instead of SEMS for hospital and patient insurance cost, respectively.

DISCUSSION

SEMS are considered preferable to SEPS for treatment of malignant or benign esophageal conditions, due to decreased technical difficulties^[8,9]. However, comparative studies between stent types are limited^[10-12]. The present study was designed to assess whether if differences exist between SEMS and SEPS use for benign or malignant esophageal disorders with regard to safety, efficacy, clinical outcomes, placement ease and cost. The results indicate SEPS and SEMS are equivalent when used for benign or malignant esophageal conditions with regard to initial placement time, complication frequency, time to initial complication, in-hospital mortality, repeat intervention need, 30 d post procedure survival and length of hospital stay. In addition, SEPS use results in decreased costs without impacting care for either benign or malignant esophageal conditions.

The current investigation is the first to compare use of SEMS and SEPS on a combined population of benign and malignant conditions of the esophagus. All stents were placed successfully which is consistent with previous literature evaluating stent placement in exclusive subsets of either benign or malignant esophageal disease (98%-100%)^[10-12]. Comparison of procedure time required for initial SEMS and SEPS placement was only performed by 1 group previously^[10]. Conio *et al*^[10] found initial SEPS placement was significantly longer than SEMS by a median of 12 min. However, no difference was seen between mean initial placement procedure time based on stent type in the present study. Moreover, no significant difference was present regarding lesion type stented in the SEMS and SEPS groups removing a potential confounder for initial placement time and suggesting equivalent placement ease in all cases in spite of different delivery systems used.

Complication rates following SEMS and SEPS were equal in both stent groups. Interestingly, the rate observed (23% for both SEMS and SEPS) was less than the reported in the literature (46%-48%)^[10-12]. The main complication seen was stent migration in both stent groups which is consistent with the majority of studies

evaluating stent type for either benign or malignant esophageal lesions^[11,12]. However, no difference was seen between SEMs and SEPS in frequency of migration. Of note, earlier data has been inconclusive with regard to migration rates with one study suggesting fully covered stents (either metal or plastic) are more likely to migrate while another indicated SEPS migrated more frequently^[10,12]. Only one patient had recurrent dysphagia following stent placement (received SEMs) which was treated conservatively. Furthermore, no difference was observed in re-intervention requirement, in-hospital mortality, length of initial hospital stay and 30 d survival between SEMs and SEPS groups.

Health care costs remain a significant concern in the United States in spite of the Affordable Care Act of 2010^[13]. In addition, placement of esophageal stents decrease costs for both benign and malignant esophageal conditions^[14]. The present study indicated that if using SEPS in contrast to SEMs for either benign or malignant conditions reduced cost between \$255-410 per SEPS used. Moreover, as outcome was not affected by stent type used in our investigation, significant cost savings could be achieved with SEPS use only for esophageal conditions requiring endoscopic intervention.

Of note, a third, less commonly used self-expandable esophageal stent, the biodegradable (BD) - stent, has been developed as an alternative to SEPS. Currently available BD stent designs are the ELLA-BD stent (ELLA-CS, Hradec Kralove, Czech Republic), which is composed of polydioxanone, a surgical suture material and the poly-L-lactic acid (PLLA)-BD stent (Marui Textile Machinery, Osaka, Japan), which consists of knitted PLLA monofilament. These stents can be degraded by hydrolysis, which is accelerated at low ambient pH. Generally, BD stents begin to degrade after 4 to 5 wk following placement and dissolve completely after a period of 2 to 3 mo. The major strength of BD stent over SEMs or SEPS is that it does not require removal, even after migration, as it is dissolved by gastric acid, thus avoiding further procedures and potential morbidity^[15].

We are aware of the limitations of the present investigation. The primary limitation is the retrospective design. In addition, our study had a small sample size for SEPS patients. Nevertheless, the majority of previously published studies have included small samples of SEPS patients as well. Furthermore, classification of stents used according to degree covered (fully or partially) may have had an impact in the results but given the small number of subjects, this was not performed. Finally, selection bias could have impacted the results observed as stent type selected for insertion was dependent on the endoscopist performing the procedure.

In conclusion, SEPS should be considered as a treatment option for any esophageal indication, benign or malignant, with no increase in complications and equivalent efficacy to SEMs. In addition, SEPS use appears cost effective for management of esophageal lesions requiring restoration of luminal patency compared to SEMs. Performance of prospective clinical trials

comparing SEMs and SEPS should be implemented to validate these findings. Furthermore, investigations comparing esophageal stents should occur and include biodegradable stents as well as longitudinal evaluations of biodegradable stents with an increased *in vivo* half-life, to assess longer term stent patency, mitigate stent-related complications, and whether the need for repeat interventions is required.

COMMENTS

Background

Self-expanding esophageal metal stents (SEMS) are preferable to self-expanding esophageal plastic stents (SEPS) for treatment of malignant or benign esophageal conditions, due to decreased technical difficulties. Comparative studies between stent types evaluating differences between SEMs and SEPS for these conditions with regard to safety, efficacy, clinical outcomes, placement ease and cost are lacking.

Research frontiers

To evaluate if differences exist between SEMs and SEPS placed for benign or malignant esophageal disorders with regard to safety, efficacy, clinical outcomes, placement ease and cost.

Innovations and breakthroughs

Stent placement outcome, complication rate, most frequent complication and in-hospital mortality after placement was equivalent between stent types. SEPS was less costly than SEMs. SEPS and SEMs have similar outcomes when used for malignant/benign esophageal conditions but SEPS results in decreased costs without impacting care.

Applications

SEPS should be considered as a treatment option for any esophageal indication, benign or malignant, with no increase in complications and equivalent efficacy to SEMs. In addition, SEPS use appears cost effective for management of esophageal lesions requiring restoration of luminal patency compared to SEMs.

Terminology

SEPS are made from durable polymers and SEMs are made from metal alloy compounds.

Peer-review

Both SEMs and SEPS are considered useful for treatment of malignant or benign esophageal conditions. However, few comparative studies between stent types have been reported. The study compared the safety, efficacy, clinical outcomes, placement ease and cost between SEMs and SEPS for benign or malignant esophageal disorders and found SEPS is cheaper. This may be helpful for clinical doctors in choosing stent types.

Abstract

AIM: To assess the clinical impact of capsule endoscopy (CE) in the long-term follow-up period in patients with obscure gastrointestinal bleeding (OGIB).

METHODS: One hundred and forty-one patients who applied CE for OGIB between 2009 and 2012 were retrospectively analyzed, and this cohort was then questioned prospectively. Demographic data of the patients were determined *via* the presence of comorbid diseases, use of non-steroidal anti-inflammatory drugs anticoagulant-antiaggregant agents, previous diagnostic tests for bleeding episodes, CE findings, laboratory tests and outcomes.

RESULTS: CE was performed on 141 patients because

of OGIB. The capsule was retained in the upper gastrointestinal (GI) system in two of the patients, thus video monitoring was not achieved. There were 139 patients [62% male, median age: 72 years (range: 13-93 years) and a median follow-up duration: 32 mo (range: 6-82 mo)]. The overall diagnostic yield of CE was 84.9%. Rebleeding was determined in 40.3% (56/139) of the patients. The rebleeding rates of patients with positive and negative capsule results at the end of the follow-up were 46.6% (55/118) and 4.8% (1/21), respectively. In the multivariate analysis, usage of NSAIDs, anticoagulant-antiaggregant therapies (OR = 5.8; 95%CI: 1.86-18.27) and vascular ectasia (OR = 6.02; 95%CI: 2.568-14.146) in CE were detected as independent predictors of rebleeding. In the univariate analysis, advanced age, comorbidity, and overt bleeding were detected as predictors of rebleeding.

CONCLUSION: CE is a reliable method in the diagnosis of obscure GI bleeding. Negative CE correlated with a significantly lower rebleeding risk in the long-term follow-up period.

Core tip: This study determines the results of using capsule endoscopy in obscure gastrointestinal bleeding in long-term. Our main aim was to describe the long-term clinical impact of capsule endoscopy during follow-up period. Positive capsule endoscopy results correlated with higher rebleeding rates. Independent predictors of rebleeding were detected to be usage of non-steroidal anti-inflammatory drugs, anticoagulant/antiaggregant therapy and vascular ectasia.

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) is a frequent problem in the daily gastroenterology practice that represents nearly 5% of all gastrointestinal (GI) hemorrhages^[1-3]. The most extensive location of OGIB is small bowel, where it is usually far beyond the range of a standard endoscopic examination. Therefore, capsule endoscopy (CE) is the preferred technique to assess patients with OGIB^[4-6]. The high specificity and sensitivity of CE in OGIB cases and increased diagnostic value of this method was shown in several previously published

studies. Even though diagnostic value of CE is the focus point of most studies, in the literature there is not enough data about the long-term results of using CE and its effectiveness in predicting and assessment of rebleeding risks. In this study, our main aim was to determine the long-term clinical impact of capsule endoscopy during follow-up period.

MATERIALS AND METHODS

Patients

The data obtained from the patients presented to gastroenterology department and referred to endoscopy unit with OGIB from January 2009 to December 2012 was analyzed in a retrospective design. This cohort was then questioned prospectively.

Before the CE procedure, all of the patients were applied colonoscopy and upper GI endoscopy (GIE) in our endoscopy unit. The collected data from the patients included their demographics, previous intake of anticoagulant/antiaggregant therapy, non-steroidal anti-inflammatory drugs (NSAIDs), present comorbidities, their previous diagnostic test results [upper GIE, colonoscopy, radiological studies of small bowel, computerized tomography (CT) imaging], CE findings and follow-up data.

Before the CE procedure, the passage opening was evaluated using CT. CE was not undertaken in patients who had strictures or obstructions.

The study was done after the patients were informed about this study and the patients' written informed consents were taken according to Helsinki Declaration. The study was obtained from local ethics committee.

CE procedure

CE procedures were performed on an outpatient basis without hospitalization. Pillcam SB2 (Given Imaging, Yoqneam, Israel) was used for the procedure. Patients' bowel preparation was done using 4 L polyethylene glycol solution one day before the procedure. The patients swallowed the capsules (Pillcam SB2) in the outpatient clinic. Fluid intake was permitted 2 h and eating was allowed 4 h after the initial administration of capsules. Patients were instructed to check their stool for the ejection of capsule and to notify the endoscopy unit if it was not ejected. Failure of the capsule ejection in more than 2 wk was defined as capsule retention in the GI tract. One gastroenterologist (F-A) with extensive experience in small bowel endoscopy evaluated the recorded CE images.

Follow-up

Charts were used to gather full follow-up information including OGIB recurrence and CE complications. Each patient was called and reevaluated for the follow-up results. The period between the initial CE and last recorded follow-up appointment was defined as follow-up period. Overt bleeding or the decrease in Hb levels >

CE: Capsule endoscopy.

2 g/dL were considered as "rebleeding".

Statistical analysis

Statistical analysis was performed using Number Cruncher Statistical System 2007 with Power Analysis and Sample Size 2008 statistical software. The data was analyzed by definitive methods (mean, standard deviation, median, minimum, maximum, frequency, ratio,) together with Pearson's χ^2 test, Fisher-Freeman-Halton test, Yates's Continuity Correction test. In the determination of multivariate effects of the variables on rebleeding, Stepwise logistic regression analysis was used. Significance levels were determined as $P < 0.01$ and $P < 0.05$.

RESULTS

CE was performed on 141 patients with OGIB. The capsule was retained in the upper GI tract in two patients thus video monitoring was not achieved. The first patient was diagnosed as having achalasia after CE, and the second had gastric diabetic gastroparesis by further investigation. A total of 139 patients (62% male) who applied CE had available follow-up data. Median age of patients was 72 years (13-93) and median follow-up duration was 32 mo (6-82 mo). In 112 of the 139 (80.6%) patients, capsule transit time to caecum was within the recording time. Spontaneous elimination of the capsule within 2 wk was seen in 133 (95.4%) patients. Capsule retention was found in 6 patients (4.6%). The overt obscure bleeding rate was 61.9% ($n = 86$), whereas the rate for occult obscure bleeding was 38.1% ($n = 53$). Comorbidities were detected in 35.5% ($n = 50$) of the patients. NSAIDs, anticoagulant-antiaggregant drugs were used at a rate of 18.9% ($n = 26$). CE was positive in 118 (84.9%) patients (Table 1).

Long-term outcome of CE

Rebleeding was seen in 40.3% of the patients (26.4% occult and 48.8% overt bleeding, $P = 0.015$). The rebleeding rate was 46.6% (55/118) in patients with positive CE

Table 2 Evaluation of rebleeding according to the demographic data n (%)

OGIB: Obscure gastrointestinal bleeding; NSAIDs: Non-steroidal anti-inflammatory drugs.

and 4.8% (1/21) with negative CE results at the end of follow-up period. Evaluation of rebleeding in relation with the demographic data is shown in Table 2. Both univariate and multivariate analyses were performed to find out the factors related with a higher risk of rebleeding. When we evaluated the effects of comorbidity, age, overt presentation, NSAIDs-anticoagulant-antiaggregant therapy and vascular lesion on rebleeding by stepwise logistic regression analysis, the OR for the effect of NSAIDs-anticoagulant-antiaggregant therapy on rebleeding was 5.8 (95%CI: 1.86-18.27), and 6.027 (95%CI: 2.56-14.14) for vascular lesions. Although, OR was 2.274 (95%CI: 0.86-5.98) for comorbidities, it was not statistically significant. The association analysis is detailed in Table 3. One patient who had diverticulosis coli and negative CE died because of bleeding at 46 mo. The specificity of the CE was found to be 95.2% and positive predictive value was 98.2% in the prediction of rebleeding. Treatment was applied to 29 patients (51.7%): Surgery ($n = 4$), argon plasma coagulation ($n = 11$), transcatheter aortic valve implantation (TAVI) (the reason of the bleeding was aortic stenosis so to treat that TAVI procedure was applied) ($n = 2$), hormonal therapy ($n = 2$), reason based treatment (NSAIDs, anticoagulant, antiplatelet, antiaggregant drugs withdrawal) ($n = 10$). Seven patients died at the end of the follow-up and six of them died because of a rebleeding episode.

DISCUSSION

For the diagnosis of OGIB, capsule endoscopy is a useful imaging technique. Therefore, it is accepted as a gold standard method and should be the first step in the management of patients with OGIB^[7]. The number of studies about the results of CE in long-term is limited^[8-10]. In this study, we assessed the impact of CE in the long-term period (median: 32 mo) in patients with OGIB. The diagnostic yield of CE was 84.9%. Rebleeding was determined in 40.3% (56/139) in patients with OGIB. Specificity of CE was 95.2% and positive predictive value for rebleeding was 98.2%. CE: Capsule endoscopy.

literature reported lower bleeding ratios in patients with negative CE results in comparison with positive^[11-13]. Delvaux *et al*^[14]'s study on 44 patients in one-year follow-up period reported that the negative predictive values was 100% in patients with negative CE and the positive predictive values of CE were 94.4% in patients with positive CE results. Arakawa *et al*^[15] also reported that none of their patients who had a normal CE had rebleeding. As compatible with the literature, only one patient has a rebleed who had a normal CE in our group. The follow-up time is important for patients who have negative CE. In our study, the mean follow-up duration for patients was 46 ± 21 mo (range: 6-82 mo). The rebleeding rate is variable in the literature (0%-36%, Table 4)^[11-14,16-18]. However, the main restriction of these studies is the small group of patients and their relatively short follow-up periods. Rahmi *et al*^[19] showed that overt OGIB at presentation was a risk factor for rebleeding. We also found that the rebleeding ratio was higher in overt obscure bleeding when compared with occult obscure bleeding (48.8% vs 26.4%, $P = 0.015$). Vascular lesions were more susceptible to rebleeding when it was compared with the others (72.1% vs 27.9%, $P = 0.001$). These results also confirm the results of previous studies^[20,21]. In present study, NSAIDs-anticoagulant-antiagregant therapy (OR = 5.8; 95%CI: 1.86-18.27) and vascular ectasia (OR= 6.02; 95%CI: 2.568-14.146) were detected as an independent risk factors for rebleeding in the multivariate analysis. In univariate analysis; advanced age, comorbidity, overt bleeding, were also detected as a predictors of rebleeding. Therefore, anticoagulant/antiagregant/NSAIDs users, and vascular lesions in CE should be follow-up carefully because of the high rebleeding rate. Our long-term follow-up results

were compatible with the short-term follow-up results in the literature^[20-23].

In conclusion, CE is a reliable method in the diagnosis of obscure GI bleeding. Negative CE correlated with a significantly lower rebleeding risk in the long-term follow-up period.

COMMENTS

Background

Obscure gastrointestinal bleeding (OGIB) is a frequent problem in the daily gastroenterology practice that represents nearly 5% of all gastrointestinal (GI) hemorrhages. The most extensive location of OGIB is small bowel, where it is usually far beyond the range of a standard endoscopic examination. Therefore, capsule endoscopy (CE) is the preferred technique to assess patients with OGIB. The high specificity and sensitivity of CE in OGIB cases and increased diagnostic value of this method was shown in several previously published studies. Even though diagnostic value of CE is the focus point of most studies, in the literature there is not enough data about the long-term results of using CE and its effectiveness in predicting and assessment of rebleeding risks.

Research frontiers

Diagnosis of OGIB is mostly dependent on CE. However, there is not enough data about the long-term outcomes of patients with OGIB who applied CE.

Innovations and breakthroughs

The authors evaluated 139 patients with OGIB diagnosed by CE in a long-term follow-up study. Several risk factors for rebleeding were detected. Negative CE correlated with a significantly lower rebleeding rate.

Applications

CE is a safe, well-tolerated and powerful diagnostic tool which may also provide prognostic implications.

Terminology

OGIB usually originates from small bowel and is not detected by both

esophagogastroduodenoscopy and colonoscopy. CE is a device with a tiny camera. Following the administration of the capsule, the camera within the capsule can obtain pictures of GI tract and gut as it passes through the GI system of the patient. The images obtained are transferred into an external disk using wireless technology and those images are later reviewed by the gastroenterologist.

Peer-review

It is an important novel study on CE for diagnosis of obscure GI bleeding and rebleeding rates on long term basis.

Abstract

AIM: To evaluate the risk factors for postoperative bleeding after gastric endoscopic submucosal dissection (ESD) based on the latest guidelines.

METHODS: A total of 262 gastric neoplasms were treated by ESD at our center during a 2-year period from October 2012. We analyzed the data of these cases retrospectively to identify the risk factors for post-ESD bleeding.

RESULTS: Of the 48 (18.3%) cases on antithrombotic treatment, 10 were still receiving antiplatelet drugs perioperatively, 13 were on heparin replacement after oral anticoagulant withdrawal, and the antithrombotic therapy was discontinued perioperatively in 25 cases. Postoperative bleeding occurred in 23 cases (8.8%). The postoperative bleeding rate in the heparin replacement group was 61.5%, significantly higher than that in the non-antithrombotic therapy group (6.1%). Univariate analysis identified history of antithrombotic drug use, heparin replacement, hemodialysis, cardiovascular disease, diabetes mellitus, elevated prothrombin time-international normalized ratio, and low hemoglobin level on admission as risk factors for post ESD bleeding. Multivariate analysis identified only heparin replacement (OR = 13.7, 95%CI: 1.2-151.3, $P = 0.0329$) as a significant risk factor for post-ESD bleeding.

CONCLUSION: Continued administration of antiplatelet agents, based on the guidelines, was not a risk factor for postoperative bleeding after gastric ESD; however, heparin replacement, which is recommended after withdrawal of oral anticoagulants, was identified as a significant risk factor.

Key words: Postoperative bleeding; Antithrombotic treatment; Gastric neoplasms; Endoscopic submucosal dissection

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: There are few data on the risk factors for postoperative bleeding after gastric endoscopic submucosal dissection (ESD) in patients continued on antithrombotic treatment during the perioperative period. This study was aimed to evaluate the risk factors for postoperative bleeding after gastric ESD in patients continued or not continued on antithrombotic treatment. Univariate analysis showed that an antithrombotic agent user, especially heparin replacement was significantly associated with risk factors for postoperative bleeding. Multivariate analysis identified heparin replacement as the independent risk factor for post ESD bleeding. Therefore, patients with heparin replacement should be carefully observed after gastric ESD.

Shindo Y, Matsumoto S, Miyatani H, Yoshida Y, Mashima H. Risk factors for postoperative bleeding after gastric endoscopic submucosal dissection in patients under antithrombotics. *World J Gastrointest Endosc* 2016; 8(7): 349-356 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i7/349.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i7.349>

INTRODUCTION

Early gastric cancer is defined as a tumor confined to the mucosa or submucosa, irrespective of the presence/absence of lymph node metastasis^[1]. Endoscopic submucosal dissection (ESD) is a widely used procedure now for early gastric cancers and gastric adenomas^[2,3]. The major complications of this procedure are perforation and postoperative bleeding. Postoperative bleeding after gastric ESD is reported to occur in 4.8%-9.4% of patients not receiving antithrombotic agents/patients in whom these drugs are discontinued during the perioperative period^[4-9]. While several factors (large resected tumor size^[6,8], advanced age of the patient, long procedure time^[10,11], patient under dialysis, and ulcerative lesions^[12,13]) have been suggested as risk factors for postoperative bleeding after gastric ESD, no consensus has been reached yet with regard to the precise risk factors for postoperative bleeding after gastric ESD.

Recently, the incidence of gastric cancer has been increasing, owing to the increasing lifespan of the general population^[14]. The number of patients suffering

from gastric cancer and taking antithrombotic agents is also growing as a result of the increasing prevalence of ischemic heart disease, cerebrovascular disease, and other arteriosclerotic diseases. The previous guidelines published by the Japan Gastroenterological Endoscopy Society (JGES) focused primarily on the prevention of hemorrhage after gastrointestinal endoscopy associated with continuation of antithrombotic therapy in the perioperative period, without considering the risk of thrombosis associated with withdrawal of the therapy^[15]. The new edition of the JGES guidelines for gastroenterological endoscopy in patients undergoing antithrombotic treatment was published in July 2012. The new guidelines include discussions of the risk of gastroenterological hemorrhage associated with continuation of antithrombotic therapy, as well as of the risk of thromboembolism associated with discontinuation of antithrombotic therapy^[16]. There are few data on the risk factors for postoperative bleeding after gastric ESD in patients continued on antithrombotic treatment during the perioperative period.

We have been performing ESD for gastric neoplasms based on the new guidelines since October 2012. This study was aimed at evaluating the risk factors for postoperative bleeding after gastric ESD in patients continued or not continued on antithrombotic treatment.

MATERIALS AND METHODS

Patients

The subjects were 283 cases who underwent ESD for gastric neoplasms at Saitama Medical Center from October 2012 to September 2014. Of these cases, 21 cases were excluded from this retrospective study for the following reasons: Multiple lesions were removed on the same day (19 cases), and the procedure could not be completed (2 cases).

Patient characteristics

We retrospectively reviewed the patient's medical records and collected the following data: Age, sex, hemoglobin level, prothrombin time-international normalized ratio (PT-INR), comorbidities (hypertension, diabetes mellitus, cardiovascular disease, hemodialysis, or liver cirrhosis), the Charlson comorbidity index^[17,18], and details about any antithrombotic therapy. Patients taking antithrombotic agents were classified into three groups based on the guidelines: A group in which the antithrombotic therapy was discontinued, a group in which antiplatelet drug therapy was continued (including replacement of thienopyridine with aspirin or cilostazol)^[16], and a group in which oral anticoagulant treatment was replaced by heparin. We used continuous infusion of unfractionated heparin for heparin replacement. The start dose of unfractionated heparin was 10000 to 15000 units. Check activated partial thromboplastin time during continuous infusion; adjust to target of 1.5 to 2 times the upper limit of control. We stopped continuous heparin infusion four to six hours

before procedure.

ESD procedure

ESD was performed using the conventional single-channel endoscope (GIF-Q260J, or -H260Z; Olympus, Tokyo, Japan) and a high-frequency electrical generator (VIO 300D; Erbe, Tübingen, Germany) by 15 endoscopists. An expert endoscopist was defined as one who had the experience of performing more than 50 gastric ESDs. After marking dots circumferentially on the surrounding normal mucosa 5–10 mm away from the lesion demarcation line, a mixture of 10% glycerin and 0.4% sodium hyaluronate solution (Mucoup; Johnson and Johnson, Tokyo, Japan) containing indigo carmine and 0.01% epinephrine was injected submucosally. A circumferential incision was performed using the Dual knife (KD-650L; Olympus, Tokyo, Japan) or Flush knife (DK2618JN20; Fujinon, Tokyo, Japan). After the circumferential incision was completed, the submucosa was dissected using the Dual knife, Flush knife, or IT2 knife (KD-611L; Olympus, Tokyo, Japan). Hemostatic forceps (FD-410LR; Olympus, Tokyo, Japan) were used to control the bleeding during and after the procedure. A second-look endoscopy was performed routinely the following weekday, and preventive coagulation of visible vessels was performed^[19]. A proton pump inhibitor, that is, omeprazole 20 mg, was administered intravenously twice a day starting on the day of the ESD until the day before the start of a soft diet. Then, oral administration of esomeprazole 20 mg was started and continued for 8 wk after the ESD.

Lesion characteristics and curability

All lesions were pathologically examined on the basis of the Japanese Classification of Gastric Carcinoma^[1]. The macroscopic type was classified as the protruded type, flat type, or depressed type. The size of the tumor and the resected area were measured on the specimen. The location of the tumor was classified as the upper third, middle third, or lower third of the stomach. The depth of the tumor invasion was classified as pT1a (up to the mucosa) or pT1b (up to the submucosa). Invasion of the submucosal layer (SM) was divided into SM1 (less than 0.5 mm from the muscularis mucosae) and SM2 (more than 0.5 mm submucosal invasion). The tumor differentiation grade was based on the most dominant differentiation grade, and the tumors were classified as adenoma, differentiated cancer (including well-differentiated, moderately differentiated, tubular, and papillary adenocarcinoma), or undifferentiated cancer (poorly differentiated adenocarcinoma and signet-ring cell carcinoma).

En bloc resection was defined as resection in a single piece. Complete resection was defined as *en bloc* resection of a tumor with a negative horizontal margin and vertical margin. Curative resection was defined as follows: *En bloc* resection, tumor size ≤ 2 cm, differentiated-type tumor, pT1a, ulceration (UI)-negative, no lymphovascular infiltration [ly(-), v(-)],

negative horizontal margin (HM0), and negative vertical margin (VM0). The expanded indications of curative resection were as follows: *En bloc* resection, ly(-), v(-), HM0, and VM0, as well as: (1) tumor size ≥ 2 cm, differentiated-type tumor, pT1a, UI(-); (2) tumor size ≤ 3 cm, differentiated-type tumor, pT1a, UI(+); (3) tumor size ≤ 2 cm, undifferentiated-type tumor, pT1a, UI(-); and (4) tumor size ≤ 3 cm, differentiated-type tumor, pT1b (SM1)^[20,21]. All other lesions were classified as non-curative resection.

Adverse events

Postoperative bleeding was defined as bleeding events, including hematemesis and/or melena, after the procedure requiring endoscopic hemostasis, or a decrease of the hemoglobin level by more than 2 mg/dL as compared to the preoperative hemoglobin level.

Statistical analysis

Data are expressed as mean \pm SD or as percentages. Statistical analysis was carried out using student's *t*-test or Fisher's exact test. Factors identified as significant by the univariate analysis ($P < 0.15$) were entered into a multivariate logistic regression analysis model. All data analyses were carried out using the StatView software (version 5.0; SAS Institute Inc., Cary, North Carolina, United States). Differences with *P* values of less than 0.05 were considered as denoting significance. The statistical methods of this study were reviewed by Dr. Satoshihiro Matsumoto from the Department of Gastroenterology, Jichi Medical University, Saitama Medical Center, Saitama, Japan.

RESULTS

The overall clinicopathological profiles of the 262 gastric neoplasms in 250 patients are shown in Table 1. Twelve patients had received treatment for 2 lesions occurring metachronously during the investigation period, and were counted twice. The mean age of the patients was 71 ± 8 years (range 32–87) (M:F = 190:72). Of the 262 cases, 48 (18.3%) had a history of receiving antithrombotic therapy for cardiovascular diseases. The details of the antithrombotic therapy were as follows: Aspirin 28 cases, clopidogrel 6 cases, ticlopidine 1 case, cilostazol 4 cases, and warfarin 14 cases. Perioperative management of the antithrombotic therapy was as follows: The antithrombotic drugs were discontinued in 25 cases, the antiplatelet agents were continued in 10 cases, and oral anticoagulant treatment was replaced by heparin in 13 cases (most of the patients who were under warfarin treatment received heparin replacement, except one patient who had past history of paroxysmal atrial fibrillation).

The mean tumor size was 15.9 ± 10.9 mm (range, 2–85 mm). The gastric tumors were mainly located in the lower third and in the lesser curvature of the stomach. The *en bloc* resection rate was 98.8% (259 cases) and the curative resection rate was 66.8%

(175 cases). The curative resection rate according to the expanded indications was 21.8% (57 cases). The non-curative resection rate was 11.5% (30 cases). Postoperative bleeding occurred in 23 cases (8.8%). Perforation during ESD occurred in 2 cases. No events of thromboembolism occurred with discontinuation of the antithrombotic therapy. Among the 23 patients who had postoperative bleeding, 6 (26.1%) needed blood transfusion. One patient needed blood transfusion due to underlying anemic disease.

Univariate analysis carried out to determine the risk factors for postoperative bleeding identified antithrombotic agent user ($P = 0.0011$), heparin replacement ($P < 0.0001$), hemodialysis ($P = 0.0321$), diabetes mellitus ($P = 0.0435$), cardiovascular disease ($P = 0.0069$), PT-INR ($P < 0.0001$), and the hemoglobin level on admission ($P < 0.0153$) as risk factors for postoperative bleeding (Table 2).

The postoperative bleeding rates in the group in which the antithrombotic therapy was discontinued and the group in which the antiplatelet agents were continued were 0% (0/25) and 20% (2/10), respectively. These rates were not significantly different from the rate in the non-antithrombotic therapy group (6.1%, 13/201). On the other hand, the postoperative bleeding

rate in the heparin replacement group was 61.5% (8/13), which was significantly higher than the rate in the non-antithrombotic group (6.1%) ($P < 0.0001$) (Figure 1).

Multivariate analysis identified heparin replacement (OR = 13.7; 95%CI: 1.2-151.3, $P = 0.0329$) as the only significant risk factor for post ESD bleeding. It appeared that the tumor location in the lower third of the stomach may be related to postoperative bleeding; however, the difference in the bleeding rate was not statistically significant (OR = 2.9, 95%CI: 0.92-8.94, $P = 0.0697$) (Table 3).

DISCUSSION

We investigated risk factors for postoperative bleeding in patients undergoing gastric ESD based on the new guidelines published by the JGES^[16]. The postoperative bleeding rate in the group not under anti-thrombotic therapy was 6.1% (13/214), which was consistent with previous reports (4.81%-9.4%)^[4-9]. Antithrombotic agents were used in 18.3% of the cases (48/262), and the postoperative bleeding rate increased in the following order, depending on the perioperative management of antithrombotic therapy: Group in which the antithrombotic therapy was discontinued (0%, 0/25), group in

which antiplatelet agents were continued (20%, 2/10), and the group which received heparin replacement (61.5%, 8/13).

While one previous report suggests that antiplatelet drugs do not increase the risk of postoperative bleeding after ESD^[22], there are several reports contending that antiplatelet drugs increase the risk of postoperative bleeding^[23-25]. On the other hand, withdrawal of anti-thrombotic therapy has been reported to increase the risk of development of thromboembolic events^[22].

Although there is no mention about ESD, the 2009 guidelines published by the American Society for Gastrointestinal Endoscopy (ASGE) recommend continuation of aspirin in endoscopy candidates at a high risk of thrombosis. And in patients taking thienopyridines, ASGE recommends substitution of the thienopyridine with aspirin for 7-10 d^[26]. The 2011 guidelines of the

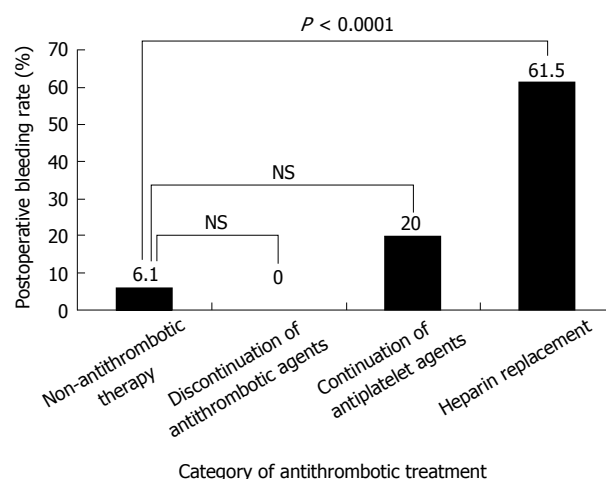

Figure 1 Comparison of the postoperative bleeding rate after gastric endoscopic submucosal dissection according to category of antithrombotic treatment. NS: Not significant.

European Society of gastrointestinal Endoscopy also recommend continuation of aspirin in patients at a high risk of thrombosis. However, the risk of bleeding doubles when the lesions are removed by ESD rather than by endoscopic mucosal resection. Discontinuation of all antiplatelet agents, including aspirin, is recommended, provided that the patient is not at a high risk for thrombotic events^[27]. The new JGES guidelines suggest

that withdrawal of aspirin monotherapy is not required in patients who would be at a high risk of thromboembolic events following withdrawal of the drug. Aspirin can be withdrawn for 3 to 5 d in patients who are low-risk candidates for thromboembolism. Thienopyridines should be discontinued for 5 to 7 d, and substitution with aspirin or cilostazol should be considered^[16]. In our study, the postoperative bleeding rate in the patient group that was continued on antiplatelet drug therapy during the perioperative period was 20%, which is not significantly higher than the reported rate in patients not on antithrombotic drug therapy.

On the other hand, the JGES guidelines recommend heparin replacement after oral anticoagulant agent withdrawal for patients who need to be continued on anticoagulant therapy. Such patients should be treated as high-risk patients, because once thromboembolic complications have occurred, they are often serious^[16]. In this study, 13 of the 14 patients who were on oral anticoagulant therapy received heparin replacement. Although the sample size in this study was small, the postoperative bleeding rate in the heparin replacement group was significantly higher (61.3%, 8/13) as compared with that in the patient group not on antithrombotic drug therapy (6.1%, 13/201). Thus, heparin replacement was identified as an independent, significant risk factor for postoperative bleeding after gastric ESD by both univariate analysis and multivariate analysis. Four of the 6 patients who required blood transfusion after gastric ESD were from the heparin replacement group (data not shown). This suggests that heparin replacement is associated with a significant increase in the risk of massive bleeding as compared to the other groups once postoperative bleeding occurred. There are few reports of investigation of the safety of heparin replacement after withdrawal of anticoagulant therapy in patients undergoing gastric ESD; however, all report high postoperative bleeding rates (23.8%-37.5%)^[24,28]. In our study, the postoperative bleeding rate was much higher (61.3%, 8/13) than that reported in previous studies. According to Yoshio *et al.*^[28] reported that in the heparin replacement group, postoperative bleeding occurred in 2 of 8 cases with tumors in the upper third of the stomach, 5 of 9 cases with tumors in the middle third, and 2 of 7 cases with tumors in the lower third of the stomach. The corresponding values in our study were 2/3, 0/0 and 6/10. Thus, the tumor location might have some influence on the postoperative bleeding rate; however, investigation including a larger number of cases would be required.

Recently, several new oral anticoagulants (NOACs) have been introduced. The NOACs show prompt effects and have shorter half-lives than warfarin^[29,30]. Therefore, in patients on anticoagulant therapy scheduled for gastric ESD, it may be better to substitute warfarin with NOACs rather than with heparin. Tsuji *et al.* reported that use of polyglycolic acid sheets and fibrin glue decreased the risk of bleeding after gastric ESD^[31]. This technique, as well as preventive coagulation of visible vessels^[19], should be

considered to prevent postoperative bleeding in high-risk patients, such as those receiving heparin replacement.

Our investigation had some limitations, as follows: The study was a retrospective study from a single center, and the sample size was small. Detailed prospective investigations are necessary in the future.

In regard to the risks associated with gastric ESD in patients on antithrombotic therapy, continuation of antiplatelet drugs, based on the guidelines, during the perioperative period was not associated with an elevated risk of postoperative bleeding after gastric ESD; the heparin replacement after oral anticoagulant agent withdrawal for patients should be considered carefully for postoperative bleeding after gastric ESD.

COMMENTS

Background

The latest guidelines for gastroenterological endoscopy in patients undergoing antithrombotic treatment, published in July 2012 by the Japan Gastroenterological Endoscopy Society, include discussions of postoperative bleeding associated with continuation of antithrombotic therapy, as well as of the risk of thromboembolism associated with withdrawal of antithrombotic treatment.

Research frontiers

The new guidelines include discussions of the risk of gastroenterological hemorrhage associated with continuation of antithrombotic therapy, as well as of the risk of thromboembolism associated with discontinuation of antithrombotic therapy. There are few data on the risk factors for postoperative bleeding after gastric endoscopic submucosal dissection (ESD) in patients continued on antithrombotic treatment during the perioperative period.

Innovations and breakthroughs

The postoperative bleeding rate in the heparin replacement group was 61.5%, significantly higher than that in the non-antithrombotic therapy group (6.1%). Multivariate analysis identified only heparin replacement as a significant risk factor for post-ESD bleeding.

Applications

The heparin replacement after oral anticoagulant agent withdrawal for patients should be considered carefully for postoperative bleeding after gastric ESD.

Terminology

Polyglycolic acid is an absorbent suture reinforcement material, which expected for the prevention of post-ESD bleeding in patients with a high risk of bleeding undergoing gastric ESD.

Peer-review

This study was well written and presented. ESD is a novel technique. Endoscopists have to accept the need for advanced endoscopic techniques for performing this technique. Anti-coagulants and anti-platelet agents are widely used to prevent thromboembolic disease.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Endoscopy*, Vincent Lam, MD, Associate Professor, Surgeon, Discipline of Surgery, Sydney Medical School, the University of Sydney, Sydney, NSW 2006, Australia

AIM AND SCOPE

World Journal of Gastrointestinal Endoscopy (*World J Gastrointest Endosc*, *WJGE*, online ISSN 1948-5190, DOI: 10.4253) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGE covers topics concerning gastroscopy, intestinal endoscopy, colonoscopy, capsule endoscopy, laparoscopy, interventional diagnosis and therapy, as well as advances in technology. Emphasis is placed on the clinical practice of treating gastrointestinal diseases with or under endoscopy.

We encourage authors to submit their manuscripts to *WJGE*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Endoscopy is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

AIM: To ascertain whether the Prague circumferential (C) length and maximal (M) length criteria for grading the extent of Barrett's esophagus can be applied prior to its widespread application in South Korea.

METHODS: Two hundred and thirteen consecutive cases with endoscopic columnar-lined esophagus (CLE) were included and classified according to the Prague C and M criteria.

RESULTS: Of 213 cases with CLE, the distribution of maximum CLE lengths was: 0.5-0.9 cm in 99 cases (46.5%); 1.0-1.4 cm in 63 cases (29.6%); 1.5-1.9 cm in 15 cases (7.0%); 2.0-2.4 cm in 14 cases (6.6%); 2.5-2.9 cm in 1 case (0.5%); and 7.0 cm in 1 case (0.5%). Twenty cases (9.4%) had columnar islands alone. Two hundred and eight cases (97.7%) lacked the circumferential CLE component (COMx). Columnar islands were found in 70 cases (32.9%), of which 20 cases (9.4%) had columnar islands alone.

CONCLUSION: In regions where most CLE patients display short or ultrashort tongue-like appearance, more detailed descriptions of CLE's in < 1.0 cm lengths and

columnar islands, as well as avoidance of repeating the prefix "C0" need to be considered in parallel with the widespread application of the Prague system in South Korea.

Key words: Barrett's esophagus; Endoscopy; Columnar-lined esophagus; Prague criteria

Core tip: This was a prospective study to assess the feasibility of the Prague circumferential length and maximal length criteria for the endoscopic description of columnar-lined esophagus in South Korea. In regions like South Korea where the prevalence and endoscopic features of this condition are quite different from the West, we suggest possible modifications that may fit the characteristics of the South Korean source population more properly.

Choe JW, Kim YC, Joo MK, Kim HJ, Lee BJ, Kim JH, Yeon JE, Park JJ, Kim JS, Byun KS, Bak YT. Application of the Prague C and M criteria for endoscopic description of columnar-lined esophagus in South Korea. *World J Gastrointest Endosc* 2016; 8(8): 357-361 Available from: URL: <http://www.wjgnet.com/1948-5190/full/v8/i8/357.htm> DOI: <http://dx.doi.org/10.4253/wjge.v8.i8.357>

INTRODUCTION

Barrett's esophagus (BE) is defined as a histological change of the distal tubular esophagus, from squamous to columnar epithelium, which displays an intestinal metaplasia containing goblet cells^[1,2]. Because BE is characterized by an upward shift of the squamocolumnar junction (SCJ) proximal to the gastroesophageal junction (GEJ), the resulting columnar-lined mucosa of the distal esophagus can be identified by its salmon-pink color during endoscopic examination^[3,4]. Moreover, multiple endoscopic biopsies at the extended columnar-lined epithelium are needed to confirm BE diagnosis.

BE is associated with gastroesophageal reflux disease (GERD) and is considered a premalignant lesion for esophageal adenocarcinoma^[5,6], the incidence of which is steadily rising in the United States and Europe^[7,8]. Increasing GERD incidence in South Korea is considered to result from more consumption of westernized foods^[9,10]. As patients with chronic GERD are at a higher risk of developing BE^[11,12], the expected increase in BE and esophageal cancer incidence rates in the future is a matter of potential concern in South Korea.

Various studies have examined BE length as a risk factor for esophageal adenocarcinoma^[13-15]. Results from a study showed that a doubling in BE length resulted in a 1.7-fold increase in the risk of developing esophageal adenocarcinoma^[15], and others revealed that a significantly increased risk of dysplasia or adeno-

carcinoma was related to greater lengths of BE^[13,14]. Therefore, accurate measuring of columnar-lined esophagus (CLE) lengths and describing in well-defined clinical terms are important in appropriate risk assessment and surveillance. Although previous diagnostic criteria for BE were based on the 3-cm length threshold of columnar-lined esophagus (CLE), by which BE was divided into 2 types, long (≥ 3 cm) and short (< 3 cm), this simple classification of variable endoscopic findings of CLE was a rather crude approach in describing BE. Furthermore, as considerable inter- and intra-observer variability in detecting and describing the CLE are common, the establishment of an accurate BE diagnosis and surveillance may be tricky^[16-18].

Therefore, the Prague classification system that measures the circumferential (C) and maximal (M) extents for endoscopic standardization of BE lengths was developed and finally introduced by the International Working Group for the Classification of Oesophagitis (IWGCO) in 2004^[19]. However, the overall reliability and validity of the Prague C and M criteria for BE diagnosis continues to be challenged^[20-22]. Moreover, its performance in South Korea where the incidence of BE is low and the short-segment BE is the predominant type remains unclear.

In the present study, we aimed to assess the feasibility of the Prague C and M criteria for the endoscopic description of CLE in South Korea where the prevalence and endoscopic features of this condition are quite different from the West and to suggest possible modifications that may fit the characteristics of the South Korean source population more properly.

MATERIALS AND METHODS

This prospective study was conducted from the endoscopy data of consecutive CLE patients who underwent esophagogastroduodenoscopy (EGD) at Endoscopy Center of the Korea University Guro Hospital, Seoul, South Korea. Exclusion criteria included the presence of esophageal varices, acute upper gastrointestinal bleeding, malignancy near GEJ, and history of gastric surgery. Before each EGD, written informed consent was obtained. All endoscopic procedures were performed by an experienced endoscopist.

GEJ and SCJ were carefully assessed during the insertion of the endoscope. The distal margin of the palisade blood vessels of the lower esophagus was used as a marker of GEJ^[23]. If the palisade vessels could not be seen adequately, the proximal margins of the gastric folds were used to identify GEJ. SCJ was used as a marker for upper border of CLE. The length of CLE, that is the distance from GEJ to SCJ, was measured by the insertion depths with the centimeter markings on the endoscope. CLE's shorter than 0.5 cm in length were ignored to avoid possible observation errors that may lead to overdiagnosis. Careful observation was done to look for any presence of islands of columnar mucosa.

The C and M extents of CLE were recorded accord-

Table 1 Application of Prague circumferential and maximal criteria in cases with ultrashort, short, and long columnar-lined esophagus (*n* = 213)

Lengths of CLE (cm)	<i>n</i> (%)	COMx cases (%)
0 (islands only)	20 (9.4)	20 (100)
0.5-0.9	99 (46.5)	99 (100)
1.0-1.5	63 (29.6)	61 (96.8)
1.5-1.9	15 (7.0)	14 (93.3)
2.0-2.4	14 (6.6)	12 (85.7)
2.5-2.9	1 (0.5)	1 (100)
≥ 3.0	1 (0.5)	1 (100)
Total	213 (100)	208 (97.7) ¹

¹Exceptions: 2 cases with C1M1 and 3 cases with either C1M1.5, C1M2, or C1.5M2. CLE: Columnar-lined esophagus.

Table 2 Application of Prague circumferential and maximal criteria in cases with short and long columnar-lined esophagus (*n* = 139)

Lengths of CLE (cm)	<i>n</i> (%)	COMx cases (%)
0 (islands only)	45 (32.4)	45 (100)
1.0-1.4	63 (45.3)	61 (96.8)
1.5-1.9	15 (10.8)	14 (93.3)
2.0-2.4	14 (10.1)	12 (85.7)
2.5-2.9	1 (0.7)	1 (100)
≥ 3.0	1 (0.7)	1 (100)
Total	139 (100)	134 (96.4) ¹

¹Exceptions: 2 patients with C1M1 and 3 patients with either C1M1.5, C1M2, or C1.5M2. CLE: Columnar-lined esophagus.

ing to the Prague C and M criteria proposed by the IWGCO^[19]. M lengths were divided into long (≥ 3 cm), short (1-2.9 cm), and ultrashort (< 1 cm) segments.

RESULTS

Patient demographic characteristics

A total of 213 CLE patients consisting of 154 men and 59 women, with 53.8 ± 12.3 years in age (mean ± SD) were enrolled.

Distribution of CLE lengths and application of the Prague C and M criteria

Analysis of cases with CLE's including ultrashort CLE's:

Distribution of CLE's according to their M values, including those with ultrashort CLE's, is shown in Table 1. Among the total 213 cases, 99 (46.5%), 63 (29.6%), 15 (7.0%), 14 (6.6%), 1 (0.5%), and 1 (0.5%) had CLE's of 0.5-0.9 cm, 1.0-1.4 cm, 1.5-1.9 cm, 2.0-2.4 cm, 2.5-2.9 cm, and ≥ 3.0 cm in lengths, respectively. The remaining 20 cases (9.4%) had columnar islands alone. Therefore, 99 cases (46.5%) had ultrashort CLE's (CLE < 1.0 cm), 113 (53.1%) had short CLE's (1-2 cm) and only one (0.5%) had a long CLE (≥ 3 cm), showing a CLE of 7.0 cm in length.

When the cases were classified by the Prague criteria, 208 (97.7%) had no C component (COMx). Two cases had C1M1 and the remaining three cases had

either, C1M1.5, C1M1, or C1.5M2. Columnar islands were observed in 70 (32.9%) cases, of which 20 (9.4%) had columnar islands alone.

Analysis of cases with CLE's excluding ultrashort CLE's:

Distribution of CLE's according to their M values among those excluding ultrashort CLE's is shown in Table 2. Among 139 cases, 63 (45.3%), 15 (10.8%), 14 (10.1%), 1 (0.7%), and 1 (0.7%) had CLE's of 1.0-1.4 cm, 1.5-1.9 cm, 2.0-2.4 cm, 2.5-2.9 cm and ≥ 3.0 cm in lengths, respectively. Therefore, 138 (99.3%) out of all 139 cases had short CLE's, and only one showed an exceptionally long CLE.

When 139 cases were classified by the Prague criteria, 134 (96.4%) had CLE's without C component (COMx). Two cases had C1M1 and the remaining three patients had either C1M1.5, C1M1, or C1.5M2. Columnar islands were found in 70 (50.4%) cases, of which 45 (32.4%) showing columnar islands alone.

DISCUSSION

BE is a very well known risk factor for the development of dysplasia and esophageal adenocarcinoma^[24-26]. The risk of dysplasia and adenocarcinoma in metaplastic epithelium reportedly increases in parallel to the lengths of BE^[13-15]. A recent multicenter study conducted by Gaddam *et al.*^[13] revealed that for every 1-cm extension in BE length, the risk of high-grade dysplasia and esophageal adenocarcinoma increased by 21%. The study demonstrated that the increase in BE lengths significantly widens the area of metaplasia, which is associated with the progression to high-grade dysplasia/esophageal adenocarcinoma^[13]. Although a novel technique using a computer software program to create a two-dimensional image map of the esophagus has been introduced to accurately and reproducibly measure the extent of CLE^[27], such a complicated approach is not suitable for a daily clinical practice. Therefore, assessment of BE extent by simple measurement of the height of metaplastic CLE remains as the most commonly used procedure to distinguish short- from long-segment BE^[13-15]. However, the study of the clinical course and therapeutic response of BE has been limited because this classic method only provides gross estimates of the area. This system does not measure the surface areas of metaplastic mucosa, which may be more important than the endoscopic lengths^[19]. The presence of an irregular border of columnar tissue or interspersed metaplastic mucosal islands can hamper the precise measurement of the extent of CLE^[20].

The Prague C and M criteria, suggested by IWGCO, not only allows a more detailed description of the length of the endoscopically recognized CLE, using "C" and "M" values above the GEJ, but can also assist the objective calculation of the actual surface area, which may be more important in the risk assessment of the neoplastic transformation^[19-21]. These advances in CLE description have facilitated the depiction and reporting of various

circumferential and tongue-like longitudinal CLE lengths by using a method that can be understood easily and comprehensively. Importantly, high inter-observer reliability in the grading of endoscopically suspected CLE was demonstrated among gastroenterology experts and trainees^[22].

In recent years, accelerated life style changes have increased the prevalence of GERD in Asian populations, including South Koreans^[9,10,28,29], and BE incidence is also expected to increase^[12]. BE prevalence in South Korea was 0.2%-3.6% in the year 2000^[11,12,30], lower than in Western countries. Lengths and shapes of CLE's as well as their prevalence in South Korea are quite different from those of the Western countries. Long-segment BE is more common in Western countries, wherein 14%-31% of BE patients show this type^[31,32]. However, most cases of BE are short-segment type in South Korea, where long-segment type BE's are extremely rare^[11]. In our study, with the exception of the only one case, 212 (99.5%) out of 213 CLE cases were short-segment type (< 3 cm); and from these, 99 cases (46.5%) had ultrashort CLE (< 1 cm). Lee *et al.*^[33] reported that the reliability coefficients of the C and M values in the endoscopic recognition of short-segment type CLE were 0.90 (95%CI: 0.80%-1.00%) and 0.92 (95%CI: 0.87%-0.98%), respectively. However, the reliability of such coefficients for the recognition of the ultrashort (< 1 cm) CLE extent type was very low, with C and M coefficients of 0.18 (95%CI: 0.03%-0.32%) and 0.21 (95%CI: 0.00%-0.51%), respectively^[33].

Therefore, the routine applicability of the Prague C and M criteria as a standardized validated method for the detailed endoscopic description of ultrashort BE and short-segment BE, the most dominant BE types in South Korea, requires further analysis. As our study showed, all ultrashort CLE and almost all short-segment CLE cases lacked the C component and were classified as C0Mx. Therefore, it appears appropriate for us to propose to omit of the prefix "C0" from all C0Mx cases in order to avoid needless repetitions when describing most cases in regions like South Korea. Because the presence of columnar islands is a frequent finding as we have observed in this study and they also may change to dysplasia^[34], we propose to add this to the Prague system, which currently does not include this category. Resultant examples following our proposals are: C2M5, if 2.0 cm of C component with 5.0 cm of M component; M2, if 2.0 cm of M component without C component; C2M5i or M2i, if columnar island(s) is/are found in addition to C2M5 or M2 CLE; and M0i, if only columnar island(s) is/are found.

In summary, the Prague C and M system is simple and useful in daily description of endoscopic feature of CLE's. However, in regions like South Korea where most cases with CLE display only short or ultrashort types without C component, we propose to omit the needless repetition of "C0" prefix from C0Mx and to add i component to describe the presence of columnar islands which also may have a potential to be dysplastic.

COMMENTS

Background

The Prague circumferential (C) length and maximal (M) length criteria have been adopted widely for grading the extent of Barrett's esophagus (BE). However, its validity in regions with low prevalence of BE, remains unclear. This study was designed to ascertain whether these criteria can be applied prior to its widespread application in South Korea.

Research frontiers

The Prague C and M system is simple and useful in daily description of endoscopic feature of BE's. But, the overall reliability and validity of the Prague C and M criteria for BE diagnosis continues to be challenged. In this study, there are some suggestions of possible modifications that may fit the characteristics of the South Korean source population more properly.

Innovations and breakthroughs

In regions like South Korea where most cases with columnar-lined esophagus display only short or ultrashort types without C component, the authors propose to omit the needless repetition of "C0" prefix from C0Mx and to add "i" component to describe the presence of columnar islands which also may have a potential to be dysplastic.

Applications

This study serves as additional evidence supporting the investigation in parallel with the widespread application of the Prague system in South Korea.

Terminology

Barrett's esophagus: A histological change of the distal tubular esophagus, from squamous to columnar epithelium, which displays an intestinal metaplasia containing goblet cells; The Prague classification criteria: A system to measure the C and M extents for endoscopic standardization of BE lengths.

Peer-review

The study is has clear defined inclusion and exclusion criteria and is well conducted despite the lack of a control group. This study is innovative and would be interesting to see if the findings are reproducible in other countries where BE is not as common as in the West.

Abstract

AIM: To evaluate the impact of endoscopic ultrasonography (EUS) quality assessment on EUS procedures

by comparing the most recent 2013-2014 local EUS procedural reports against relevant corresponding data from a 2009 survey of EUS using standardized quality indicators (QIs).

METHODS: Per EUS exam, 27 QIs were assessed individually and by grouping pre-, intra-, and post-procedural parameters. The recorded QI frequencies from 200 reports (2013-2014) were compared to corresponding data of 100 reports from the quality control study of EUS in 2009. Data for QIs added after 2009 to professional guidelines (added after 2010) were also tabulated.

RESULTS: Significant differences (P -value < 0.05) were found for 13 of 20 of the relevant QIs examined. 4 of 5 pre-procedural QIs, 6 of 10 intra-procedural QIs, and 3 of 5 post-procedural QIs all demonstrated significant upgrading with a P -value < 0.05.

CONCLUSION: Significant improvements were demonstrated in QI adherence and thus EUS reporting and delivery quality when the 2013-2014 reports were compared to 2009 results. QI implementation facilitates effective high-quality EUS exams by ensuring comprehensive documentation while limiting error.

Key words: Endoscopic ultrasound; Improvement; Fine needle aspiration; Quality indicators

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Consistent implementation of these endoscopic ultrasonography (EUS) quality indicators by endosonographers facilitates effective high-quality EUS procedures by ensuring comprehensive procedural documentation while also limiting error.

INTRODUCTION

Endoscopic ultrasonography (EUS) is an endoscopic procedure that has benefited from quality control (QC) analysis and quality indicator (QI) analysis, a benchmark of widely-used guidelines being those of the American Society of Gastrointestinal Endoscopy (ASGE)^[1]. Bluen *et al*^[2] 2012 demonstrated how responsible QC, including systemic monitoring and evaluation, is critical to rendering EUS fine needle aspiration (EUS-FNA) protocol more effective. The consistency with which practitioners adhere to or comply with these QIs, whether they are pre-, intra- or post-procedure, goes a long way in optimizing the significance of the endoscopic exam. Coe *et al*^[3] 2009 studied physician adherence to EUS QIs over an eight-year span and observed statistically significant findings: Improvement was achieved in the EUS areas previously evaluated to have been weak by quality assessment. Lachter *et al*^[4] in 2013, explored adherence to EUS QIs at ten different Israeli medical centers with international comparison to the University of Chicago when measured using a standardized table of relevant QIs and observed that an overall improvement in documented quality of EUS exams was found in centers ensuring comprehensive documentation and stronger guideline adherence.

The ASGE and the American College of Gastroenterology (ACG) formed a task force of expert endoscopists and pioneered a way in which efforts of QC could be efficiently carried out to document the quality of endoscopic services and to promote optimal procedural performance^[1]. These QIs were developed by the task force to serve as guidelines for the 4 major endoscopic procedures: Esophagogastroduodenoscopy, colonoscopy, endoscopic retrograde cholangiopancreatography, and EUS. A recent update of QIs common to all GI endoscopic procedures was put forth prioritizing indicators that have wide-ranging clinical application, are associated with variation in practice and outcomes, and were validated in clinical studies^[5]. This update to the original version in 2006, framed by the ASGE/ACG task force, promotes performance targets for the QIs to help direct continuous quality improvement and an evidence-based system of benchmarks for each QI^[5].

The present study aims to evaluate the impact of the EUS quality assessment on the improvement of these procedures by comparing 2013-14 local EUS procedural reports against relevant corresponding data from a 2009 survey of QIs (Lachter *et al*^[4]). That is, whether the EUS operators are improving their adherence/compliance to the QIs, and if the incorporation of and adherence to the QIs enhance the overall quality of EUS

exams and patient outcomes.

MATERIALS AND METHODS

Two hundred EUS exam reports from 2013-2014 in Rambam were reviewed for each of the active echo-endoscopists. Each EUS report was assessed by a pre-established standardized table of EUS QIs (Table 1). Per EUS exam, QIs are evaluated individually as well as by the following categories: Pre-procedural, intra-procedural, and post-procedural. The hospital medical statistician was consulted and statistics are in accord with her recommendations using SPSS version 21. The comparison group for this study was from a 2009 survey of QIs for 100 EUS examinations. This was used as a comparative baseline to determine whether measures to increase implementation of these QIs were successful in yielding improvements in EUS procedure documentation and quality.

The methods of collection of data are that each of ten echoendoscopists was asked to submit ten EUS anonymized reports in 2008. The results were shared, at a meeting of the national gastroenterology society, without naming any of the echoendoscopists regarding the scores for their respective EUS reports, but rather only giving the pooled results, and comparison of the per-echoendoscopist results, regardless of their years of experience in performing EUS or their volume of procedures performed yearly. The images from EUS were not used, only the verbal reports. The reports were from multiple institutions. Each echoendoscopist could use either radial or linear or both kinds of endoscope. For the 2014 review, three echoendoscopists were reviewed, with varying experience from 3-18 years of experience, from only one institution. Trainees are not authorized to sign off on final EUS reports.

We also emphasize that we cannot be sure that every one of the many echoendoscopists nationally are always maintaining the highest quality standards, but we believe that continual monitoring and reporting the results publically of quality assessments lead to the long-term knowledge that reviews will be made and will be made public. This method of ensuring quality has been shown by various authors, including most recently by Abdul-Baki *et al*^[6], to be of significant value in raising quality of procedural documentation of endoscopies.

Reporting frequencies of each QI in EUS reports were calculated. Comparison between our study results with those of the previous study, regarding 20/27 listed standardized QI parameters (Table 1) plus demographics, were tested by Fisher Exact Test. Frequencies for indications for EUS procedures were calculated and then compared in 6 out of the 10 total indications as that was the number of indications that matched the 2009 study. A $P < 0.05$ was considered as significant. Twenty out of the 27 listed QIs were compared with 2009 data for statistical analysis because only 20/27 QIs

Table 1 Endoscopic ultrasound quality indicators (American Society of Gastrointestinal Endoscopy 2006)

Pre-EUS indicators
Indications for procedure
Detailed description of the patient by the referring physician
Patient completed procedural preparation of minimum 6 h NPO
Antibiotics per protocol were given in the need to perform FNA of pancreatic cysts
Listing of sedatives administered prior to and during EUS
Patient signed agreement of informed consent for EUS and/or if consented for research
Intra-procedural indicators
A detailed description of the methods used to visualize routinely evaluated EUS organs. If there is any suspicion of organ pathology, the respective organ parenchyma should be described:
Suspected pancreatic lesions should include a parenchymal description including the body, head, tail, and duct
Common bile ducts and gallbladder contents should be detailed and a description of the biliary tree for sludge, stones, or other findings
If found, prominent lymph nodes should be described in detail as well as the kidneys and left liver lobe for the presence or absence of lesions
The celiac axis should be described for general arterial structure along with the aorta and superior mesenteric artery as well as the presence or absence of identifiable lymph nodes
Description of abnormal/pathological results:
Description of any tumor by the tumor, node, and metastasis system
Accurate detailing of the lesions and its surroundings in accordance with layers visualized by EUS degree of tumor penetration into organ mucosa and surrounding structures
Detailing the presence of lymph nodes when suspicious for malignancy and when performing FNA
Presence or absence of any mechanical problems or difficulties including past abdominal surgeries or ascites
Patient awakened/uncooperative during the procedure
Details of the number of FNAs performed with respective number of passes into each suspected lesion including:
Number of passes
Needle size
Number of needles
Impressions of aspirate (bloody, mucinous, color, etc.)
Cytology and/or histological examination
In-room tentative diagnosis
Post-procedural indicators
Summary of medical diagnoses
Examination findings, even if not relevant to the reason for EUS referral, should be listed
Physician recommendations shall be listed with respect to examination findings including instructions for the patient
Instructions for how patients will receive the results and for referring physician
After EUS, the incidence of adverse events should be listed, including pancreatitis, bleeding, and/or infections and the need for hospitalization

EUS: Endoscopic ultrasonography; NPO: Nil Per Os; FNA: Fine needle aspiration.

corresponded exactly with the previous study's data.

RESULTS

Significant differences (P -value < 0.05) were found in 13/20 QIs (Table 2). For pre-procedural QIs: Minimum 6 h Nil Per Os (NPO); Antibiotics per protocol prior to FNA of pancreatic cysts; Listing of anesthesia administered prior to and during EUS; Patient signed agreement of informed consent. For intra-procedural QIs (P -value < 0.05): Suspected pancreatic lesions should include parenchymal regional descriptions citing pancreatic head, body, tail, and duct; common bile duct (CBD) and gallbladder imaging should be detailed including a description for sludge, stones or other findings; lymph node (LN) description as well as pole of left kidney and left liver lobe for lesions; Celiac axis described for arterial structures along w/aorta, superior mesenteric artery and LNs; Presence or absence of mechanical problems or difficulties including past abdominal surgeries or ascites; Patient awakened or uncooperative during procedure. For post-procedural QIs (P -value < 0.05): Exam findings, even if not relevant to reason/indications for EUS referral, instructions for how patient will receive cytology/chemistry results, and incidence or

absence of adverse events should also be documented.

The mean patient age was 57 years old with a standard deviation of 16 and a range of 18-92 years of age. Fifty-nine point five percent of patients were females. Although there were specific differences in QI adherence among the three EUS operators, there was no statistical significance in such differences found. The primary indications for referral for EUS included suspected CBD (19%), pathologic findings on imaging (9%), mostly of the pancreas, and need for FNA and/or biopsy, as shown in Table 3.

DISCUSSION

Pre-procedural 6-h NPO preparation was found in 100% of EUS reports, a statistically significant improvement over the 8% of the 2009 results (P < 0.001). The considerable disparity in this result may or may not be due to simple documentation error as opposed to so many patients not aptly preparing for the procedure. Antibiotics per protocol was documented as being given to every (100%) relevant patient prior to FNA of pancreatic cyst, which is a significant improvement over the 40% coverage of the previous study. Although the efficacy of antibiotics prophylaxis is as yet unproven, it

EUS: Endoscopic ultrasonography; FNA: Fine needle aspirations; CBD: Common bile duct.

is considered by professional societies to be warranted and should be documented. Anesthesia administered was listed prior to and during EUS for 99.5% of patients reported, statistically more significant than the 94% of the 2009 data. The specifics of sedation and/or anesthesia for EUS procedures is an important area

for research, involving the use of large endoscopes and sometimes prolonged procedures. One hundred percent of patients signed informed consent agreement for procedures compared with the 61% documented by Lachter *et al*^[4] (Table 2). While it is likely that every patient also gave consent in the latter study, it is critical

that it all be documented so as to maintain the integrity, quality, and completeness of the reports.

As evidenced by the above results (Table 2), most of the intra-procedural QIs saw significant improvement in operator compliance, making for better-executed and well-reported EUS exams. Adherence to a parenchymal description of suspected pancreatic lesions and detailing of biliary contents and pathology (stones, sludge, etc.) was 100% and 95% respectively. These were significant improvements over the 40% and 64%, respectively, of the previous study. Prominent LN and/or kidney and left liver lobe lesions were detailed when relevant and present in 98% of patients, which was a QI not adhered to previously. Also, the celiac axis was described half the time, an apparently significant improvement over the 35% in 2009 ($P = 0.04$). Description of tumors by the Tumor Node Metastasis system is an area for great improvement as only 13% of patients with tumors were reported accordingly. The detailing of submucosal lesions and surroundings in accordance with layers visualized by EUS was always adhered to (100%), but this was not a significant improvement over the previous study's outcome (95%). This difference highlights the difficulty of demonstrating statistically significant improvement when dealing with high outcomes (the upper limit of adherence can't exceed 100%). The 200 EUS reports detailed level of tumor penetration in 75% of patients and detailed LN presence when suspicious for malignancy and when performing FNA for 80% of patients (Table 2). More intra-procedural issues such as mechanical problems like past abdominal surgeries or ascites and patient awakening or uncooperativeness during procedure were documented for 100% of patients, showing a very significant improvement over the 6% and 2% results, respectively, in the 2009 data (Table 2). Checklisting of these items facilitated documentation without having "mandatory" fields.

While the 2009 results consolidated the FNA performance details (number of passes, needle size, etc.) into one QI entity, our study meticulously examined each of the QIs for detailing FNAs individually in the EUS procedural reports. As such these QIs (numbered 17-22 in the table) were not comparable as is for statistical analysis. Frequencies were computed: 78% of reports documented number of passes, 67% for needle size, 99% for number of needles, 40% described impressions of aspirate, and 100% adhered to the cytology/histological examination and in-room tentative diagnosis indicators (Table 2).

Post-procedural QIs were documented for almost all of the patients: 100% of reports included summary of diagnoses, 95% of examination reports contained findings unrelated to the original reason for referral—a significant improvement from the 37% adherence previously. Physician recommendations and instructions for patients including how they receive results were included in 100% and 99% respectively, showing an improvement in the latter QI from 52% ($P < 0.001$). As per Table 2, the incidence of adverse events was

listed 100% of the EUS procedural reports. A caveat, however, must be noted: Incidence of post-EUS adverse events, as pancreatitis, bleeding, and/or infection, were checked and recorded only for immediate (within 48 h) follow-up of patients. Long-term adverse effects (14 d following) of procedures were not documented and this was an area in post-hoc analysis considered to be in need of QC monitoring.

Limitations

This study had limitations. It was a comparative retrospective study, and as such did not garner the intrinsic advantages that it would have if done prospectively, such as better oversight and control over variables, confounders, and study conditions. Second, while most of the QIs evaluated overlapped for proper statistical comparison, not every QI did. Thirdly, there was no patient satisfaction data collected and assessed in this study, an area which should be developed. Notably, in the past, a local survey was of importance in determining the satisfaction of referring physicians from the EUS examinations; this too should be revisited periodically, as such a survey may improve an EUS service, recognizing that the secondary clients of an EUS service include the referring physicians^[7].

In conclusion, consistent implementation of these EUS QIs by endosonographers facilitates effective high-quality EUS procedures by ensuring comprehensive procedural documentation while also limiting error. Moreover, results of the present study demonstrated that there have been significant improvements in EUS delivery quality and QI adherence when comparing this study to a previous audit of EUS results. The Hawthorne effect describes how workers do better when knowing that their work is being watched and evaluated. By this token, vigilance regarding QIs in EUS, when recorded and published, seems to enhance the adherence to optimizing EUS reports and examinations, as such is the case for this center.

With increasing demand for EUS and the robust number of physicians performing these procedures, recommendations for QIs will continue to evolve and excellence in quality of care will continually be collaboratively pursued.

COMMENTS

Background

Endoscopic ultrasonography (EUS) is an endoscopic procedure that has benefited from quality control analysis and quality indicator (QI) analysis, a benchmark of widely-used guidelines being those of the American Society of Gastrointestinal Endoscopy.

Innovations and breakthroughs

The present study aims to evaluate the impact of the EUS quality assessment on the improvement of these procedures by comparing 2013-14 local EUS procedural reports against relevant corresponding data from a 2009 survey of QIs. That is, whether the EUS operators are improving their adherence/compliance to the QIs, and if the incorporation of and adherence to the QIs enhance the overall quality of EUS exams and patient outcomes.

Applications

Vigilance regarding QIs in EUS, when recorded and published, seems to enhance the adherence to optimizing EUS reports and examinations, as such is the case for this center.

Peer-review

This manuscript evaluated the impact of EUS quality assessment on EUS procedures by comparing the most recent 2013-2014 local EUS procedural reports against relevant corresponding data from a 2009 survey of EUS. The authors used standardized QIs for EUS quality assessment.

Abstract

Perforation is an important procedural complication of endoscopic submucosal dissection (ESD) for early gastric cancer. Although the incidence of delayed perforation after ESD is low, extreme caution is necessary because many cases require surgical intervention. Among 1984 lesions of early gastric cancer treated in our hospital by ESD in 1588 patients from September 2002 through March 2015, delayed perforation developed in 4 patients (4 lesions, 0.25%). A diagnosis of delayed perforation requires prompt action, including surgical intervention when required.

Key words: Endoscopic submucosal dissection; Early gastric cancer; Delayed perforation

INTRODUCTION

The development of endoscopic submucosal dissection (ESD) has facilitated the *en bloc* endoscopic resection of larger lesions, as well as lesions with an ulcer scar. Such lesions are now included in the expanded indications for ESD^[1].

Perforation is an important procedural complication of ESD, reported to occur at an incidence of 3.6% to 8.7%. Most cases of intraoperative perforation can be closed by clipping^[2-4]. In contrast to intraoperative perforation diagnosed during endoscopic treatment, delayed perforation detected after ESD is often associated with peritonitis at time of diagnosis and frequently requires emergency treatment, including surgical intervention^[5]. Few studies have reported on delayed perforation, and its management remains controversial. We describe our experience with 4 patients (4 lesions) who underwent emergency surgery for delayed perforation that developed after ESD in our hospital.

CASE REPORT

Patients and methods

A total of 1984 consecutive lesions of early gastric cancer treated by endoscopic resection between September 2002 and March 2015 were studied. Informed consent was obtained from all patients in accordance with our institutional protocol.

We defined delayed perforation as the abrupt onset of abdominal pain and signs and symptoms of peritoneal irritation accompanied by the presence of free air on chest and abdominal radiography or abdominal computed tomography (CT) in a patient who showed no evidence of perforation during ESD or free air immediately after ESD, as proposed by Hanaoka *et al.*^[5].

ESD procedures

The circumference of the lesion was marked with a needle knife. After injecting glycerol solution into the submucosa, an initial cut was made with a needle knife outside the marking. An IT Knife (Olympus Medical Systems, Tokyo, Japan) was inserted into this cut and operated to cut around the lesion^[6]. The marked lesion was separated from the surrounding normal mucosa.

Then, the submucosal layer was dissected using the IT Knife, and the lesion was finally removed. An IT Knife was used to perform ESD until the end of March 2007, and an IT Knife2 (Olympus Medical Systems) was used from April 2007 onward^[7].
