The risk of CRC in patients with IBD was recognized as far back as 1925 for UC and 1948 for CD^[24]. There were many reports of risk for colon cancer development about UC patients mainly, and which ratio was indicated from 16% to 43%^[25-28]. In 2001 Eaden *et al.*^[13] estimated CRC risk as 2% at 10 years, 8% at 20 years and 18% at 30 years using a widely cited meta-analysis of 116 studies with age stratified data. Interestingly, recent studies we could get two different conclusions about IBD with CRC. Jess *et al.*^[29] suggested that the risk of CAC is almost same between UC patients and the general population in a population-based study from Denmark. In contrast, the risk of CRC is 60% higher with IBD than without IBD matched cohorts of people from California, and the risk remained the same throughout the study period of 14.5 years by Herrinton *et al.*^[15]. There are few reports from Asia on CRC in UC which reports that the pressure ranges from 0.87% to 1.8% in the general population, and it can be as high as 13.5% in patients with extensive type of UC. Thus, the risk of CRC is increased in IBD, though there is variation due to various

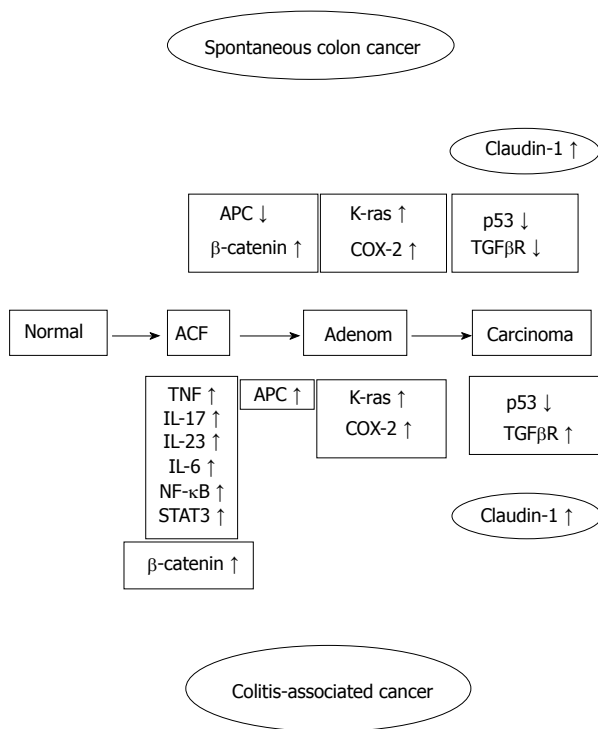

Figure 1 Mechanisms of colorectal cancer and colitis-associated cancer development. APC: Adenomatous polyposis coli; TGFβ: Transforming growth factor beta; NF-κB: Nuclear factor-κB; TNF: Tumor necrosis factor; IL: Interleukin; STAT3: Signal transducer and active of transcription 3.

factors, such as hospital- or population-based data, referral center bias, and small numbers of patients.

IBD is a lifelong diseases that primarily affects young patients. Sustained mucosal healing is becoming the standard objective of the long-term treatment of IBD^[30]. This objective can be achieved currently by maintenance treatment with immunosuppressants, including thiopurines, methotrexate, and anti-tumor necrosis factor (TNF)^[31,32]. Unfortunately, there is no major trend towards the spontaneous extinction of IBD activity with time^[33,34], and disease activity often recurs after the withdrawal of immunosuppressants^[35,36]. Similarly, another report showed that there is an unclear risk of colonic HGD and CRC among patients with IBD treated with immunosuppressants. Beaugerie *et al.*^[37] analyzed data on CRC development among patients with IBD and found that patients with IBD and long-standing extensive colitis are at increased of CRC, although the risk is lower among patients receiving thiopurine therapy. Patients without long-standing extensive colitis have a risk for CRC similar to that of the general population, but they can develop IBD-related lesions within 10 years after their diagnosis of IBD. Table 1 compares CAC with CRC.

DOSE THE SURVEILLANCE STRATEGY NEED TO TAKE INTO ACCOUNT THIS DECREASING RISK OF CAC IN UC PATIENTS?

We have to debate about the surveillance techniques for

Table 1 A comparison colitis-associated cancer and sporadic colorectal cancer

CAC: Up to 20% of UC patients develop CAC within 30 yr of disease onset
CAC: High overall mortality rate
NSAID use reduces the risk of CRC, suggesting a potential role for anticytokine therapy
CRC: Classic adenoma to carcinoma sequence
CAC: Chronic inflammation, injury, dysplasia, and CRC
The common genetic and signaling pathways are different between CRC and CAC including β-catenin, p53, k-ras, B-raf
Both CRC and CAC are associated with transcription factors, such as NF-κB and/or STAT3 which mediate the immune response and oncogenesis
Both CRC and CAC depend on the quality and quantity of intestinal microflora

CRC: Colorectal cancer; CAC: Colitis-associated cancer; UC: Ulcerative colitis; NSAID: Nonsteroidal anti-inflammatory drug; NF-κB: Nuclear factor-κB; STAT3: Signal transducer and active of transcription 3.

CAC and high grade dysplasia whether adequate or not under currently way^[38]. Presently, surveillance of using colonoscopy for UC patients is recommended every 2 years over 8 years after the onset of UC diagnosis. However, sometimes it is very hard to determinate the CRC findings under the UC mucosa, and do not match between the biopsy results and excisional tissue results in pathological diagnosis, this is that colonoscopy is often burdensome for the patient with UC patients^[39-41]. Surprisingly, 20% to 50% of UC patients with CRC were diagnosed with only dysplasia in preoperative pathological diagnosis. This indicates that it is difficult surveillance for UC patients using colonoscopy.

Furthermore, endoscopic findings of IBD-related cancers have been found to easily overlook by colonoscopy because it is not a mass-like lesions to compared with sporadic CRC. As a result, it is very difficult to appropriate for diagnosis of adenocarcinoma for UC patients using biopsied tissue taken from the lesion. Meanwhile, we could find unexpectedly in a specimen resected for medically refractive IBD without previous diagnosis of dysplasia or adenocarcinoma^[42,43].

It is clear that colonoscopic surveillance in the present form is neither ideal nor practical. We should reconsider the guidelines about the colonoscopy surveillance based on the other new reliable date and method. The ideal frequency of surveillance is not clear. Further studies are necessary to optimize the frequency of surveillance, including cost-effectiveness, and to make guidelines considering emerging methods and technologies.

Despite the proven usefulness of colonoscopy surveillance protocols and increased risk of CRC with UC, we could not determinant a useful in clinical diagnosing such as genetic or serological marker. After analyzing the association of the whole genome, the single nucleotide polymorphism (SNP) 300 or more and the genetic loci 160 or more were found to be associated with IBD^[44]. There was another genetic instability report^[45] that sought to identify IBD-associated SNPs that are potential

Figure 2 Hematoxylin-eosin (A, D) and immunostaining of claudin-1 (B, E) and β -catenin (C, F) in ulcerative colitis mucosa (A-C) and ulcerative colitis-associated colorectal cancer tissue (D-F) of a patient with ulcerative colitis-associated colorectal cancer.

markers for CAC by comparing groups of UC patients with and without neoplasia matched for sex, disease duration and age at diagnosis. Their conclusion was that none of the 314 studied IBD-associated SNPs were strongly associated with UC-neoplasia which may be the result of genetic mutations in molecular pathways other than those that predispose to inflammation.

On the other hand, there was a unique report that applied the tree models by considering the response variable as the CAC or UC group and the explanatory variable as the criteria studied by univariate analysis^[46].

We proposed the useful method which analysis is a tree model permits the automatic execution of the process of determining the factors, setting the threshold value and by differentiating the patients successively into two groups during the process automatically. Therefore, it might be another possibility to help identify the indication and timing for surgery in UC patients, because the ideal surveillance methods have not yet been established.

Treatment for CAC including surgery

The overall prevalence of CRC in patients with UC has been estimated as 3.7% in a meta-analysis^[13]. Chronic UC for > 10 years and pancolitis are known risk factors for CAC^[47]. On the other hand, sporadic adenoma and adenocarcinoma can arise coincidentally in patients with UC. From the perspective of clinical considerations, accurate pathological diagnosis is very important for distinguishing between different pathological entities, given their different therapeutic consequences such as sporadic adenocarcinoma and CAC.

Anal function and quality of life differ substantially

between total proctocolectomy with ileal pouch anal anastomosis (IPAA) and low anterior resection (LAR). A key point is that further proctocolectomy and IPAA may be suitable for sporadic cancers in the lower rectum. In patients with UC, irrespective of the degree of colitis, LAR should not be selected for sporadic cancer in the lower rectum except in older patients, based on considerations of quality of life and risk of further colitis. In elderly patients with poor anal function, surgical procedures should obviously be considered based on overall considerations including prognosis of the cancer, degree of inflammation with colitis, and potential requirements for further treatment. In view of the risk of recurrent colitis and cancer, partial resection might be less advantageous than proctocolectomy. Proctocolectomy with IPAA may be safe for advanced CRC regardless of the origin as colitic or sporadic cancer, because of the difficulty of differentiation, ready invasive behavior against an inflamed background and worsened potential for further progressive colitis in younger patients. Decisions on surgical procedures should be made based on full consideration of background factors including age, degree of colitis and cancer prognosis.

There was an interesting report on the risk of ileoanal pouch neoplasia in patients with IBD^[48]. Although restorative proctocolectomy with IPAA substantially reduces the risk of CRC in patients with IBD, subsequent pouch neoplasia can develop. The purpose of their study was to determine the cumulative incidence of pouch neoplasia in patients with IBD and to identify risk factors for developing pouch neoplasia. The incidence and prevalence of pouch neoplasia in patients with IBD

are probably low. According to the latest review, only 42 pouch adenocarcinomas have been described in the literature^[49]. A previous study reported a cumulative incidence of pouch neoplasia of 1.9% after 15 years and 5.1% after 25 years^[50]. However, these data were collected in a single tertiary pouch referral center and may not be representative of the general IBD population with IPAA. Furthermore, the relatively low incidence makes it difficult to assess risk factors for the development of pouch neoplasia. The result of the study indicated that the incidence of pouch neoplasia in patients with IBD without a history of colorectal neoplasia is relatively low. Prior dysplasia or colon cancer is associated with an approximately 4- and 25-fold increase in risk, respectively, of developing pouch neoplasia.

CONCLUSION

UC is a benign disease. However, according to the recent reports that the rate of CAC is increasing in UC patients, and such cases have a worse prognosis. As such, there is a need for appropriate diagnosis and treatment. Actively introducing the surgical treatment in addition to medical treatment should be considered. Several physicians should analyze UC from their unique perspectives in order to establish new clinically relevant diagnostic and treatment methods in the future. We should determine the risk factors for UC patients with cancer based on a large body of data, and we should attempt to prevent the increase in the number of such patients using these newly identified risk factors in the near future.

Abstract

Pancreatic cancer is one of the deadliest cancers with a very poor prognosis. Recently, there has been a significant increase in research directed towards identifying potential biomarkers that can be used to diagnose and provide prognostic information for pancreatic cancer. These markers can be used clinically to optimize and personalize therapy for individual patients. In this review, we focused on 3 biomarkers involved in the DNA damage response pathway and the necroptosis pathway: Chromodomain-helicase-DNA binding protein 5, chromodomain-helicase-DNA binding protein 7, and mixed lineage kinase domain-like protein. The aim of this article is to review present literature provided for these biomarkers and current studies in which their effectiveness as prognostic biomarkers are analyzed in order to determine their future use as biomarkers in clinical medicine. Based on the data presented, these biomarkers warrant further investigation,

and should be validated in future studies.

Key words: Chromodomain-helicase-DNA binding protein 5; Chromodomain-helicase-DNA binding protein 7; Mixed lineage kinase domain-like protein; Pancreatic adenocarcinoma; Biomarker

Chromodomain-helicase-DNA binding protein 5, 7 and proneurotic mixed lineage kinase domain-like protein serve as potential prognostic biomarkers in patients with resected pancreatic adenocarcinomas. *World J Gastrointest Oncol* 2016; 8(4): 358-365 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i4/358.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i4.358>

INTRODUCTION

With an estimated 39590 deaths in 2014, pancreatic cancer is the fourth leading cause of death from cancer in the United States^[1]. Pancreatic adenocarcinoma (PAC), the most common type of pancreatic cancer, has a very poor prognosis with a five-year survival rate of 5% for patients with all stages of disease^[2]. Patients with early-stage resected PAC have the best prognosis when followed by treatment with adjuvant therapy^[3,4], with a median overall survival (OS) of approximately 3 years^[5]. Potential predictive and prognostic biomarkers could play an important role in determining the most effective and productive treatment for individual patients. PAC is genetically heterogeneous and several well-known and some newly defined core signaling pathways likely play a role in development and behavior of PAC, including necroptosis, a form of cell death, and the DNA damage response pathway^[6]. In this review, we will explore those pathways and putative biomarkers associated with them^[7].

BIOMARKERS AND PAC

The Food and Drug Administration (FDA) defines a biomarker as "any measureable diagnostic indicator that is used to assess the risk or presence of disease"^[8]. In recent years, there has been a tremendous increase in research

directed towards identifying biomarkers in specific cancers. There are many biomarkers being used in other cancers that aid in the diagnosis and establishment of personalized treatment for patients. Though the use of biomarkers in the treatment of cancer is expanding, the role of biomarkers in the treatment of patients with PAC trails behind. To date, CA 19-9, discovered in 1981, remains as the only FDA approved biomarker in diagnosing PAC. Other cancers are also associated with elevated CA 19-9 levels including the following: Colorectal^[9], esophageal^[10], lung^[11], ovarian^[12], and breast^[10], making CA 19-9 a nonspecific marker. Patients with pancreatitis, elevated bilirubin levels, and cirrhosis can also present with elevated CA 19-9 levels^[13]. This makes it difficult to determine whether these levels are high due to tumor involvement or non-cancerous events. CA 19-9 is also viewed as a poor prognostic tool due to the fact that it is not expressed in 10% of Caucasians and 40% of Africans^[14]. This is due to a deficiency in fucosyltransferase enzyme which is involved in the production of CA 19-9 and Lewis antigen. Currently, CA 19-9 is most useful as a diagnostic tool when measured after resection for disease recurrence^[15].

Prognostic biomarkers that hold promise are SMAD4 and glypican-1 (GPC1). GPC1 is a cell surface proteoglycan located on cancer-cell-derived exosomes. Melo *et al*^[16] were able to distinguish between healthy subjects and patients with a benign pancreatic disease from patients with early- and late-stage pancreatic cancer by measuring serum levels of GPC1⁺ circulating exosomes (crExos). Levels of GPC1⁺ crExos also were found to connect with tumor burden and the survival of pre- and post-surgical patients^[16].

Mutations that inactivate SMAD Family Member 4 (SMAD4) occur most commonly in pancreatic cancers vs other cancer types^[17]. SMAD4 is silenced in 53% of pancreatic cancer cases^[18]. SMAD4 expression is lost through loss of heterozygosity and intragenetic mutations along with other alterations such as KRAS mutations^[19]. KRAS mutations, located in 95% of pancreatic cancers^[20], are usually followed by loss of SMAD4 in late development of PAC^[21]. Loss of SMAD4 promotes the progression of preneoplastic lesions and is associated with worse prognosis in patients with PAC. Numerous studies support this claim^[22-27]. Blackford *et al*^[22] determined that patients whose cancers lacked SMAD4 expression had significantly worse survival outcomes than patients with normal SMAD4 expression. Tascilar *et al*^[23] built on this observation by showing that the loss of expression of the SMAD4 protein by immunolabeling is associated with poor prognosis in patients with resected PAC, and patients with intact SMAD4 expression survived significantly longer than patients whose cancers lacked SMAD4 (median survival, 19.2 vs 14.7 mo; $P = 0.03$). Biankin *et al*^[24] concluded that SMAD4 expression predicted increased survival and improved response to surgery. Reduced survival in colon cancer was associated with decreased SMAD4 expression in a study conducted by Isaksson-Mettävainio *et al*^[25]. Reduced SMAD4 expression is also present in head- and - neck squamous cell carcinomas and esophageal squamous cell carcinoma^[19]. SMAD4 expression is lost

in 40%-50% of colon cancers^[25] and 25% of prostate cancers^[26]. In 45% of cholangiocarcinomas, loss of SMAD4 expression is present and associated with more aggressive tumor behavior^[27].

Identifying biomarkers

Identification and validation of predictive biomarkers for responsiveness to adjuvant therapy is extremely important for patients with PAC. These markers can be used clinically to optimize and personalize therapy for individual patients. At this point, no biomarkers have been identified to reliably predict patient outcome, and more knowledge of potential biomarkers may aid in tailoring and directing patient therapy. Our group has previously identified several potential prognostic markers involved in either the necroptotic or DDR pathway including chromodomain-helicase-DNA binding protein 5 (CHD5), CHD7, and mixed lineage kinase domain-like protein (MLKL) (Table 1).

DDR serves as cancer barrier

As defined by Curtin^[28] the DDR is a series of pathways that “coordinates the repair of DNA and the activation of cell cycle checkpoints to arrest the cell to allow time for repair”. The DDR has evolved in order to maintain the genomic integrity of the cell. It constantly protects the cell from endogenous and environmental damage that could disrupt DNA by causing single stranded breaks or double stranded breaks (DSBs). The DDR acts as a cancer barrier by activating DNA repair mechanisms and apoptosis so that unstable cells will not replicate and result in DDR related diseases and precancerous lesions.

One pathway of the DDR is homologous recombination repair (HRR). Occurring during the S and G₂ phases of the cell cycle^[29], HRR is associated with familial forms of pancreatic cancer associated with the following genes: *BRCA1*, *BRCA2*, *PALB2*, *ATM*, *RAD51D*, and *RAD51C*^[30]. HRR repairs DSBs. γ H2AX foci are markers for DSBs in precancerous lesions. These markers are produced during a phosphorylation reaction following chromatin engulfing the DSB^[31,32].

Data has shown that the DDR may promote the survival of PAC that outgrows the selection pressure of DDR activation^[33]. Many *DDR* genes are somatically mutated in PAC, including *ATM*, *BRCA2*, *CDKN2A*, *FANCI*, *HELB*, and *RAD9*^[34]. Dysregulated expression of tumor suppressor genes that induce DDR activation can function as biomarkers for poor outcome.

CHD5 functions as a tumor suppressor gene

CHD5 is a member of a family of chromodomain enzymes that belong to the ATP-dependent chromatin remodeling protein superfamily. It has been suggested that CHD5 is the master regulator of a tumor-suppressive network^[35]. CHD5 is regulated by DNA methylation of its promotor and histone modifications. The ability of CHD5 to bind unmodified histone 3 is essential for tumor suppression^[36]. CHD5 is epigenetically silenced in

neuroblastoma^[37], colorectal cancer^[38], breast cancer^[39], cervical cancer^[39], hepatocarcinoma^[39], gastric cancer^[40] and lung cancer^[41]. Mutations in CHD5 have been found in head and neck squamous cell carcinoma^[42], prostate cancer^[43], ovarian cancer^[44], ovarian clear cell carcinoma^[45], cutaneous melanoma^[46], hepatocellular carcinoma^[47], neuroblastoma^[48], breast and colorectal cancer^[49]. In a study conducted by Bagchi *et al*^[50] loss of CHD5 enhanced tumor proliferation whereas restoration of CHD5 inhibited proliferation. The function of CHD5 has mainly been studied in neural tissues where it was determined to control cell death and replication *via* the p19(Arf)/p53 pathway^[50]. CHD5 is also a putative substrate of the ATM/ATR checkpoint kinases, suggesting that it may have a role in the DDR^[51].

Silencing of CHD5 activates the DDR

Expression of CHD5 corresponds with a cell's capability of locating and repairing DNA damage in cells. In a study conducted by Hall *et al*^[33] preclinical data showed increased levels of γ H2AX foci markers suggesting increased levels of DSBs in pancreatic cancer cells. This was correlated with low CHD5 expression in those cells. As a result, activation of the DDR presumes due to the presence of collapsed replication forks^[33].

Low CHD5 expression is associated with worse clinical outcomes

In the same study by Hall *et al*^[33] the relationship between CHD5 levels in pancreatic cells and DDR activation was evaluated in a clinical population. The OS of 80 patients with resected PAC was analyzed in conjunction with CHD5 expression. Low CHD5 expression was associated with decreased recurrence free survival (RFS) and decreased OS in patients with PAC (5.3 vs 15.4 mo, $P = 0.03$)^[33]. The association between low CHD5 expression and poor survival has also been documented in other cancers, including gallbladder carcinoma^[52], neuroblastoma^[53], ovarian cancer^[54] and breast cancer^[55].

CHD5 as a prognostic biomarker

Available data seems to reflect that low CHD5 expression suggests a poor prognosis. If validated in an independent cohort, low CHD5 expression could be used to select patients with particularly aggressive disease for further adjuvant therapy. Due to its clinical relevance as both a tumor suppressor and a prognostic factor in numerous cancers, study of CHD5 function in the DDR warrants further review.

CHD7 as a potential DDR substrate

CHD7 is a member of a family of chromodomain enzymes that encode an ATP-dependent chromatin remodeler. Mutations in CHD7 causes CHARGE syndrome, a multiple anomaly disorder that presents with a variety of phenotypes, including ocular coloboma, heart defects, choanal atresia, retarded growth and development, genitourinary hypoplasia, and ear abnormalities^[56]. Mutations in CHD7

Table 1 Summary of chromodomain-helicase-DNA binding protein 5, 7 and mixed lineage kinase domain-like protein biomarkers in pancreatic adenocarcinoma

Biomarker	Pathway affected	Biomarker type for pancreatic cancer from literature and studies? (prognostic, predictive, diagnostic)	Mechanism of action	Other cancers	Comments
CHD5 ^[33]	DDR	Prognostic	Tumor suppressor gene. Binds to histone 3	Epigenetically silenced in neuroblastoma ^[37] , colorectal cancer ^[38] , breast cancer ^[39] , cervical cancer ^[39] , hepatocarcinoma ^[39] , gastric cancer ^[40] and lung cancer ^[41] . Mutations found in head and neck squamous cell carcinoma ^[42] , prostate cancer ^[43] , ovarian cancer ^[44] , ovarian clear cell carcinoma ^[45] , cutaneous melanoma ^[46] , hepatocellular carcinoma ^[47] , neuroblastoma ^[48] , breast and colorectal cancer ^[49]	Low expression correlates with worse clinical outcomes
CHD7 ^[66]	DDR	Prognostic	Interacts with SOX2 to regulate gene expression	-	Decreased expression is associated with improved clinical outcomes
MLKL ^[74]	Necroptosis	Prognostic	Forms necrosis-inducing complex called a "necrosome" along with RIPK1 and RIPK3	Ovarian ^[75]	Low expression is associated with worse clinical outcomes

DDR: DNA damage response pathway; SOX2: (Sex Determining Region Y)-Box 2; RIPK1: Receptor-interacting serine/threonine-protein kinase 1; RIPK3: Receptor-interacting serine/threonine-protein kinase 3.

also cause Kallman Syndrome, a genetic disorder marked by hypogonadotropic hypogonadism and anosmia^[57], and associated with colorectal carcinomas^[58]. CHD7 helps to regulate neural crest gene expression^[59], regulates ribosomal RNA biogenesis^[60], and interacts with SOX2 to regulate gene expression^[61]. CHD7 is also a potential substrate of the ATM/ATR checkpoint kinases, suggesting a role in the DDR^[51,62]. CHD7 is also dysregulated in 13% to 35% of cases of pancreatic adenocarcinoma, with aberrant expression, copy-number variation, and somatic mutations^[63-65].

Low CHD7 expression associated with better prognosis

Colbert *et al.*^[66] suggested that CHD7 deficiency may play a role in gemcitabine sensitization in pancreatic adenocarcinoma cells and delayed pancreatic tumor xenograft growth in mice treated with gemcitabine. Additionally, they showed that CHD7 knockdown impaired ATR-dependent phosphorylation of CHK1 and increased gemcitabine-induced DNA damage *in vitro*, revealing a novel function for CHD7 as a DDR protein: The maintenance of genome integrity in response to gemcitabine^[66]. Low CHD7 expression was also associated with improved RFS and OS in a retrospective analysis of patients with early-stage resected pancreatic adenocarcinoma treated with adjuvant gemcitabine^[65].

CHD7 as a prognostic biomarker

The study conducted by Colbert *et al.*^[66] suggests that CHD7 expression could potentially be explored as a prognostic biomarker to personalize adjuvant therapy for these patients by determining which patients will receive greater benefit from gemcitabine therapy and

allowing clinicians a way to better select patients for specific adjuvant therapy regimens in the future.

The necroptotic pathway and MLKL

Cell death is mediated through two processes, necrosis and apoptosis. Apoptosis is characterized by chromatin condensation, cell shrinkage, plasma membrane blebbing, and formation of apoptotic bodies^[67]. Necrosis is characterized by oncosis, organelle swelling, and plasma membrane rupture^[68]. Many cancer treatments, including chemotherapy and radiation, induce necrotic cell death^[68-70]. Necrosis has been deemed a passive and unregulated process in contrast to apoptosis, however, emerging evidence has shown that necrosis can occur in a regulated and controlled manner^[71]. Tumor necrosis factors (TNF)-induced necrotic death is called necroptosis^[72]. Necroptosis is dependent on the activities of receptor-interacting protein kinase 1 (RIPK1) and 3 (RIPK3)^[68].

Along with RIPK1 and RIPK3, MLKL forms the necrosis-inducing complex called a "necrosome"^[73]. MLKL is considered a dead kinase due to its lack of phosphate-binding glycine-rich P loop and the absence of a key amino acid, aspartate, required for kinase activity. The necrosome induces cell death through the phosphorylation of MLKL by RIPK3 through the kinase-like domain^[73]. The activity between MLKL and RIPK3 is amplified by TNF- α -mediated RIPK1 activation^[73].

Low MLKL associated with worse prognosis

Colbert *et al.*^[74] explored MLKL expression as a potential prognostic biomarker in patients undergoing resection for

early-stage PAC. Low expression of MLKL was associated with decreased OS regardless of whether adjuvant therapy was used^[74]. The HR for death associated with low MLKL expression became stronger in the group of patients treated with adjuvant therapy than in all patients, and was strongest in those patients receiving gemcitabine chemotherapy^[74]. In a study conducted by He *et al.*^[75] low expression of MLKL was significantly associated with decreased DFS and OS in patients with primary ovarian cancer. The finding low MLKL expression is associated with worse outcomes in patients with primary ovarian cancer and early-stage PAC may be a result of decreased necroptosis signaling. This suggests that necroptosis is an important determinant of cancer cell death and outcome of patients with these cancers^[75]. Study of this gene warrants further analysis as patients with low MLKL expression may benefit from more aggressive chemotherapy regimens or participation in clinical trials due to the low probability that they will benefit from traditional adjuvant therapy. Although MLKL expression may be a useful prognostic marker, further studies should be performed in other patient populations and in larger studies for validation. Also, future studies should also examine the role of MLKL in predicting response to gemcitabine therapy.

CONCLUSION

In the biomarker studies conducted for CHD5, CHD7, and MLKL, each individual gene might serve as an independent prognostic biomarker for patients with early-stage resected PAC. The findings presented provide hypothesis generating momentum to study the expression of these genes in prospective cohorts undergoing adjuvant therapy for PAC. In future studies, using larger patient cohorts, it can be determined whether multiple gene expression provides a more accurate prognostic value than single gene expression alone. The potential exists for clinicians to use biomarkers such as CHD5, CHD7, and MLKL to select the most beneficial therapy regimens and tailor them for individual patients in the future.

Abstract

The emergence of the "precision-medicine" paradigm in oncology has ushered in tremendous improvements in patient outcomes in a wide variety of malignancies. However, pancreas ductal adenocarcinoma (PDAC) has

remained an obstinate challenge to the oncology community and continues to be associated with a dismal prognosis with 5-year survival rates consistently less than 5%. Cytotoxic chemotherapy with gemcitabine-based regimens has been the cornerstone of treatment in PDAC especially because most patients present with inoperable disease. But in recent years remarkable basic science research has improved our understanding of the molecular and genetic basis of PDAC. Whole genomic analysis has exemplified the genetic heterogeneity of pancreas cancer and has led to ingenious efforts to target oncogenes and their downstream signaling cascades. Novel stromal depletion strategies have been devised based on our enhanced recognition of the complex architecture of the tumor stroma and the various mechanisms in the tumor microenvironment that sustain tumorigenesis. Immunotherapy using vaccines and immune checkpoint inhibitors has also risen to the forefront of therapeutic strategies against PDAC. Furthermore, adoptive T cell transfer and strategies to target epigenetic regulators are being explored with enthusiasm. This review will focus on the recent advances in molecularly targeted therapies in PDAC and offer future perspectives to tackle this lethal disease.

Key words: Pancreas neoplasm; Vaccines; Targeted therapy; Immunotherapy; Kirsten rat sarcoma oncogene

Core tip: The treatment of pancreas ductal adenocarcinoma is in an exciting phase due to a tremendous surge in knowledge regarding the molecular mechanisms that underlie pancreas cancer that has fueled interest in devising novel strategies to target signal transduction factors downstream to kirsten rat sarcoma oncogene, desmoplastic tumor stroma and cancer stem cells. Furthermore, immunotherapy by utilizing vaccines and immune checkpoint inhibitors is gaining momentum. Alluring results from studies evaluating molecularly targeted therapies have not only proven the feasibility of this approach but are also indicative of a paradigm shift in management of pancreatic cancer in the near future.

INTRODUCTION

Over the past few decades, pancreas ductal adenocarcinoma (PDAC) has claimed notoriety by proving to be one of the most recalcitrant solid-organ malignancies. As a telltale sign of its lethality, PDAC accounts for less than 3% of new cancers diagnosed annually in developed nations and in the United States, yet it is the fourth leading cause of cancer related mortality^[1]. Ominously, PDAC is also poised to surpass breast, prostate and colon cancers to become the second leading cancer related cause of death by 2030^[2]. Owing to the late stage at presentation, most patients with PDAC are not candidates for surgical resection. Even patients with early-stage disease who undergo surgical resection and adjuvant therapy eventually relapse and succumb to it^[3,4].

Patients with advanced disease have a dismal prognosis with 5-year survival rates of less than 5%^[5]. Following the initial success of gemcitabine in the metastatic setting^[6], oncologists have traditionally relied upon cytotoxic chemotherapy to tackle locally advanced and metastatic disease but with limited success. After nearly two decades of research to identify optimal regimens for metastatic PDAC, the PRODIGE 4/ACCORD 11 and MPACT trials have proven the efficacy of combination chemotherapy with meaningful increase in overall survival (OS) although accompanied by the risk of increased toxicity^[7,8]. The median survival for patients with metastatic disease still remains less than 1 year^[7,8].

MOLECULAR THERAPEUTICS IN PDAC

The dawn of the era of precision-medicine in oncology has led to tremendous gains in understanding various molecular mechanisms of PDAC oncogenesis, but translating this knowledge to the bedside with targeted therapy has been a daunting task. The complex biology of PDAC has posed a formidable challenge against successful targeted interventions (summarized in Table 1). However, in recent years several innovative approaches have achieved early success to pave the way for impactful molecular therapeutic strategies.

GENETIC HETEROGENEITY OF PDAC

Similar to the adenoma-carcinoma sequence in colon cancer, the development of PDAC represents the culmination of progressive increments in dysplasia in precursor lesions collectively termed pancreatic intra-epithelial neoplasia (PanIN)^[9]. Molecular profiling studies in genetically engineered mouse models (GEMM) have demonstrated that histological progression of PanINs

from low to high-grade occurs in tandem with successive accumulation of gene mutations such as activation of the *KRAS* oncogene, inactivation of the tumor suppressor cyclin dependent kinase-N2A (*CDKN2A*) gene and the eventual inactivation of TP53 and deleted in pancreatic cancer 4 (*DPC4/SMAD4*) genes^[10]. All of the same genetic alterations also occur in established PDAC but at a higher frequency (Table 2). Patients with familial forms of PDAC also harbor germ-line mutations in *BRCA2* and partner and localizer of *BRCA2* (*PALB2*) genes^[11,12]. In a sentinel genomic analysis of 24 pancreatic tumors, Jones *et al.*^[13] classified the genetic alterations in PDAC into a core set of 12 cellular signaling pathways that encompass an incredibly high 63 gene mutations within an individual tumor. A recent study of 109 micro-dissected pancreatic tumors by whole-exome sequencing corroborated the high mutational burden and also identified other novel genetic mutations that confer adverse prognosis such as *MYC* amplification^[14]. Abnormalities in Wnt and Hedgehog signaling, chromatin remodeling and DNA repair mechanisms occur at a high frequency in PDAC^[14,15]. In addition to remarkable variations in genetic abnormalities in individual tumors, the realization that PDAC genes function through a relatively small number of pathways confers a level of genetic heterogeneity that makes molecular targeting exceptionally difficult.

Targeting *KRAS* and downstream signal transduction

The four human *RAS* genes encode for small guanosine triphosphatases (GTPases) and under normal circumstances cycle between an active GTP-bound and an inactive guanosine diphosphate (GDP) bound state^[16]. Upwards of 95% of PDACs possess activating mutations of the *KRAS* gene, most commonly at the G12 residue^[17]. Mutant *KRAS* remains persistently active in the GTP-bound state and results in uninterrupted downstream signal transduction of growth signals such as rapidly activated fibrosarcoma homolog B (*BRAF*), mitogen activated protein kinase (MAPK) and phosphatidylinositol-3 kinase (*PI3K*)/mammalian target of rapamycin (*mTOR*)^[16].

Despite intensive efforts, direct pharmacologic inhibition of *KRAS* has been unsuccessful because of the high binding affinity of the oncoprotein to GTP and inability to identify an easily accessible active site within *KRAS* that is susceptible to competitive allosteric inhibition^[18]. To overcome these difficulties, alternate approaches have been attempted but with limited success. Van Cutsem *et al.*^[19] attempted inhibition of farnesylation, a crucial step in post-translational modification of *KRAS* proteins that is essential for membrane anchorage of *RAS*, using the farnesyl-transferase inhibitor tipifarnib in combination with gemcitabine. But no improvement in OS was observed when compared to gemcitabine plus placebo in patients with advanced PDAC. Likewise, other strategies such as dislodging *KRAS* from the plasma membrane and preventing interactions with *KRAS* activating proteins have been effective in pre-clinical models but are yet to be translated to the clinical setting^[20,21].

Substantial efforts have also been devoted to inhibition

Table 1 Barriers to effective molecularly targeted therapy in pancreatic ductal adenocarcinoma

PDAC biology	Barrier
Genetic heterogeneity	Inability to directly inhibit <i>KRAS</i>
	Convergence of signal transduction pathways downstream from <i>KRAS</i> with feedback inhibitory loops
Overexpression of EGFR, IGF-1R	Escape from growth factor dependence in later stages of tumorigenesis
Desmoplastic stroma	Hypoxic tumor milieu impairs effective drug delivery
Overexpression of angiogenic factors	Secretion of angiostatic factors in tumor microenvironment
PDAC stem cells	Difficult to eradicate subpopulation of cells capable of self-renewal
	Resistance to chemotherapy, radiation
Low immunogenicity	Evasion of host immunity
	Abundance of immunosuppressive cells in tumor milieu

PDAC: Pancreatic ductal adenocarcinoma; *KRAS*: Kirsten rat sarcoma oncogene; EGFR: Epidermal growth factor receptor; IGF-1R: Insulin like growth factor-1 receptor.

of downstream signal transduction, especially the PI3K and MAPK (RAF/Mek/ERK) pathways, as they are more amenable to pharmacological inhibition^[22-24]. Disconcertingly, this strategy has proven unsuccessful because inhibition of the MEK pathway resulted in feedback activation of the PI3K pathway mediated by the epidermal growth factor receptor (EGFR)^[25]. To counter this Ko *et al*^[26] investigated the effect of dual inhibition of EGFR and MEK with erlotinib and selumetinib respectively. In this phase II non-randomized trial of 41 patients with chemotherapy refractory PDAC, 26% had stable disease for 12 wk or more and 38% of patients had a greater than 50% decline in CA 19-9 levels^[26]. Though this combination approach showed promise, it needs to be validated in larger studies.

Targeting *BRCA2* and *PALB2*

The main role of the tumor suppressor genes *BRCA2* and *PALB2* is to repair double stranded DNA breaks by homologous recombination. In patients with germ-line mutations of these genes, DNA repair occurs by alternate means, predominantly by base-excision repair mediated by the enzyme poly(ADP-ribose) polymerase (PARP). Inhibition of PARP in patients with BRCA mutations renders tumor cells incapable of repairing DNA damage and cell death ensues. This concept is known as “synthetic lethality” and represents a great example of targeted therapy in PDAC^[27].

In a preclinical study, the PARP inhibitor 3-amino-benzamide in combination with gemcitabine showed strong anti-tumor activity by inducing apoptosis in PDAC cell lines^[28]. Remarkably, neoadjuvant iniparib plus gemcitabine induced a complete pathological response in a patient

with recurrent PDAC harboring the *BRCA2* mutation^[29]. In a phase I study of olaparib plus gemcitabine in patients with advanced solid tumors that also included 15 patients with PDAC, no differences in efficacy endpoints were noted with the combination^[30]. However, these patients were genetically unselected and were unable to receive full-dose gemcitabine due to myelotoxicity attributed to olaparib. The role of PARP inhibitors in PDAC might thus be limited to patients with *BRCA2* mutations. The combination of PARP inhibitors with cytotoxic chemotherapy is also being investigated (ClinicalTrials.gov identifiers: NCT01585805 and NCT01296763, Table 3).

OVEREXPRESSION OF GROWTH-FACTOR RECEPTORS ON TUMOR CELLS

PDAC cells overexpress the EGFR and its ligand transforming growth factor- α (TGF- α)^[31]. In transgenic mouse models, EGFR signaling mediated by TGF- α has been shown to be essential for the onset of ductal metaplasia, a precursor lesion that progresses to PanIN and eventually to PDAC^[32]. EGFR signaling is perceived to be a vital cog in mediating the oncogenic effects of *KRAS* as evidenced in mouse models wherein genetic or pharmacological inhibition of EGFR signaling eliminates tumorigenesis^[33,34]. The exact mechanism by which EGFR overexpression contributes to the development of PDAC is unclear but could be related to induction of the Notch pathway^[35]. EGFR overexpression is also associated with increased propensity for liver metastasis and poor prognosis^[36]. Paradoxically, despite compelling pre-clinical evidence, the EGFR inhibitor erlotinib showed only a marginal clinical benefit for patients with advanced PDAC by prolonging OS by a mere 2 wk^[37]. It is hypothesized that EGFR signaling might be essential earlier in tumorigenesis while advanced PDAC cells escape EGFR dependence^[38].

Targeting insulin-like growth factor-1 receptor

PDAC cells also overexpress insulin-like growth factor-1 receptor (IGF-1R)^[39]. IGF-1R signaling promotes tumorigenesis by activating PI3K, MAPK, AKT and Rac pathways^[40]. This results in uncontrolled cellular proliferation, survival and metastasis. Based on exciting and positive results from preclinical^[41] and early-phase trials^[42,43], ganitumab, a fully humanized monoclonal antibody against IGF-1R combined with gemcitabine was investigated in a phase III, double-blind, placebo-controlled randomized controlled trial (RCT) as first-line therapy for patients with metastatic PDAC^[44]. Though the ganitumab-gemcitabine combination was safe, the study was terminated early based on results of a pre-planned futility analysis which revealed no improvement in the primary objective of OS, and the reason for lack of efficacy is yet unclear^[44]. Inhibition of IGF-1R using small interfering RNA (siRNA) had an anti-proliferative effect on HPAC and Panc-1 pancreatic cancer cell lines invoking the possibility of a novel target for

Table 2 Frequency and consequences of common genetic mutations in pancreatic ductal adenocarcinoma

Mutation category	Frequency in PDAC	Effects of mutation	Consequence
Gain of function <i>KRAS</i>	> 95%	Continuous transduction of downstream growth signals (BRAF/MAPK, PI3K/mTOR)	Enhanced cell growth and survival
Loss of function <i>CDKN2A</i>	95%	Disruption of RB1 by CDK4	Uncontrolled cellular proliferation
<i>TP53</i>	75%-85%	Impaired DNA damage repair, loss of cell cycle checkpoint activation	Chromosomal instability, aneuploidy
<i>DPC4/SMAD4</i>	50%	Loss of inhibition of TGF- β	Loss of cell growth inhibition
<i>BRCA2</i>	6%-17%	Impaired DNA damage repair by homologous recombination, loss of cell-cycle checkpoint activation	Genomic instability
<i>PALB2</i>	1%-3%	Impaired <i>BRCA2</i> function	Genomic instability

KRAS: Kirsten rat sarcoma oncogene; *BRAF*: Rapidly activated fibrosarcoma homolog B; *MAPK*: Mitogen activated protein kinase; *PI3K*: Phosphatidylinositol-3 kinase; *mTOR*: Mammalian target of rapamycin; *CDK*: Cyclin dependent kinase; *DPC4*: Deleted in pancreatic cancer 4; TGF- β : Transforming growth factor- β ; *BRCA2*: Breast cancer 2; *PALB2*: Partner and localizer of *BRCA*.

Table 3 Summary of selected ongoing clinical trials evaluating molecular therapies in pancreatic ductal adenocarcinoma (according to www.clinicaltrials.gov, accessed July 2015)

Category	Clinical trial number	PDA setting	Medications studied	Phase	Status	Estimated completion
Tumor suppressor genes	NCT01585805	Locally advanced/ metastatic	Gem and Cisplatin \pm Veliparib <i>vs</i> Veliparib alone	II	Recruiting	07/2017
	NCT01296763	Advanced	Irinotecan + Cisplatin + Mitomycin C \pm Olaparib	I / II	Ongoing, not recruiting	01/2014
Recombinant hyaluronidase	NCT01959139	Metastatic	FOLFIRINOX \pm PEGPH20	I / II	Recruiting	12/2017
	NCT01839487	Metastatic	Gem + Nab-paclitaxel <i>vs</i> Gem + Nab-paclitaxel + PEGPH20	II	Recruiting	04/2016
Vaccine therapy	NCT02004262	Metastatic	Cy + GVAX + CRS-207 <i>vs</i> Chemotherapy <i>vs</i> CRS-207	II	Recruiting	12/2016
	NCT01072981	Adjuvant	Chemotherapy <i>vs</i> Chemo-radiotherapy \pm Algenpantucel-L	III	Ongoing, not recruiting	06/2016
	NCT01836432	Neoadjuvant	FOLFIRINOX \pm Algenpantucel-L	III	Recruiting	09/2015
Immune checkpoint	NCT02472977	Metastatic	Ulocuplumab (CXCR4) and nivolumab (PD1)	I B	Recruiting	7/2017
CAR-T cell therapy	NCT01897415	Metastatic	Autologous redirected RNA mesothelin specific CAR-T cells	I	Not recruiting	01/2015
	NCT01583686	Metastatic	CAR-T cell receptor	I / II	Recruiting	12/2018
Micro-RNA-21 targeted therapy	NCT01274455	Locally advanced	Gem + Plasmid DNA CYL-02	I	Not recruiting	12/2013
Signal transduction inhibitors						
Janus kinase targeted	NCT02119663	Locally advanced/ metastatic	Capecitabine + Ruxolitinib <i>vs</i> Capecitabine + Placebo	III	Recruiting	06/2017
	NCT02117479	Locally advanced/ metastatic	Capecitabine + Ruxolitinib <i>vs</i> Capecitabine + Placebo	III	Recruiting	12/2015
Wnt targeted	NCT02050178	Metastatic	OMP-54F28 + Gem-Nab-paclitaxel	I	Recruiting	12/2016
	NCT01764477	Metastatic	PRI-724 + Gem	I	Recruiting	03/2016
Notch inhibitor	NCT01647828	Locally advanced/ metastatic	OMP-59R5 + Gem-Nab-paclitaxel	I / II	Recruiting	01/2016
	NCT01373164	Locally advanced/ metastatic	LY2157299 + Gem	I / II	Not recruiting	11/2015

PDA: Pancreas ductal adenocarcinoma; Gem: Gemcitabine; FOLFIRINOX: 5-fluorouracil, leucovorin, irinotecan, oxaliplatin; CAR-T: Chimeric antigen receptor T cell; TGF- β : Transforming growth factor- β ; Cy: Cyclophosphamide.

future clinical studies^[45].

DESMOPLASTIC STROMA

The stroma of PDAC is characterized by an intense fibrotic reaction termed “desmoplasia”^[46]. This is attributed to collagen, laminin, fibronectin, hyaluronan and various other components of the extracellular matrix (ECM) secreted by activated pancreatic myofibroblasts (stellate cells) in response to stimuli from TGF- β , platelet derived growth factor (PDGF) and fibroblast growth factors (FGF) produced by the tumor microenvironment (TME)^[46]. The accumulation of ECM components renders the tumor milieu rigid, and the ensuing increase in extracellular fluid pressure results in collapse of blood vessels in the tumor stroma. The resultant hypoxic peritumoral milieu is thus a significant impediment to the effective delivery of chemotherapy to the tumor^[47]. Furthermore, matrix metalloproteinases (MMP) produced in the ECM damages the structural integrity of the ECM to self-perpetuate tumor invasion and metastasis^[48]. The desmoplastic stroma in PDAC represents an ever-changing compartment that not only functions as a mechanical barrier to drug delivery, but also favors tumorigenesis and invasion.

STROMAL TARGETING STRATEGIES

Pegylated recombinant hyaluronidase

Hyaluronan is a visco-elastic glycosaminoglycan found in abundance in normal tissues, notably in joint cartilage^[49]. It is also found in the stroma of PDAC, where it contributes to significantly elevated interstitial fluid pressure (IFP) and vascular collapse^[47]. In the KPC mouse model, enzymatic depletion of hyaluronan with pegylated recombinant hyaluronidase (PEGPH20, Halozyme, San Diego, CA) rapidly normalized the IFP and hence restored normal vascular caliber^[50]. Importantly, co-administration of PEGPH20 and gemcitabine resulted in an 83% increase in survival and a dramatic decrease in metastatic burden in mice, owing to the enhanced delivery of gemcitabine to the tumor^[50]. Based on the encouraging results from a phase I b trial that combined PEGPH20 with gemcitabine^[51], this strategy is now being investigated in phase II trials in combination with conventional chemotherapy regimens for metastatic PDAC (ClinicalTrials.gov identifiers: NCT01959139 and NCT01839487, Table 3). Initial reports demonstrate that patients with high hyaluronan expressing tumors have greater clinical benefit^[52].

Nanoparticle albumin-bound (nab)-paclitaxel with gemcitabine

Though cytotoxic agents are not considered to be within the realm of targeted therapy, nab-paclitaxel might be an exception. In a small yet novel study, the combination of nab-paclitaxel and gemcitabine was administered to 16 patients in a neo-adjuvant fashion^[53]. The effects on tumor stroma were determined by endoscopic

ultrasound (EUS) elastography and examination of surgically resected tumor specimens. Not only was there a significant decrease in tumor stiffness on EUS elastography, but also a decrease in cancer associated fibroblasts (CAF) and significant disruption of the intense collagen architecture^[53]. Similarly, stromal disruption was also noted in a patient-derived xenograft mouse model treated with the same combination^[54]. In this study, genetically engineered mice bearing tumors received nab-paclitaxel, gemcitabine or the combination of the two. The intra-tumoral concentration of gemcitabine was nearly 3-fold higher in mice treated with nab-paclitaxel plus gemcitabine than in those receiving gemcitabine alone. The exact mechanism of action of nab-paclitaxel in depleting tumor stroma has not been elucidated, but could be mediated by secreted protein acidic and rich in cysteine (SPARC) - a matrix glycoprotein and marker of activated fibroblasts^[55] proposed to be a crucial driver of PDAC invasiveness^[54,56,57].

Targeting myofibroblasts/stellate cells

Though the anti-inflammatory properties of 1,25(OH)₂D₃ have been well established^[58], the finding that activated myofibroblasts (also known as stellate cells) overexpress the vitamin D receptor (VDR) was an unexpected finding^[59]. The VDR plays an important role in the transcriptional regulation of activated myofibroblasts by converting them back to their quiescent state^[59]. This is substantiated by a preclinical study in mouse models in which calcipotriol, a VDR agonist resulted in stromal depletion, facilitated intra-tumoral delivery of gemcitabine and caused reduction in tumor volume^[59]. Unlike other therapies that focus on stromal ablation, reprogramming the stroma using vitamin D analogs might be a useful adjunct to PDAC therapy.

Hedgehog pathway inhibition

The hedgehog (Hh) signaling cascade activates the Gli family of receptors when the sonic Hh ligands bind to its receptor Patched1 that in-turn relieves the repression on Smoothened1 (Smo)^[60]. This paracrine signaling is vital for the proliferation of the desmoplastic stroma in PDAC^[60]. IPI-926 is a powerful inhibitor of Smo, which when administered in combination with gemcitabine to KPC mice resulted in increased mean vessel density in the stroma and increased intra-tumoral concentration of gemcitabine^[61]. However, when the combination of gemcitabine with IPI-926 resulted in worse progression free survival (PFS) and OS compared to gemcitabine plus placebo in a phase II trial that had to be terminated early^[62]. More recent studies have shown a possible protective effect of the stroma, which when depleted resulted in a more aggressive and hypervascular phenotype^[63,64]. The incongruity in outcomes between pre-clinical and clinical trials is a fine example to exemplify the complexity of targeting the TME in PDAC.

ANGIOGENESIS

Tumor cells can activate quiescent endothelial cells through

an “angiogenic switch” which causes overexpression of pro-angiogenic factors, chiefly vascular endothelial growth factor (VEGF)^[65]. VEGF and its two high-affinity tyrosine kinase receptors namely flk-1/KDR and flt-1 are overexpressed in PDAC and associated with disease progression^[66]. VEGF enhances MAPK phosphorylation in pancreatic cancer cell lines, and PD9805 an inhibitor of MAPK inhibits the proliferative effects of VEGF^[67]. In contrast to pancreatic cancer cell lines, actual pancreatic tumors have a much lower microvessel density compared to normal pancreatic tissue^[68]. Unsurprisingly, anti-angiogenic therapy directed against circulating VEGF using bevacizumab in combination either in combination with gemcitabine alone or with gemcitabine and erlotinib has been unsuccessful^[69,70]. Likewise, VEGF receptor targeted agents such as axitinib and aflibercept have not improved outcomes either^[71,72]. As explained previously, the desmoplastic stroma contributes significantly to altered vasculature. Additionally, the abundance of angiostatic factors such as angiostatin and endostatin that are secreted in the TME also explains the discordance between VEGF overexpression and lack of clinical benefit with VEGF inhibition^[46,73].

TUMOR STEM CELLS

Cancer stem cells (CSC) constitute a very small proportion of pancreatic tumors (< 1%), but have the potential for unlimited proliferation^[74]. They were identified in PDAC using a xenograft model of immunocompromised mice and proven to have a 100-fold higher tumorigenic potential compared to non-tumorigenic cancer cells^[74]. A distinct population of CD133⁺ PDAC stem cells also predicts propensity to metastasis^[75]. Moreover, cancer stem cells are extremely resistant to chemotherapy and radiation^[76,77], attributed to the overexpression of the early developmental sonic hedgehog (SHH) pathway^[78]. The self-renewing nature of CSCs poses a significant challenge in molecular therapeutics of PDAC.

Targeting CSCs in PDAC

Data emerging from preclinical studies have demonstrated that it is indeed possible to target and eliminate CSCs. Salinomycin, an antibiotic with a greater than 100-fold efficacy against CSCs compared to paclitaxel, inhibited the growth of CD133⁺ pancreatic CSCs and the effects were synergistic with gemcitabine, which curbed the growth of non-CSC cells^[79]. Pancreatic CSCs also overexpress epithelial cell adhesion molecule (EPCAM) and this feature has been the focus of immunotherapy directed against CSCs^[80]. MT110 is a bi-specific T cell engaging antibody (BiTE) that simultaneously targets EPCAM on CSCs and T cell-CD3 complexes on T cells to effectively eliminate the highly tumorigenic CSCs both *in vivo* and *in vitro* in a mouse model of PDAC^[80]. Natural agents such as isoflavones, 3,3'-diindolylmethane (DIM) and curcumin analogues have also garnered attention because of their inhibitory effects on CSCs through cell-signaling

molecules and microRNAs (miRNA)^[81]. Pancreatic CSCs also overexpress Nodal and Activin belonging to the TGF- β superfamily and pharmacological inhibition or knockdown of their receptor activin-like 4 and 7 (Alk 4/7) reversed gemcitabine resistance in an orthotopic mouse model and dramatically reduced their tumorigenicity^[82]. In addition to newer agents, the anti-neoplastic effects of the timeworn drug metformin are also attributed to its activity against pancreatic CSCs^[83]. Results from these preclinical studies await clinical translation.

IMMUNE BIOLOGY OF PDAC

The immune system serves as an innate defense against tumorigenesis and metastasis. To counteract immune-surveillance, tumors develop adaptive mechanisms and PDAC is adept at immune evasion because of its inherently low immunogenicity^[84,85]. The lack of anti-tumor effector T lymphocytes in preclinical mouse models of PDAC compared to a very high proportion of immunosuppressive cells such as regulatory T cells (Tregs), tumor-associated macrophages and myeloid derived suppressor cells tips the balance in favor of tumorigenesis^[85]. Tumor and stromal cells also secrete several inflammatory mediators, notably TGF- β and interleukin 10 (IL-10) which down-regulate T cell and antigen presenting cell (APC) proliferation in the PDAC microenvironment^[86,87]. Despite the purported low immunogenicity of PDAC, the presence of CD4⁺ helper T cells and CD8⁺ cytotoxic T cells (CTL) in resected pancreatic tumors was associated with longer OS, suggestive of a definite immune response against PDAC^[88]. Though it has been a challenging endeavor to devise effective strategies to harness the host's immune system against PDAC, results of recent vaccine trials and immune checkpoint inhibitors in PDAC have been quite encouraging.

VACCINE THERAPY

Immune mediated anti-tumor response occurs in two steps; first, tumor associated antigens (TAA) are presented by APC, notably dendritic cells to effector/CTL, which in turn recognize antigenic epitopes bound to major histocompatibility (MHC) molecules. Next, concomitant binding of co-stimulatory molecules such as B7-1 on APCs and CD28 on T cells results in T cell activation. However, tumor cells lack the additional co-stimulatory molecules and immune evasion ensues^[89]. Vaccine-based therapies are designed to circumvent immune evasion by delivering TAAs to APCs and stimulate a robust cell-mediated immune response to attack and eliminate tumor cells.

Initial vaccine designs for PDAC utilized peptide antigens such as mucin-1 (MUC1), carcinoembryonic antigen and protein products of *KRAS* oncogene that are capable of binding exact MHC molecules^[89]. Because peptide vaccines contain only single antigenic epitopes, it leads to immune tolerance with minimal and transient efficacy^[90]. The expansion of proteonomics and gene expression based assays has led to the identification of

several TAAs that are selectively expressed by pancreatic cancer cells and has widened the scope for development of whole-cell vaccines that utilize these antigens to trigger tumor-specific immunity. Mesothelin is one such example of a TAA that is overexpressed in nearly all PDACs (but not in normal cells) and is implicated in cell adhesion and metastases^[91,92]. Mesothelin-specific CD8⁺ T cell responses have been associated with improved OS following vaccine therapy^[93].

Granulocyte-macrophage colony-stimulating factor vaccines

GVAX: GVAX is a whole-cell irradiated allogeneic vaccine that is composed of tumor cells from two pancreatic cell lines (Panc 10.05 and Panc 6.03) that have been genetically modified using a plasmid vector encoding for the granulocyte-macrophage colony-stimulating factor (GM-CSF) gene^[94]. When injected transdermally, high GM-CSF secretion at the vaccine site causes mobilization and differentiation of APCs, a feature that patients with PDAC typically lack. APCs subsequently migrate to regional lymph nodes and activate CD4⁺ and CD8⁺ T cells to mount an effective anti-tumor response^[95].

Initial trials demonstrated the safety and tolerability of GVAX when administered in the adjuvant setting followed by conventional chemoradiation. Delayed-type hypersensitivity (DTH) reactions and induction of mesothelin-specific CD8⁺ cells correlated with prolonged disease free survival in the phase I and phase II trials respectively^[94,96]. Based on the favorable results in the adjuvant setting, GVAX was studied in the metastatic setting in patients who had progressive disease after gemcitabine^[97]. In this open-label phase II study, the combination of GVAX with immune-modulating dose of cyclophosphamide (Cy) was compared to GVAX alone. The rationale for adding Cy was to enhance treatment related immune response by inhibiting immunosuppressive Tregs. Although OS was better in the combination arm compared to GVAX alone, the results were not statistically significant (median OS - 4.7 mo vs 2.3 mo). CD8⁺ T cell responses to mesothelin were enhanced in the combination arm and associated with a trend towards prolonged PFS^[97]. Whether metronomic Cy plus GVAX will counter immune tolerance mediated by Tregs is being evaluated in a randomized clinical trial (NCT00727441, Table 3).

GVAX-prime and CRS-207-boost

CRS-207 is a live-attenuated strain of *Listeria monocytogenes*, genetically engineered to secrete mesothelin into the cytosol of APCs. In addition to activating effector T cells by delivering TAAs directly to the APCs, the cytokine mediated inflammatory response that is triggered by CRS-207 also serves to recruit more APCs^[95]. The synergy between GVAX and CRS-207 was demonstrated in a phase I trial^[98] which led to a multi-center, randomized phase II trial among 90 patients exclusively with PDAC^[99]. Patients with previously treated metastatic PDAC were randomized 2:1 to either 2 doses of GVAX immune

priming followed by 4 doses of CRS-207 as a boost (arm A) or 6 doses of GVAX alone (arm B). All patients received Cy to inhibit Tregs. After a median duration of follow-up of 6.6 mo, the OS was 6.1 mo in arm A compared to 3.9 mo in arm B (HR for death, 0.59; 95%CI: 0.36 to 0.91, $P = 0.02$). Toxicity with the combination was minimal and included transient fevers, fatigue, lymphopenia and elevated liver enzymes. As with previous studies, detection of enhanced mesothelin specific CD8⁺ T cell responses was associated with longer OS regardless of treatment arm^[99]. A larger phase II b trial is currently underway to compare the combination of GVAX plus CRS-207 to CRS-207 alone or chemotherapy alone in the metastatic setting (NCT02004262, Table 3).

Algenpantucel-L

Algenpantucel-L (NewLink Genetics Corporation, Ames, IA) is an allogeneic vaccine that contains two PDAC cell lines (HAPa-1 and HAPa-2) that have been genetically engineered to express $\alpha(1,3)$ -galactosyl epitopes (α -Gal)^[100]. Though human cells lack the α -Gal epitopes, the gut flora stimulates antibodies against it. These antibodies are the primary mediators of hyperacute rejection characterized by rapid organ destruction through complement activation within minutes of organ transplantation^[100]. When these antibodies are coupled with tumor cells such as in algenpantucel-L, it promotes opsonization and phagocytosis of tumor cells by APCs and results in T cell activation. In a phase II study of 70 patients with resected PDAC, algenpantucel-L was added to either gemcitabine or 5-fluorouracil based chemoradiotherapy^[100]. After a median follow-up of 21 mo, the DFS and OS at 1 year were 62% and 86% respectively. Notably, the OS in this trial was better than the reported 81% in the sentinel RTOG-9704 trial using the same chemoradiotherapy regimen. Patients who received a higher dose of 300 million cells/dose fared better than those who received 100 million cells/dose with regard to both DFS (81% vs 51%) and OS (81% vs 68%) at 12 mo respectively, suggesting a strong dose-response effect. Apart from mild adverse events such as injection site pain and induration the vaccine was well tolerated. Phase III trials evaluating algenpantucel-L in the adjuvant (NCT01072981) and neoadjuvant setting (NCT01836432) are ongoing (Table 3).

Immune checkpoint inhibitors

Cytotoxic T lymphocyte antigen-4 (CTLA-4) is expressed on the surface of activated T cells and down-regulates immune activation by competitively inhibiting the binding of CD28 to B7-1 and turning off the intracellular signaling cascade of B7-1^[101]. Monotherapy with ipilimumab (Yervoy, Bristol-Myers Squibb Company), an anti-CTLA-4 mAb, was ineffective in the treatment of locally advanced or metastatic PDAC^[102]. However, the combination of GVAX with ipilimumab showed striking clinical and immunological synergy in previously treated patients with advanced PDAC^[103]. Compared to single-agent ipilimumab, patients

in the combination therapy arm had better OS at 1 year (27% vs 7%) although the study was not powered to detect differences in OS. Significantly however, combination therapy was not associated with increased adverse events, despite the higher dose of ipilimumab (10 mg/kg) used in this study. Increase in peak mesothelin-specific T cells and enhancement of the T cell repertoire was associated with longer OS^[103]. Most responders in this study required at least 12 wk of therapy, thus underscoring the need for selecting patients with early stage disease in future trials to evaluate delayed responses often seen with immunotherapy.

Programmed cell death ligand-1 (PD-L1) and its receptor PD-1 are expressed on the cell surface of tumor cells as well as activated T cells. This receptor-ligand interaction down-regulates CD4⁺ and CD8⁺ T cells and is a natural immune checkpoint to prevent excessive immune mediated tissue damage^[104]. PD-L1 expression is up regulated in PDAC cells and results in a blunted T cell response against the tumor^[104]. Blocking the interaction between PD-1 and PD-L1 successfully augmented anti-tumor immune responses *in vitro* and formed the basis for investigating the efficacy of BMS-936559, an anti-PD-L1 mAb in various solid tumors^[105]. Durable responses were noted in patients with melanoma, non-small cell lung cancer and renal-cell carcinoma but disappointingly no responses were seen in 14 patients with PDAC^[105]. The resistance to PD-L1 inhibition in PDAC is due to the high expression of fibroblast activation protein (FAP) by carcinoma-associated fibroblasts (CAF) in the tumor stroma^[106]. These FAP⁺ CAFs produce chemokine (C-X-C motif) ligand 12 (CXCL12) that binds with chemokine receptor 4 (CXCR4) to prevent T cells from infiltrating the tumor and causing local immunosuppression. Inhibition of CXCR4 by AMD3100 in a GEMM of PDAC caused cancer regression synergistically with PD-L1 inhibition^[106]. Therefore it might be feasible to overcome tumoral immunosuppression through a combined approach. A clinical trial to test this hypothesis has recently opened to enrollment as a phase I study of ulocuplumb (anti-CXCR4) and nivolumab (anti-PD1) (NCT02472977, Table 3). Since these immune-modulating agents are not cancer T cell specific and can cause activation of other quiescent T cell populations, autoimmune toxicities occur frequently^[107]. Hence future studies will also need to focus on effective management of these toxicities.

CD40 agonist therapy

CD40 belongs to the tumor necrosis factor receptor superfamily and is expressed by multiple APCs including dendritic cells, B cells and macrophages^[108]. Activated CD40 plays a crucial role in the priming and activation of tumor-specific T cells, but also mediates T cell independent antitumor immunity by activating macrophages^[108]. CP-870, 893 is a CD40 agonistic mAb that potentiates anti-tumor immunity by these aforementioned mechanisms. In the initial pre-clinical study CP-870, 893 when administered in combination with gemcitabine in the KPC mouse model caused rapid regression of tumors mediated by

T cell-independent macrophage infiltration^[109]. Notably, depletion of tumor stroma was also noted and attributed to the effect of stromal infiltrating macrophages. In a phase I trial conducted subsequently, 22 patients with previously untreated advanced PDAC were administered CP-870, 893 with gemcitabine^[110]. The radiological response rate (19% vs 9.4%) and median OS (8.6 mo vs 6.8 mo) were better than expected with single agent gemcitabine. The addition of gemcitabine is postulated to cause antigenic release akin to that of a vaccine with co-stimulation of APCs by CD40 agonist therapy^[111]. Apart from transient cytokine release syndrome and depletion of B cells, none of the auto-immune toxicities seen with the immune check-point inhibitors were noted^[110].

FUTURE STRATEGIES

Adoptive T cell transfer

Stemming from the successes in hematological malignancies notably acute lymphoblastic leukemia^[112], adoptive T cell transfer is an exciting new paradigm that holds tremendous promise in PDAC. This therapeutic strategy involves *ex vivo* genetic engineering of T cells collected from patients to produce chimeric antigen receptors (CAR) capable of recognizing mesothelin expressed on PDAC cells^[113,114]. Infusion of CAR-T cells back to the patient results in immediate recognition of tumor cells and obviates antigen processing and HLA expression. In preclinical studies, CAR-T cells exhibited potent anti-tumor activity^[115]. Beatty *et al*^[116] have also reported a marked decline in ascitic fluid malignant cell burden in a patient with metastatic PDAC, in addition to transient decline in [¹⁸F] fluorodeoxyglucose uptake on positron emission tomography (PET) scan after infusion of CAR-T cells. CAR-T cell therapy is a subject of active research in PDAC and studies are ongoing (ClinicalTrials.gov identifiers: NCT01897415 and NCT01583686, Table 3).

Targeting epigenetic regulators

Epigenetics is the study of changes in gene expression by mechanisms other than changes in the DNA code. Histone modification by acetylation or methylation, DNA methylation and miRNA expression are the main mechanisms of epigenetic regulation^[117]. Histone acetylation by histone acetyltransferase promotes transcriptional activity but histone deacetylases (HDAC) repress transcription of tumor suppressor genes and are overexpressed in PDAC^[118]. HDAC inhibitors serve to abrogate the transcriptional repression and impair tumorigenesis by playing a crucial role in differentiation, cell-cycle inhibition and apoptosis in tumor cells^[117]. Multiple HDAC inhibitors such as hydroxamic acid derivatives (vorinostat), cyclic peptides (romidepsin), short-chain fatty acids (valproic acid) and benzamides have been studied, but results in PDAC have been disappointing^[119,120]. However, the recognition that miRNAs play an important role in PDAC has resulted in increased attention towards exploiting them as potential

therapeutic targets^[121]. Acting at the post-transcriptional level, these non-coding RNAs play a crucial role in apoptosis, differentiation and proliferation. Aberrant overexpression of multiple miRNAs, particularly miRNA-21 has been demonstrated in PDAC and its inhibition by Lentiviral vectors has shown promising antitumor effects in preclinical studies^[121,122]. MiRNA targeted therapy especially in combination with chemotherapy is in its early stages and expected to gain momentum in the future (ClinicalTrials.gov identifier: NCT01274455, Table 3).

Targeting signal transduction

As described previously, targeting signaling pathways downstream from *KRAS* has been unsuccessful so far. However, there is renewed interest in targeting the effects of Janus kinase/signal transducer and activator of transcription (JAK/STAT) signaling pathway after its importance in PDAC and associated cachexia became apparent^[123,124]. The addition of the JAK inhibitor ruxolitinib to capecitabine in patients with refractory metastatic PDAC in a phase II trial showed OS benefit for a subgroup of patients with elevated levels of C-reactive protein^[125] and has formed the rationale for phase III trials evaluating ruxolitinib in metastatic PDAC (ClinicalTrials.gov identifiers: NCT02119663 and NCT02117479, Table 3). Global genomic analysis data also revealed alterations in genes in the Wnt/Notch and TGF- β signaling pathways in all PDACs^[13]. Ongoing clinical trials to evaluate the efficacy of specific inhibitors of these pathways are currently underway (ClinicalTrials.gov identifiers: NCT02050178, NCT01764477: Wnt inhibitors, NCT01647828: mAb against Notch, NCT01373164: Oral anti TGF- β receptor type 1, Table 3).

CONCLUSION

As evinced in this review, with improved understanding of the biology, genetic basis and molecular mechanisms that initiate and propagate PDAC carcinogenesis, the focus has shifted from identifying effective cytotoxic chemotherapy regimens to molecularly targeted therapies. These efforts have been further burnished by significant strides in the field of onco-immunology that now allows for cautious optimism that effective therapeutic options for PDAC are finally within reach.

Abstract

Preclinical modelling studies are beginning to aid development of therapies targeted against key regulators of

pancreatic cancer progression. Pancreatic cancer is an aggressive, stromally-rich tumor, from which few people survive. Within the tumor microenvironment cellular and extracellular components exist, shielding tumor cells from immune cell clearance, and chemotherapy, enhancing progression of the disease. The cellular component of this microenvironment consists mainly of stellate cells and inflammatory cells. New findings suggest that manipulation of the cellular component of the tumor microenvironment is possible to promote immune cell killing of tumor cells. Here we explore possible immunogenic therapeutic strategies. Additionally extracellular stromal elements play a key role in protecting tumor cells from chemotherapies targeted at the pancreas. We describe the experimental findings and the pitfalls associated with translation of stromally targeted therapies to clinical trial. Finally, we discuss the key inflammatory signal transducers activated subsequent to driver mutations in oncogenic Kras in pancreatic cancer. We present the preclinical findings that have led to successful early trials of STAT3 inhibitors in pancreatic adenocarcinoma.

Key words: Pancreatic cancer; Inflammation; Stroma; Microenvironment

Core tip: Many advances have been made in preclinical assessment of therapies in pancreatic cancer. Here we review the successes and failures of translation to clinical trial of therapies targeting the pancreatic cancer microenvironment. Using data from preclinical trials we expose opportunities for further clinical trial within pancreatic cancer. We focus on therapies that modulate the immune response to pancreatic cancer, stromally active therapies and therapies targeting inflammatory signal transduction that are key in pancreatic cancer progression. We provide experimental results that have led to clinical trial and those findings that may be exploited in future. We attempt to rationalize the failure of certain therapies to

translate to clinical practice and provide a realistic overview of why at present tumor microenvironment targeted therapies are not licensed in pancreatic cancer.

INTRODUCTION

Rationale for targeting inflammation in pancreatic cancer

Inflammation is a hallmark of cancer^[1]. For over 100 years scientists have been interested in the relationship between inflammation and cancer. Researchers within Glasgow Royal Infirmary have for some time been interested in the relationship between cachexia, inflammation and poor prognosis in cancers of different origins. The modified Glasgow Prognostic Score (mGPS) that assesses blood albumin in combination with inflammation, C-reactive protein (CRP), has for over a decade been used to accurately predict outcome across a range of tumor types. Raised mGPS correlates with poor patient prognosis in colorectal, renal and pancreatic cancers^[2]. Additionally, large observational studies have analyzed both cancer incidence and outcome based on daily aspirin use during previously performed randomized controlled trials. The long-term use of aspirin, a non-selective COX inhibitor, improves survival from cancer as a result of reduction in cancer incidence and metastatic burden^[3-5]. These findings demonstrate a clear link between inflammation and cancer initiation and behaviour. Thus, there is observational evidence that inflammation promotes incidence, enhances progression and impacts on prognosis in patients with cancer.

Pancreatic adenocarcinoma (PDAC) presents at a late stage of progression and is associated with very poor outcomes (www.cancerresearchuk.org/cancer-info/cancerstats/). Surgery remains the only potentially curative treatment, though as few as 15% of patients have disease amenable to surgical intervention, and despite surgery the majority of these patients will succumb to recurrent disease. Therefore, new therapies and methods of instituting these therapies are required if survival is to improve in PDAC.

In addition to standard clinicopathological features, presence of systemic inflammation, as assessed by CRP, is a poor prognostic factor in patients undergoing surgical resection for PDAC. In a cohort of 135 patients who underwent potentially curative Whipple's resection for PDAC an elevated mGPS was independently associated with lower overall survival^[6]. Furthermore a high neutrophil to lymphocyte ratio (NLR), a further index of host innate response, has been categorically shown to confer poor

prognosis in PDAC^[7]. Interestingly, in this study of 74 patients, NLR had improved utility at predicting disease recurrence than CRP. This phenomenon was not confined to resectable cases of PDAC, inoperable cases of PDAC appear to respond poorly to chemotherapy in the presence of a raised NLR^[8]. Indeed in the randomized controlled clinical trial of nab-paclitaxel in PDAC an elevated NLR conferred poor prognosis in both treatment arms^[9]. Therefore, assessment of host inflammation at the time of diagnosis of PDAC, has clinical implications for patient survival regardless of therapeutic modality.

The treating physician should consider the inflammatory insults they are subjecting patients to during their treatment course. Over the last decade minimally invasive surgery of the pancreas has increased significantly. When 65033 resections of liver and pancreas were assessed, patients who had minimally invasive pancreatic resections had reduced morbidity, mortality, and length of stay in hospital compared with those having open resections. Traditionally inflammatory insults generated by minimally invasive surgery are smaller than open procedures, however, at present, studies show no oncological benefit^[10]. Intra-operative blood transfusion is associated with loss of immune surveillance in cancer patients, with associated increases in morbidity and mortality following surgery. These data suggest transfusion should be avoided in the peri-operative period if possible^[11]. Furthermore, a profoundly elevated systemic inflammatory response in the post-operative period has been associated with increasing rates of infectious complications following a number of operations including pancreatectomy^[12]. To our knowledge no randomized controlled data exist to confirm the findings of this meta-analysis, however, the study raises the question of the benefits of use of anti-inflammatories in the post-operative setting. Such benefits would have to be offset against potential increases in the risk of anastomotic leak. Thus, when dealing with the small percentage of patients who have PDAC suitable for operative management, surgeons must consider the implications of their treatments. Limiting inflammatory insults involved seems sensible but requires clarification *via* clinical trial.

In vivo models of PDAC

Preclinical studies in PDAC have improved greatly in the past decade with the development of murine models that genetically and histologically recapitulate the human disease. Murine models use pancreas specific promoters to drive oncogenic *Kras* and tumor suppressor gene mutations including mutant *Tp53* to create experimental PDAC murine models with an active microenvironment. These models permit preclinical interrogation of targeted therapies in the hope of translation to patients *via* clinical trial.

Importantly, progression of murine models of PDAC based on initiating oncogenic *Kras* mutations are greatly accelerated in the presence of pancreatic specific inflammation^[13]. Further work by the same authors

revealed this was due to the requirement of pancreatitis to overcome oncogene-induced senescence, which can be blocked by anti-inflammatory medication^[14]. Lee *et al.*^[15] found that when Kras was mutated within the pancreas, pancreatic inflammation led to reduction in *Ink4a* expression. Low levels of Ink4a allowed tumor cells to escape senescence and progress to form tumors. In the presence of Kras mutations, pancreatic inflammation is sufficient to induce tumor formation.

Following initiation of PDAC, inflammation promotes tumor progression. Within the tumor microenvironment there are many pro and anti-tumoral interactions^[16]. Immune cells present have plasticity that permits differing both pro or anti-tumorigenic actions based on received stimulus. Ultimately, during PDAC evolution, a myriad of stromal elements, immune cells and key transducers of inflammatory signals cooperate to permit disease progression. Improvements in understanding the tumor microenvironment are permitting trial of novel therapeutics against key disease progression mediators. Ongoing research in this area will elucidate more completely the complex interactions within the tumor microenvironment and help future development and assessment of multi-target drug regimens.

DISCUSSION

Inflammatory targets identified by in vivo modeling studies in PDAC

Possible inflammatory therapeutic targets in PDAC can be classified into one of three categories: (1) immune modulation to target tumors; (2) targeting tumor stroma; (3) targeting signal transduction (Table 1).

This review will consider the progress made by preclinical studies in each of these three areas and how better understanding of the PDAC microenvironment has potential to translate to the clinical arena. Figure 1 provides a summary of potential inflammatory targets for therapy in PDAC.

Immune modulation

Tumor immunosurveillance is a term that refers to identification and clearance of tumor cells in the early stages of tumorigenesis by the adaptive immune system. It is the role of CD8⁺ T cells to provide cytotoxic protection against "foreign" tumor cells, and hence the development of tumor immunogenicity. Different facets of immunosurveillance are now being interrogated to establish how PDAC so effectively evades detection.

Dendritic cells are a good example of an immune cell capable of adopting dual roles within the PDAC microenvironment. Dendritic cells can engage both CD8⁺ and CD4⁺ T cell responses dependent on stimulus^[17]. Chemokine CXCL17 may be important for migration of dendritic cells to tumor sites while ICAM 2 upregulation was necessary for activation of a CD8⁺ cytotoxic response against tumor cells. Downregulation of CXCL17 and ICAM2 by tumor cells during evolution from precursor lesions to

PDAC allowed tumors to develop immune tolerance^[18]. In contrast Ochi *et al.*^[19] have demonstrated that blockade of TLR4 signaling promotes CD4⁺ T helper cell activity which has a positive effect on pancreatic tumorigenesis through mediation of pro-tumorigenic inflammatory responses. The plasticity of the immune system was highlighted by the findings of Beatty *et al.*^[20]. In patients with metastatic PDAC, targeting CD40 with monoclonal antibodies led to tumor regression. Authors anticipated CD40 ligation would result in enhanced anti-tumoral T cell responses, however in fact resulted in anti-tumoral effects through macrophage infiltration. This phase 1 trial holds promise for trials of similar agents to activate an anti-tumoral immune response.

Tumor-associated macrophages (TAMs) are ever present from pre-invasive Pan-Ins to established PDAC^[21]. TAMs exhibit an M2 phenotype that is pro-tumorigenic while suppressing adaptive immunity^[22]. In cancer, signals received by macrophages from tumor cells including interleukin (IL)-10 and transforming growth factor (TGF)- β lead to adoption of an M2 phenotype^[22]. Macrophages are attracted to the tumor microenvironment *via* production of chemokines by tumor cells^[23]. CSF1 and CCL2 are crucial mediators of this chemo-attraction. CCL2 overexpression mediates migration of M2 macrophages to PDAC and is thought to play a key role in recruiting pro-tumorigenic macrophages to metastatic sites in development of the metastatic niche^[24,25]. *In vivo* studies of anti-CCL2 drugs were effective in enhancing tumor immunity and impacting on metastasis in PDAC^[26]. In addition, patients with high CCL2 expression and low CD8 T cell infiltration suffer poor outcomes following tumor resection.

Direct depletion of TAMs may also be a therapeutic option. Trabectedin has recently been licenced for study in PDAC and is currently in phase 2 trials in advanced disease (NCT01339754). Trabectedin can actively target macrophages *via* caspase-8 dependent apoptosis with selectivity to TAMs achieved through differential expression of TRAIL receptors by macrophages^[27].

Promotion of anti-tumoral cell mediated responses has been successful, particularly in metastatic melanoma. These strategies focus on engaging T cell responses. CTLA4 inhibitor, ipilimumab, was the first drug shown to improve outcome in patients with metastatic melanoma. Following this development and success of Programmed cell death 1 (PD1)/Programmed cell death ligand (PDL1) T cell checkpoint inhibitors has led to great excitement in the field of oncology. These drugs have made a significant impact on survival of patients with metastatic melanoma. CTLA4 is a cell surface protein that suppresses T cell function. When drugs such as Ipilimumab bind CTLA4, T cell function is activated. Likewise, PD1 inhibits T cell function. Production of PD1s major ligand PDL1 by tumor cells and pro-tumorigenic immune cells permits tumors to escape T cell mediated adaptive immunosurveillance^[28]. Hence PD1 is an ideal target when attempting to generate anti-tumoral immune responses.

Concerns exist that PDAC may not respond to such

Table 1 Preclinical assessment of inflammatory targets in pancreatic adenocarcinoma

Target	Drug	PMID	Year	Authors summaries
Hedgehog acyltransferase (Hhat)	RU-SKI 43	24469057	2015	<i>In vivo</i> mouse study targeting Hedgehog acyltransferase (Hhat). A lentivirally delivered hairpin RNA impeded the proliferation of pancreatic cancer <i>in vitro</i> and <i>in vivo</i>
Hedgehog	GDC-0449	25679326	2015	Combination therapy with GDC-0449 or miR-let7b <i>vs</i> single agent therapy effectively inhibited tumor growth when injected to athymic nude mice bearing ectopic tumors generated using MIA PaCa-2 cells
Sonic hedgehog pathways	Ormeloxifene	25840985	2015	Ormeloxifene caused potent inhibition of the SHH signaling pathway <i>via</i> downregulation of SHH and its related important downstream targets. Ormeloxifene potentiated the antitumorigenic effect of gemcitabine by 75% in PDAC xenograft mice
Hedgehog pathway	MEDI-5304	24344235	2014	MEDI-5304 displayed robust pharmacodynamic effects in stromal cells that translated to antitumor efficacy as a single agent in an HT-29/MEF coimplantation model of paracrine hedgehog signaling. MEDI-5304 also improved responses to carboplatin in the HT-29/MEF model. The antibody, however, had no effect as a single agent or in combination with gemcitabine on the CSC frequency or growth of several primary pancreatic cancer explant models
Hedgehog	GDC-0449	25278454	2014	GDC-0449 for 3 wk leads to downmodulation of GLI1 and PTCH1, without significant changes in CSCs compared with baseline. GDC-0449 and gemcitabine were not superior to gemcitabine alone in the treatment of metastatic pancreatic cancer
Hedgehog pathway	Metformin	24692708	2014	<i>In vitro</i> , BxPC3 human pancreatic cancer cells were treated with metformin, and Sonic hedgehog (Shh) mRNA and protein levels were examined. Metformin reduces the expression of Shh in several cancer cell lines including pancreatic cancer cells
Hedgehog	Curcumin	23563640	2013	Curcumin can inhibit the proliferation of TGF- β 1-stimulated PANC-1 cells, it can induce apoptosis, and reverse the EMT. The possible underlying molecular mechanisms are through inhibition of the Shh-GLI1 signaling pathway
COX 5-lipoxygenase (5-LOX)	Dietary licofelone	25906749	2015	<i>In vivo</i> mouse study of licofelone, an agent that targets both COX-2 and 5-LOX
LOX	Zileuton	25483364	2014	Zileuton suppressed the proliferation of SW1990 cells in a concentration- and time-dependent manner. In addition, zileuton induced SW1990 cells to undergo apoptosis and significantly decreased 5-LOX expression
STAT3	Thiosemicarbazones	25561562	2015	<i>In vitro</i> and <i>in vivo</i> iron-binding ligands inhibit constitutive and interleukin 6-induced activation of STAT3 signaling DFO, Dp44mT, and DpC significantly decreased constitutive phosphorylation of the STAT3 transcription factor at Tyr705 in the pancreatic cancer cell lines and when injected <i>in vivo</i>
STAT3	Aspirin metformin	26056043	2015	Metformin combined with aspirin significantly inhibited the phosphorylation of mTOR and STAT3, and induced apoptosis as measured by caspase-3 and PARP cleavage Taken together, the combination of metformin and aspirin significantly inhibited pancreatic cancer cell growth <i>in vitro</i> and <i>in vivo</i>
JAK2 STAT3	MicroRNA (miR)-216a	25220761	2014	MiR-216a overexpression markedly inhibited the JAK2/STAT3 signaling pathway and xenograft tumor growth <i>in vivo</i>
ALK pathway including STAT3	Crizotinib	25193856	2014	Crizotinib strongly suppressed the growth and proliferation of pancreatic cancer cells in a dose-dependent manner. Crizotinib strongly inhibited the expression of activated ALK in pancreatic cancer cells, modulating its downstream mediators such as STAT3, AKT, and ERK
STAT3 NF- κ B COX-2 EP4	Nexrutine	24520096	2014	Nexrutine treatment inhibited growth of pancreatic cancer cells through induction of apoptosis Reduced levels and activity of STAT3, NF- κ B, and their crosstalk led to transcriptional suppression of COX-2 and subsequent decreased levels of prostaglandin E2 (PGE2) and PGF2. Nexrutine intervention reduced the levels of NF- κ B, STAT3, and fibrosis <i>in vivo</i> . Expression of prostaglandin receptor EP4 that is known to play a role in fibrosis was significantly elevated in human pancreatic tumors. Dual inhibition of STAT3-NF- κ B by Nexrutine may overcome problems associated with inhibition of either pathway
JAK/STAT Src/FAK	Guggulsterone	23920124	2013	<i>In vitro</i> , guggulsterone treatment decreased mucin MUC4 expression in Capan1 and CD18/HPAF cells through transcriptional regulation by inhibiting Jak/STAT pathway
Notch JAK2	GSI IX and AG-490	24293409	2014	Combinational treatment with anti-NOTCH and JAK/STAT drugs significantly attenuates tumor progression <i>in vivo</i> and suppresses conversion from acinar-ductal-metaplasia to PDAC

Outlines the significant interest shown by preclinical researchers in targeting inflammation in PDAC. Using the search criteria pancreatic cancer/pancreatic adenocarcinoma + hedgehog, JAK/STAT, LOX we identified preclinical studies that have attempted to assess therapeutics targeted against these important inflammatory mediators of PDAC progression in the past 2 years. We have included those published in journals with an impact factor > 5. PDAC: Pancreatic adenocarcinoma; PARP: Poly-ADP-ribose polymerase; JAK: Janus kinase; STAT: Signal transducer and activator of transcription.

T cell interference because they are extremely fibrotic and desmoplastic. As a result PDACs have a relative

Figure 1 Changes in the pancreatic adenocarcinoma microenvironment during tumor formation. Pancreatic cancer forms from normal tissue via progression through pre-invasive pancreatic intra-epithelial neoplasia (Pan-IN) to invasive PDAC. Changes in immune cell components, stroma, and inflammatory signaling pathways all contribute to PDAC progression. Here we identify possible targets for therapy in PDAC. PDAC: Pancreatic adenocarcinoma; NF-κB: Nuclear factor kappa B; STAT: Signal transducer and activator of transcription; IL: Interleukin; MDSCs: Myeloid derived suppressor cells.

paucity of anti-tumoral T lymphocytes seen at histology compared with other epithelial tumors. Preliminary studies assessing ipilimumab have proven unsuccessful as a single agent^[29]. Feig *et al.*^[30] have recently shown that immunosurveillance can be overcome in PDAC *in vivo* by expression of fibroblast activating protein (FAP) and production of CXCL12 by cancer associated fibroblasts (CAFs). These CAFs were able to prevent T cell infiltration to the tumor microenvironment. Interestingly when these CAFs were depleted genetically, or indeed CXCL12 was inhibited, tumors were sensitised to T cell checkpoint inhibition. Furthermore, myeloid derived suppressor cells (MDSCs) are orchestrated by PDAC to suppress proliferation and induce apoptosis in activated T cells^[31]. Selective depletion of this granulocytic subset of MDSCs led to enhanced CD8⁺ T cell responses promoting immunosurveillance. These data suggest that greater understanding of the processes of evasion of tumor immunosurveillance by PDAC will open up therapeutic opportunities *via* combination with therapies that enhance the effectiveness of immunogenics.

Tumor vaccines are designed to target tumor specific antigens, activating adaptive immunity, eradicating tumor cells. Studies have assessed PDAC specific antigens including MUC-1 that is expressed by over 90% of PDAC cells. Vaccine PANVAC-VF was developed

to be active against cells expressing MUC-1, oncofetal protein carcinoembryonic antigen (CEA) and 3 co-stimulatory molecules. Unfortunately no survival benefit was seen with the addition of PANVAC-VF to standard therapy in a phase III trial in palliative PDAC patients^[32]. Ribonucleoprotein enzyme Telomerase, which maintains telomeric stability, has been assessed unsuccessfully as a potential vaccine target in the Telovac trial^[33]. 1062 palliative patients were randomised to standard chemotherapy, sequential chemotherapy with Telovac or concurrent chemotherapy and Telovac. Neither Telovac groups showed any survival advantage. Smaller trials have been established against other targets including KRAS, although none has proven successful in clinical trial as yet showing how difficult it is to raise a successful adaptive immune response against PDAC.

Targeting tumor stroma

The majority of the tumor bulk of PDAC is composed of stromal cells. This dynamic network of immune cells, stellate cells and extracellular matrix is now believed to play a crucial role in sustenance and support for invasive tumor cells^[34]. Stellate cells are key coordinators of fibrosis as a result of received signals from tumor cells in PDAC^[35]. SPARC is one such factor present in high levels in the tumor microenvironment. SPARC functions

normally to promote wound healing, however its role in PDAC is less certain. High expression of SPARC is associated with poor patient survival in resected cohorts of PDAC patients^[36]. Albumin-bound Paclitaxel (nab-paclitaxel) binds SPARC-expressing fibroblasts, allowing therapeutic targeting of this cell type. When nab-paclitaxel was combined with gemcitabine patients with metastatic PDAC survived significantly longer compared with standard gemcitabine chemotherapy^[37]. Surprisingly no appreciable histological changes to the stroma were evident in the tumors of mice treated with nab-paclitaxel raising the possibility that targeting SPARC improved outcome *via* a different biological mechanism than predicted^[38].

PDAC is desmoplastic, avascular and relatively acellular. These attributes are believed to be responsible for failure of chemotherapies to adequately access tumor cells. Recently, high tissue pressures within the PDAC stroma have been suggested to prevent chemotherapy delivery to tumor cells^[31]. Preclinical model work has suggested relieving such pressures will enhance chemotherapy delivery and subsequent tumor cell death. Unfortunately, these findings have not translated to patients with drugs including anti-MMP and VEGF inhibitors failing to have a therapeutic effect in clinical trials^[35]. Sonic hedgehog paracrine signaling through smoothened has been implicated in the coordination of stromal elements by tumor cells in PDAC. Despite this, a phase II trial based on preclinical data assessing smoothened inhibition in PDAC was stopped early as patients receiving gemcitabine alone survived longer than those receiving the smoothened inhibitor in addition to gemcitabine^[39] (clinicaltrials.gov, Infinity Pharmaceuticals, Cambridge, MA). In addition Catenacci *et al.*^[40] have recently found that Vismodegib, a Sonic hedgehog antagonist, when combined with gemcitabine provided no survival benefit in advanced PDAC patients than gemcitabine alone in a multicentre randomised controlled phase II trial. Hyaluronan is a prominent element within the stroma of PDAC and when targeted in preclinical studies experimenters have found significant improvements in tumor vasculature and lowering of tissue pressures permitting access by chemotherapeutics^[41,42]. This agent is currently the subject of phase II clinical trials in combination with best current chemotherapeutic regimens FOLFIRINOX and gemcitabine/nab-paclitaxel (clinicaltrials.gov: NCT01959139 and NCT01839487).

At present no stromal agent is licenced for therapeutic use in PDAC, with sonic hedgehog in particular representing a cautionary tale of “bench to bedside” medicine. Recent studies, contrary to the findings of Olive *et al.*^[39], have proven that deletion of Shh specifically within the pancreas of *in vivo* PDAC models led to development of more aggressive tumors^[43]. Furthermore, Özdemir *et al.*^[44] found eliminating CAFs from the tumor microenvironment led conversely to suppression of immunosurveillance, increasing numbers of T regulatory cells infiltrating the microenvironment, leading to tumor

progression. What is clear from this work is that the PDAC stroma exists in a state of flux, with an interdependent network of stromal components which when manipulated therapeutically do not always produce expected results.

Targeting inflammatory signal transduction

Mutant *KRAS* is the major oncogenic driver of PDAC in more than 90% of cases^[45]. Development of temporally controlled, inducible models of PDAC has recently permitted interrogation of signaling mechanisms required for PDAC tumorigenesis and progression. Use of inducible and reversible *Kras* alleles has demonstrated the requirement of ongoing stimulus from *Kras* for precursor lesions to progress to PDAC. Removal of *Kras* stimuli prevented progression from pan-INs to PDAC. However, when mutant *Kras* expression remained switched on, striking stimulation of the hedgehog signaling pathway was observed in addition to upregulation of inflammatory mediators IL-6, STAT3, and COX2. *Kras* inactivation resulted in decreased expression of these inflammatory mediators and resultant pan-IN regression^[46], providing clear evidence of the relationship between *Kras* mutation and coordination of the inflammatory response in PDAC. *KRAS* activates RAF phosphorylation resulting in production of chemokines including CXCL1 and CXCL8^[47]. CXCR2 a G-protein coupled receptor is crucial for MDSC migration to the tumor microenvironment and metastatic sites in breast and colon cancer and is activated by CXCL1, 2, 5, 7 and 8^[48,49]. CXCR2 inhibition in preclinical models of PDAC successfully delayed tumor progression, suggesting it merits further study^[50].

Ochi *et al.*^[51] recently reported high expression of TLR7 in PDAC. Activation of TLR7 promotes PDAC formation *via* downstream signalling through inflammatory signalling pathways including STAT3 and nuclear factor kappa B (NF- κ B). When TLR7 was knocked out of immune cells within a murine model of PDAC and exposed to the same pro-tumorigenic conditions animals were completely protected from pancreatic carcinogenesis. Pharmacological TLR7 inhibition is yet to be assessed.

Transcription factor STAT3 represents a key-signaling node in PDAC^[52,53]. When mouse models expressing endogenous mutant *Kras* combined with experimentally induced pancreatitis were assessed, STAT3 activation was significantly increased. Absence of *STAT3* from the pancreata of these mice led to a block in acinar to ductal metaplasia and pan-IN formation, while reduced immune cell infiltration and IL-6 expression was also observed. Infiltrating macrophages were identified as producing IL-6 leading to STAT3 upregulation. Corcoran *et al.*^[54] have proposed that patients could be selected to trial based on phosphoSTAT3 levels as they predict PDAC cell sensitivity to JAK/STAT inhibitors. As the Jak/STAT signaling cascade has been recognised to impact on survival following resection for PDAC, investigators are now beginning to target it in randomized controlled trials^[55].

Ruxolitinib targets the IL6/JAK/STAT signaling cascade. Assessment *via* double blind randomised controlled trial in

advanced PDAC with capecitabine vs capecitabine/placebo showed a marginal survival advantage in the ruxolitinib group^[56]. Intriguingly, those patients that benefited most were those with high mGPS scores. This work and that in preclinical studies by Corcoran *et al.*^[54] suggests trial of anti-inflammatory agents requires careful patient selection to optimise outcome in PDAC. Two ongoing phase III trials of JAK/STAT inhibition in PDAC, JANUS 1 and 2, basing patient selection on high systemic inflammatory scores, will test the hypothesis of the need for better patient selection in PDAC trials of inflammatory targeted agents.

NF- κ B is also important in PDAC progression downstream of Kras mutation, specifically IKK2/ β releases NF- κ B from inhibition leading to progression of pancreatitis, ductal metaplasia, PanIN formation and eventually PDAC formation^[57]. Genetic inactivation of IKK2/ β in preclinical PDAC models led to failure of mice to develop tumors, while IKK2/ β deficient animals showed reductions in pancreatic cell proliferation rates and reduced inflammatory cell infiltrate. These observations support a critical role for NF- κ B in PDAC tumorigenesis. Unfortunately NF- κ B is difficult to pharmacologically target effectively due to the complexity of regulation within the signaling cascade. Inhibitors of IKK2/ β have so far failed to reach clinical trial.

SUMMARY

Preclinical trials are beginning to inform us as to tumor generated and tumor associated inflammation, how these factors help progress PDAC, and how they may be countered therapeutically.

Robust murine models of human disease now exist to allow preclinical trial of therapeutic agents. From these models researchers have established MDSCs, CAFs and TAMs are key cellular mediators of immunosuppression. Targeting these cells may sensitise tumors to immunotherapies such as anti-PD1 and CTLA4 antibodies. Immunotherapies have been extremely successful in diseases such as metastatic melanoma and if tumors can be “unmasked” from immunosuppressive elements this strategy is an exciting prospect in PDAC. IL-6/STAT3 and NF- κ B represent established inflammatory signaling nodes that progress PDAC. Trial of JAK/STAT inhibition shows early promise in clinical trial. However, NF- κ B remains an extremely difficult target to develop drugs against.

Early trials with trabectedin (immune cells), targeting hyaluronan (tumor stroma), and JAK/STAT inhibitors (inflammatory signaling), are extremely promising, however, as yet no large randomised controlled phase III trials have been published.

In future, we envisage combination trials targeting all three aspects of the pro-tumoral PDAC microenvironment will lead to better results in carefully selected patients. Pre-clinical assessment of such strategies is already under trial in robust mouse models of PDAC. A number of inflammatory targets, as outlined in this commentary, have been identified for trial, therefore the next decade of randomised controlled clinical trial data will determine the

effectiveness of agents against these key inflammatory mediators in PDAC.

It is important to note the relative lack of success of translation of stromal/inflammation targeting therapies to clinical trial from the laboratory at present. Only those therapies that demonstrate the most robust preclinical data should be taken forward. Patient selection for tumor microenvironment targeted therapies is a key issue, as is identification of biomarkers of response to such therapies. While those patients presenting with high levels of inflammation are easy to identify clinically, objective monitoring of response to therapy is more difficult due to the lack of robust biomarkers and paucity of available tissue to assess response. Strategies that incorporate pre and post-treatment endoscopic ultrasound biopsies must be considered to help develop techniques required to run robust clinical trials. Immune cell profiling could be employed to stratify subgroups of resected PDACs, potentially enabling individualized targeted immunotherapeutic strategies.

In PDAC the multitude of pathways and factors that determine progression remains the main obstacle in combating this aggressive disease. It is probable that to generate durable responses, in such a plastic disease as PDAC, carefully selected combination therapies will be required. Such strategies are likely to evolve to incorporate chemotherapeutics, immunogenics and therapies targeted against tumor stroma and signal transduction. The recent steady progression made in advanced PDAC with FOLFIRINOX and nab-paclitaxel will hopefully progress further with complementary therapeutics targeted against these different components of the tumor microenvironment.

Abstract

Gastro-entero-pancreatic neuroendocrine neoplasms (GEP-NENs) represents a various family of rare tumours. Surgery is the first choice in GEP-NENs patients with localized disease whilst in the metastatic setting many other treatment options are available. Somatostatin analogues are indicated for symptoms control in functioning tumours. Furthermore they may be effective to inhibit tumour progression. GEP-NENs pathogenesis has been extensively studied in the last years therefore several driver mutations pathway genes have been identified as crucial factors in their tumourigenesis. GEP-NENs can over-express vascular endothelial growth factor (VEGF), basic-fibroblastic growth factor, transforming growth factor (TGF- α and - β), platelet derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1) and their receptors PDGF receptor, IGF-1 receptor, epidermal growth factor receptor, VEGF receptor, and c-kit (stem cell factor receptor) that can be considered as potential targets. The availability of new targeted agents, such as everolimus and sunitinib that are effective in advanced and metastatic pancreatic neuroendocrine tumours, has provided new treatment opportunities. Many trials combining new drugs are ongoing.

Key words: Neuroendocrine neoplasms of the gastro-entero-pancreatic system; Chemotherapy; Targeted agents; Somatostatin analogues; Everolimus; Sunitinib

INTRODUCTION

Neuroendocrine neoplasms of the gastro-entero-pancreatic system (GEP-NENs) include a heterogeneous group of disease emerging from neuroendocrine cells of gastro-intestinal tract and pancreatic islets^[1]. Nevertheless, despite their morphologic, clinical and prognostic heterogeneity, GEP-NENs are often considered as a single entity^[2].

Although still considered a rare disease, SEER data showed an increasing incidence in the last three decades up to 3.65/100000 per years^[3]. This may be due to a remarkable improvement of diagnostic technique as well as a real change in population demography^[4]. GEP-NENs are more frequently detected in adult population^[5] and in about 50% of cases nodal (25%) or distant (25%) metastases are already existing from the beginning^[3,6]. On the basis of their morphologic features and proliferation index, NENs are currently stratified in two groups, according to WHO 2010 classification criteria^[7]: Neuroendocrine carcinomas, G3 tumours with ki67 proliferation index > 20%, and neuroendocrine tumours (NETs), including G1 (ki67 < 3%) and G2 (ki67 between 3% and 20%) neoplasms. Neuroendocrine carcinomas represent a separate cluster in the family of NENs, with specific biological features and a more aggressive behavior, so chemotherapy is currently considered the standard of care in this specific set^[8,9]. Conversely well and moderately-differentiated NENs do not represent a single entity and their pathogenesis has become clearer in recent years. In fact many driver mutations pathway genes have been identified as crucial factors in their tumourigenesis. Therefore altered pathways represent as a profitable therapeutic choice in neoplastic disease and also in NENs^[10-13].

Despite extensive and remarkable medical exertions, therapeutic choices are still unsatisfactory, mainly due to the lack of a broad knowledge of biological mechanisms and predictive factors. This review aims to summarize the present knowledge about chemotherapy and the pathways involved in sporadic well and moderately differentiated GEP-NETs, highlighting available evidences and new biological perspectives on biological and targeted therapies.

CHEMOTHERAPY

Although most of the studies were conducted on a heterogeneous population and the relationship between response rate (RR) and proliferation index value is often not clearly defined, GEP-NENs, therapy should include cytotoxic agents, especially in symptomatic subjects, progressive disease, moderated differentiation and more aggressive features. Chemotherapy should also be evaluated when the aim is to obtain a response in case of bulky lesions. However the best sequence for chemotherapy still remains uncertain^[14-18].

The most common used chemotherapy schemes include alkylating agents [streptozotocin (STZ), dacarbazine, temozolomide], antimetabolites [5-fluorouracil (5-FU), capecitabine] and platinum derivatives.

Temozolomide combined with 5-FU^[19] or capecitabine^[20] can represent the regimen of choice in G1 and G2 advanced P-NENs. Retrospective data showed a RR of 70% and progression-free survival (PFS) of 18 mo for temozolomide and capecitabine combination^[20].

Furthermore the association of STZ and 5-FU is frequently evaluated as a first-line therapy for advanced P-NENs with RRs between 6% to 40%, with the benefit in PFS ranging between 5 and 20 mo and with a median overall survival of 16-24 mo^[19].

Then, oxaliplatin in combination with capecitabine could also be considered for different setting of G1-G2 GEP-NETs^[15]. None of small retrospective studies or case reports conducted with other chemotherapy regimens have demonstrated sufficient efficacy in GEP-NETs.

SOMATOSTATIN

Many studies have shown the importance of somatostatin in the regulation of NENs' physiological functions. Currently, a cluster of five distinct somatostatin receptors (SSTRs) has been characterized in humans (SSTR1-SSTR5)^[21,22].

The presence of SSTRs has been demonstrated in over 80% of well-differentiated GEP-NENs, with a clear predominance of SSTR2 both in GI-NENs (90%) and P-NETs (80%)^[23,24].

Among the different SSTR subtypes, SSTR2 is usually the most prevalent in NENs, after that SSTR1 and SSTR5, whilst SSTR3 is less commonly expressed and SSTR4 almost absent^[25-27].

In general, tumour dedifferentiation is usually associated with a reduction of receptor density and changes in receptor subtype profile; thus, the presence of SSTRs might be also useful as a tumour specific predictor of prognosis.

Furthermore, the presence of SSTR5 seems to correlate with a major risk of angioinvasion and distant metastasis^[28]; instead, the loss expression of SSTR2 could be highly associated with the dysregulation of tumour proliferation, consequently promoting tumour growth^[29]. The lack of SSTR2

induces the generation of new membrane dimers, with development of different receptors, characterized by new function^[29-36]. It remains unclear if only numeric reduction of SSTRs or also their down-regulation are linked with tumour dedifferentiation^[37]. In pancreatic gastrinomas, glucagonomas and VIPomas, SSTRs are high expressed (80%-100% of patients). However, SSTRs seem to be expressed in 50%-70% of insulinomas, especially SSTR5 mRNA expression was demonstrated to be positively correlated with histopathological features of tumour aggressiveness in primary insulinomas^[38].

Therefore, in P-NENs subtypes, which express less SSTR, short synthetic analogues of somatostatin (SSAs) show a reduced activity in symptoms' control with a worsen hypoglycaemia^[39,40]. This high and heterogeneous expression does not show any relevant correlation between the subtype(s) expressed and the primary tumour origin, or a specific hormone secretion^[41-43].

The intracellular pathways activated by SSTRs appear different in several types of tumour cells and depend on the specific SSTR distribution pattern, signalling elements, as well as to receptor desensitization, internalization, and cross talk^[44,45].

The activation of G-proteins regulates the different critical enzymatic proteins such as adenylyl cyclase and protein kinase A, phospho-tyrosine phosphatases (PTPs) and mitogen activated kinases (MAPKs)^[22,46,47].

In particular SSTR1 induces MAPK pathway activations, SSTR2 improves SHP1 and epidermal growth factor receptor (EGFR) work, up-regulate p21 and Rb reducing MAPK switching on and blocking cellular proliferation. SSTR3 activates p53 and Bax inducing apoptosis, besides it blocks vascular EGFR (VEGFR). SSTR5 induce the activations of PTPs. Globally, these mechanisms leads to an inhibition of cellular proliferation and hormones secretion. Conversely, SSTR4 promotes cell mitosis up-regulating MAPK/ERK1/2 pathway^[21,48].

Since the 80s', several SSAs including octreotide, lanreotide, vapreotide, seglitide and pasireotide, were studied. In contrast to the endogenous somatostatin, these peptides have a more durable half-life (1.5-2 h vs 1-2 min) and activity, as they have a greater resistance to peptidase^[49].

Furthermore, compared to native somatostatin, they have diverse affinity for the aforementioned receptor subtypes^[25,37,50]. In particular the natural ligands of SSTR1-5 can bind all SSTRs with high affinity. Conversely different SSAs, in the same cell type, may elicit differential effects, due to the activation of different subsets of intracellular mediators^[45,51,52].

The analogues octreotide, lanreotide, vapreotide and seglitide exhibit elevated affinity for SSTR2 and lower for SSTR3 and SSTR5. Multi-SSTR-targeted analogue SOM230 (pasireotide) shows higher binding capacity towards SSTR1 and activates also SSTR 2, 3 and 5^[50,53].

The various SSTR binding show a different affinity with their own ligands, which is responsible for the distinct biological and clinical activity^[37]. Imam *et al.*^[54] and Eriksson *et al.*^[55] demonstrated a pro-apoptotic role of

SSAs. In fact they analysed tumor samples of GEP-NENs patients, who received high doses of SSAs^[54,55], finding increased apoptosis processes. The antiproliferative effect of SSAs is mediated by direct and indirect mechanisms. The inhibition of SSTRs, if expressed on tumour cells' membrane, operates directly on cell proliferation, stimulating antimitotic and apoptotic activities. SSAs induce cell growth inhibition also with indirect activities, such as angiogenesis inhibition, modulation of immune system and growth factors' block.

The indirect antiproliferative efficacy of SSAs does not require SSTR tumour expression and is shown by an antiangiogenic or immunomodulation mechanism, mediated by stimulation of the production of natural-killer cells^[56-58]. The antiproliferative activity of SSAs has been shown through various experimental models^[59-64]. The indication of using SSAs as fundamental therapy in NETs derives mainly from two studies: PROMID and CLARINET trials^[65,66]. The PROMID study showed a significant benefit with octreotide LAR (long-acting release) therapy in 85 subjects affected by advanced midgut NENs.

This study demonstrated an advantage in time to progression (TTP). In fact in patients treated with octreotide LAR a mTTP of 14.3 mo was observed, whilst patients in the control arm, receiving placebo, reported a mTTP of 6 mo. Sixty-four percent of subjects in the experimental arm showed stable disease (SD), which was observed only in 37.2% of subjects assuming placebo. Furthermore, patients treated with octreotide LAR experienced a 67% risk reduction of tumour progression compared with patients receiving placebo. The benefit of octreotide LAR was independent either of chromogranin level or hormone secretion.

The study did not show significant differences in OS, presumably due to the few deaths' percentage in both treatment arms. Furthermore the failure of the demonstration of an impact of octreotide in survival could be also done to the high rate of cross-over^[67].

Based on PROMID results, octreotide LAR has been approved as treatment of recurrent and advanced neuroendocrine tumors' patients, irrespective of the site of primary tumour, functional status and symptoms' presence. Lanreotide is another SSA with a similar *in vitro* hormone release inhibitory profile to octreotide^[68].

Recently, the CLARINET trial focused on 204 subjects suffering of nonfunctioning GEP-NENs who were randomized to receive either depot lanreotide, 120 mg every 4 wk for 96 wk, or placebo. The study demonstrated an improvement in PFS for patients treated with lanreotide (mPFS not reached in lanreotide arm; mPFS of 18 mo in placebo arm). This benefit was confirmed both in patients with P-NENs and midgut NENs.

Pasireotide, a new SSA, is characterized by an elevated binding affinity to four of the five SSTR sub-types^[69]. Hence, due to its broad binding profile, pasireotide may represent an effective therapeutic opportunity in tumours refractory to octreotide or lanreotide^[70]. However, its role in GEP-NETs still remains to be defined. In a phase III study pasireotide did not improve the control of flushing

Table 1 Ongoing phase III trials in gastro-entero-pancreatic neuroendocrine tumours

ClinicalTrials.gov Identifier	Investigated drug	Target	Type of enrolled pts
NCT00171873	Octreotide LAR 30 mg	SSTR	Locally inoperable or metastatic well differentiated NETs of the midgut Naïve pts
NCT01524783	Everolimus plus BSC <i>vs</i> PBO plus BSC	mTOR	Unresectable or metastatic G1 or G2 neuroendocrine tumours of GI or lung Treatment-naïve pts and pre-treated pts (all available treatment options are allowed) with PD
NCT00842348	Lanreotide autogel 120 mg	SSTR	Non-functioning GEP-NETs
NCT00690430	Pasireotide LAR 60 mg <i>vs</i> Octreotide LAR 40 mg	SSTR	Metastatic carcinoid tumours
NCT00774930	Somatuline depot (lanreotide) <i>vs</i> PCB	SSTR	Pts with disease-related symptoms inadequately controlled by somatostatin analogues Carcinoid tumours with liver metastasis
NCT00092287	Lanreotide autogel <i>vs</i> Sandostatin LAR	SSTR	Treatment-naïve pts and pts pre-treated with and responsive to somatostatin analogues Carcinoid tumours localized in lung, stomach or midgut
NCT00263659	Telotristat etiprate (LX1606) <i>vs</i> PBO	TPH	Treatment-naïve pts and pts pre-treated with and responsive to somatostatin analogues Well-differentiated metastatic NETs with carcinoid syndrome
NCT01677910	Telotristat etiprate (LX1606) <i>vs</i> PBO	TPH	Treatment-naïve pts Well-differentiated metastatic NETs with carcinoid syndrome Pts with disease-related symptoms inadequately controlled by somatostatin analogues

GEP-NETs: Gastro-entero-pancreatic neuroendocrine tumours; LAR: Long acting release; SSTR: Somatostatin receptor; mTOR: Mammalian target of rapamycin; BSC: Best supportive care; PBO: Placebo; PD: Programmed death; TPH: Tryptophan hydroxylase; pts: Patients.

or diarrhea in patients affected by refractory carcinoid syndrome^[71] (Table 1). The antiproliferative effects are being tested in several clinical studies^[72,73]. Telotristat etiprate (LX1606) is an oral serotonin synthesis inhibitor used in patients with diarrhoea related to carcinoid syndrome^[74].

A recent randomized prospective single-arm study has been conducted in patients with carcinoid tumour and diarrhoea (≥ 4 bowel movements/day) inadequately controlled by octreotide. Among patients treated with telotristat etiprate, 28% experienced a $\geq 30\%$ reduction in bowel movements frequency for more than 2 wk and 56% had a biochemical response. These results suggest a potential activity of telotristat etiprate in controlling carcinoid syndrome and diarrhoea. Pavel *et al.*^[75] made a prospective exploratory dose escalating 12-wk open label multicentre study of telotristat etiprate in metastatic well-differentiated NETs with ≥ 4 -bowel movements/day. Whole patients experienced reductions in bowel movements, 74.2% mean reduction in metabolites of serotonin and 75% of patients reported adequate relief of GI symptoms (Table 1).

MAMMALIAN TARGET OF RAPAMYCIN PROTEIN KINASE B, PHOSPHOINOSITIDE 3-KINASE AND PHOSPHATASE AND TENSIN HOMOLOG PATHWAY

A considerable number of intracellular pathways seem to conditionate tumorigenesis and neoplastic spread in NENs, as receptor tyrosine kinases (RTKs) and G-protein coupled receptors (GPCRs) transduction mechanisms. Their action seems to be modulated by Ras/Raf, MAPK, phosphoinositide 3-kinase (PI3K)-protein kinase B (AKT)-mammalian target of rapamycin (mTOR) and JNK

increasing cells' growth and number. The AKT family of serine/threonine kinases is an important mediator of PI3K signaling, promoting the principal cellular functions^[76]. Akt isoforms seem to be an eminent target for GEP-NENs therapy^[77]. PI3K/AKT/mTOR pathway is especially activated among P-NENs^[78] and their somatic mutations are detected among a minority of P-NETs^[79]. Although discrete mutations in the aforementioned pathway are rarely found in GEP-NENs, overexpression of mTOR and/or its downstream targets is being individuated in a high frequency of cases and it is correlated with higher proliferative activity and adverse clinical outcomes^[80,81]. mTOR is composed by two complexes working together guarantying many cells' activities^[82-91]. The importance of mTOR inhibitors results from the aforementioned considerations^[92,93]. RADIANT-1 (phase II study) represents the first trial demonstrating everolimus utility in GEP-NETs^[94]. The trial compared everolimus alone *vs* everolimus plus octreotide in 160 patients. Regarding combined therapy arm the median PFS was 16.7 mo with a quite well tolerance.

In RADIANT-2 (phase III trial) subjects affected by symptomatic well-differentiated NETs received everolimus plus octreotide *vs* octreotide alone. A lack of significant benefit in PFS was showed in the combination arm. The most common grade 3/4 side effects in the everolimus arm were stomatitis (6.5%), diarrhea (6%), infections (5.1%), and hyperglycemia (5.1%)^[95]. RADIANT-3 (phase III trial) contemplated everolimus *vs* placebo^[96]. The study recruited only G1-G2 P-NETs subjects. Everolimus arm was associated with a better PFS although a low ORR. Therefore everolimus was approved in the management of advanced P-NETs.

RADIANT-4 (ongoing phase III trial) investigates role of everolimus in gastrointestinal/pulmonary neuroendocrine tumors. It may lead to a better definition of the role of

Table 2 Ongoing phase II trials in gastro-entero-pancreatic neuroendocrine tumours

everolimus in patients with carcinoid tumours. Finally, other targeted therapies are being studied in NETs (Table 1). Furthermore temsirolimus, another mTOR inhibitor, was evaluated in NETs^[97]. However, the results were not considered clinically relevant and further studies with this agent in NETs won't be performed.

Another fundamental target implicated is PTEN (phosphatase and tensin homologue). Loss of PTEN is commonly individualized in a several human cancers^[98] and it is related to the presence of metastases and therapy resistance towards mTOR inhibition^[99-103]. PTEN is localized in the nucleus. Its activation through internalization leads to a reduction of Act^[104-106]. PTEN is frequently mutated in P-NETs and a low expression of PTEN correlates with high grading^[107].

PI3K pathway represents a hot point in NETs proliferation and some studies evaluating its inhibition are ongoing. BEZ235 is a PI3K inhibitor studied associated with everolimus (phase II study) (Table 2). Then a phase I study is on-going using BYL179 in combination with everolimus and exemestane in P-NETs.

INSULIN GROWTH FACTOR-1

Insulin growth factor 1 (IGF-1) represents a fundamental factor in tumour expansion, so its inhibition may reduce tumour proliferation. NETs have demonstrated to secrete

a significant quantity of IGF-1, then its receptor (IGF-1R) shows a key role in GEP-NETs tumorigenesis^[108,109].

Furthermore, many evidences have related a major IGF-1R expression with the presence of functioning and symptomatic NETs^[109-118]. Cixutumumab (CIX), a monoclonal antibody competitively binding IGF-1R and then causing its degradation, is currently being evaluated in an on-going trial in association with octreotide depot (Table 2). The usefulness of CIX has already been demonstrated in combination with many other therapeutic options^[119].

VEGF

Angiogenesis displays a crucial role for tumour expansion and distant spread and it's mediated by VEGF and its receptors (VEGFRs). Four VEGF forms were identified: VEGF-A, VEGF-B, VEGF-C and VEGF-D, with a different affinity to their three own receptors^[120-129]. Octreotide showed an inhibition of angiogenesis probably mediated by an interaction with VEGF pathway^[130]. The tyrosine kinase inhibitor (TKI) sunitinib^[131] has been demonstrated a valid targeted therapy option in NENs.

A phase II trial evaluated the efficacy of sunitinib in GEP-NETs demonstrating a significant antitumour activity in P-NETs, while among patients with carcinoid tumours OR were only 2.4%; the treatment was average well

tolerated with especially gastrointestinal toxicities^[132].

As a consequence of these results, a phase III trial evaluated sunitinib vs placebo in 171 low- and intermediate-grade advanced P-NETs^[133]. In the experimental arm was demonstrated an improvement of PFS although the RRs associated with the drug were only 9.3%. The benefit was independent of previous treatments and concomitant administration of SSAs. Considering the importance of VEGF in pathogenesis of NENs, bevacizumab, an antibody directed against VEGF^[134], has been used either alone or in combination with other drugs with favourable results^[135].

CYTOTOXIC T-LYMPHOCYTE ANTIGEN-4 AND PROGRAMMED DEATH-1

Recently, immunotherapy was demonstrated to be an important treatment option in various cancers. In fact several new immune-target drugs, directed towards specific immune checkpoints, showed an important antitumoral effect.

The first developed immune agents were directed against mediator of immunity inhibition, as cytotoxic t-lymphocyte antigen-4 (CTLA-4) and programmed death-1 (PD-1). These mediators are both membrane glycoprotein, which are mainly expressed in activated T-lymphocyte.

CTLA-4, known also as CD152, owns an elevated kinship with CD28 and plays a crucial role regulating immunity's homeostasis, through the switching-off of T-lymphocyte activation. Its expression seems to be mayor stimulated in switched-on effector T-lymphocytes (Teff cells)^[136]. CTLA-4 is constitutive and represented in regulatory T lymphocytes (Treg)^[137]. As aforementioned said, it joints CD28, thanks to theirs high affinity, to costimulatory proteins (CD80, CD86) represented in antigen-presenting cells (APC).

Several humanized monoclonal antibodies directed vs CTLA-4, were studied, such as ipilimumab and tremelimumab. The programmed cell death protein-1, PD-1, a membrane protein, acts inhibiting a large group of molecules owning to CD28 family of T-lymphocytes regulators. PD-1 is most represented on surface membrane of activated monocytes, T lymphocytes, and B lymphocytes. PD-1 have different ligands, the most known are PD-L1^[138] and PD-L2^[139].

PD-L1, a transmembrane protein notably presents in macrophages, in T-lymphocytes, B lymphocytes and dendritic cells (DCs), its concentration increases since cellular activating processes. PD-L1 may be presented also in some tissues not involved in immune system. The principal function of PD-1 seems to be reducing autoimmunity and switching off T-lymphocyte activities involved in inflammatory response to infection^[140-142].

In conclusion the linkage between PD-1, mainly expressed in activated T-lymphocytes and PD-L1, principally expressed in tissue DCs, induce a switching-off of T-lymphocytes activation and a blockage of their effector activity^[143]. Identifying a selected group of NENs' patients

that could benefit from immunotherapies is not still possible because no predictive biomarkers to immune drugs have been found. Further studies are needed to evaluate the exact expression of aforementioned target immune proteins (PD-1, PD-L1/L2) in the various NENs.

EGF AND TRANSFORMING GROWTH FACTOR ALPHA

EGF and transforming growth factor alpha (TGF- α) are polypeptides that bind the EGFRs regulating cellular responses to growth signals through activating signal transduction pathways (RAS-RAF-MAPK). From a biological point of view, EGF is a mitogen factor regulating growth, proliferation and differentiation of numerous cell types; abnormalities in EGF-signalling pathways have been related to tumour growth and progression^[144].

The EGFR belongs to the HER receptor family. Gastrointestinal (GI) and pancreatic NETs express and activate EGFRs^[145]. Papouchado *et al*^[146] demonstrated a most elevated presence of EGFR (> 91%) in GI-NENs, (especially in rectal NETs), whilst in P-NENs its expression was lower (< 25%).

Srivastava *et al*^[147] showed instead an elevated presence of EGFR and TGF- α , in P-NENs. Sixty-three per cent of neoplasms in fact showed positivity for TGF- α and 65% for EGFR. However the study did not demonstrate an association with measure, functional status, ability to secrete hormones, or biologic behaviour^[147].

TGF- α is expressed in approximately 70%-100% of NETs depending on the technique used (immunohistochemistry or northern blot analysis)^[148-150] and is commonly over-expressed in larger rectal NETs with a high Ki-67 index^[150]. TGF- α binds with high affinity to the EGFR extracellular domain. Cytoplasmic substrates phosphorylation occurs and initiates a signalling cascade (RAS/RAF/MAPK-ERK) that drives pro-proliferative gene expression, cytoskeletal rearrangement, and increased cell proliferation^[144].

Gefitinib is a targeted agent that selectively inhibits receptor tyrosine kinases, including EGFR. A phase II trial enrolling subjects affected by advanced NENs, gefitinib exhibited somewhat promising initial results. At 6 mo, 61% of patients affected by carcinoid tumours and 31% affected by P-NEN were progression-free; however, objective responses for each group were low, 5% and 9.6%, respectively^[151].

BASIC FIBROBLASTIC GROWTH FACTOR

The basic fibroblastic growth factor (bFGF) is involved in both physiological and pathological processes by interaction with determinated receptors localized in cellular membrane^[152,153].

Because overexpression of bFGF and/or its receptors is frequently detected in tumours, the development of antagonists to bFGF and its receptors has been studied as a potential strategy for cancer therapy^[154-156].

Figure 1 Illustration of principal pathways involved in cellular differentiation, proliferation, survival and apoptosis: Somatostatin receptors, mammalian target of rapamycin protein kinase B, phosphoinositide 3-kinase and phosphatase and tensin homolog, insulin-like growth factor 1 receptor, vascular endothelial growth factor receptor, epidermal growth factor receptor, transforming growth factor receptor, fibroblast growth factors. SSTRs: Somatostatin receptors; mTOR: Mammalian target of rapamycin; Akt: Protein kinase B; PI3K: Phosphoinositide 3-kinase; PTEN: Phosphatase and tensin homolog; IGFR: Insulin-like growth factor receptor; VEGFR: Vascular endothelial growth factor receptor; EGFR: Epidermal growth factor receptor; TGFR: Transforming growth factor receptor.

Almost five isoform of transmembrane FGF receptors (FGFR), able to dimerize, are well known. The first four subtypes are characterized by a tyrosine kinase activity^[157]. Chaudhry *et al.*^[158] searched for mRNA expression of 6 different transmembrane receptors (FGFR, EGFR, IGF-1R, TGF-betaR1 and betaR2), and the presence of SSTRs in determinate subtypes of GEP-NENs tissues (gastrinoma, insulinoma, tumours with carcinoid syndrome, not-functioning neoplasms) using reverse transcriptase-polymerase chain reaction. Among the four tumour subtypes, expression frequencies of the receptors aforementioned varied significantly^[158]. Taken together, these studies have accounted for high growth factor abundance in GEP-NENs. Considering these results GEP-NENs seems to have an elevated growth factors concentration.

C-KIT/ PLATELET DERIVED GROWTH FACTOR

The c-kit receptor, also referred to CD117 or platelet derived growth factor receptor (PDGFR) is a type I transmembrane glycoprotein. It is usually included in the family of tyrosine kinase receptor (RTK)^[159].

In tumor cells, PDGF promotes proliferation and neoplastic spread^[160-163]. Various subtypes of c-kit receptor have been already identified^[164] but their ligand still remains stem cell factor (SCF), a hematopoietic cytokine involved in cell survival, proliferation and differentiation^[165].

Few pre-clinical studies performed of GEP-NETs have shown a variable expression of c-kit, with ranges from 0% to 38%, and PDGFR α in carcinoids^[166], with a particularly high expression in gastrinomas (up to 100% of c-kit expression)^[167].

MULTI-TARGETED AGENTS

Famitinib is an oral tyrosine-inhibitor agent targeting at c-kit, PDGFR, VEGFR2, VEGFR3, Flt1 and Flt3. Its efficacy in GEP-NETs is currently being evaluated (Table 2).

Regorafenib is a novel multi-kinase inhibitor (c-RAF; BRAF, VEGFR-1, 2, 3; PDGFR α , FGFR-1; c-kit; RET; Flt-3) belonging to the group of biaryl urea chemicals^[168-170]. Pazopanib is an oral inhibitor of several specific cellular pathways involved in neoplastic growth and dissemination^[171]. Its efficacy in NENs was demonstrated in a phase II clinical trial combining pazopanib and SSA achieving a 17% RR in G1 P-NETs^[172]. Data related to ongoing trials with pazopanib and with regorafenib in NETs are summarized in Table 2.

CONCLUSION

In GEP-NETs tumourigenesis and progression are often involved SSTRs, mTOR/Akt/PI3K and PTEN, IGF-1, VEGF, EGF, TGF, FGF and c-kit/PDGF and its corresponding receptors^[145,148,149,173-177] (Figure 1). The recent availability

of novel drugs has provided new treatment opportunities and holds promise given the expression in GEP-NENs of this variety of targets^[33,178,179].

Abstract

Published reports have revealed increased risk of colorectal cancers in people exposed to chlorinated drinking water or chemical derivatives of chlorination. Oestrogen plays a dual positive functions for diminishing the possibilities of such risk by reducing the entrance, and increasing the excretion, of these chemicals. In addition, there are supplementary measures that could be employed in order to reduce this risk further, such as boiling the drinking water, revising the standard concentrations of calcium, magnesium and iron in the public drinking water and prescribing oestrogen in susceptible individuals. Hypo-methylation of genomic DNA

could be used as a biological marker for screening for the potential development of colorectal cancers.

Key words: Chlorinated drinking water; Oestrogen; Sex hormones; Gender; Colorectal cancers; Trihalomethanes; Carcinogenesis; DNA hypo-methylation

Core tip: Oestrogen inhibits the absorption and increases the excretion of xenobiotics and their metabolites *via* the bile. Oestrogen has anti-hypo methylation activity on the genomic DNA by reducing the plasma levels of homocysteine. Colorectal carcinomas are the third most common tumour in both sexes across the globe. The hazard to develop tumours in different specific sites including colon and rectum in association with the long-term exposure to water disinfectants in drinking water is well established. The risk to develop tumours in the large intestines is dependent on the concentrations and frequency of exposure to the trihalomethanes in the used water for drinking. The risk to develop malignant tumours due to water pollution is higher amongst user of swimming pools and is also dependent on the frequency of showering. Indeed, this risk is much higher in those who are avid consumers of fatty foods and/or their meals lacks vegetables and fruits in this susceptible group amongst those who are users of swimming pools. Yet, this risk could be reduced by adding calcium, magnesium and removing iron from the drinking water. Boiling of drinking water is another effective measure for reducing such risk. Colorectal carcinomas arising from long exposure to trihalomethanes in drinking water are characterised an aggressive courses of development and are rarely diagnosed in early stages. Accordingly, it is quite necessary to screen for their occurrence amongst the susceptible persons. Global DNA hypomethylation is most common amongst all subjects who are susceptible to develop malignant tumours and the levels of hypo methylation increase with the prognosis of the disease. Thus screening for the hypo methylation of the relevant genomic DNA and the plasma concentration of homocysteine would be useful criterion for identifying those at risk.

INTRODUCTION

Carcinomas of the large intestines are remarkably common across the globe with around 1.4 million new cases diagnosed in 2012^[1]. The risk of developing colorectal cancer increases with age and is higher in men than in women^[2].

An association between water chlorination and the development of colorectal carcinoma is well established^[3-13].

The different frequencies of cancers in different genders, the recurring diagnosis of malignant tumors of the large intestines in women with breast cancer, the prophylactic effect of gravidity, together with the decreased risk among women on pills after menopause suggest that female hormones may play a role^[14].

In animal models, for example, male rats that were exposed to dimethyl hydrazine (a carcinogenic mediator), had twice the risk of developing colonic tumors and noticeably shorter survival times than their female peers^[14].

Estrogen mainly exerts its actions through its receptors (ERs) that exist on the target cells. ERs have been found in several malignant tumors including those of the alimentary tract^[15].

Yet, whether estrogen contributes in the carcinogenic activity of the trihalomethanes that leads to the development of colorectal carcinoma is still unknown. The objective of this review is to explore the possible mechanism played by oestrogen in the cancer development process.

METABOLISM AND EXCRETION OF XENOBIOTICS

Poisons, cancer initiators and medicines are examples of xenobiotics. Many metabolizing enzymes are involved in their detoxification. The cluster of cytochrome P450 isoenzymes is one of two known classes that are responsible for the metabolism of these compounds. It consists of many isoforms^[16] leading to the oxidation (mainly hydroxylation) of the particles^[17]. Isoforms in the clusters 1, 2 and 3 accelerate metabolism of many exogenous compounds. Many poisons and cancer promoters usually necessitate activation by cytochrome P450 isoenzymes in order to be expelled outside the body. In general, the enzymatic activity of cytochrome P450 isoenzymes has three specific and consecutive phases: Phase I metabolism, is largely for catalysing the first step of biotransformation. However, if this catalysing activity follows a variety of conjugation steps it is entitled phase II metabolism. This stage is usually accelerated by a variety of enzymatic systems, of which UDP Glucuronosyltransferases is the most important^[18]. The

purpose for conjugating the xenobiotics to the glucuronic acid is to make them soluble in water and consequently fit for excretion in bile^[19,20]. Other models of phase II systems include sulfotransferases, acetyltransferases and glutathione-s-transferase.

Later reports^[21] have added the transport steps and considered them as part of the detoxification process. The role of the export pumps is to reduce the cellular concentrations of these poisons and thereby decreasing the associated harm.

These transport proteins mainly exist in the apical membrane of epithelial cells, such as enterocytes, which lie directly opposite to these exogenous toxins. The protein transporters can limit the entrance of the harmful compounds and facilitate the excretion of their metabolites as well. The last step is entitled "phase III metabolism" in order to link it to the oxidation and conjugation steps. Yet, directing the poisons to enter into the enterocytes has been considered as first line of defence and accordingly has been entitled "phase 0 metabolism".

These protein transporters exert their activities in an active ATP dependent manner against the concentration gradients. The two most common models of these transporters are the multidrug resistance transporter 1 (MDR1) and multidrug resistance associated protein 2 (MRP2). These transporters play a remarkable role in phase 0 and phase III defence against xenobiotics. They are present in both the intestine and liver and thence can reduce the oral bioavailability by direct inhibition of gut absorption and speedy excretion of xenobiotics and their metabolites *via* bile^[19,20].

MDR1 is active against xenobiotics in both the blood-brain barrier and in the gut^[22]. MDR1 are expressed in the small and large intestines but they are mostly manifested in the large intestine^[23,24].

MRP2 was first identified in the apical membrane domain of hepatocytes^[25]. The main function of MRP2 is to facilitate the transport of a variety of organic anions, especially the conjugated formulas, into bile and thence out of the body^[26]. This means that MRP2 are capable of restricting whole body load of endogenous and exogenous toxins. MRP2 are also expressed in the kidney, in the epithelial cells of the intestine^[27], in the placenta^[28], and in the blood-brain barrier^[29]. In the rat intestine, MRP2 expression is highest in the duodenum but few are found in the colon^[30] MRP2 actively ejects the xenobiotics after hydroxylating them in the form of glucuronide, sulfate or glutathione conjugates.

REGULATION OF EXPRESSION AND ACTIVITY OF MULTIDRUG RESISTANCE PROTEINS MRP2 AND MDR1 BY ESTROGENIC COMPOUNDS IN CACO-2 CELLS

The influence of pharmacological levels of ethynylestradiol (EE) on the expression and activity of MRP2, MDR1

and breast cancer resistance proteins (BCRP) in *in vitro* models of drug transport, such as CaCo2 cells has been examined^[31].

Cells treated with either 0.5 or 5 pmol/L EE for 48 h showed an increase in MRP2 (+75% and +88%) and MDR1 (+158% and +162%) protein expression, with respect to control cells. Yet, no effects were observed when cells were treated with all other concentrations tested^[29]. In additional experiments performed to determine protein expression of MRP2 and MDR1 in total cellular membranes as well as their mRNA levels in cells treated with 5 pmol/L EE, an increase in MRP2 (+56%) and MDR1 (+128%) protein expression, with respect to control cells was noted.

When MRP2 activity was evaluated using DNP-SG as a model substrate treatment with 5 pmol/L EE increased the ratio of protein expression by 39% when compared to control cells^[28]. To the contrary, when MDR1 activity was evaluated using Rh123 as a model substrate the intracellular accumulation of Rh123 correlated inversely with MDR1 extrusion activity. Treatment with 5 pmol/L EE decreased substrate accumulation by 19% when compared to control cells^[31]. Such decreased accumulation will lead to reduction in the length and concentrations of exposure and accordingly a reduction in the risk of the associated hypomethylation of repetitive DNA elements^[32].

Further, when the protective effect of EE against CDNB and PQ cytotoxicity was evaluated through determination of the cell survival IC50 value related to CDNB, IC50 values were higher in cells treated with 5 pmol/L EE (33.3 ± 0.5) than in control cells (25.5 ± 0.5)^[31]. Likewise, the IC50 value related to PQ cytotoxicity was higher in cells treated with 5 pmol/L EE (8.8 ± 0.8) vs control cells (6.8 ± 0.5 mmol/L)^[31].

The same researchers also tried to evaluate whether ER mediates transporter modulation by EE. For achieving that goal, they measured MRP2 and MDR1 protein expression after treatment with 5 pmol/L EE for 48 h, in the presence or absence of ICI 182/780. The findings were that MRP2 and MDR1 protein up-regulation was abolished by the ER antagonist (EE vs EE + ICI)^[31].

DNA HYPO-METHYLATION IS A SIGNIFICANT INDICATOR OF THE DEVELOPMENT OF CANCERS

The first reported epigenetic changes in human cancer of losses of DNA methylation (methylated 5C component was replaced by non-methylated C component) was published in 1983^[33]. In their study, Gama-Sosa *et al*^[33] noticed this change in DNA methylation thru the genome in a variety of carcinomas against a broad diversity of ordinary tissues. Then in further published work, Feinberg *et al*^[34,35] reported hypomethylation of unrelated gene areas to cancer in colon adenocarcinomas compared with normal controls.

DNA hypo-methylation appears much more extensive in metastases. Many subsequent reports have confirmed

the recurring global genomic hypo-methylation in cancers when compared with normal tissues^[36-42]. This conclusion has been recently bolstered^[43]. In a 2014 report by Kaz *et al*^[43] genetic alterations in the methylation of genes known for their participation in the colonic carcinogenic process of the normal colon, where no colonic tumour existed suggest that these genetic alterations precede any changes in the colonic tissues and could be potentially used as predictors for the development of colorectal cancers^[43].

Phases of DNA Hypo-methylation status is a significant feature during the early stages of the development of tumours or in other abnormal growths, such as hyperplasia^[42,44-46]. This conclusion was confirmed further by the findings of DNA hypo-methylation prior to the identification of aneuploidy in gastrointestinal cancers^[47]. Hypo-methylation of DNA, in general, increases with the tumour progression or grade of malignancy^[48-51]. Yet, cancers arising from long exposure to chlorinated water are not exceptional^[52]. In a study on an animal model, Coffin *et al*^[52] examined the influence of the exposure to trihalomethanes in the used water for drinking on the tumour progression and DNA methylation of female B6 C3 F1 mouse liver cell line. The main finding of this study was that the trihalomethanes administered by gavage enhanced the multiplicity of the hepatocytes and decreased the methylation of the *c-myc* gene^[52].

ER- α GENE HYPER-METHYLATION IS A POTENTIAL INDICATOR FOR COLORECTAL CARCINOMA

Oestrogen has anti-cancer activity and plays a significant role in suppressing the development of colorectal cancer^[53]. This clearly appears from the frequently reported hyper-methylation of the *ER- α* gene in malignant tumours of the large intestines^[54,55], suggesting that *ER- α* gene hypermethylation could be used as a predictor for the development of large bowel cancers. *ER- α* is a transcription factor that, upon binding to oestrogen transfers to the nucleus to activate various genes including those involved in the inhibition of cell multiplicity^[56]. The insertion of *ER- α* gene into ER-negative colon cancer cells suppressed cell proliferation^[57]. Retrieval of an epigenetically inactivated *ER* gene resulted in suppression of large bowel cancer cells development *in vitro* and *in vivo*^[58]. Experimental work have shown that *ER- α* gene is also hypermethylated in azoxymethane (AOM)-induced carcinoma of the large intestines in rats, lending support to a pragmatic approach to cancer suppression^[59].

THE INFLUENCE OF LONG-EXPOSURE TO TRIHALOMETHANES IN THE USED WATER FOR DRINKING AND THE DEVELOPMENT OF CANCERS

Chloroform, Bromodichloromethane, Chlorodibromome-

thane, and Bromoform are common contaminants in chlorinated water.

Chloroform is considered a facilitator for the development of cancers in humans based on data from animal studies.

Oral contact to chloroform initiated tumours in two kinds of rats and at two different places. Direct gastric administration of chloroform by stomach tube caused hepatocellular carcinoma in mice of both sexes^[60] and renal epithelial tumours in male mice and rats^[61,62].

Benign hepatic adenomas were observed in female rats drank contaminated water with chloroform^[63,64] and in female mice breathed contaminated air with Chloroform^[64]. Renal tubular-cell adenomas, carcinomas, or adenocarcinoma were observed in male rats drank contaminated water with chloroform^[62,63], in male mice breathed contaminated air with chloroform^[65], and in male rats following combined exposure to chloroform *via* breathing and drinking contaminated suppliers^[66].

No cause-effect relationship has been established between human cancer and exposure specifically to chloroform. However, an association between exposure to contaminated water and development of specific kinds of cancers has been established by community-based, cohort and case control studies^[67,68], but a causal relationship could not be inferred^[69-77].

Similarly, bromodichloromethane is also considered a facilitator for the development of cancers in humans based on data from animal studies. Drinking contaminated water with bromodichloromethane caused tumours at several different places in mice and rats. Direct gut administration of bromodichloromethane by a stomach tube caused renal tubular-cell adenomas and adenocarcinomas in male mice and in rats of both sexes, hepatocellular adenomas and carcinomas in female mice, and colonic adenomatous polyps and adenocarcinomas in rats of both sexes^[71,77-79].

Drinking contaminated water with bromodichloromethane increased the frequencies of hepatocellular adenomas and carcinomas in males^[80] and caused hepatocellular adenomas in females^[81].

The data available from epidemiological studies are not conclusive to confirm on a possible relationship between the development of cancers in humans and the exposure specifically to bromodichloromethane. Several epidemiological studies indicated a possible association between drinking chlorinated water and increased risk of cancer, but these studies could not provide information on whether any observed effects were specifically related to bromodichloromethane^[78].

When the risk to develop cancers due to long-term exposure to trihalomethanes *via* drinking, breathing and dermal contact from supply water of five water suppliers were analysed chloroform was the major component that caused cancer risk through both oral and dermal routes whereas bromodichloromethane was the major component through inhalation^[82]. The main risk factors that enhance the development of cancers are the existence of Chloroform in the contaminated water, body weight and then the long-term exposure to chlorinated

water^[82,83].

Evidence exists to prove that low concentrations of calcium (Ca) and/or magnesium (Mg) in the used water for drinking increase the carcinogenic effect of TTHM and thence the development of cancers of oesophagus^[83], kidney^[84], rectum^[85] and pancreas^[86].

On the other hand, it was found that the presence of Fe³⁺ increases the carcinogenic activity of THMs in humans^[87]. It was estimated that the risk to develop cancer from long-term skin exposure to trihalomethanes while swimming is as high as 94%^[88].

THE EFFECT OF OESTROGEN ADMINISTRATION ON THE DNA METHYLATION

In a randomized double-blind, placebo-controlled, cross-over study consisting of two different stages, placebo and conjugated horse oestrogen, Friso *et al*^[89] investigated the effect of administration of oestrogen in thirteen volunteer postmenopausal women on the genomic and promoter DNA methylation in peripheral mononuclear cells and on the plasma concentrations of homocysteine, folate, vitamins B6 and B12. In this study, oestrogen was prescribed as oral pills containing 0.625 mg CEE while placebo consisted of twin pills but lacking the active constituent. Each course lasted 8 wk and these two courses were separated by a 4-wk period^[90]. At week 8 of each stage, blood samples were taken for measuring plasma homocysteine, plasma pyridoxal-50-phosphate, serum folate and vitamin B12 levels. DNA was extracted from peripheral blood mononuclear cells in order to estimate genomic and promoter DNA methylation status.

The findings of this study were that: (1) plasma homocysteine levels were markedly decreased during the CEE phase compared with the placebo; (2) mean homocysteine levels during the placebo phase were 9.29 mmol/L (it was within the normal reported range by Stabler *et al*^[91] in 2004; (3) the oestrogen treatment reduced the mean concentration of homocysteine to 8.08 mmol/L; (4) the extent of genomic DNA methylation in peripheral mononuclear cells was noticeably increased after the oestrogen treatment as opposed to the placebo; (5) there was no significant difference in the promoter DNA methylation of the *ERa*, *ERb* and *p16* genes between the oestrogen and placebo; and (6) there were no significant differences in serum folic acid, vitamin B12 and plasma vitamin B6 levels between the two treatment arms. These findings indicate that oestrogen administration could increase the methylation of the genomic DNA. Together with the well-documented data proving that a decreased level of genomic DNA methylation is a common feature of tumorigenesis, that it appears early prior to the DNA mutation that takes place later in the evolution of neoplasm^[45] this means that oestrogen administration has a prophylactic function against the development of cancers by enhancing genomic DNA methylation.

Table 1 Effect of heating and boiling water on trihalomethane content

Compound	Level (µg/L)				
	Original tap water	80 °C 1 min	100 °C 0 min	Boiling 1 min	Boiling 5 min
Chloroform	45.6	23.2	12.3	9.4	4.1
Bromodichloromethane	44.6	24.1	13.5	10.8	4.6
Chlorodibromomethane	42.3	24.1	14.4	12.3	5.5
Bromoform	35.9	21.3	13.9	13.5	6.8

DISCUSSION AND CONCLUSION

Chlorine is commonly used as a chemical disinfectant in water supplies, in the prevention of algal, bacterial and general slime growths in treatment plants and pipe works, in the control of tastes and odours, and in the removal of iron, manganese and colouring additives^[92].

Trihalomethanes are derivatives of the outcome of the reaction between chlorine/chloride, with contaminants in water supplies, such as organic compounds, bromide and iron.

The associated health threats including colorectal cancers are dependent on the frequency of exposure to and the levels of trihalomethanes in the used water for drinking. These threats could be reduced by restricting the use and contamination by trihalomethanes of public drinking water^[83,93], or by boiling the water^[94] (Table 1), or by adjusting the concentrations of calcium, magnesium and iron^[83-87].

Genomic DNA hypo-methylation could be used as a reliable biomarker for identifying susceptible cases and oestrogen replacement therapy could be used for reversing detected hypo-methylation and consequently reducing the risk of the carcinogenesis^[86,89,90].

However, in cancers of the colon and rectum, like other ER-linked cancers, the ablation of the sex hormones would be necessary, once the disease occurs, for delaying the progress of the disease. It is well-documented that once the disease manifests the role of oestrogen would be altered in that it will enhance global DNA hypo-methylation^[95] and thereby restricting of its availability would be beneficial.

Abstract

AIM: To compared the prognosis of middle third gastric carcinoma (MGC) patients with those of patients with proximal/distal gastric carcinoma (PGC/DGC).

METHODS: Of 3299 patients diagnosed with gastric carcinoma who underwent surgery at our hospital over a 15-year period, 919 (27.9%) were diagnosed with MGC. For each patient, the following information was obtained from hospital records: Age, sex, tumor size, depth of invasion, histologic type, nodal involvement, extent of lymph node dissection, hepatic metastasis, peritoneal dissemination, stage at initial diagnosis, operative type, curability, and survival rate.

RESULTS: T1 category tumors were more common in patients with MGC than in patients with PGC ($P < 0.001$). Tumor stage (stage I), N category (N0), and T category (T1) significantly influenced the 5-year survival rates for patients with curatively resected tumors. A multivariate analysis showed that age, tumor size, serosal invasion, lymph node metastasis, and curability were significant predictors of survival in patients with MGC. The survival rate for MGC patients was similar to that for PGC/DGC patients (52.8% vs 44.4%/51.4%, $P = 0.1138$). The 5-year survival rate for MGC patients with curative resection was higher than that for MGC patients with non-curative resection (62.9% vs 8.7%, $P < 0.001$).

CONCLUSION: These results indicate that tumor

location did not affect the prognosis. Curative resection is important for improving the prognosis of patients with MGC.

Key words: Middle third gastric carcinoma; Prognosis; Curative resection

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The clinicopathological features of the patients with middle third gastric carcinoma (MGC) were reviewed retrospectively. Tumor location did not affect the prognosis. When the MGC group was divided into patients with or without curative resection, the survival rates were higher for patients with curative resection. Therefore, curative resection is important for improving the prognosis of patients with MGC.

INTRODUCTION

Although the incidence of gastric carcinoma is declining, it remains one of the leading causes of death from malignant tumors worldwide and advanced gastric carcinoma patients still have unfavorable prognoses^[1]. Generally, the prognosis of patients with middle third gastric carcinoma (MGC) is better than that of patients with proximal or distal third gastric carcinoma (PGC/DGC)^[2]; however, few studies have described the follow-up of patients with MGC. Therefore, it is important to analyze the prognostic factors in patients with MGC. We compared the clinicopathological features and outcomes of MGC with those of more proximally or distally located gastric carcinomas.

MATERIALS AND METHODS

Patients

Between 1987 and 2004, 3299 patients with gastric carcinoma were admitted to the Division of Gastroenterologic Surgery, Department of Surgery, Chonnam National University Medical School, Gwangju, South Korea. Of these, 919 (27.9%) had MGC. The clinicopathological features of the patients with MGC were reviewed retrospectively. Patients with carcinomas involving the entire stomach were excluded. Following the Japanese classification of gastric carcinoma outlined by the Japanese Research Society for Gastric Cancer^[3], the location of each tumor was described as the proximal, middle, or distal third of the stomach. The following information about each patient was obtained from hospital records: Age, sex, tumor size, depth of invasion,

histologic type, nodal involvement, extent of lymph node dissection, hepatic metastasis, peritoneal dissemination, stage at initial diagnosis, operative type, curability, and survival rate.

Statistical analysis

The survival rates of the patients were calculated using the Kaplan-Meier method, and the relative prognostic importance of the parameters was investigated using the Cox proportional hazards model. The χ^2 test was used to evaluate the statistical significance of differences, and *P* values less than 0.05 were considered significant.

RESULTS

Of the 3299 patients diagnosed with gastric carcinoma who underwent surgery at our hospital over a 17-year period, 919 (27.9%) were diagnosed with MGC. Table 1 describes the clinicopathological features of these 919 patients and the 2312 patients with PGC/DGC. There was a significant difference in the mean age of the patients with MGC (55.8 years) compared to the patients with DGC (57.6 years) (*P* < 0.001). Of the 919 patients with MGC, 602 (65.5%) were male and 317 (34.5%) were female. There were more males than females in each group, but there was no significant difference in the sex ratio of each group. Carcinomas in the middle third of the stomach were smaller than were carcinomas in the proximal third of the stomach (4.2 cm vs 4.7 cm), and the difference in mean tumor size was significant (*P* < 0.001).

Using the pTNM system, 296 patients with MGC were classified as pT1, 112 as pT2, 410 as pT3, and 101 as pT4. T1 tumors were more common in patients with MGC than in patients with PGC (32.2% vs 13.1%, *P* < 0.001). Using the grade of anaplasia, 324 (35.3%) of the MGC tumors were differentiated and 595 (64.7%) were undifferentiated adenocarcinomas. Of the patients with MGC, 561 (61.1%) had no lymph node metastases (pN0) and 358 (38.9%) had lymph node metastases. Lymph node metastasis was less common in patients with MGC than in patients with PGC (*P* < 0.05).

Hepatic metastases from MGC were found in 20 patients (2.2%), and peritoneal dissemination was present in 81 patients (8.8%). No significant differences were found in the frequency of hepatic metastasis or peritoneal dissemination among the groups. Of the patients with MGC, 396 (43.1%) were classified as either stage III or IV at the initial diagnosis. In MGC patients, 55.6% of the tumors extended to the serosa or adjacent organs (pT3 and pT4), while 72.5% of the PGCs extended beyond the serosa.

Compared with its use in MGC/DGC, total gastrectomy was performed significantly more frequently for the treatment of PGC (85.6% of cases, *P* < 0.001). The curative resection rate for patients with MGC was 83.1%, similar to that for patients with PGC/DGC (81.4%/82.9%,

MGC: Middle third gastric carcinoma; PGC: Proximal third gastric carcinoma; DGC: Distal third gastric carcinoma.

$P > 0.05$).

The clinicopathological variables tested in our univariate analysis are shown in Table 2. Factors influencing the 5-year survival rate were patient age, sex, tumor size, depth of invasion, histologic type, presence of hepatic metastasis, lymph node invasion, extent of lymph node dissection, and stage at initial diagnosis. When corrected for depth of invasion, tumor stage, and lymph node invasion in the two groups, tumor stage (stage I), N category (N0), and T category (T1) significantly influenced the 5-year survival rates for patients with curatively resected tumors (Table 3). A multivariate analysis showed that age, tumor size, serosal invasion, lymph node metastasis, and operative curability were significant predictors of survival for patients with MGC (Table 4). Figure 1 shows the patient survival rate according to tumor location. The 5-year survival rate for patients with MGC (52.8%) was higher than that for patients with PGC/DGC (44.4%/51.4%), but not significantly ($P > 0.05$). When the MGC group was divided into patients with or without curative

resection, the respective 5-year survival rates were 62.9% and 8.7% ($P < 0.001$) (Figure 2). There were no significant differences in the survival rates among MGC, PGC, and DGC when the patients were divided into early and advanced gastric carcinoma (Figures 3 and 4).

DISCUSSION

The prognosis of gastric carcinoma varies with tumor location^[4-6]. Although MGCs are reported to have relatively better outcomes than carcinomas in other parts of the stomach^[2], there is limited information on the prognostic factors for MGC. Therefore, we compared the clinicopathological features and prognosis of MGC patients with those of patients with PGC/DGC.

Investigators have discussed various prognostic factors for MGC. Serosal invasion, lymph node metastasis, and lymphatic involvement were found to have significant correlations with prognosis in univariate analyses, and serosal invasion and lymphatic involvement were independent prognostic factors in a multivariate analysis^[7].

MGC: Middle third gastric carcinoma; PGC: Proximal third gastric carcinoma.

Other authors have reported similar findings^[8,9]. An anterior location was clearly an independent prognostic factor for patients with MGC based on a multivariate

Table 4 Multivariate analysis of survival for middle third gastric carcinoma patients

Variables	Risk ratio	95%CI	P value

analysis. It has been postulated that tumors in the anterior wall metastasize more easily to the peritoneum compared with tumors elsewhere because there are no organs on the abdominal side of the anterior wall^[5]. This explanation seems reasonable, although others do not agree^[7]. In this study, we found that age, tumor size, serosal invasion,

Figure 3 Survival curves of early middle third gastric carcinoma, proximal third gastric carcinoma and distal third gastric carcinoma. MGC = 87.8%, PGC = 77.9%, DGC = 89.5%; $P = 0.0936$. MGC: Middle third gastric carcinoma; PGC: Proximal third gastric carcinoma; DGC: Distal third gastric carcinoma.

lymph node metastasis, and curability were independent predictors of survival in patients with MGC in a multivariate analysis.

The operation type for patients with MGC is controversial. One prospective randomized trial conducted in Italy stated that distal gastrectomy was sufficient for treating tumors located in the middle third of the stomach if a cancer-free microscopic margin could be achieved^[10]. However, that study included a relatively small number of MGCs. Therefore, many surgeons still recommend total gastrectomy for MGC because they are concerned about the possibility of local recurrence due to the short proximal resection margin and less extensive lymph node dissection in distal gastrectomy^[11,12]. In a separate report, distal gastrectomy was performed in only 39.3% of patients with a middle third advanced gastric carcinoma for the same reasons, although the authors stated that the type of gastric resection and length of the proximal resection margin did not affect the long-term prognosis. They also reported that distal gastrectomy was sufficient to achieve a tumor-free resection margin in many cases^[13]. Other authors have reported that if curative surgery can be performed, the long-term prognosis of patients with MGC is not affected by the extent of gastric resection, and a distal gastrectomy is feasible^[14-16]. When determining the type of operation for MGC, we also stress tumor-free resection. The statistical analysis in this study showed that operation type was not a prognostic factor.

Generally, the prognosis of patients with MGC is better than that of patients with PGC/DGC^[2]; the present study showed that tumor location did not affect the prognosis. We thought that the possible reason was due to similar curative resection rates. A significant difference in survival between patients with early and advanced gastric carcinomas has been reported^[7]. We also found a significant difference in survival rates between patients with early (87.8%) and advanced (40.8%) gastric carcinomas. The survival rate for patients with MGC was 52.8%, and the cumulative survival rate for patients with

MGC was slightly better than that for patients with PGC/DGC. When the MGC group was divided into patients with or without curative resection, the respective 5-year survival rates were 62.9% and 8.7%. Furthermore, we evaluated the relationship between the survival of patients with gastric carcinoma after curative resection and the depth of invasion. There was no significant difference in cumulative survival between the groups when the depth of invasion was that of T2-T4 tumors.

In patients with MGC, as the tumors progress the lymph nodes around the splenic artery and hilum are also frequently involved^[5]. Several studies have reported that the incidence of lymph node metastasis is 9.7%-20% along the splenic artery and 9.2%-17% at the splenic hilum in advanced PGC and MGC^[17-19]. In our department, splenectomy is not routine for patients with advanced MGC. However, we perform a splenectomy when the tumor invades the spleen directly or when metastasis to the splenic hilar lymph nodes or lymph nodes around the splenic artery is suspected.

Regarding adjuvant chemotherapy, we administered postoperative chemotherapy to select patients according to the pathologic findings instead of tumor location. Since the chemotherapeutic regimen varied during the study period, we did not analyze the effect of postoperative adjuvant chemotherapy.

In conclusion, our results show that tumor location did not affect the prognosis of MGC. When the MGC group was divided into patients with or without curative resection, the survival rates were higher for patients with curative resection. Therefore, curative resection is important for improving the prognosis of patients with MGC.

COMMENTS

Background

The prognosis of patients with middle third gastric carcinoma (MGC) is better

than that of patients with proximal or distal third gastric carcinoma; however, few studies have described the follow-up of patients with MGC.

Research frontiers

The prognosis of gastric carcinoma varies with tumor location. Although MGCs are reported to have relatively better outcomes than carcinomas in other parts of the stomach, there is limited information on the prognostic factors for MGC.

Innovations and breakthroughs

The authors did not find any difference in survival rates according to the tumor location. When the MGC group was divided into patients with or without curative resection, the survival rates were higher for patients with curative resection.

Applications

The study shows the importance of curative resection in patients with MGC.

Terminology

The stomach is anatomically divided into three portions: The upper (U), middle (M), and lower (L) parts. If more than one portion is involved, all involved portions should be described in order of degree of involvement, the first indicating the portion in which the bulk of the tumor is situated.

Peer-review

These authors provided an overall review of the middle third gastric cancer. These authors described several clinico pathological parameters of MGC compared to PGC/DGC. In this article, authors also demonstrated the significant difference between curative resection is one of the prognostic factors for MGC. It is interesting and acceptable for publication.

TOPIC HIGHLIGHT

- 416 MicroRNA in rectal cancer
Azizian A, Gruber J, Ghadimi BM, Gaedcke J

REVIEW

- 427 Role of Raman spectroscopy and surface enhanced Raman spectroscopy in colorectal cancer
Jenkins CA, Lewis PD, Dunstan PR, Harris DA
- 439 Current adjuvant treatment modalities for gastric cancer: From history to the future
Kilic L, Ordu C, Yildiz I, Sen F, Keskin S, Ciftci R, Pilanci KN

MINIREVIEWS

- 450 Multitarget stool DNA for colorectal cancer screening: A review and commentary on the United States Preventive Services Draft Guidelines
Berger BM, Levin B, Hilsden RJ
- 459 Urinary metabolites as noninvasive biomarkers of gastrointestinal diseases: A clinical review
Sarosiek I, Schicho R, Blandon P, Bashashati M
- 466 Non-surgical factors influencing lymph node yield in colon cancer
Wood P, Peirce C, Mulsow J

ORIGINAL ARTICLE

Retrospective Study

- 474 Intensity modulated radiation therapy with simultaneous integrated boost based dose escalation on neoadjuvant chemoradiation therapy for locally advanced distal esophageal adenocarcinoma
Zeng M, Aguila FN, Patel T, Knapp M, Zhu XQ, Chen XL, Price PD

Contents

World Journal of Gastrointestinal Oncology
Volume 8 Number 5 May 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Shu-Yu Zhang, PhD, Associate Professor, School of Radiation Medicine and Protection, Medical College of Soochow University, Suzhou 215123, Jiangsu Province, China

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

rectal cancer, a neoadjuvant chemoradiotherapy (CRT) is recommended before any surgery. However, response to CRT ranges from complete response (responders) to complete resistance (non-responders). To date we are not able to separate in advance the first group from the second, due to the absence of a valid biomarker. Therefore all patients receive the same therapy regardless of whether they reap benefits. On the other hand almost all patients receive a surgical resection after the CRT, although a watch-and-wait procedure or an endoscopic resection might be sufficient for those who responded well to the CRT. Being highly conserved regulators of gene expression, microRNAs (miRNAs) seem to be promising candidates for biomarkers. Many studies have been analyzing the miRNAs expressed in rectal cancer tissue to determine a specific miRNA profile for the ailment. Unfortunately, there is only a small overlap of identified miRNAs between different studies, posing the question as to whether different methods or differences in tissue storage may contribute to that fact or if the results simply are not reproducible, due to unknown factors with undetected influences on miRNA expression. Other studies sought to find miRNAs which correlate to clinical parameters (tumor grade, nodal stage, metastasis, survival) and therapy response. Although several miRNAs seem to have an impact on the response to CRT or might predict nodal stage, there is still only little overlap between different studies. We here aimed to summarize the current literature on rectal cancer and miRNA expression with respect to the different relevant clinical parameters.

Key words: Polymorphism; MicroRNA; Rectal cancer; Response; Chemoradiotherapy; Expression

Abstract

In rectal cancer, one of the most common cancers worldwide, the proper staging of the disease determines the subsequent therapy. For those with locally advanced

Core tip: In rectal cancer, a proper staging of the disease determines the subsequent therapy. Also, prediction of prognosis or therapy response could serve to individualize therapy. MicroRNAs (miRNAs) are highly conserved

regulators of gene expression, and seem to be promising candidates for biomarkers. Several miRNAs are part of a specific expression profile in rectal cancer tissue, while others have been correlated to clinical parameters and therapy response. However the comparison of different studies shows only little overlap and even partly oppositional results. Differences between analytical methods and tissue storage types can contribute to that. Further functional analyses are needed to fully understand the impact of miRNAs in rectal cancer.

INTRODUCTION

Colon and rectal cancer

Taken together, colon and rectal cancer is the third most common cancer worldwide, accounting for 1.36 million newly diagnosed colorectal cancers in 2012^[1] with rectal cancer accounting for 30%. The main purposes to differentiate between colon and rectal cancer are anatomical^[2] and molecular differences^[3]. Several studies have also shown that disease-correlated genetic and lifestyle factors differ between colon and rectal cancer^[3-8]. Differences in survival, fewer inherited syndromes, and younger age at diagnosis in rectal cancer patients further strengthen the rationality of separating the two diseases^[8].

Specifically due to the anatomical differences in comparison to colon cancer, local recurrence is a considerable concern in the treatment of rectal cancer. This led to the introduction of radiation in the treatment of rectal cancer patients and represents fundamental therapeutic differences to colon cancer. While treatment of upper rectal cancer provides primary surgical resection and can therefore be compared to colon cancer, the standard treatment of locally advanced cancer in the lower and middle rectum includes preoperative chemoradiotherapy (CRT), followed by total mesorectal excision (TME)^[9]. The introduction of preoperative chemoradiotherapy requires additional challenges in diagnostics and therapy planning which differ from colon cancer, requiring a precise pretherapeutic staging.

The rectal cancer staging can be made according to the TNM staging system from the World Health Organization: The Union for International Cancer Control (UICC). Depending on tumor status, nodal status, and metastases, rectal cancer is subdivided in UICC I - IV. While tumor status is determined by magnetic resonance imaging and trans-rectal endoscopic ultrasound, metastasis status is assessed by computed tomography of thorax and abdomen and ultrasound of the latter. Defining nodal status remains the most challenging and is evaluated today using all aforementioned imaging

techniques. Correct staging of patients with rectal cancer is actually required at two time points: First, before starting any treatment, and second, after neoadjuvant chemoradiotherapy, because response to CRT is heterogeneous; it ranges from resistance to complete pathological response. Response to CRT, measured as tumor regression grade (TRG), correlates significantly with disease-free- and overall-survival. The first staging is crucial for deciding if a preoperative CRT is needed, hence only locally advanced stages receive CRT. The second staging acquires more and more importance with regard to the possibility of organ-preserving strategies, which have been recently suggested as an alternative to TME for patients that responded very well to CRT. Basis for this upcoming approach can be found in the side effects of rectal cancer surgery. However, if lymph node metastases are undetected these have to be considered as origin of local relapse. In this respect molecular markers may play an increasing role as potential predictive marker.

miRNAs

MicroRNAs (miRNAs) are short non-coding RNAs, 20-22 nucleotides in length discovered in 2001^[10,11]. They are highly conserved between vertebrates, invertebrates and plants^[12]. Through base-pairing with their target mRNA, miRNAs induce post-transcriptional gene silencing by mRNA degradation or translational blocking^[13,14]. Consequently, they present master regulators of gene expression and therefore influence many physiological and patho-physiological processes^[15].

Some conservatively estimated 60% of all human mRNAs are regulated by miRNAs, which represent virtually all cellular and molecular functions. Thus, it is not surprising that miRNAs are involved in diverse processes including embryonic development, cell differentiation, cellular proliferation, metabolism, adaptation to environmental stress, and apoptosis^[13]. Thus, miRNAs play important roles in many human diseases, and even in the human aging process^[16]. By now the impact of specific miRNAs is reported not only for almost every cancer type but also for other diseases like diabetes, cardiovascular diseases, neurological diseases and even psychological diseases like schizophrenic disorder. Therefore miRNAs are of great interest as possible biomarkers in various diseases due to their abundance and cell-type specificity.

Many human miRNA loci are located within intronic (miRtrons) regions^[17,18]. While it is a general belief that intronic miRNAs are released from excised introns after the splicing, an interesting study of Kim *et al.*^[19] indicates that intronic miRNAs can be processed from unspliced intronic regions, ensuring both miRNA biogenesis and protein synthesis from a single primary transcript, supporting the assumption that the intronic miRNAs and their hosting genes are co-regulated^[20]. miRNAs are transcribed by RNA Polymerase II (pol II). The primary transcripts (pri-miRNA) are 5'-capped and polyadenylated. They have at least one stem-loop structure that encodes an individual miRNA sequence within the stem. Drosha, a nuclear RNase III type enzyme, and DGCR8, a double-

stranded RNA-binding protein, work as a complex known as microprocessor, which cleaves the primary structure of the pri-miRNA in a process called "cropping"^[10]. The products of this reaction are the pre-miRNAs, which are exported to the cytoplasm by exportin-5^[21,22]. In the cytoplasm the pre-miRNAs are further processed by the cytoplasmic RNase III called Dicer. Only one strand of the produced duplex of RNA is incorporated into the effector complex RNA-induced silencing complex (RISC), acting as the guide strand, while the passenger strand is rapidly degraded. However, either arm of the pre-miRNA can be selected to become the guide strand. The strand-selection differentially or coherently processes mature miRNAs, giving rise of gene regulatory RNAs with distinct target-spectra. This process of flexible arm selection has been reported for many small RNAs, including canonical and intronic miRNAs^[23,24]. Eventually, RISC migrates to P-bodies to scan and bind to the 3' untranslated region of the target mRNA.

The miRNA-mRNA binding is specific due to the sequence complementarity of the "seed" region of the miRNA. The canonical seed is a tract of 7-8 nucleotides usually located at the 5' end of the miRNA molecule, which is fully base pairing one or multiple sites within the sequence of a target mRNA^[25] capable of follow structures of miRNA-5'-seeds or alternative seed architectures.

Hence, the core of the target-region with high complementarity is short, which results in multitude of transcripts with possible binding sites for a given miRNA. Therefore a single miRNA has the potential to regulate hundreds of different mRNA targets^[26], while on the other hand a single mRNA is regulated by diverse miRNAs simultaneously.

Genome-wide miRNA-expression-profiling studies have demonstrated a specific profile of upregulated and downregulated miRNAs in almost all cancer types^[27,28]. In particular, due to their lack of complex post-transcriptional modifications in contrast to mRNAs and other RNA classes (rRNA, tRNA), the potential of miRNAs as biomarkers for cancer diagnosis, prognosis, and response to treatment is expected high. Not only miRNAs can be found in serum or plasma of patients and healthy individuals, but also in other body fluids such as tears, breast milk, bronchial lavage, colostrum and seminal, amniotic cerebro-spinal, pleural and peritoneal fluids^[29]. The diagnostic potential of miRNAs relies in part on their stability to storage handling: miRNAs remain stable even in conditions most RNAs would normally degrade (extreme pH-levels, boiling, etc.)^[30].

Cell-free and circulating miRNAs can be vesicle associated (exosomes and microvesicles), or stable AGO-miRNA complexes and became well accepted biomarkers for non-invasive biomarkers for numerous cancer types^[31-36].

LITERATURE SEARCH

A systematic literature search was conducted using PubMed for "rectal cancer", "miRNA" and "miRNA". A total of 27 studies containing miRNA research from

rectal cancer tissue, normal mucosa tissue, and body fluids were included for review. Five studies were involved in differential expression of miRNAs in rectal cancer, six studies explored specific miRNAs which showed a correlation to clinical parameters, and nine studies analyzed miRNAs concerning alteration during chemoradiotherapy and response prediction. Five studies conducted further *in vitro* analyses for rectal cancer specific miRNAs. Three studies were found to be dealing with polymorphism in miRNAs in rectal cancer patients.

DIFFERENTIAL EXPRESSION OF MIRNA IN RECTAL CANCER

It is widely accepted that tumors share specific oncogenic pathways. *Vice versa* the tissue of origin has also an impact on the molecular features of each tumor. These are of great interest as they may explain cellular processes such as carcinogenesis, progression, or therapy resistance. Accordingly, rectal cancer specimens and normal mucosa tissue were analyzed. In a first analysis Slattery *et al.*^[8] compared colorectal cancer tissue [formalin-fixed paraffin embedded (FFPE)] to normal tissue samples and also compared normal rectal tissue to normal colon tissue using microarray analysis. All samples were further subdivided according to their CpG island methylator phenotype status or the mutational status of *KRAS* or p53, revealing 129, 143, and 136 unique miRNAs respectively. The availability of miRNA expression data of normal colon and rectal tissue samples enabled a comprehensive comparison, which identified 73 differentially expressed genes (based on a two-fold fold change) and thus highlighted also important molecular differences between colon and rectal cancer. A comparable study by Li *et al.*^[37] involving miRCURY Array LNA miRNA chips and technical validation by RT-PCR analyzed expression profiles from six rectal cancer tissues and paired adjacent non-tumor tissue, which identified 67 upregulated and 39 downregulated miRNAs associated with rectal cancer. The number of rectal cancer tissues used ($n = 6$) is extremely low and, by using an array platform with several hundreds of miRNAs, it is required to correct for multiple testing. This did not occur; therefore the findings are potentially inapplicable.

In a larger study, our own group^[38] used LNA-enhanced miRCURY microarrays to map the expression of 2090 miRNAs. Tumor biopsies and matched mucosa samples of 57 patients with locally advanced rectal cancer were profiled. Forty-nine miRNAs differed with high significance between normal and rectal cancer tissue, 20 of these 49 miRNAs were upregulated while 29 were downregulated in rectal cancer vs mucosa. Upon employing a combination of fold-change and *P*-value for selection, the expression of 10 miRNAs was validated using 48 samples (24 matched tumor-mucosa samples) by semi-qRT-PCR; in 8 of the 10 miRNA expression levels correlated very well with miRCURY data as they showed the same alteration in both methods and both sets of tissue.

Studies by Wang *et al.*^[39] could confirm that the expression level of two miRNAs (miR-34a, miR-200c) that were previously found to be differentially regulated in various types of cancer, also were significantly upregulated in rectal cancer by analyzing 72 rectal cancer samples *via* qPCR.

Comparison of different studies to identify overlapping miRNA expression differences, *e.g.*, between rectal cancer and normal tissue is subject of certain restriction: Starting from tissue retrieval (*e.g.*, taking the biopsy during rectoscopy vs tissue excision from the resected surgical specimen that obviously already has a certain ischemia time) over tissue storage (*e.g.*, liquid nitrogen, RNA later, formalin fixation) and tissue work up to the final application of the various techniques that are available for miRNA measurement (*e.g.*, miRNA arrays from different companies, qPCR, sequencing). In this specific application, the reference tissue is of importance. Biases arise depending on whether paired normal mucosa or mucosa from different patients were used as a reference. On the other hand, miRNAs that finally overlap between different studies attract attention as they may be represent basic differences between the compared tissues. In this respect we aimed to identify the overlap between published data sets that were previously introduced, which currently involve only two relevant datasets comparing rectal cancer and normal tissue^[37,38]. Of these, 11 miRNAs were overlapping. Seven miRNAs were significantly upregulated (miRNAs 17, -18a, -21, -31, -135b, -223 and -492) while four were significantly downregulated (miRNAs-29c, -145, 147b and -375). In both studies also the expression of let-7f, miR-148 and -190 were significantly altered in rectal cancer, however they showed an oppositional regulation of these miRNAs comparing with the first two studies questioning their relevance for assessing differential expression. For miR-145 even a third study performed by Wang *et al.*^[40] confirmed a significant in rectal cancer. Figure 1 shows an overview about the differential expression of miRNAs found according to the mentioned studies.

A closer look to the differentially expressed miRNAs reveals a broad range of different function. As a member of the miR-17/92 cluster miR-17 and 18a are both known to be involved in a large number of processes including normal development, tumorigenesis, immune-, cardiovascular-, and neurodegenerative diseases as well as aging^[41]. Renal fibrosis^[42], myelodysplastic syndromes^[43], inflammatory processes^[44], and especially cancer are only a few processes that are regulated by miR-21^[2,45,46]. For miR-31 a decent number of cancer related studies have been published^[47] indicating a more aggressive disease of colorectal cancer^[48] if highly expressed. However, a relation to metastatic disease^[47,49] and an inverse meaning of increased expression status has been shown in other cancer entities such as breast cancer^[48]. The presence of higher expression in different cancer types was reported for miR-135b as well. Nonetheless, it was predominantly analyzed in colorectal cancer and its overexpression by APC loss, PTEN/PI3K

pathway deregulation, and SRC overexpression was demonstrated to promote tumor transformation and progression^[50]. An oncogenic functionally relevant expression has also been found for miR-223 showing a wide range of different tumor entities^[51,52]. In contrast to previous miRNAs, data on the function of miR-492 and its oncogenic relevance are rare. Downregulation of miR-29c - a member of the miR-29 family - is known in several cancer types and its role as a tumor suppressor has been established^[53]. Furthermore, its relevance as antifibrotic miRNA is under debate^[54]. Initial functional relevance of miR-375 was found as a pancreatic islet-specific miRNA. Recently, miR-375 has been found significantly downregulated in multiple types of cancer, targeting several important oncogenes like AEG-1, YAP1, IGF1R and PDK1^[55]. miR-145 is presumed to be a tumor suppressor with apoptosis inhibitor 5, ERK5, K-RAS, and insulin receptor substrate 1 as predicted targets, which are cell cycle and survival regulators^[56]. Data on miR-147 is rare; one study postulates that miR-147 is induced upon Toll-like receptor stimulation and regulates murine macrophage inflammatory responses^[57]. Taken together, the identified miRNAs from both studies revealed functionally characterized regulators that have, in the vast majority, no organ specificity.

CORRELATION OF MIRNA EXPRESSION TO CLINICAL PARAMETERS

Currently, the most reliable tumor marker to assess clinical outcome is the staging system by TNM classification. As this classification is now more than 100 years old, molecular features for different tumor entities are increasing in number markers for a more precise prognosis are expected. In this respect the aforementioned study of Gaedcke *et al.*^[38] identified miR-135b. Its expression correlated significantly with disease-free and cancer-specific survival in an independent cohort of 116 patients. miR-135b was also found by other groups to be of importance. Xu *et al.*^[58] used frozen tissues, performed qPCR analysis, and found miR-135b to have the highest fold-change (17.7-fold) among the upregulated miRNAs in Duke stage IV cases (that are known to be of poor prognosis). They also identified miR-145 to be highly downregulated with a negative fold change between 18 and 23 in stages II, III and IV CRC respectively. Furthermore, they identified significantly decreased expression miR-374a for the identification of patients without metastasis, its effectiveness was confirmed with a sensitivity of 93.33% but a low specificity of only 66.67%. miR-4634 was related to lymph node metastasis in stage III with a sensitivity of 75% and specificity of 83.33%. In this analysis, however, the limitation of a mixed study population of colon and rectal cancer must be acknowledged.

Slattery *et al.*^[59] analyzed data from 1141 CRC cases *via* microarray to identify the impact of 121 miRNAs on disease stage and survival. Five miRNAs were associated with advanced disease stage: hsa-miR-145-5p and hsa-

Figure 1 Differential expression of microRNAs in rectal cancer. The differentially expressed microRNAs (miRNAs) in rectal cancer compared to normal rectal tissue are listed, sorted by studies, respectively. The correlating circles show the number of differentially expressed miRNAs in the mentioned studies and point out the number of miRNAs overlapping between those studies.

miR-31-5p were increased and hsa-miR-200b-3p, hsa-miR-215 and hsa-miR-451a were decreased in advanced stages of CRC. In rectal cancer, 13 miRNAs were significantly associated with mortality after a diagnosis with rectal cancer (Table 1). In addition, they showed that miR-21 expression had an inverse association with mortality in rectal cancer (but not colon cancer patients). However, Nielsen *et al.*^[60] used *in situ*-hybridization and real-time qPCR on FFPE tissue, and identified miR-21 to predict a short disease-free survival in colon cancer, but not in rectal cancer. Interestingly, the *in-situ*-hybridization showed that the miR-21 expression was detected predominantly in the stromal compartment of the tumors. Yang *et al.*^[61] showed in an microarray analysis of samples from 40 patients a significant overexpression of miR-21, miR-155, miR-29a and miR-92a in rectal cancer samples and found only miR-155 had the capacity to discriminate nodal positive from negative cases as well as Duke A/B stages from Duke C/D stages.

Stratmann *et al.*^[62] did not investigate miRNAs directly but the expression level of Dicer - one of the key enzymes in the miRNA generating process - and revealed

that the Dicer expression in rectal cancer is higher than in normal mucosa (and higher than in colon cancer), while Dicer expression in liver metastases was decreased in comparison to either the primary tumor or mucosa. Furthermore, patients with a high expression of Dicer mRNA in the normal mucosa had a worse prognosis (poor survival) than those with a lower expression level.

ALTERATION DUE TO THERAPY AND PREDICTING THERAPY RESPONSE

While imaging techniques (computer tomography, magnetic resonance imaging and ultrasound) manage to diagnose tumor stage, nodal stage or distant metastasis initially in an appropriate manner, their ability to identify the response after chemoradiotherapy is poor, particularly the differentiation between vital tumor cells and scar tissue is challenging for imaging techniques. Response to neoadjuvant chemoradiotherapy measured as TRG is therefore usually determined by pathologists after investigating the operative specimen. An adequate

Table 1 Association of microRNA expression and clinical parameters

microRNA	Clinical parameter	Change of expression	Ref.
miR-17-5p miR-20a/20b-5p miR-21-3p/5p miR-25-3p miR-29a/29c-3p miR-31-5p miR-135b	Association with rectal cancer survival	No further explanation	Slattery <i>et al</i> ^[59]
miR-135b	Association with advanced tumor stage Correlation with disease-free and cancer-specific survival	Increased expression level in advanced tumor stage Patients with a high expression level of miR-135b had a better disease-free and cancer-specific survival	Slattery <i>et al</i> ^[59] Gaedcke <i>et al</i> ^[38]
miR-135b	Correlation with Duke stage IV	Upregulated with the highest fold-change (17.7-fold) among 9 upregulated miRNAs	Xu <i>et al</i> ^[58]
miR-141-3p miR-145	Association with rectal cancer survival Correlation with Duke stage II, III, IV	No further explanation Downregulated with a -18.15, -18.9, -23.8-fold change in stage II, III and IV CRC respectively	Slattery <i>et al</i> ^[59] Xu <i>et al</i> ^[58]
miR-145-5p miR-155	Correlation with advanced tumor stage Correlation with nodal stage and Duke stage	Increased expression level in advanced tumor stage Discrimination of nodal positive from negative cases as well as Duke A/B stages from Duke C/D stages	Slattery <i>et al</i> ^[59] Yang <i>et al</i> ^[61]

CRC: Colorectal carcinoma.

evaluation of response before surgery could spare patients with complete response the surgical resection of the rectum (with all the associated disadvantages), but until today there is no validated biomarker for that. Moreover, since patients respond differently to CRT, a biomarker to predict response to neoadjuvant chemoradiotherapy in rectal cancer patients even before CRT could spare the non-responders the CRT. Understandably, there is a great interest to use miRNAs as possible biomarkers to predict therapy response. Some studies analyzed descriptively the changes in miRNA expression after chemoradiotherapy while others were able to identify miRNAs in tumor tissue, which seem to predict the response to therapy.

Svoboda *et al*^[63] performed microarray analysis on tumor biopsies of 31 patients with locally advanced rectal cancer before and 2 wk after chemoradiotherapy with capecitabine (a 5-FU prodrug). They found a significant increase of miR-125b and miR-137 expression levels after 2 wk of chemoradiotherapy. Moreover, they also demonstrated that high levels of miR-125b and miR-137 are associated with a worse response to chemotherapy. However, the sample size is quite short (31 patients), and there is an intertumoral variability described, which should not be neglected. Interestingly, the same group investigated in 2012 in a similar setting 20 patients with locally advanced rectal cancer, whose tumors were classified as most sensible ($n = 10$) or most resistant ($n = 10$). They used TaqMan Low Density Arrays analysis to quantify 667 human miRNAs in the tumor tissue samples (preoperative biopsies of untreated primary tumors) and found 8 miRNAs to be significantly differently expressed between the responders and non-responders: miR-215,

miR-190b and miR-29b-2 were overexpressed in non-responders while let-7e, miR-196b, miR-450a, miR-450b-5p and miR-99a were down regulated in non-responders^[64]; the previously identified miRNAs miR-125b and miR-137 were not mentioned.

Drebbler *et al*^[65] did real-time-PCR analysis to identify the expression of miR-21, miR-143 and miR-145 in macrodissected FFPE tumor tissue of 40 patients before and after chemoradiotherapy. They described a significant upregulation of miR-143 and miR-145 in post-therapeutic tumor tissue compared to pre-therapeutic tumor tissue. In addition, they showed a significant correlation between a low miR-145 expression in the post-therapeutic tumor tissue and a worse response to CRT. However, this result does not address the problem to predict therapy response in advance: The low expression of miR-145 was measured in the post-therapeutic tumor tissue. To predict tumor response miRNA profiles in the pre-therapeutic tissue are needed.

More adequate to this purpose, Della Vittoria Scarpati *et al*^[66] analyzed miRNA expression by microarray and confirmed by qRT-PCR in primary tumor biopsies of patients with locally advanced rectal cancer who underwent neoadjuvant CRT followed by surgery ($n = 38$). Eleven miRNAs were significantly upregulated in patients with a complete response (miR-1183, miR-483-5p, miR-622, miR-125a-3p, miR-1224-5p, miR-188-5p, miR-1471, miR-671-5p, miR-1909, miR-630, miR-765) and two were downregulated (miR-1274b, miR-720). However, the small cohort of patients' needs additional validation in an independent cohort^[66]. Though, none of the mentioned 13 miRNAs was found when Kheirleisid *et al*^[67] performed a similar study by using microarray

analysis of 12 FFPE pre-therapeutic tissue samples of rectal cancer to answer to same question by identifying differentially expressed miRNAs. The promising miRNAs in this study were miR-16, miR-590-5p and miR-153 to predict complete vs incomplete response and miR-519c-3p and miR-516 to discriminate between good vs poor response. Unfortunately, they do not clarify how these miRNAs are altered between the responders and non-responders (downregulated or upregulated).

A possible reason for the different identified miRNAs may be the difference between the tissues used: Della Vittoria Scarpati *et al.*^[66] used fresh biopsies frozen in liquid nitrogen while Kheirleiseid *et al.*^[67] used FFPE. However, if we act on the assumption that the type of preservation (FFPE, Kryo, *etc.*) differs the miRNA expression, the next question posed would be: What is the preservation effect on miRNA expression and which miRNA expression profile derives from the different tumor characteristics? On the other hand, Hotchi *et al.*^[68] used also fresh frozen biopsies from 43 rectal cancer patients before starting CRT and did both microarray analysis and RT-PCR of miRNAs concerning response prediction. They found out that miR-223 was higher expressed in tissue from patients with a good response to CRT and declared miR-223 (which is not mentioned by any other study investigating miRNAs in rectal cancer patients for therapy response prediction) as a promising biomarker for the prediction of response to CRT^[68]. Other studies found other different miRNAs: Lopes-Ramos found miR-21-5p to be over expressed in tumor biopsies of rectal cancer patients with complete response using fresh biopsies frozen in liquid nitrogen^[69], Bhangu *et al.*^[70] found miR-200c as a possible biomarker to predict CRT response as it shows a significantly reduced expression in non-responders using FFPE material. Figure 2 shows the important miRNAs concerning response to CRT in rectal cancer patients.

In a recent study of our own group, we were able to show with qPCR-analysis a significant decrease of miR-18b and miR-20a during CRT in plasma of patients with a negative nodal stage after CRT (ypN0) compared to those with a positive nodal stage (ypN+). This data presents miR-18b and miR-20a as possible candidates for biomarkers predicting nodal stage after CRT^[71]. However, this data requires validation in a larger cohort.

IN VITRO ANALYSES FOR RECTAL CANCER SPECIFIC MIRNAS

Beside the *in vivo* analyses, functional data of specific miRNA that obviously play a role in rectal cancer have been analyzed. One of these is miR-21 that has already been described above. Using tumor biopsies Chang *et al.*^[72] showed an inverse relationship between miR-21 and programmed cell death protein 4 (PDCD4), a known tumor suppressor^[72]. They hypothesized the post-transcriptional modulation of PDCD4 *via* mRNA degradation. These findings were based on data from Asangani *et al.*^[73],

who transfected Colo206f cells with miR-21 and found a significant suppression of PDCD4 proteins *in vitro*.

For miR-182 Amodeo *et al.*^[74] investigated the effect on thrombospondin-1 (TSP-1), a protein inversely correlated with tumor vascularity and metastasis. In CRC, TSP-1 is shown to be downregulated. After transfection with anti-miR-182, expression level of TSP-1 increased. Hence, the authors concluded that anti-miR-182 could be used to restore TSP-1 expression in CRC to inhibit the angiogenic and invasive events in CRC.

For another rectal cancer associated miRNA, namely miR-455, rapidly accelerated fibrosarcoma (RAF1) seems to be a target gene: In 20 mucosa and 20 CRC biopsies miR-455, miR-484 and miR-101 seem to be down-regulated. An overexpression of miR-455 in SW480 cells showed inhibition of proliferation and invasion. Western Blot analyses showed a downregulation of RAF1 in cells with an overexpression of miR-455, although, on mRNA-level, there was no effect shown^[75]. Also the relevance of miRNAs concerning the sensitivity towards CRT could be assessed *in vitro*: Using 12 colorectal cancer cell lines, the miRNA expression profile indicating sensitivity towards an *in vitro* treatment of 5-FU and radiation was established by our own group^[76]. These data were validated by the transfection of let7g, miR-132, miR-224 and miR-320a that led to the expected shift of therapy resistance towards sensitivity. For let-7g the higher expression as a good prognostic marker was validated in patient samples.

POLYMORPHISMS IN MIRNAS

Since miRNAs represent one of the important mechanisms of gene expression control, the relevance of polymorphisms concerning miRNAs has been explored in few studies. Naccarati *et al.*^[77] showed in a case-control study that two single nucleotide polymorphisms within the 3'untranslated regions of target DNA repair genes (nucleotide excision repair genes), hence the miRNA-binding sites, were significantly associated with rectal cancer: rs7356 in RPA2 (predicted binding miRNA: hsa-miR-3149 and hsa-miR-1183) and rs4596 in GTF2H1 (predicted binding miRNA: hsa-miR-518a-5p, hsa-miR-527 and hsa-miR-1205). This study points out that not only the expression levels of miRNAs are relevant, but also their ability to interact with their target gene.

Jang *et al.*^[78] tried to identify polymorphisms in miRNA genes which have a prognostic value in rectal cancer patients and found 196a2C > T (allele of hsa-miR-196a2) polymorphism to be a significant risk factor for the overall survival of rectal cancer patients. The mentioned allele has been reported by other studies to be involved in increased risk of various cancer types^[79-81]. Recently, Mao *et al.*^[82] found miR-146a being decreased in rectal cancer tissue compared to adjacent normal mucosa and they also showed an association between the genetic variant in miR-146a, rs2910164 polymorphism and the risk of CRC.

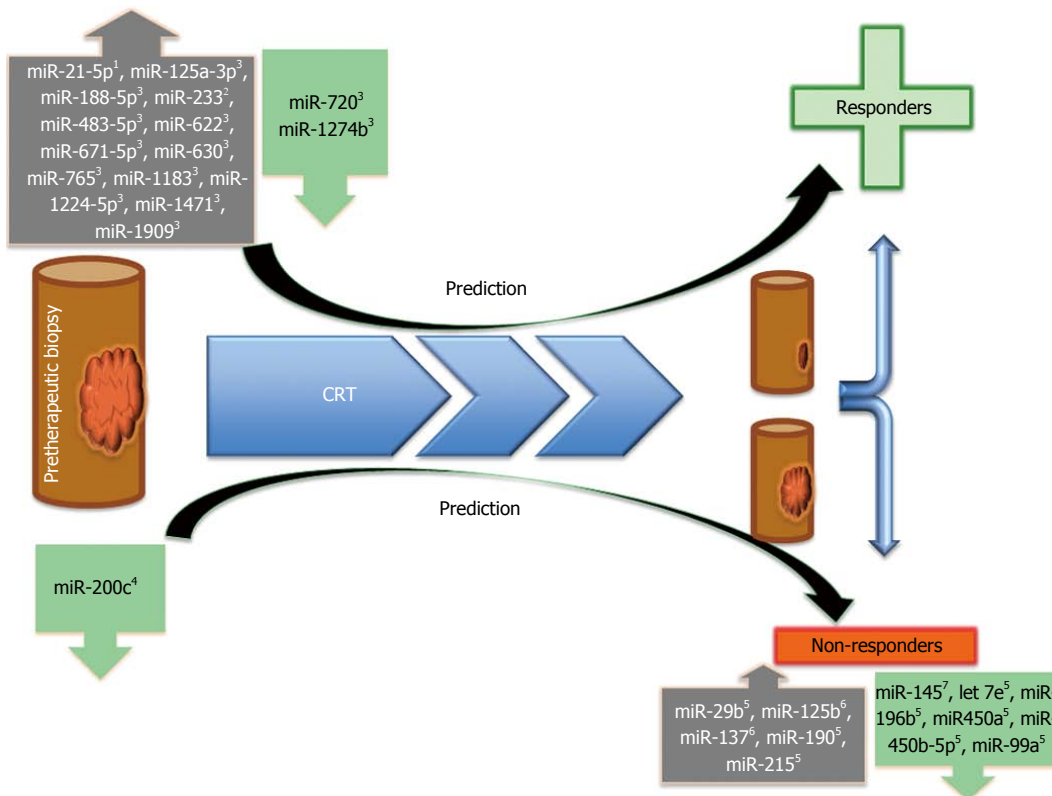

Figure 2 Differential expression of miRNAs dependent on response to preoperative chemoradiotherapy. miRNAs in up arrow callouts are significantly higher expressed; those in down arrow callouts are significantly lower expressed. On the left site there are miRNAs, isolated from pretherapeutic biopsies, which are supposed to predict response or non-response, respectively. The miRNAs in the bottom localized on the right side, are found to be significantly higher or lower expressed in post-therapeutic tumor biopsies of non-responders after chemoradiotherapy compared to pretherapeutic biopsies. ¹Lopes-Ramos *et al.*^[69], 2014; ²Hotchi *et al.*^[68], 2013; ³Della Vittoria Scarpati *et al.*^[66], 2012; ⁴Bhangu *et al.*^[70], 2014; ⁵Svoboda *et al.*^[64], 2012; ⁶Svoboda *et al.*^[63], 2008; ⁷Drebber *et al.*^[65], 2011.

CONCLUSION

miRNAs are widely accepted to play a crucial role in physiological and pathological processes. Interestingly, in contrast to the relevance of rectal cancer and its frequency, especially compared to colon cancer, the number of available studies is rather small. The amount of studies as well as the small number of patients per study may be one of the reasons why only few overlapping miRNAs have been identified. Importantly, a small number of miRNAs were identified with relevance in rectal cancer. Many of these are rather known from cancer specific mechanisms than display rectal cancer specificity. Accordingly, the relevance of miRNAs as a predictive or prognostic biomarker in rectal cancer is questionable. Furthermore, the relevance of functional miRNAs does not appear to be as obvious as in previous studies that are typically cell-line based. However, before ignoring the relevance of miRNAs it should be taken into account that human cancer tissue is functionally a rather complex cell system. The analyses are impeded by the heterogeneity of tumor biopsies that in general include different amounts of non-tumor cells such as stroma or the surrounding tissue. Different analyzing techniques applied to identify miRNA (PCR, microarray, etc.) or the varying fixation media (FFPE, fresh frozen biopsies, etc.) further complicate the comparability of the data. Furthermore, subtle expression differences of a

given miRNA that potentially change complex regulatory mechanism simply may not be identified. This may due to the techniques applied or has simply not been part of the analyses that, in general, focus on expression fold changes.

Specifically for miRNAs, there may be alternative reasons for varying results, such as the highly variability of miRNA expression due to external influences such as nutrition. Humphreys for example, showed that the expression of oncogenic miRNAs can be altered by dietary manipulation: A high red meat intake leads to elevated miR-17-92 (cluster) and miR-21 in rectal mucosa tissue of healthy volunteers. While organ specificity is well known for miRNA, Li *et al.*^[37] identified miRNA expression differences (e.g., miR-182) in CRC between African and Caucasian Americans. Possibly, there are further influences like medications used by the patients, gender differences, or age associated variations that are much higher than currently expected.

Overall, there is a large number of possible reasons as to why a clear identification of miRNAs still failed. However, compared to alternative molecular markers in rectal cancer such as proteins, mRNA or DNA, miRNA are not inferior as there are currently no well established markers. Acknowledging some of the previously listed points, miRNA analyses in rectal cancer aiming to identify regulatory mechanisms or to establish marker for

prediction or prognosis should be endorsed. Furthermore, these efforts should be expanded to blood samples as it has been done in many other cancer types.

FUTURE PERSPECTIVES

Validity of cell free and cellular miRNAs as a prognostic or diagnostic tool remains, at least in parts, elusive. The incomplete understanding of biological processes yielding circulating RNAs and their physiological relevance needs to be addressed in more detail, *e.g.*, by application of less bias-sensitive technologies and combinations of, *e.g.*, high-throughput sequencing, qPCR and microarray techniques^[83]. Functional characterization of altered miRNAs in CRC and surrounding healthy tissue with respect to more recent findings of modifications that impact miRNA processing and target-gene regulation will improve quality and interpretability of the datasets originating from quantitative analysis^[84]. Investigations on differential or coherent expression of miRNAs in affected tissues, changes of strand-selection during tumor progression, and treatment as well as in-deep analyses of the physiological relevance of secreted miRNAs and other non-protein coding RNAs can clarify roles of these and feasibilities to choose particular candidates as markers for prognosis and diagnostics or candidates for therapies^[23,36].

cancer in the United Kingdom and is the second largest cause of cancer related death in the United Kingdom after lung cancer. Currently in the United Kingdom there is not a diagnostic test that has sufficient differentiation between patients with cancer and those without cancer so the current referral system relies on symptomatic presentation in a primary care setting. Raman spectroscopy and surface enhanced Raman spectroscopy (SERS) are forms of vibrational spectroscopy that offer a non-destructive method to gain molecular information about biological samples. The techniques offer a wide range of applications from *in vivo* or *in vitro* diagnostics using endoscopic probes, to the use of micro-spectrometers for analysis of biofluids. The techniques have the potential to detect molecular changes prior to any morphological changes occurring in the tissue and therefore could offer many possibilities to aid the detection of CRC. The purpose of this review is to look at the current state of diagnostic technology in the United Kingdom. The development of Raman spectroscopy and SERS in clinical applications relation for CRC will then be discussed. Finally, future areas of research of Raman/SERS as a clinical tool for the diagnosis of CRC are also discussed.

Core tip: This review focuses of the current role of Raman spectroscopy and surface enhanced Raman spectroscopy (SERS) in clinical applications of colorectal cancer. This includes a review of the current research into *in vivo* endoscopic Raman probes, non-destructive analysis of biofluids and the use of SERS in order to detect low concentration analytes that previously could not be detected with Raman spectroscopy. Both the advantages and disadvantages of the technology are discussed along with possible avenues of future research.

Abstract

Colorectal cancer (CRC) is the fourth most common

spectroscopy and surface enhanced Raman spectroscopy in colorectal cancer. *World J Gastrointest Oncol* 2016; 8(5): 427-438 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i5/427.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i5.427>

INTRODUCTION

Colorectal cancer (CRC) is the fourth most common cancer in the United Kingdom and is the second largest cause of cancer related death in the United Kingdom after lung cancer^[1]. Currently in the United Kingdom there is not a diagnostic test that has sufficient differentiation between patients with cancer and those without cancer so the current referral system relies on symptomatic presentation in a primary care setting^[2,3]. CRC results from the progressive accumulation of genetic and epigenetic alterations that disrupt normal cellular mechanisms^[4]. The 5-year survival rate for CRC detected in early stages are > 90%, however the 5-year survival rate for later-stage cancers is < 10%^[1,5]. This highlights the need for a simple, reliable diagnostic test that can detect early signs of the disease. The majority of CRCs present symptomatically in a primary care setting so it is important that general practitioners can identify patients who are at highest risk^[2]. The risk associated to patients is based on the referral guideline, in the United Kingdom is this based on a combination of symptoms and age of the patient^[6]. The relationship between initial symptoms and mortality as a diagnostic indicator have previously been discussed in depth^[2,3,7,8]. Unfortunately initial symptoms associated with CRC can also be symptoms of benign diseases such as irritable bowel syndrome^[6], and there is currently no diagnostic test available in primary care that has sufficient differentiation to base referral on^[3]. Furthermore the detection of CRC using symptoms has been shown to be ineffective for decreasing mortality rates in comparison to the European average^[9].

Raman spectroscopy and surface enhanced Raman spectroscopy (SERS) could hold many advantages for use as a diagnostic tool for CRC. These techniques have previously been used to discriminate between cancerous and non-cancerous tissue, biofluid samples, as well as in the development of *in vivo* Raman systems for use in endoscopy. The techniques are non-destructive to samples so can provide molecular information about a sample without the need for staining or in some cases without the need for resection. Raman and SERS have the potential to detect molecular changes in cancerous cells/tissues and biofluids that precede morphological changes such as the development of precursor lesions. The techniques could offer the potential for an early detection tool that detects molecular changes before the stage at which a traditional histopathology would be able to detect. This review paper will discuss the previous applications of Raman spectroscopy and SERS to detect CRC.

CURRENT DIAGNOSTIC PATHWAYS

In United Kingdom, CRC survival outcomes are lower than the European average, this is be attributed to a higher proportion of cancer being diagnosed at late-stage^[9]. In order to combat the NHS rolled out a national screening program in 2006. There are currently two types of screening method available to screen for CRC and late-stage adenoma namely flexible sigmoidoscopy (FS) and measurement of markers in faecal samples^[10]. FS is a procedure involving the insertion of an endoscope into the rectum of a patient in order to examine the distal colon and rectum; the procedure must be carried out by a trained doctor. Atkin *et al.*^[11] (2010) conducted a United Kingdom study into the effectiveness of a single FS procedure as a screening tool. A procedure for patients aged 55-64 years the study saw a 33% reduction in CRC cases and a 43% mortality reduction, however this is only applicable with respect to the distal colon^[11]. However, the cost of a FS is high in comparison to tests that look for markers in faecal samples because it involves trained staff^[12]. Moreover, it can be argued that the results of tests reliant on the opinion of a practitioner can be subjective depending on the experience of the practitioner.

In England and Wales the guaiac faecal occult blood test (gFOBT) is commonly used as a screening tool. The test is simple and cheap compared to other methods^[12]. Problems that occur with gFOBT regarding dietary requirements of patients before taking the test are solved using immunochemical faecal occult blood testing (iFOBT)^[13]. There are different types of iFOBT, all of which detect human specific haemoglobin in faecal samples. Investigations and meta-analysis studies have shown iFOBT to have improved sensitivity in the detection of CRCs and late-stage adenomas in both high-risk, average-risk and populations with no overt rectal bleeding compared to gFOBT without compromising on specificity^[14-17]. However, despite the improved sensitivity of iFOBT tests patient uptake of the screening programme in general is poor. In October 2008 of the 2.1 million people that had been invited to partake in the screening programs in England uptake was just 55%-60%^[18]. Other diagnostic methods available to clinicians in the United Kingdom include double barium enema, computed tomography colonoscopy, MRI imaging and colonoscopy. Outside of the United Kingdom there are other diagnostic tests are also in use such as the tumour M2-pyruvate kinase (tumour M2-PK) test. This is a faecal test that investigations have shown this to also be more sensitive than FOBT^[19]. However, the cost effectiveness and the sensitivity and specificity of the M2-PK especially compared to the iFOBT still needs to be established in the United Kingdom as published results are in disagreement as to whether it is more effective than iFOBT^[20]. There is also a real time polymerase chain reaction based blood test that is available outside of the United Kingdom that detects methylated Septin 9 (mSept9). The blood test

Figure 1 Energy shifts involved in light scattering interactions. Adapted from Lin *et al.*^[23].

has been shown to have sensitivity and specificity ranging from 50%-90% and 88%-91% respectively^[21]. A blood test is a potentially more attractive option for patients compared to faecal and colonoscopy tests so studies are underway to determine if the higher cost of mSept9 would be recovered by higher screening uptake^[22].

Raman spectroscopy could offer a highly sensitive and less invasive alternative/complimentary technique to aid CRC detection. However, Raman spectroscopy has not yet found its way into a routine clinical setting. This review will examine the current research status of the application of Raman spectroscopy for detecting CRC to critique the prospective translation of the technique to a clinical setting.

Methods for review

A systematic literature search (PubMed, MEDLINE, Web of Science) was conducted using the following terms: "Diagnosis", "Raman spectroscopy", "Surface enhanced Raman spectroscopy", "SERS", "CRC", "Tissue", "Biofluids", "Immunoassay", "CEA". Following these searches 30 studies were selected for inclusion based on the criteria: (1) That they are original studies based on the clinical applications of Raman spectroscopy, SERS or both for CRC detection in human tissue, biofluids or cell lines; and (2) in the case where there are large amounts of similar studies that they were the first to report such data. Only studies published up to January 2015 were included in this review.

RAMAN SPECTROSCOPY AND SERS FOR THE DETECTION OF CRC

Introduction

Raman spectroscopy is a type of vibrational spectroscopy that allows the user to gain molecular information about a sample through the scattering of incident light. In general, when light is passed through or onto a sample a small proportion of the photons are scattered (approximately 10^{-5}). The majority of this is Rayleigh or elastic scattering; where the energy of the incoming photon is equal to the energy of the scattered photon (Figure 1)^[23]. Around 1 in 10^7 of the incident photons are in-elastically scattered resulting in the incident photon and the scattered photon

having a difference in energy.

The inelastic scattering is a relatively weak effect which was first observed in 1928 by Sir CV Raman and is known as Raman scattering^[24]. When scattered light is measured with a spectrometer a series of lines are observed, the shift in the energy [measured by wave-number (cm^{-1})] from the Rayleigh line (equal to incident energy) is known as the Raman shift. The shift recorded corresponds to specific vibrational or rotational modes of the sample molecule. The intensity of the "Raman shift" for a particular molecule is directly proportional to the concentration of that molecule within a sample so the resulting spectrum of a sample will be a superposition of Raman response of all the Raman active molecules from within a sample, e.g., proteins, nucleic acids, etc. It is interpreted as the molecular "fingerprint" of the sample, an example of a spectrum can be seen in Figure 2. It is due to the "fingerprint" that Raman is seen to be desirable for application to cancer detection because it offers the possibility of detecting minute differences in analyte concentrations and is a non-destructive technique.

Vibrational techniques

It should be noted that Raman is not the only type of vibrational spectroscopy that has been reviewed for clinical applications^[25,26]. One of the other main areas of vibrational spectroscopy being applied to clinical applications is fourier transform infrared spectroscopy (FTIR) and a type of enhancement infrared attenuated total reflection. FTIR relies on either the absorbance or the transmission of light through a sample, then similar to Raman the difference in the emitted and absorbed or transmitted light is measured to gain molecular information about a sample. This technique has also been used for diagnosis of CRC independently and also coupled with immunohistochemical staining^[27,28]. Compared with other vibrational spectroscopy techniques Raman holds many desirable properties for the application to a screening method. One of the biggest advantages of using Raman spectroscopy is that samples can be in aqueous solutions due to water having a small Raman cross-section at near-infrared wavelengths, water has a high absorbance in FTIR and therefore can interfere with a spectrum. Table 1 shows a comparison table constructed from literature to give an overview of the strengths and weaknesses of FTIR, Raman and traditional hematoxylin and eosin staining (H and E) when used for clinical applications^[25,29,30]. It suggests that for the application to biological samples such as tissues and biofluids Raman could be the most favorable option. Like FTIR it is non destructive and can be performed in real time compared to H and E staining. However, Raman spectroscopy has the advantage over FTIR of being able to scan over a larger wavenumber range than FTIR and with better spatial resolution than both FTIR and H and E. Furthermore, Raman is a technique that relies on scattering so measurements can be taken with single ended endoscopic probes. This is advantageous for *in vivo* applications because it makes it possible to study

Table 1 A comparison of Raman spectroscopy, fourier transform infrared spectroscopy and hematoxylin and eosin staining strengths and weaknesses

	Raman spectroscopy	FTIR	Hematoxylin and eosin staining
Method of detection	Inelastic scattering of monochromatic (laser) light	Absorbance (polychromatic light source)	Combination of basic and acidic dyes
Real time	Yes	Yes	No
Wavenumber range (cm ⁻¹)	50-4000	400-4000	N/A
Spatial resolution	1 µm	5 µm	Cellular
Enhancement techniques	SERS, TERS, CARS, SORS, SRS	ATR	"Special" staining
Effect of water	Minimal	Large absorbance in NIR region	No
Destructive to sample	No	No	Yes

SERS: Surface enhanced Raman spectroscopy; TERS: Tip enhanced Raman spectroscopy; CARS: Coherent anti-Stokes Raman spectroscopy; SORS: Spatially offset Raman spectroscopy; SRS: Stimulated Raman spectroscopy; ATR: Attenuated total reflection; FTIR: Fourier transform infrared spectroscopy; NIR: Near-infrared; N/A: Not available.

Figure 2 Example Raman spectrum of dried human serum. Spectrum of dried droplet of human serum taken with 785 nm laser excitation, 10 s acquisition time with an InVia Raman spectrometer (Renishaw, United Kingdom).

samples that are optically too thick for transmission techniques^[31]. This, along with the need for a less invasive diagnostic tool that can analyse liquid biofluids leads to the remainder of this review focusing on the application of Raman and SERS technology.

Data manipulation

Many clinical applications of Raman and SERS use chemometric data analysis techniques in order to aid data manipulation and to pick out the small differences that could indicate disease. Details of principle component regression (PCR) and partial least squares can be found in Kramer (1998)^[32]. Principle component analysis (PCA) applications can be found in Shinzawa *et al.*^[33] (2009). This review will only state the technique that has been used in each study.

CLINICAL APPLICATIONS OF RAMAN SPECTROSCOPY IN CRC

Histopathological analysis of tissue biopsies is still con-

sidered the gold standard for the diagnosis of malignant tissues that have been surgically resected. Typically, thin sections of tissue are "fixed" usually using formalin and then mounted onto glass slides and stained using various methods in order to determine TNM stage, tumour type, histologic grade and the level of vascular invasion. However, histopathology is a slow process that requires a trained pathologist, it is also inherently subjective^[34]. Raman spectroscopy offers the possibility of determining the presence of malignancy by detecting differences in Raman spectral features between normal and malignant tissue. Previously, Raman spectroscopy has been applied to *in vivo* probes that have the ability to discriminate multiple tissue types^[35,36], biofluid analysis^[37] and also analysis of cancerous cell lines for both discrimination and characterization^[38,39]. The motivation behind using Raman used *in vivo* is to aid rapid diagnosis and help to identify possible areas of tissue for biopsy that might otherwise be missed. A summary of the literature and different applications of Raman towards clinical applications for CRC can be found in Table 2.

Table 2 A summary of the different clinical applications of Raman spectroscopy to colorectal cancer

Method	Sampling type	Sample number	Ref.	Year	Spectral region (cm ⁻¹)	Laser excitation (nm)	Data analysis
Probe	<i>In vivo</i> (tissue)	20	Shim <i>et al</i> ^[42]	2000	450-1800	785	PCA, PLS, ANN
Probe	<i>In vivo</i> and <i>ex vivo</i> (tissue)	9	Molckovsky <i>et al</i> ^[44]	2003	900-1800	785	PCA, LDA, LOOCV
Micro-spectrometer	<i>In vitro</i> (primary tissue)	10	Chen <i>et al</i> ^[38]	2006	500-1900	782.5	PCA
Probe	<i>Ex vivo</i> (tissue)	59	Widjaja <i>et al</i> ^[45]	2008	800-1800	785	PCA, SVM, LOOCV
Micro-spectrometer	<i>Ex vivo</i> (tissue)	54	Beljebbar <i>et al</i> ^[47]	2009	600-1800	785	SVM, PCA
Micro-spectrometer	<i>In vitro</i> (serum)	120	Li <i>et al</i> ^[37]	2012	800-1800	785	PCR, PLSR, LDA
Micro-spectrometer	<i>In vitro</i> (cell lines)	N/A	Ranc <i>et al</i> ^[39]	2013	400-1800	532	PCA
Probe	<i>In vitro</i> (tissue)	177	Wood <i>et al</i> ^[43]	2014	800-1800	830	PCA, LDA, LOOCV
Micro-spectrometer	<i>In vivo</i> (tissue)	50	Bergholt <i>et al</i> ^[78]	2014	800-1800 and 2900-3600	785	PLS, LDA

PCA: Principle component analysis; LDA: Linear differential analysis; PLS/PLSR: Principle least squares regression analysis; LOOCV: Leave one out cross validation; ANN: Artificial neural network; SVM: Support vector machine; PCR: Principle component regression.

Table 2 shows that most clinical applications of Raman have been in the near-infrared (NIR) region using 785 nm laser excitation analysing tissue samples. This is likely due to reduced fluorescence of biological; samples in the NIR region, furthermore 785 nm laser is less powerful than visible region lasers so is less likely to cause damage to biological samples. The work is generally done in the "fingerprint region" of the Raman spectrum, *i.e.*, 400-1800 cm⁻¹ due to molecular bonds present in biological samples being Raman active in this region. All of the studies use chemometric data analysis so it seems for NR this is essential to differentiate the small differences in the Raman spectra when using biological samples. It is also clear that work in the field has previously been dominated work towards *in vivo* Raman probes for use during endoscopy but more recent work has used both Raman probes and microspectrometers.

Tissue analysis

Reviews dedicated to Raman spectroscopy for the use of *in vivo* probes for clinical use for many types of tissue including tissues of the gastrointestinal (GI) tract are already available^[25,40,41]. Briefly, the *in vivo* probes for use during endoscopy for use with GI tissue was first introduced by Shim *et al*^[42] (2000). In general, the *in vivo* probes use a laser excitation source in the NIR wavelength range (light is non-mutagenic in this region) coupled to an optical fibre probe. The probe can then act as both a source of light and a detector relaying a signal back to a charged coupled device detector and computer analysis. The development of the probes is not a simple process, some materials that the probes are manufactured from have a large Raman cross sections leading to design challenges regarding signal to noise ratio (gaining unwanted noise from the material). Other issues can be caused by tissue fluorescence signal being larger than the Raman signal making data acquisition difficult and spectral acquisition times to be impractical for clinical applications (more than 10 min). Nevertheless, some research groups have been successful in designing probes for specific use with gastrointestinal tissue for

use in routine endoscopy that have short acquisition times^[35,43].

Shim *et al*^[42] (2000) successfully applied an *in vivo* probe to gain Raman spectra of colonic and oesophageal tissues from 20 patients. The pressure spectral acquisitions were made with 5 s exposure time and repeated at normal and malignant sites within both areas of interest. In the colonic tissue subtle differences between spectral area 1100-1800 cm⁻¹ were identified however no significant prominent changes were evident. PCA and LDA analysis was then introduced in order to try and distinguish accuracy for application to GI diagnostics however no specific results relating to diagnostics were published.

Molckovsky *et al*^[44] (2003) were the first to assess the diagnostic potential of near infrared Raman spectroscopy on colonic tissue by using adenomatous polyps as a model for dysplasia. The group used a custom-made fiber-optic Raman probe and used PCA-LDA analysis and LOOCV to analyse a total of 33 polyps from 8 patients. After an initial *ex vivo* study of polypectomy specimens that involved a total of 54 spectra the analysis algorithm identified a sensitivity of 91% and a specificity of 95%. An *in vivo* study was then conducted with a total of 19 spectra from 9 polyps, after spectral analysis the algorithm identified adenomas with a sensitivity of 100% and specificity of 89%. A similar study involving a higher number of specimens for a similar use on *ex vivo* tissues was conducted by Widjaja *et al*^[45] (2008), the group were able to differentiate cancerous tissue with 100% sensitivity and 98.1%-99.7% specificity using a diagnostic algorithm using PCA and LDA.

Raman spectroscopy has also been investigated as a complimentary technique to histopathology. The first application of Raman spectroscopy for characterisation of colonic tissue (among others) to discriminate between cancerous vs normal was by Feld *et al*^[46] (1995). The group looked at the difference spectra between normal and cancerous tissue, this results showed potential that spectral differences in the tissue could be due to higher nucleic acid levels in the cancerous samples^[46].

Beljebbar *et al*^[47] (2009) used a Raman micro

Figure 3 An example spectrum of a surface enhanced Raman spectroscopy response vs Raman response of human blood plasma. Raman spectrum and SERS spectrum of dried human plasma droplet at 10% laser power with 785 nm laser excitation, 10 s acquisition time with an InVia Raman spectrometer (Renishaw, United Kingdom). SERS response gained by 1:1 mixing with 40 nm raw gold nanoparticles (Nanocs, United States). Purple: SERS response of plasma; Blue: Raman response of plasma. SERS: Surface enhanced Raman spectroscopy.

spectrometer on 27 normal and 27 cancerous *ex vivo* frozen tissue samples. Unsupervised hierarchical cluster analysis to differentiate between normal and adenocarcinomatous human colonic tissues was discussed. The technique was based on the spatial distribution of molecular changes in colon constituents such as proteins, lipids and nucleic acids. The spectroscopic data was then used to create pseudo-colour Raman images of tissues for comparison with histopathological slides. The data was then used to create databases for the purpose of comparing unknown specimens. Six extra frozen unknown samples specimens were fed into the database and were correctly identified as either cancerous or normal^[47]. This study showed the potential for Raman spectroscopy to aid histopathology by adding structural molecular information to the visible information gained from H and E staining. This study used frozen tissue samples but there are different fixation methods available. There have been studies on the effect that different fixation methods of both cell lines and tissue samples taken from resection has on the Raman spectral signature but these will not be discussed further in this review^[48-50].

It should be noted that Raman spectroscopy used as an adjunct to histopathology has not just been applied to CRC. Some groups have investigated the use of stimulated Raman spectroscopy (SRS) to create spectral histopathological images for breast, brain and skin tissue among others^[51-54]. For example, Satoh *et al.*^[54] (2014) used SRS and PCA multivariate analysis to produce Raman map images of damaged liver tissue in mice. The images could then be compared to different staining methods used in histopathology.

DETECTION OF CRC IN BLOOD SAMPLES

The advantage of Raman spectroscopy over other vibra-

tional techniques is its ability to analyse samples in aqueous solution with minimal background. This is advantageous for the study of samples such as urine and blood as they can be analysed without changing their composition by drying.

Berger *et al.*^[55] (1999) introduced the idea that Raman had potential for the analysis of biofluids, in particular human blood. Premasiri *et al.*^[56] (2012) found that the NR spectra of whole human blood are dominated by the normal modes of either oxygenated or deoxygenated haemoglobin porphyrin macrocycle and haemoglobin. This leads to the assumption that if NR is to be used for the analysis of blood components such as malignancy specific proteins for CRC other than those associated with red blood cells (RBC) an enhancement mechanism has to be used or blood samples must have RBC removed in order to overcome this issue (Figure 3).

For example, Harris *et al.*^[57] (2009) discussed the potential of peripheral blood samples analysed by NR to provide cancer screening in head and neck cancer. Using Raman spectroscopy and LDA analysis alone the study found this technique to have approximately 65% specificity and sensitivity for the discrimination of cancer in peripheral blood samples. The use of non-enhanced Raman spectroscopy for the discrimination of blood serum between normal and CRC was first reported by Li *et al.*^[37] (2012). Li *et al.*^[37] presents a study using clinical samples from 44 colon, 46 rectum and 30 healthy controls. Raman peak parameters and fluorescence background were used along with multivariate analysis techniques such as PCR and PLSR for the dimension deduction of spectral data. Then, LDA on PC's is used to see diagnostic performance. Three distinct, Raman peaks were found to have significance at 1029 cm⁻¹, 1538 cm⁻¹ and 1170 cm⁻¹. The 1538 cm⁻¹ peak was assigned to beta-carotene and 1170 cm⁻¹ to tryptophan and phenylalanine. The average spectra from the three sample groups were then compared and the latter two peaks were shown to decrease compared to the control group. This is explained as a decrease in anti-cancer related molecules.

This study showed that it is possible to discriminate between serum samples of patients with and without CRC. The result of the PCR-LDA analysis was promising as it identified normal samples with 87.5% accuracy and 96.7% specificity and colon cancer samples with a sensitivity of 84.8%.

SERS detection methods

Raman spectra are subject to interference from samples that exhibit fluorescence; a fluorescence signal is far greater than the Raman response so it can "hide" any Raman signal. Fluorescence is fairly common when using wavelengths less than 785 nm that are commonly used in biological studies. Also, when Raman is used on complex biological samples Raman peaks can be additive, making differentiation between biological markers difficult to resolve, this results in a reliance on data manipulation in order to detect small spectral differences. SERS offers a resolution to some of these

issues as it reduces the effects of inherent fluorescence while increasing the intensity of the Raman response of the sample. Premasiri *et al.*^[58] (2001) demonstrated the need for an enhancement mechanism in order to detect some low concentration analytes in urine analysis by Raman spectroscopy. It was found that urea had a sufficiently high concentration to be analysed by NR in liquid form however, lower-level nitrogen compounds needed enhanced Raman spectroscopy in order to detect these compounds^[58]. Therefore SERS was used as an enhancement mechanism in order to be able to detect the compounds that were in concentrations too small to detect with Raman.

The basic principle of SERS is to amplify the Raman response of a given analyte. The SERS effect was first discovered in 1974, and understood to be an enhancement of Raman scattering in 1977^[59,60]. This is generally achieved by having an analyte attached or close to the surface of a nanoscale metal substrate causing an enhancement factor of up to $10^{14,15,61,62}$. The exact mechanism of SERS enhancement is still an area of active research, however it is generally accepted that two mechanisms contribute to the enhancement^[63]. One is based on electromagnetic field enhancement due to excitation of electromagnetic resonances in the SERS active nanoscale metal substrate. The other is known as "chemical enhancement" which is a result of the metal electrons causing a charge transfer between the metal substrates and the adsorbates. The result of the combined enhancement is an extremely powerful technique that combines ultra sensitive detection limits with the molecular structure information from Raman spectroscopy giving the possibility of single molecule detection^[64].

Clinical applications of SERS for CRC

The main use of SERS in clinical applications for CRC has been as a detection method. Lin *et al.*^[65] (2011) were the first to report SERS serum analysis for the detection of CRC. In their study colloidal gold nanoparticles were simply mixed with serum samples from 38 patients and 45 control samples and dropped onto an aluminium substrate. This technique is known as label-free SERS. It generally relies on blood constituents being adsorbed onto the surface of metallic nanoparticles causing an enhanced Raman response. In the Lin *et al.*^[65] study a Raman micro-spectrometer (Renishaw, Great Britain) fitted with a 785 nm diode laser was used to gain spectra in the $300\text{--}1800\text{ cm}^{-1}$ range. Spectra from the two groups were normalised to the integrated area under the curve in the $350\text{--}1750\text{ cm}^{-1}$ wavenumber range. The mean spectrum for the normal serum and the cancer serum were then compared to isolate wavenumbers that showed the most variation between the two groups. Then an empirical diagnostic algorithm based on peak intensities at 725 cm^{-1} and 638 cm^{-1} was used to classify the normal and the cancer samples. These were chosen based on previous studies by Han *et al.*^[66] (2008) that showed the ratio to be important

disease marker. This technique was compared PCA-LDA multivariate approach. The PCA analysis then used whole spectra to discern the spectral components that had the largest variation. After comparison the group found PCA-LDA to be more effective at detecting CRC. With specificities for detecting cancer to be 68.4% and 97.4% for the empirical approach and the multivariate approach respectively.

This study showed that through simply mixing gold nanoparticles with serum that it is possible to discriminate between normal and cancer samples using SERS along with both empirical and multivariate analysis techniques. The potential for using whole spectra coupled with PCA-LDA to be used as a screening technique for CRC was then discussed using the PCA-LDA methods in a second publication from the same group^[65]. The two publications also included tentative peak assignments and major vibrational bands that have been previously observed in serum samples. The peak assignments are vital to being able to accurately describe what is happening at the molecular level when a patient has a disease. However, due to the additive nature and complex compounds found in serum samples it can sometimes be difficult to be sure of peak assignments. Furthermore, the methods described above such as looking at the 725 cm^{-1} band can be a marker for disease but it is not specific to CRC. In order for the technology to become useful as a diagnostic there is a need to have a Raman/SERS marker that is specific to CRC.

The need for specific detection has motivated the development of "labelled" SERS probes. These probes have previously been used for detecting disease specific proteins in both tissue and serum samples^[67-71]. They have also been used for the detection of circulating tumour cells^[72]. However there is little reported on the specific application of targeted SERS probes for use in detecting CRC^[73]. In general targeted SERS techniques rely on either aggregation of antibody-functionalised nanoparticles after exposure to a protein or they are used to form of sandwich immunoassay similar to that of an ELISA setup but using SERS active probes rather than fluorescent-tagged antibodies (Figure 4).

Both techniques offer advantages and disadvantages; techniques relying on the aggregation of nanoparticles use fewer antibodies and in general have very simple protocols that can be done on cheap substrates. However, when dealing with the aggregation of nanoparticles it can be difficult to "find" the correct spot on a sample where the SERS intensity is greatest. Furthermore, studies relying on aggregation can be susceptible to large variation as controlling the aggregation can be difficult. SERS based immunoassay holds the advantage over aggregation because if the disease specific protein is in a sandwich style assay then the area to probe is easier to locate and the Raman signal is less likely to be variable, as one would expect more even coverage of the protein over the assay area. One advantage of both of these techniques over current fluorescence methods is that Raman bands are much

Figure 4 Different methods of producing a surface enhanced Raman spectroscopy response with biological samples. A: Mixing based methods with both non-labeled mixing and labeled or "aggregation" based mixing; B: Labeled surface enhanced Raman spectroscopy based immunoassay. SERS: Surface enhanced Raman spectroscopy.

narrower than those in fluorescence which means there is the potential to use more probes in a multiplex assay than is currently possible with fluorescent probes. Chen *et al.*^[74] (2013) developed a SERS based immunoassay for the detection of carcinoembryonic antigen (CEA) in serum of patients with CRCs. CEA antibody functionalised glass slides were used in conjunction with SERS active probes that were also functionalised with CEA^[74]. A range of concentrations from 5×10^{-3} – 5×10^5 ng/mL CEA were prepared and the SERS response monitored. The SERS intensity was linearly correlated with the concentration of CEA in the characteristic peak or the Raman reporter molecule at 1077 cm^{-1} and hence a calibration curve was established. CEA concentrations in serum samples from 26 patients with CRC were then analysed with both SERS immunoassay and electrochemical luminescence. The results were then compared and it was found that the two techniques had similar agreement. Using the calibration curve for the patient samples a detection limit of 5 pg/mL was achieved. This is the only study specifically using CEA for the detection of CRC, however there is other work in the literature using CEA conjugated antibodies but towards use for other diseases^[69,70].

Ito *et al.*^[75] (2014) developed a SERS based assay that used silver nanoscale hexagonal columns (NHC) on phosphor bronze chips. The chips were negatively ionized and 36 clinical serum samples from patients with benign diseases, gastric and CRCs were dropped

onto the chips. Using a 632.8 nm laser excitation, measurements were taken and two peaks appeared to be prominent in the SERS spectra at 1350 cm^{-1} and 1570 cm^{-1} . Polynomial fitting was then used to determine SERS peak height for each of the samples. In order to validate that the SERS peak height and the concentration of the serum samples were correlated the measurements were repeated at different dilutions of the same serum sample. It was found that 10-fold dilutions were the saturating dilution for the NHC chips so 10 fold dilutions were used throughout the rest of the experiment. Finally the SERS peak height for both of the prominent peaks was compared between the three groups of samples and it was found that the SERS peak heights in the benign samples was indeed significantly lower than in the cancerous samples. This was calculated using the Pearson product-moment correlation coefficient and the non-parametric Spearman's rank correlation coefficient.

Another slightly different approach to using SERS for clinical use for CRC is using SERS as a characterisation/validation tool when developing other nanoscale devices such as the work done by da Paz *et al.*^[76] (2012). In this study SERS was used as a characterisation tool in the development of maghemite nanoparticles as a theragnostic device for CRC^[76]. The SERS active nanoparticles used in this study were functionalised with Anti-CEA antigen in the hope that they can be used to detect primary and metastatic CRC, it was hoped by the authors that these nanoparticles could then be developed for a variety of applications including magnetic resonance imaging (MRI) enhancement and targeted drug delivery.

Limitations of Raman and SERS in clinical applications

Raman and SERS based tools have shown potential that they will have a place as either an alternative or an adjunct to current diagnostic methods. The development of SERS biomarker detection could also lead to its use in personalized medicine. However, there are still some limitations of Raman and SERS techniques that will need to be overcome before they are routinely used in a clinical setting. These include: (1) Many Raman studies involve costly equipment and expensive substrates, there will need to be investigations into cost reduction for large scale applications; (2) Raman and SERS studies that are carried out in a laboratory will require sample handling and storage, the effect of handling samples and storage techniques on the performance of Raman based tools will need to be quantified; (3) Thermal damage thresholds of *in vivo* tissue and *ex vivo* tissue samples from the colon and rectum will need to be established; (4) Many studies for clinical use different analytical techniques, and still require the skill of the user to determine the results of these techniques. User-friendly software for diagnostic analysis of the spectra will need to be developed and tested for multi-user reliability; (5) Inter equipment variability studies will need to be carried out, Raman equipment can often be susceptible to variability from external factors such as room temp, laser stability, etc.; and (6) SERS based techniques have been subject

to reproducibility issues, CRC is a heterogeneous disease so if immunoassay style tools are to be used then large scale studies with clinical samples will need to be carried out.

CONCLUSION

In the field of cancer detection Raman spectroscopy and SERS has gone through a period of rapid progress in the last decade. The use of Raman in clinical applications for CRC has previously been dominated by the discrimination of cancerous vs non-cancerous tissue with only a few studies on the use of Raman with biofluids for CRC detection. There are currently successful *in vivo* Raman tools for real-time use during endoscopy. These tools can be used to gain molecular information through Raman imaging and traditional spectroscopy. Therefore, they aid current endoscopic techniques by giving extra molecular information that could potentially be missed using traditional methods. However, Raman tools are still in general expensive to produce and require specialist knowledge in order to operate the machinery. Furthermore, thermal thresholds for the damage of GI tissue need to be properly established before these tools can be ready for use in a routine clinical setting. In future, national multi-site trials that include large patient numbers are needed to study the thermal threshold of tissues. Future research into the large-scale manufacture (and miniaturisation) of Raman tools needs to be carried out to investigate variability between sites and investigate the cost effectiveness of Raman tools compared to current technology.

In order to detect low concentration analytes SERS has started to become an alternative method to Raman. SERS offers enhanced signals and reduced fluorescence compared to Raman. Current research uses different techniques to gain a SERS response from samples. One of the limitations of SERS based techniques has been that the variations in the plasmon resonance of nanostructures that cause a SERS response are subject to large variability. Therefore, in mixing style SERS methods research into reducing the variability in SERS response even across a single sample will need to be investigated. Another method of gaining a SERS response is through a SERS based immunoassay; this has been successfully used to detect the current accepted biomarker for CRC CEA. The immunoassay design is based on reducing variability by controlling separation of the SERS substrates. SERS immunoassay has the potential to have multiplex detection of analytes in both tissue and biofluids. This could be one of the biggest areas of development if CRC research follows that of diseases such as nasopharyngeal cancer^[77]. Furthermore, if SERS is successfully used to detect different concentrations of biomarkers then this opens up the possibility into research towards personalised medicine and detecting changes in the levels of biomarkers using less invasive methods than are currently available in the United Kingdom (*i.e.*, through blood based testing). There are currently other CRC

detection tests in development that are more advanced than SERS such as mSept9 blood based testing. However, SERS based detection aims to have detection limits below the current available technology; therefore it offers the possibility of research into new biomarkers for CRC based on Raman or SERS spectral signals. Furthermore SERS and Raman based techniques still have the ability to be developed into techniques that are used in conjunction with other developing detection methods.

Both Raman and SERS techniques will also need further research into producing a universal method of background subtraction and analysis of data. Currently many research groups use different methods of data analysis that can be complex and still require clinicians to interpret results using spectral knowledge. In order for Raman and SERS based detection to be implemented into a clinical setting simple, user-friendly programs will need to be produced that remove the need for interpretation of spectra by a user. If the spectral analysis is automated then Raman and SERS techniques have the potential to become "observer-independent" tools.

Raman and SERS techniques are currently still in development with the aim to be in regular use in a clinical setting. If the technological limitations are overcome then the techniques have the potential to produce more specific, affordable detection and screening for CRC that can be routinely used in a clinical setting as an alternative or an adjunct to current methods.

The final limitation to Raman and SERS based techniques will be that of persuading clinicians that the new technology can replace existing techniques, it is possible that national based trials showing the robustness of Raman and SERS techniques will go some way to achieving this.

Abstract

The discrepancy between the surgical technique and the type of adjuvant chemotherapy used in clinical trials and patient outcomes in terms of overall survival rates has led to the generation of different adjuvant treatment protocols in distinct parts of the world. The adjuvant treatment recommendation is generally chemoradiotherapy in the United States, perioperative chemotherapy in the United Kingdom and parts of Europe, and chemotherapy in Asia. These options mainly rely on the United States Intergroup-0116, United Kingdom British Medical Research Council Adjuvant Gastric Infusional Chemotherapy, and the Asian Adjuvant Chemotherapy Trial of S-1 for Gastric Cancer and Capecitabine and Oxaliplatin Adjuvant Study in Stomach Cancer trials. However, the benefits were evident for only certain patients, which were not very homogeneous regarding the type of surgery, chemotherapy regimens, and stage of disease. Whether the dissimilarities in survival are attributable to surgical technique or intrinsic biological differences is a subject of debate. Regardless of the extent of surgery, multimodal therapy may offer modest survival advantage at least for diseases with lymph node involvement. Moreover, in the era of individualized treatment for most of the other cancer types, identification of special subgroups comprising those who will derive more or no benefit from adjuvant therapy merits further investigation. The aim of this review is to reveal the historical evolution and future reflections of adjuvant treatment modalities for resected gastric cancer patients.

Key words: Adjuvant chemoradiotherapy; Biomarker; Gastric cancer; Lymph nodes

Core tip: Despite extensive surgery, gastric cancer will likely recur for most patients. Fortunately, additional treatment modalities either in the perioperative or post-operative setting provide varying degrees of survival

advantage. Although there is considerable data regarding adjuvant chemotherapy and chemoradiotherapy since the Intergroup-0116 study, there is still no established uniform treatment protocol depending on the type of surgery, histological subgroup, or extent of disease. The present review is aimed at identifying the advances in treatment strategies and discussing the pros and cons of each strategy.

INTRODUCTION

Gastric cancer is the fifth most common cancer in the world, with 952000 new cases being diagnosed in 2012^[1]. The cornerstone for treatment of gastric cancer is surgical resection with lymph node dissection (LND). An extended lymph node resection, which is commonly defined as a D2 resection for gastric cancer, includes the removal of the whole stomach, the greater and lesser omentum, and the N1 and N2 (groups 1-11) lymph nodes. For tumours located in the proximal stomach, resection of the spleen and the tail of the pancreas may be necessary for removing groups 10 and 11 lymph nodes. While a D2 lymph node dissection is considered a standard surgical procedure for resectable gastric cancer in Japan and Korea, the necessity of a D2 dissection still remains a subject of controversy in Western countries. The overall 5-year survival rates in the United States is around 10% to 40%; however, in Japan and South Korea, it is reported to be 50% or higher^[2-4]. It is unclear whether removing additional lymph nodes during the operation contributes to a difference in survival. Additional information on lymph nodes may provide more accurate staging, which is currently only available for patients that undergo a D2 dissection. Other factors such as early diagnosis, case selection, surgical skill, and post-operative care may also contribute to this observed difference in survival.

Despite difficulties with surgical techniques, data from the National Cancer Data Base in the United States points at a 10-year survival rate of 65% for patients with resected stage IA disease and 3%-42% for those with more advanced disease^[5]. Thus, the high rate of both locoregional and distant relapse, even after complete resection, makes adjuvant treatment mandatory for patients with stomach cancer.

The timing and sequence of adjuvant/neoadjuvant strategies and combination therapies have been questioned in numerous phase II and phase III trials. The landmark Intergroup (SWOG 9008/INT-0116) trial demonstrated a survival benefit for resected stage IB-IV, M0 gastric

cancer patients following adjuvant chemoradiotherapy^[6]. However, the extent of surgery and the chemotherapy (CT) regimen, which was associated with high rates of toxicity, was seriously critiqued in this study. Although an extensive (D2) LND was recommended, only 10% of the patients had undergone a D2 dissection. The relative inadequacy of locoregional control with limited LND was supposed to be compensated with adjuvant radiotherapy.

Although there is large amount of data from randomized, controlled trials (RCT) and recommendations from several guidelines, recent analysis from the National Cancer Data Base have revealed that real-life practices somewhat diverge from the evidence-based results^[7]. Trends in American cancer centres have shown that out of stage III patients who received surgery at community hospitals, less than 50% also received adjuvant chemoradiotherapy in 2009. However, the large number of patients involved in the RCTs constitute a heterogeneous population where the benefit from adjuvant therapy may be difficult to interpret for some specific subgroups of patients. Moreover, there is still no phase III data supporting the tailoring of treatment according to stage of disease after surgery, unlike colon and breast cancers, since each stage may benefit from adjuvant therapy to a varying degree. This review will focus on the evidences of adjuvant treatment strategies dependent on the recent RCTs and future directions for optimal approach.

ADJUVANT CHEMOTHERAPY REGIMENS

Surgical resection is the only hope for curative treatment in early stages of gastric cancer. However, only 40% of the patients with gastric cancer will remain disease free after complete resection of their tumour. Therefore, adjuvant and neoadjuvant treatment modalities are crucial for establishing better prognosis for gastric cancer patients. Extensive studies were conducted to determine the efficacy of adjuvant chemotherapy for gastric cancer. Some previous phase III randomized trials did not demonstrate absolute benefit for adjuvant chemotherapy. However, these studies usually did not enrol large datasets and generally included early stage patients^[8-10]. The Adjuvant Chemotherapy Trial of S-1 for Gastric Cancer (ACTS-GC) study was a pioneer phase III study showing a significant survival benefit following adjuvant chemotherapy after D2 LND for gastric cancer patients. The trial documented that one year adjuvant chemotherapy with an oral fluoropyrimidine, S-1 provided a clear survival benefit for stage II and III gastric cancer patients after D2 LND^[3]. Since the publication of the results of the ACTS-GC trial, chemoradiation was excluded from adjuvant treatment modalities for D2 resected gastric cancer in Japan, but this was not the case in Western countries. However, the results of the ACTS-GC study conflicted with a similar large scaled phase III Japanese trial that utilized mitomycin C, fluorouracil (FU), and oral UFT (a combination of tegafur, a prodrug of 5-FU and uracil treatment) as adjuvant chemotherapy^[11]. The investigators considered that this

result was due to high proportion of pT1 gastric cancer patients included in the trial for which surgery alone may yield a good prognosis, and there seemed to be no requirement for adjuvant therapy. Consequently, further trials usually did not include early stage patients (*i.e.*, \leq stage Ib).

Apart from the Asian studies, most of the trials performed with adjuvant chemotherapy have not demonstrated a significant survival benefit^[12-14]. However, the results of the meta-analysis by the Global Advanced/Adjuvant Stomach Tumour Research International Collaboration (GASTRIC) group with an extended follow-up time have revealed a modest but statistically significant survival advantage with adjuvant chemotherapy after curative resection of gastric cancer^[15]. There was an absolute improvement in overall survival (OS) of 6% after 5 years that was maintained at 10 years. The treatment benefit was sustained in the majority of the investigated groups of FU-based regimens, with reductions in the risk of death between 20% and 40%. This meta-analysis pointed out that adjuvant FU-based chemotherapy is associated with improved OS, and combination chemotherapy could be recommended for patients who have not received treatment in the perioperative setting.

S-1, an orally active FU analogue, is a combination of tegafur (a prodrug of 5-FU), gimeracil (an inhibitor of dihydropyrimidine dehydrogenase), and oteracil (inhibitor of the phosphorylation of FU in the gastrointestinal tract). Pharmacokinetics studies have shown that the absorption of FU derived from S-1 is not affected by gastrectomy^[16]. The response rates with S-1 alone were higher than 40% in two phase II trials among patients with advanced gastric cancer^[17,18]. Similarly, S1 demonstrated a clear survival benefit in the ACTS-GC study. After 3 years of median follow-up, the OS in the S-1 group was 33% higher than the surgery-only group^[3]. Grade 3 or grade 4 adverse events occurred in less than 5% of patients in the S-1 group. The OS rate was 80.5% in the S-1 group and 70.1% in the surgery-only group at 3 years. Thus, S-1 was approved as an effective option for adjuvant chemotherapy for patients with resected gastric cancer.

Recently Zhang *et al.*^[19] have published the analysis of 31 RCTs, which included 7120 gastric cancer patients. There was no significant difference in terms of overall mortality among the four chemotherapy regimens including FU + mitomycin (MMC) + adriamycin, FU + MMC (FM), Tegafur and MMC. The evidence for the FM regimen and MMC regimen was not strong enough. According to this meta-analysis, Tegafur was recommended as the first-line adjuvant chemotherapy regimen for patients after complete resection. However, RCTs published after 2000 have consisted of primarily combinations of cisplatin and FU. Collectively, S1 or 5-FU-cisplatin combination regimens in neo-adjuvant, adjuvant, and perioperative settings have yielded a favourable impact on survival^[20-32]. Moreover, chemotherapy seems to provide prolongation of survival for patients with mostly node-positive and T3-T4 disease (Table 1).

The combination of adjuvant with neo-adjuvant chemo-

therapy has proven its value in two randomized trials. As the pioneer study of perioperative chemotherapy for gastric cancer, the British Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial demonstrated a significant downstaging of the primary tumour and a 10% higher resectability rate with a survival benefit of 13% at 5 years^[31]. The primary goals of the ECF perioperative CT were to increase the likelihood of R0 resection while downstaging the tumour, predicting tumour sensitivity to chemotherapy, improving obstructive symptoms, and eliminating micrometastases. One of the major limitations of the MAGIC trial was that only 42% of patients in the chemotherapy group were able to receive all protocol treatment; 34% of patients who completed preoperative chemotherapy and surgery could not be administered postoperative chemotherapy, possibly due to postoperative complications, early disease progression, or the patients' will. Nevertheless, patients in the perioperative chemotherapy section had a survival advantage when compared with those who underwent surgery alone (5 years OS rate for CT group vs surgery-alone; 36% vs 23%, respectively).

New questions have arisen regarding the optimal adjuvant therapy following the increased acceptance of D2 gastrectomy. The primary goal of design for Capecitabine and Oxaliplatin Adjuvant Study in Stomach Cancer (CLASSIC) study was to answer these questions. The investigators aimed to evaluate the effect of adjuvant capecitabine plus oxaliplatin after D2 gastrectomy^[25]. The CLASSIC study reported a 44% improvement in disease-free survival (DFS) for patients randomly assigned to postoperative capecitabine and oxaliplatin (XELOX) when compared with observation. Subgroup analysis confirmed the beneficial effect of adjuvant capecitabine and oxaliplatin for all disease stages (II, III A or III B), and the extent of nodal involvement correlated with substantially more benefit ($N2 > N1 > N0$) from adjuvant CT. Three-year DFS was defined as the primary endpoint because the majority of the recurrences occur within 3 years of surgery according to the preliminary data from the GASTRIC group. Although not formally validated as a surrogate measure yet, 3-year DFS is strongly correlated with 5-year OS, which is the reference point for judging effectiveness of adjuvant therapy in gastric cancer^[15]. Additionally, after a median follow-up of 62.4 mo, the updated results supported the interim analysis findings; the estimated 5-year DFS was 68% in the adjuvant capecitabine and oxaliplatin group vs 53% in the observation alone group^[33]. The OS data from this study are not yet known; however, the data suggest an improvement in OS with capecitabine and oxaliplatin compared with surgery alone (78% vs 69%).

Whether the results of CLASSIC trial could be adapted to geographical regions where management practices differ is unclear. The CLASSIC trial had considerably better survival outcomes when compared with Western counterparts; the 3-year OS rate in the surgery-only group was 78% in the CLASSIC trial, while it was only 30%-40% in the United States Intergroup-0116 and

United Kingdom MAGIC populations. Although patients included in the CLASSIC trial had fewer T3 and T4 lesions (44% in CLASSIC vs 68% in Intergroup-0116 vs 64% in MAGIC), node-positive disease was more frequent (90% vs 85% vs 72%). The differences in survival rates are supposed to be not only due to prognostic differences but also due to intrinsic biological disparities and consistent use of D2 surgery. Since D2 gastrectomy is also a standard of care in Western countries currently, the findings of this study could be remarkable and generalized to the other regions where D2 surgery is performed by experienced surgeons.

ADJUVANT CHEMORADIOOTHERAPY

After surgery with curative intent, local or regional recurrence in the gastric or tumour bed, the anastomosis, or regional lymph nodes occurs in 40% to 65% of patients^[34]. According to the preoperative analysis of the University of Minnesota, locoregional failure was the only evidence of relapse in 29% of patients and as any component of relapse in 88% of patients. Locoregional recurrences occurred in three major locations: (1) Gastric bed (organs and structures in proximity to the primary tumour); (2) regional nodes; and (3) gastric remnant, anastomoses, and duodenal stump^[35]. Autopsies report even higher locoregional failure rates reaching up to

80%-93%^[36]. Thus, radiotherapy is supposed to be an essential adjunct of postoperative treatment in gastric cancer patients.

Two randomized trials evaluating the benefit of adjuvant radiotherapy (RT) alone after resection for gastric cancer revealed conflicting results. The first trial by the British Stomach Cancer Group included 436 patients who were randomized to undergo surgery alone or surgery followed by RT or chemotherapy with mitomycin, doxorubicin, and fluorouracil^[37]. However, more than one third of the patients had gross or microscopic residual disease following surgery. At the 5-year follow-up, there was no additional survival benefit for adjuvant RT or chemotherapy compared with surgery alone. However, there was a significant reduction in locoregional recurrence with the addition of RT to surgery. The second trial by Zhang *et al*^[38] randomized 370 patients to preoperative RT or surgery alone. Survival and resection rates were significantly improved with preoperative RT compared with surgery alone (30% vs 20%; 89.5% vs 79%, respectively). However, there was not a significant reduction in distant recurrence rates (24.3% vs 24.7%). Because only cardiac lesions were included in the trial, it is not clear whether these results can be adapted to distal lesions.

The landmark trial regarding combined modality adjuvant treatment for gastric cancer has been the

Intergroup 0116 study^[6]. A total of 556 patients with resected carcinoma of the stomach or gastroesophageal junction (stage IB through IV, M0) disease were randomized to surgery alone or surgery plus postoperative chemoradiotherapy. The median OS in the surgery only group was 27 mo, as compared with 36 mo in the chemoradiotherapy group ($P = 0.005$). An important issue regarding the surgical procedure was the extent of surgery in this trial. Although the recommendation was an extensive D2 LND, only 10% of the patients underwent a D2 dissection, 36% had a D1 dissection, and more than half had a D0 lymphadenectomy (not all of the N1 nodes were resected). This situation raised the question of whether chemoradiation was compensatory for inadequate surgery. Thus, in high-volume centres where D2 LND is routinely performed, omitting adjuvant radiotherapy has been considered due to high morbidity rates and poor tolerance. However, an observational study including patients with D2 LND has demonstrated that chemoradiotherapy as an adjunct to surgery could be tolerable with acceptable toxicity and good tumour control^[39]. The patients had received a postoperative chemoradiotherapy protocol similar to the Intergroup trial or surgery without further adjuvant treatment. The median duration of OS was significantly longer in the chemoradiotherapy (CRT) group than in the comparison group (95.3 mo vs 62.6 mo). However, these data rely on nonrandomized observation studies with suitable controls or unplanned subgroup analysis.

Updated analysis of the Intergroup trial with longer follow-up has supported the persistent benefit of adjuvant CRT^[40]. The OS and recurrence-free survival data demonstrated continued strong benefit from postoperative radiochemotherapy. Hazard ratios were virtually unchanged since the original report. Moreover, two meta-analyses comparing the efficacy of adjuvant CRT vs CT after R0 resection have confirmed the superiority of the combined modality in terms of disease-free survival^[41,42]. However, there was no OS advantage with the addition of radiotherapy in both analyses.

OPTIMAL CHEMOTHERAPY REGIMEN DURING RADIOTHERAPY

One of the most criticized aspects of the Intergroup trial was the toxicity profile of the FU/LV regimen. Therefore, other investigators have sought alternative postoperative chemoradiation regimens. In a pilot study by Lee *et al.*^[43] patients with stage III-IV (M0) gastric cancer who had undergone extensive D2 LND were administered postoperative chemoradiation with fluorouracil and cisplatin before and after capecitabine and concurrent RT. A total dose of 4500 cGy in 25 fractions over five weeks was delivered to the target volume similar to the INT-0116 trial. This study demonstrated a 3-year disease free and OS of 82.7% and 83.4%, respectively, with the use of adjuvant chemoradiotherapy. Leong *et al.*^[44] reported that postoperative chemotherapy with

epirubicin, cisplatin, and 5-FU (ECF) before and after concurrent chemoradiation with infusional fluorouracil was tolerable and efficient. A similar regimen with ECF before and after radiation with infusional fluorouracil has been compared with the INT-0116 regimen in a randomized phase III trial (CALGB 80101)^[45]. Although the ECF regimen had a more favourable toxicity profile compared with bolus fluorouracil and leucovorin, there was no significant improvement in survival.

Alternative regimens for concomitant and adjuvant treatment have also been experienced. The efficacy of paclitaxel - cisplatin and 5-FU regimen against oesophageal and gastroesophageal junction adenocarcinomas has been demonstrated previously^[46]. Results of a phase I trial conducted among patients with locally advanced gastric cancer using weekly cisplatin and RT with paclitaxel as a 96-h continuous infusion were also promising^[47]. Another trial from MD Anderson included patients with gastric cancer who received two cycles of induction chemotherapy with infusional 5-FU, cisplatin on days 1 to 5, and paclitaxel over 24 h on day 1 of each 28-d cycle^[48]. During the 5-wk course of RT, infusional 5-FU and paclitaxel were administered weekly. Complete and partial response rates were 22% and 15%, respectively, which were quite promising. In the light of these findings, a phase II trial (RTOG-0114) was designed to integrate paclitaxel and cisplatin with or without 5-FU concomitantly through radiotherapy. However, the paclitaxel, cisplatin, and 5-FU (PCF) arm were closed due to the high gastrointestinal toxicity rates, which were significantly worse than INT0116 results^[49]. For the paclitaxel and cisplatin (PC) arm, the 2-year DFS was 52% (95%CI: 36%-68%). Although the PC arm was tolerable, the DFS failed to exceed the predefined lower bound of DFS at 2 years. Thus, this regimen could not be recommended as an adjuvant modality for future randomized phase III studies. These trials suggested that intensification of adjuvant chemotherapy or chemoradiation regimens may not be as effective as expected. Table 2 summarizes the major trials evaluating adjuvant CRT.

Whether an intensified CRT regimen prolonged survival after D2 dissection was another subject of debate. The ARTIST trial was designed to answer this question; comparing six cycles of capecitabine and cisplatin (XP) chemotherapy with two cycles of XP followed by concurrent capecitabine and RT followed by two additional cycles of XP after D2 dissection^[4]. However, the study failed to demonstrate a significant DFS benefit with the addition of radiotherapy to XP (3-year DFS rates 78.2 vs 74.2% for CRT and CT arms, respectively). Treatment was completed as planned by 75.4% of patients in the chemotherapy arm and 81.7% in the CRT arm. The updated analysis with longer follow-up did not reveal DFS or OS benefit either^[50]. However, the subgroup of patients with pathologic lymph node metastasis in the CRT arm had superior DFS when compared with those who received CT alone (3-year DFS; 76% vs 72%). Besides,

Table 2 Features of major adjuvant chemoradiotherapy trials for gastric cancer

Ref.	CT Regimen without RT/with RT	n (total)	D2 rates	G3-G4 toxicity (hem/GI)	Completeness of treatment	RT technique

CT: Chemotherapy; RT: Radiotherapy; D2: D2 lymph node dissection; G3-G4: Grade 3-grade 4; hem: Hematologic; GI: Gastrointestinal; NA: Not available; 5-FU: 5-fluorouracil; LV: Leucovorin; inf: Infusional; FP: 5-FU, cisplatin; ECF: Epirubicin, cisplatin, 5-FU; PC: Paclitaxel, cisplatin; PCF: Paclitaxel, cisplatin, 5-FU; XP: Capecitabine, cisplatin; 2D: Two-dimensional; 3D: Three-dimensional; IMRT: Intensity modulated radiotherapy.

intestinal-type gastric cancer derived more benefit from CRT (3-year DFS rates were 83% and 94% in the CT and CRT arms, respectively).

The most commonly encountered nonhaematologic grade 3 to 4 side effects were stomatitis, hand and foot syndrome, diarrhoea, and vomiting, each of which occurred in 1% to 12% of patients in both arms. The rate of grade 3 and 4 neutropenia was 39% in the CT arm and 48% in the CRT arm; however, the rate of febrile neutropenia was quite low in both arms (< 1%), suggesting that postoperative treatment with cisplatin and capecitabine and is tolerable following a D2 LND. In conclusion, capecitabine at a dose of 1650 mg/m² per day with RT was well tolerated.

In the light of the studies mentioned above, combination regimens other than 5-FU/LV are still under investigation for gastric cancer. The NCCN guidelines, however, do not recommend the standard bolus 5FU/LV regimen utilized in the INT0116 trial. Relying on the data from gastric cancer trials, such as the ARTIST trial and colorectal cancer studies, capecitabine or infusional 5-FU is recommended concomitantly with RT by the NCCN due to their better toxicity profile and tolerability^[51].

RADIOTHERAPY TECHNIQUE

Since the publication of the INT0116 results, the radiotherapy technique and planning of the target volume has changed over time. Patients involved in this trial received 45 Gy of radiation in 25 fractions to the surgical bed, regional lymph nodes, and preoperative tumour volume. The regional lymph nodes included perigastric, splenic, hepatoduodenal, pancreatoduodenal, celiac, and local paraaortic lymph nodes based on patterns of failure after a D0/D1 dissection. In the Intergroup-0116 trial, two-dimensional (2D) radiation therapy was utilized and the CRT arm was associated with high rates of toxicity, with nearly three-quarters of patients experiencing grade 3/4 toxicities. Only 64% of patients in the CRT arm completed the planned treatment program, and 17% discontinued treatment due to toxicity. However, treatment-related mortality was low (1% on the chemoradiation arm vs 0% on the surgery alone arm). In addition, overall chemoradiation appeared tolerable.

Fortunately, technology has improved over time to

allow conformal radiation therapy, sparing normal tissues and allowing dose escalation. Three-dimensional (3D) conformal radiotherapy reduces the damage to normal tissues to some extent and is considerably superior to 2D radiation^[52]. Currently, modern 3D RT techniques are applied for the resected gastric cancer patients at most of the oncology centres in the world. 3D planning enables exact description of the target volume and organs at risk by visualization of anatomic changes in the internal organs after surgery^[53].

Whether or not to change the RT target volumes for patients undergoing D2 dissection is another subject of debate. The findings of the study by Chang *et al*^[54] have revealed that the most prevalent sites of regional recurrence after D2 dissection were the lymph nodes around the superior mesenteric vessels, the abdominal aorta from the upper margin of celiac trunk to the lower margin of aortic bifurcation, and the hepatoduodenal lymph nodes, which were primarily in the nodal basin outside the D2 dissection field. Consistent with these findings, the RT target volume in the ARTIST trial did not involve lymph nodes in the perigastric region and splenic hilum^[4]. The investigators have noted higher locoregional relapse rates in the CT arm (13% vs 7%, $P = 0.0033$) which supports the addition of CRT even in the presence of D2 dissection with the modified RT target volume.

Intensity modulated radiotherapy (IMRT) is a more sophisticated radiotherapy technique, with capability of delivering high doses of radiation to a targeted area with high geometrical accuracy. According to the recent studies, IMRT for gastric cancer is dosimetrically superior to conventional therapy, because IMRT is able to decrease the radiation dose to organs at risk, especially the spinal cord and kidney, while providing the intended radiation dose to the target areas^[55,56]. The most recent phase III trial comparing concomitant CT with IMRT and chemotherapy alone investigated the role of IMRT among gastric cancer patients with D2 LND^[57]. The IMRT plus CT arm was tolerable with a significant improvement in DFS (5-year DFS, 45% vs 36%); however, the results of this trial could not point at an OS benefit like the previous comparative studies (5-year OS, 24% vs 27%, $P > 0.05$). According to some investigators, IMRT appears to provide only limited advantages when compared with sophisticated 3D conformal RT planning^[58]. Moreover, the risk of a second cancer induced by radiation is reported

to increase in some patients^[59,60]. Whether 3D conformal RT or IMRT provides better protection of organs at risk remains controversial.

SELECTING PATIENTS FOR ADJUVANT CHEMORADIOOTHERAPY

Stage

Although the patients involved in the INT0116 trial were stage IB-IV (M0), the majority had advanced disease, whereas up to 60% of patients in the ARTIST trial were stage I / II. Furthermore, in the subgroup analysis of the ARTIST trial, improved DFS ($P < 0.05$) was observed in stage III and IV patients in the CRT group. The proportion of stage III/IV (M0) patients enrolled in the study by Zhu *et al.*^[57] was 71%, which demonstrated a DFS benefit for CT with IMRT after D2 dissection. The subset (node-positive) analyses of the ARTIST trial and the DFS advantage for stage III and IV (M0) patients in the Chinese trial supported that the use of adjuvant CRT for the whole stage IB to stage IV (M0) population may be overtreatment. Similarly, adjuvant CT alone may be inadequate for resected stage III-IV patients. Subgroup analysis of 5-year OS in the ACTS-GC trial from Japan showed an insufficient survival benefit of S1 for N3a and N3b stages (HR = 0.77, 95%CI: 0.53-1.13 and HR = 0.92, 95%CI: 0.47-1.79, respectively). The results indicated the necessity of adjuvant RT in these patients who were at high risk for locoregional relapse. Accordingly, in our study, which included D2 dissected pN3(M0) gastric cancer patients, the addition of RT to CT did not provide a statistically significant improvement in DFS or OS, but there was an evident difference between the CT and CRT arms numerically (median DFS 12.5 and 15.2 mo; median OS, 26.8 mo vs 34.2 mo for CT and CRT arms, respectively)^[61]. Another retrospective study from China including stage III gastric cancer patients with D2 dissection showed OS and DFS advantage for stage IIIC patients undergoing adjuvant CRT compared with CT^[62]. These studies indicate that patients with relatively advanced disease stages (III or IV) would benefit the most from adjuvant CRT.

The presence of lymphovascular invasion (LVI) or perineural invasion (PNI) have been demonstrated as significant prognostic factors for both OS and DFS among patients undergoing adjuvant treatment^[63]; however, thus far, there have not been any randomized trial data evaluating the administration of CT or CRT depending on the stage or presence of LVI or PNI, unlike for breast and colon cancers. However, the ARTIST II trial is on track to evaluate the efficacy of all available adjuvant treatment modalities after D2 dissection for node positive patients (clinicaltrials.gov NCT01761461); chemotherapy with S-1 for 1 year vs chemoradiotherapy involving two cycles of SOX followed by S-1/radiotherapy and then four additional cycles of (SOX) vs combination chemoradiotherapy with S-1 and oxaliplatin (SOX) for 6 mo. Patients were stratified according to stage, type of surgery, and the

Lauren classification.

Another phase III study is currently recruiting stage IB gastric cancer patients for evaluating adjuvant capecitabine vs observation (clinicaltrials.gov NCT01917552). The results of these trials are expected to answer the question regarding tailoring treatment to disease stages.

Histology and biomarkers

The main carcinogenic event for the evolution of diffuse type of gastric cancer is loss of expression of E-cadherin, a key cell surface protein for establishing intercellular connections. Biallelic inactivation of the gene encoding E-cadherin, CDH1, can occur through germline or somatic mutation, allelic imbalance events (e.g., loss of heterozygosity), or epigenetic silencing of gene transcription. Diffuse type cancers are highly metastatic and characterized by rapid disease progression and a poorer prognosis than intestinal cancers^[64]. Thus far, there has been no adjuvant therapy trial designed according to histological subtype. However, exploratory subgroup analysis of randomized trials point at varying degrees of benefit according to histologic subtype. The investigators of the INT0116 study reported their observation of a reduced treatment benefit in patients with diffuse histology in their updated analysis^[40]. Similarly, the patients with intestinal type gastric cancer were found to be more prone to benefit from CRT than those with diffuse type in subgroup analyses of the ARTIST trial^[50]. Patients with intestinal type histology showed a significant improvement in DFS in the CRT arm compared with the CT arm (94% vs 83%, $P = 0.01$, respectively). Whether or not this is a random observation of an unplanned subset analysis or reflective of the biologic variations is unknown, but if chemoradiotherapy is less effective in diffuse gastric cancer, future clinical trials may consider different adjuvant strategies based on histological subtype. A phase II/III study is currently recruiting patients with resectable signet-ring cell gastric carcinoma to perioperative treatment similar to MAGIC trial or surgery followed by six cycles of ECF (clinicaltrials.gov NCT01717924). This study may help determining the efficacy of intense CT with cisplatin for diffuse type gastric cancer cases.

In addition to morphologic appearance and clinical behaviour, the two distinct types of gastric adenocarcinoma differ with respect to their pathogenesis and genetic profiles^[65]. For the intestinal subtype, there is meticulous evidence for the role of *Helicobacter pylori* in the initiation of the events that lead from chronic active gastritis to atrophic gastritis, intestinal metaplasia, dysplasia, and finally adenocarcinoma. Many gene changes have been described in various stages of the preneoplastic/neoplastic cascade, but the alterations do not generally follow a sequential arrangement. Some changes are seen in early preneoplastic lesions but are not present in more advanced lesions. Therefore, it is not easy to develop an appropriate target for treatment.

Approximately 50% of intestinal-type gastric cancers have alterations in tumour suppressor genes, including

TP53, *TP73*, *APC*, *TFF*, *DCC*, and *FHIT*^[66]. In addition, epigenetic alterations, such as DNA methylation of gene promoters, can silence the expression of certain genes, including *CDH1* (the E-cadherin gene), in not only diffuse type but also in intestinal-type cancers^[67,68]. Unlike the complex molecular pathway for intestinal type, diffuse carcinomas display a discriminative molecular abnormality: Defective intercellular adhesions through the loss of expression of the cell adhesion protein E-cadherin as mentioned below. Although this knowledge has not resulted in a specific targeted therapy for diffuse gastric cancer yet, the recognition of germline *CDH1* mutations in families helps identify high-risk individuals and encourage them to receive prophylactic gastrectomy.

The struggle to identify specific biomarker for predicting a treatment benefit has not resulted in success in the adjuvant setting so far. In the ARTIST trial, the different status of the *EGFR*, *HER-2*, *MET*, *MLH1*, and *CDH1* genes were considered; however, differences in the expression of these genes between the CRT and CT groups had no effect on DFS^[50]. Inhibition of HER-2 overexpression *via* trastuzumab in metastatic disease has revealed a median of 2.7 in OS benefit in the ToGA trial, and currently this strategy is being evaluated in the adjuvant setting (clinicaltrials.gov NCT01130337, NCT01748773). Previously, the amplification of mesenchymal-epithelial transition (MET) receptor has been linked to poorer clinical outcome in patients with gastric cancer^[69]. There are some conflicting case reports on attempts to target MET in patients with gastric cancer^[69,70]. However, it seems feasible to wait until the results of the trial, which is testing a MET antibody in the metastatic setting, are reported (clinicaltrials.gov NCT01662869).

CONCLUSION

Currently, there is no doubt that adjuvant chemotherapy or chemoradiotherapy after resection of gastric cancer offers survival benefits. The major challenge for the clinicians is how and where to place the additional treatment modality (*i.e.*, CT or CRT; adjuvant or perioperative setting). The selection of the appropriate patient who will provide more or no benefit from therapy further complicates the situation. Obviously, there is lack of data to compare perioperative CT vs adjuvant CRT. However, the evidence for adjuvant CT with XELOX or S1 after D2 dissection is satisfactory. Although the evolution of the RT technique since the Intergroup study promises better tolerability, the addition of CRT after D2 dissection merits further investigation in the light of the findings from the ARTIST trial. Instead of the bolus 5-FU regimen or 5-FU combinations, infusional 5-FU or capecitabine concomitantly with RT may be preferred due to the improved toxicity profile. Nevertheless, the struggle to individualize treatment strategies for a robust combat with the resistant subgroups, such as the diffuse type of gastric cancer, should continue until optimal targets for therapy are defined.

Abstract

Multitarget stool DNA (mt-sDNA) testing was approved for average risk colorectal cancer (CRC) screening by the United States Food and Drug Administration and thereafter reimbursed for use by the Medicare program (2014). The United States Preventive Services Task Force (USPSTF) October 2015 draft recommendation for CRC screening included mt-sDNA as an "alternative" screening test that "may be useful in select clinical circumstances", despite its very high sensitivity for early stage CRC. The evidence supporting mt-sDNA for routine screening use is robust. The clinical efficacy of mt-sDNA as measured by sensitivity, specificity, life-years gained (LYG), and CRC deaths averted is similar to or exceeds that of the other more specifically recommended screening options included in the draft document, especially those requiring annual testing adherence. In a population with primarily irregular screening participation, tests with the highest point sensitivity and reasonable specificity are more likely to favorably impact CRC related morbidity and mortality than those depending on annual adherence. This paper reviews the evidence supporting mt-sDNA for routine screening and demonstrates, using USPSTF's modeling data, that mt-sDNA at three-year intervals provides significant clinical net benefits and fewer complications per LYG than annual fecal immunochemical testing, high sensitivity guaiac based fecal occult blood testing and 10-year colonoscopy screening.

Core tip: Multi-target stool DNA (mt-sDNA) testing was approved for average risk colorectal cancer (CRC) screening by the United States Food and Drug Administration (2014). The evidence supporting mt-sDNA for routine screening use is robust. The clinical efficacy of mt-sDNA every three years, measured by life-years gained, and CRC deaths averted, is similar to that of other screening strategies more specifically recommended by the United States Preventive Services Task Force. In an irregularly screened population, however, tests with the highest point sensitivity and reasonable specificity like mt-sDNA are more likely to reduce CRC related morbidity and mortality than less sensitive tests that depend on annual adherence to achieve high programmatic sensitivity.

INTRODUCTION

In its October 5, 2015 draft recommendation statement for colorectal cancer (CRC) screening, the United States Preventive Services Task Force (USPSTF) includes multi-target stool DNA (mt-sDNA) as an "alternative" screening test that "may be useful in select clinical circumstances"^[1]. However, the evidence supporting mt-sDNA for routine screening use is robust. The clinical efficacy of mt-sDNA as modeled for life-years gained (LYG), and CRC deaths averted is similar to other options more specifically recommended in the draft statement. This paper reviews the evidence supporting mt-sDNA clinical validity^[2-4], analytical validity^[5-7], and the USPSTF CRC screening modeling^[8-10]. This body of evidence supports the use of mt-sDNA at three-year intervals (mt-sDNA3y) to provide significant clinical net benefits and fewer complications per LYG than annual fecal immunochemical testing (FIT), annual high sensitivity guaiac based fecal occult blood testing (hsFOBT), and screening colonoscopy every 10 years (Colo10y). In comparison to biennial or triennial FIT (FIT2y, FIT3y) or hsFOBT (hsFOBT2y, FSFOBT3y), both of which are adherence intervals more typically achieved in clinical practice^[11,12], only mt-sDNA3y is at or within 98% of the screening test efficiency frontier^[10] as measured by the ratio of LYG to colonoscopies generated. Additionally, mt-sDNA3y generates greater than 90% of the LYG by Colo10y in the simulation model of colorectal cancer (SimCRC)^[10].

CRC is the second leading cause of cancer death in the United States. In 2015, an estimated 133000

people will be diagnosed with the disease and about 50000 will die from it^[13]. When detected early, CRC can be treated with positive outcomes. The Centers for Disease Control and Prevention estimate that 42% of Americans are not currently up to date with colon cancer screening, including millions of Americans who have avoided screening completely, and that if everyone age 50 or older was regularly screened, at least 60% of CRC deaths could be avoided^[14]. These statistics leave much room for improvement in routine CRC screening; effective, broad implementation of a non-invasive high sensitivity, low risk screening strategies like mt-sDNA could immediately help to address this serious public health issue.

THE mt-sDNA TEST

mt-sDNA uses a single random stool sample, collected by patients at home, without requiring any preparation, or change in medications or diet. The test identifies 10 biomarkers known to be associated with CRC and pre-cancerous lesion, including altered human DNA and hemoglobin. The test combines all biomarker results with the normalizing gene beta-actin in an algorithm that generates a composite, single, "Negative" or "Positive" patient result. Several detailed reviews describing the biology that underlies this screening approach and the design features of the test have been published^[5-7]. The test was systematically designed to lower patient burdens with respect to ease of sample collection and specimen handling with a custom-designed collection kit. High CRC, high-grade dysplasia, and large adenoma point sensitivity and the prolonged pre-malignant phase of colorectal carcinogenesis allow for longer screening intervals between screening tests with mt-sDNA, which significantly lowers the burdens of annual testing. The American Cancer Society currently recommends mt-sDNA at three-year intervals^[15]. Burdens on patients, providers and health care systems are further reduced through an included United States 24 h, 7 d-a-week telephonic patient navigation system. This system assists patients throughout the testing process to maximize the number of successful screening events and reports results to directly to ordering medical providers.

The mt-sDNA analytic process and biomarker selection were used to create a test with greater sensitivity for CRC and significant premalignant lesions than fecal hemoglobin as a single marker. All tests based on fecal hemoglobin alone are biologically limited in their ability to detect colorectal neoplasia, especially precancerous lesions and early stage CRC, which may bleed intermittently or not at all. The random sampling and small sample size used in FIT and hsFOBT tests contribute to sampling error and further limits detectability. In contrast, mt-sDNA detects DNA alterations, both mutations and aberrant methylation, in DNA released from cells that are constantly shed from premalignant lesions and early and late stage cancers, enhancing their detectability by mt-sDNA. Stool sampling error with mt-sDNA is significantly diminished through the

use of an aliquot of the entire stool sample homogenate and the laboratory's automated, uniform processing protocol^[2].

mt-sDNA is primarily being used in the United States and has been approved by the United States Food and Drug Administration for average risk CRC screening^[16] and is reimbursed by the United States Centers for Medicare and Medicaid Services once every three years^[17]. It was awarded a unique Clinical Procedural Terminology code of 81528 by the American Medical Association. Cologuard[®] (multi-target sDNA) has been CE marked for use in Europe, though there is limited availability to date through laboratories in England and Dubai. Additional studies to determine local efficacy in a number of Asian countries are under discussion and studies are ongoing in Italy, the United Kingdom and the Netherlands. The test cost is USD649 (USD509 for Medicare), which includes a United States patient navigation/compliance system supporting over 70 languages.

In the United States, mt-sDNA is used in both opportunistic and local invitational settings. The test, requiring no change in diet, medication or any preparation and a specimen collection at home, is appropriate for population-based use. However, the size of the specimen container, allowable 72 h transit time back to the laboratory, and cost may mitigate use in that manner, especially in low resource countries. Countries with limited colonoscopy capacity for evaluating positive tests may be challenged by somewhat lower specificity (90%) of mt-sDNA compared to FIT, measured in patients requiring no biopsies when examined with colonoscopy, in any given year. However, overall, mt-sDNA results in fewer negative colonoscopic follow-up examinations for a positive screening test than result from the compounded programmatic specificity failure of annual FIT or hsFOBT at 95% specificity^[8].

mt-sDNA PERFORMANCE IN SCREENING POPULATIONS

Three studies in screening populations show consistent results. Studies demonstrate significant greater single test application sensitivity of mt-sDNA over FIT for advanced colorectal neoplasia detection, though at lower specificity.

DeeP-C study

Results from this pivotal, prospective 90-site, 10000 patient cross-sectional clinical study were published in the New England Journal of Medicine in April 2014^[2]. The DeeP-C study compared mt-sDNA and FIT, using colonoscopy as the reference standard on all cases. The study demonstrated that mt-sDNA was significantly more sensitive than FIT (Table 1) for detecting CRC, especially early stage CRC and advanced and non-advanced adenomas. Specificity in the target screening age of 50-74 years was 92.3% compared to 97.0% for FIT in patients where no biopsy was required during

colonoscopy. Matching FIT specificity to that of the mt-sDNA test only increases FIT sensitivity 2 percentage points. Thus the lower specificity of mt-sDNA did not account for the increased sensitivity of the mt-sDNA assay over FIT.

Alaska study: This prospective study of 661 Alaska native people compared mt-sDNA to FIT with colonoscopy as the reference, the same design as DeeP-C^[3]. In the overall study population ($n = 661$), which included both higher risk and average risk individuals for routine screening (screen subgroup) mt-sDNA detected 49% of advanced colorectal neoplasms (colorectal cancer plus advanced adenoma) vs 28% for FIT ($P < 0.001$), including the identification of 100% (10/10) colorectal cancers vs 80% (8/10) for FIT. In the screen sub-group ($n = 464$), mt-sDNA detected 50% advanced colorectal neoplasia vs 31% for FIT ($P = 0.01$), including the detection of 100% (4/4) of colorectal cancers vs 75% (3 of 4) for FIT. In subjects with no adenomas detected on colonoscopy, specificity was 93% for mt-sDNA vs 96% for FIT ($P = 0.034$). mt-sDNA may provide an attractive approach to provide high sensitivity screening for populations where routine travel for colonoscopy is challenging or where colonoscopy capacity itself is limited. Similarly, individuals participating only irregularly in screening care may accrue a greater benefit using a higher sensitivity tests when provided with an opportunity for screening.

Netherlands study: mt-sDNA was compared to FIT (OC Sensor) in prospectively collected frozen archived samples ($n = 1047$)^[4] from an invitational screening cohort (COCOS) collected in the Netherlands^[18]. The study compared the performance of mt-sDNA and FIT to colonoscopy on all subjects for the detection of advanced colorectal neoplasia. mt-sDNA detected 49% (50/102) and FIT 25% (26/102) of cases of advanced colorectal neoplasia ($P < 0.001$) at specificities of 89% and 96% respectively. The findings are consistent with those of the DeeP-C and Alaska studies.

PATIENT PREFERENCES AND TEST PERFORMANCE IN DIFFERENT POPULATIONS AFFECT SCREENING PROGRAM EFFICACY

The effectiveness of a test is a function of its performance, its availability, and patient adherence. The USPSTF noted in their draft statement that "clinicians should consider engaging patients in informed decision-making about the screening strategy that would most likely result in completion, with high adherence over time, taking into consideration both the patient's preferences and local availability"^[1]. Data has begun to accrue from studies that the mt-sDNA performance and process may appeal to previously unscreened patients

Table 1 Findings from the DeeP-C cross-sectional study^[5], comparing multitarget stool DNA with fecal immunological test using colonoscopy as the reference standard on all cases (*n* = 9989 subjects)

	Colonoscopy findings <i>n</i> detected	mt-sDNA % detected	FIT % detected
Sensitivity			
Colorectal cancer (stages I-IV)	65	92.3%	73.8%
Early stage colorectal cancer (stage I and II)	50	94.0%	70.0%
AA	757	42.4%	23.8%
High grade dysplasia	39	69.2%	46.2%
Sessile serrated adenoma/polyp ≥ 1.0 cm	99	42.4%	5.1%
Specificity			
Specificity (only CRC and AA excluded)	9167	86.6%	94.9%
Specificity, no adenomas, no biopsy done	4457	89.8%	96.4%
Age-adjusted (50-74 yr) ^[31]	4032	92.3%	97.0%

FIT: Fecal immunological test; AA: Advanced adenoma.

and lead to increased screening rates. A study by Berger *et al.*^[19] surveyed a random sample of almost 3000 average-risk patients (99% participation rate) who had been prescribed mt-sDNA (Cologuard) by their physician and found that 42% of the patients, aged 50-74 years had not been previously screened.

A second study by Cole *et al.*^[20] of 675 average-risk patients, aged 50-75 years who had never been screened for CRC showed that when patients were informed regarding screening alternatives they preferred the noninvasive, mt-sDNA option by more than 50% over colonoscopy or FIT. The study went on to note that educating patients about the noninvasive mt-sDNA option and involving the patient in the shared decision-making process about test choice can increase the likelihood that noncompliant patients will get screened.

A third study by Abola *et al.*^[21] of 423 individuals (617 invited, 69% participation rate) found that 75% considered mt-sDNA more suitable for screening than colonoscopy with no significant difference between Caucasian and African American respondents. The authors concluded that "intervention to increase the uptake of sDNA (mt-sDNA) testing may reduce racial disparities in CRC".

The availability of mt-sDNA allows patients who would be screened but who will not use colonoscopy for personal or cultural reasons or who reside in rural areas where there is less access to colonoscopy, to have a high sensitivity noninvasive test option. This is especially relevant for those who will not adhere to an annual screening regime.

Addressing disparities resulting from test access and patient preference are important. Studies show that multiple screening choices increase the overall level of screening and that patients will gravitate to their preferred option. Inadomi *et al.*^[11] showed that offering colonoscopy alone was less effective (38% screened) than offering a choice of colonoscopy or gFOBT screening (69% screened) for obtaining a successful screening event within 12 mo of a physician's recommendation for screening. A large prospective randomized screening study comparing FIT to colonoscopy, conducted in Spain, by Quintero *et al.*^[22], allowed post-randomization cross-

over. Approximately 23% (1706/7355) of patients randomized to colonoscopy crossed over to FIT, with 1.2% (117/9353) of patients randomized to FIT crossing over to colonoscopy. This demonstrates a preference for non-invasive testing in a significant number of subjects. If this occurred in a clinical situation outside of a clinical trial, 23% of patients would be selecting a screening approach with much less sensitivity and a more burdensome screening requirement. These issues could be significantly mitigated by using high sensitivity mt-sDNA as a routine non-invasive choice. Additional studies have shown that test preferences for non-invasive screening over invasive screening are most attractive to certain populations related to cultural preferences, a population area where high sensitivity non-invasive screening may also improve screening efficacy.

Finally, for patients who do choose non-invasive testing, sensitivity for CRC and its precursors in the proximal colon are key to screening efficacy. African American patients and elderly patients in general have an increased prevalence of proximal colorectal neoplasia^[23-25]. In contrast to FIT which is more sensitive for lesions in the distal colon, mt-sDNA has equivalent sensitivity for CRC in the proximal and distal colon. Importantly, and key for decreasing proximal CRC incidence when using noninvasive screening, mt-sDNA has significant sensitivity for sessile serrated adenoma/polyps, the pre-cursor lesion for approximately 25% of CRC and a common cause of missed or interval cancers arising in the proximal colon. In the DeeP-C study, mt-sDNA identified 42.4% of patients with sessile serrated adenomas ≥ 1 cm in diameter whereas FIT detected only 5.1% ($P < 0.001$) as these lesions are non-hemorrhagic whereas they exfoliate aberrantly methylated DNA in the stool^[2].

MODELING mt-sDNA PERFORMANCE AS AN APPROACH FOR SETTING AN INITIAL INTER-TEST INTERVAL

Establishing an initial inter-test interval using vetted, well designed and calibrated CRC screening models is recommended for new tests^[8]. Modeled intervals can be

tempered over time to accommodate accumulating clinical experience, patient preferences and medical delivery system impacts. Comparative prospective randomized longitudinal studies with mortality endpoints are large, complex, lengthy, and expensive. Currently, only screening with low sensitivity guaiac FOBT and flexible sigmoidoscopy are supported by prospective randomized control trials (RCT's) with mortality endpoints. The use of models allows for virtual prospective studies to be done on large cohorts. These provide comparative performance of multiple tests simultaneously. Such modeling and its limitations are described below.

The predictive power of modeling has limitations related to the degree that the biology of colorectal cancer, clinical practice related factors, test uptake, and performance assumptions accurately reflect the clinical screening "ecosystem". One concern is establishing a comparative baseline by only using 100% uptake and adherence for each screening test. The USPSTF technical report^[8] assumes 100% compliance and adherence for each strategy, despite strong evidence that initial uptake of FIT/FOBT in the United States is low (10.4%)^[26,27] and adherence for FIT and FOBT declines significantly over time^[28]. A recent review of a large cohort of patients continuously insured for ten years showed that of patients who were screened according to guidelines, only 0.3% (268/97518) were current with screening as a result of completing ten consecutive annual FIT/FOBT tests^[29]. Patients who were non-adherent with colonoscopy and non-adherent to annual test use completed an average of 2.6 FIT/FOBT during the 10-year study period. Forty-six percent completed only a single FOBT/FIT test during the 10-year study period. Ninety-nine point six percent (97801/97518) of patients who were current with screening had received a colonoscopy during the 10-year study period. In a three-year follow-up^[28] of the Inadomi study^[11] reported by Liang *et al.*^[28], the annual adherence for patients in the group assigned to FOBT screening fell from 67% the first year to 27% at year two, and to 14% by year three. In the group that chose FOBT over colonoscopy, adherence dropped from 38% in the first year to 19% at year two and to 12% at year three. In highly resourced integrated health system with patient navigation infrastructure, improved programmatic adherence with annual FIT has been shown, though initial uptake remains < 50%^[30]. Despite evidence of poor year-over-year adherence, the USPSTF continues to recommend routine screening with annual FIT, hsFOBT, or annual FIT with flexible sigmoidoscopy every 10 years, based on modeling 100% adherence while acknowledging that "In practice, such high adherence is not observed either for initial or repeat screening^[8]" and considers high sensitivity mt-sDNA an "alternative test" only for use in selected patients.

This USPSTF draft CRC screening recommendation^[1] is informed by the results of three independently-developed microsimulation models of CRC that are funded by the National Cancer Institute's Cancer Intervention and Surveillance Modeling Network (CISNET) - SimCRC,

microsimulation screening analysis (MISCAN) for CRC, and colorectal cancer simulated population model for incidence and natural history. The performance of the various CRC screening tests were evaluated using these models to predict LYG, decreases in CRC incidence, CRC related mortality, number of screening tests required, and complications arising from screening^[8].

For comparative purposes, CISNET assumed 100% perfect adherence to all screening and surveillance procedures and performed no sensitivity analysis around adherence that would more accurately reflect actual test use. Further, their analysis grouped FIT, gFOBT, and mt-sDNA together because they are "exclusively stool-based screening modalities with comparable burden"^[8]. However, mt-sDNA has higher single-event CRC, and advanced adenoma sensitivity, including sensitivity for sessile serrated adenomas. It has significantly lower patient burdens given the need for far fewer test events with the recommended three-year screening schedule, a specifically designed patient collection process to minimize sample handling, and an embedded patient navigation support system. Based on the lower patient burden and the great biological differences in the test approach, mt-sDNA could have been considered in its own category for interval effect analysis, similar to all other non-stool based strategies. At the least, mt-sDNA3y could have been grouped with FIT2y and FIT 3y and hsFOBT2y and hsFOBT3y as a more clinically representative grouping for evaluation. This is an important consideration as, under CISNET modeling rules, only one strategy per "group" could ultimately be "recommended" for routine screening^[8].

This grouping and arbitrary rule led to the finding that "annual mt-sDNA" was less efficient with respect to the number of colonoscopies generated per LYG than annual FIT and hsFOBT and precluded a consideration of the multi-year interval (3 years) for which the test is already recommended by others^[9,15]. According to the draft recommendation statement, the CISNET modeling of mt-sDNA at a one-year interval (mt-sDNA1y) would "potentially yield approximately the same number of life-years gained as the recommended strategies previously listed" but when "compared with other stool-based screening tests and screening with colonoscopy every 10 years, FIT-DNA (mt-sDNA) requires a larger number of lifetime colonoscopies (a proxy for the harms of screening) per LYG"^[1]. When calculating lifetime colonoscopies using the intervals for each screening test as recommended by the American Cancer Society (Table 2)^[15], the data shows that mt-sDNA3y has the fewest lifetime colonoscopies (COL) and an equivalent number of colonoscopies per LYG compared to FIT and hsFOBT at one-year intervals (FIT1y and hsFOBT1y) (Table 3)^[8]. Colonoscopy itself generates approximately twice as many colonoscopies per LYG as any of the non-invasive strategies.

Overall, mt-sDNA3y is associated with less burdens and harms than FIT1y and gFOBT1y. In clinical practice the comparative benefits of mt-sDNA may be even greater given the lack of adherence to annual FIT or

Table 2 American Cancer Society recommended colorectal cancer screening test frequency intervals for average risk individuals

Test	Frequency (yr)
Colonoscopy	10

Flexible sigmoidoscopy	5
Multi-target stool DNA test (Cologuard, mt-sDNA)	3
High sensitivity guaiac-based fecal occult blood test	1
Fecal immunochemical test	1

CT: Computed tomography.

hsFOBT screening^[11,28-30]. A comparison reflecting actual clinical practice experience would have included a comparison of mt-sDNA3y with FIT/FOBT at 2y and 3y, which is detailed below.

A sensitivity analysis exploring non-annual adherence demonstrated more clinically relevant benefits and harms for stool-based strategies. The CISNET modeling data on FIT and hsFOBT at two-year intervals^[8] (FIT2y and hsFOBT2y) and mt-sDNA3y (Table 4), show mt-sDNA3y to be the only strategy generating greater than 90% LYG by screening colonoscopy 10y (% of COL 10y LYG) (SimCRC) in any of the models. While the colonoscopies per LYG are similar for hsFOBT and somewhat lower for FIT2y, overall LYG, CRC incidence, and related deaths are notably lower and more lives will be saved with mt-sDNA3y than with either FIT2y or gFOBT2y^[8].

The CISNET modeling data on FIT and gFOBT at three-year intervals^[8] (FIT3y, hsFOBT3y) reflects a second scenario supported by clinical experience^[8-10]. Compared to FIT3y and hsFOBT3y, mt-sDNA benefits are notably better with 19-22 CRC deaths averted, 43%-68% CRC incidence reduction, and 68%-78% mortality reduction across the three models (Table 5)^[8]. At three-year intervals, FIT and hsFOBT generate only 68%-77% of the life years gained by Colo10y vs 84%-91% for mtsDNA3^[8,10].

BALANCING BENEFITS AND HARMS

The specific harms associated with the non-invasive testing process are held to be minimal. Paradoxically, the USPSTF^[1] uses colonoscopies as a proxy for harms for the non-colonoscopy screening tests, but not for colonoscopy based screening itself. If colonoscopy related harm is a greater concern than screening benefit, especially where differences in the balance of harms and benefits is very small among non-invasive tests, mt-sDNA3y appears favorable when compared to Colo10y. mt-sDNA3y generates far fewer colonoscopies per 1000 people screened (1701-1827) across the three CISNET models^[8] than Colo10y (4007-4101) or annual hsFOBT (2230-2287) and similar numbers to annual FIT (1739-1899) (Table 3)^[8].

There are no direct harms or complications from mt-sDNA beyond those associated with a follow-up colonoscopy for a positive mt-sDNA screening test. No additional investigation is indicated for a positive mt-

sDNA test outside a careful structural examination of the colon in a well prepared patient, generally by optical colonoscopy. The aggregate contribution of other cancers of the aerodigestive tract and inflammatory diseases to the mt-sDNA false positive rate is two cases per 10000 screened patients, precluding the need for additional studies in an otherwise asymptomatic patient on the basis of a positive mt-sDNA test alone^[31]. Like all tests, mt-sDNA may be associated with false positive results and false negative results, wherein advanced colorectal neoplasia is not identified on a single screening event. Colonoscopy, however, may be associated, though rarely, with significant adverse events^[31].

The USPSTF technical report calculated complications for all model outputs. These complications are based on the serious adverse event rates summarized in the USPSTF evidence synthesis^[25] and are dependent on patient age and type of lesion removed. Table 3 shows the complications per 1000 patients screened, the LYG, the CRC deaths averted and screening related complications across the three models. mt-sDNA3y has the lowest rate of complications per LYG (0.036-0.044) vs annual FIT (0.038-0.045), annual hsFOBT (0.042-0.047) or colo10y (0.051-0.060). With respect to complications per death averted, mtsDNA3y (0.41-0.50) outperforms colonoscopy (0.58-0.68) and in two of three models, annual FIT (0.43-0.50) and annual hsFOBT (0.48-0.55)^[8].

Finally, the total number of screening tests required itself is an indicator burden. Fewer stool tests and clinical encounters are required for mt-sDNA3y than with FIT1-3y or hsFOBT1-3y (Tables 3-5). mt-sDNA3y provides significantly fewer burdens on patients, physicians, and healthcare systems than other fecal tests. Notably, this factor was not accounted for as a "burden" in the USPSTF analysis^[8].

mt-sDNA CLINICAL UTILITY CAN BE INFERRED FROM PREVIOUS RCT'S OF FOBT

The clinical utility of mt-sDNA3y with respect to reducing both CRC related mortality and CRC incidence can be inferred from previous RCT's of annual and biennial screening with the less sensitive FOBT test. No CRC screening test recommended by the USPSTF has been shown empirically to decrease CRC related mortality^[25]. Only low sensitivity guaiac based FOBT (gFOBT, *e.g.*, Hemoccult II), used annually or biennially, and flexible sigmoidoscopy alone have been shown to decrease CRC mortality in well-designed RCTs, but these are no longer widely used in the United States for screening, nor recommended by the USPSTF^[1,8,25]. However, the USPSTF infers decreases in CRC related mortality and the CRC incidence for both FIT and hsFOBT from the mortality benefit demonstrated for Hemoccult II gFOBT in these RCT's^[8]. These benefits can also be applied to mt-sDNA similarly through the same logical inference, as given mt-sDNA's superior sensitivity over FIT (Table 1) and by

CISNET: National Cancer Institute's Cancer Intervention and Surveillance Modeling Network; CRC: Colorectal cancer; SimCRC: Simulation model of CRC; MISCAN: Microsimulation screening analysis; CRC-SPIN: Colorectal cancer simulated population model for incidence and natural history; COL: Colonoscopies; LYG: Life-years gained; DA: Deaths averted; COL 10y: Colonoscopy at a 10-year interval; FIT: Fecal immunological test.

inference, superiority to low sensitivity gFOBT^[2]. CISNET modeling supports the proposition that mt-sDNA3y is more efficient^[10] and efficacious than hsFOBT2y and therefore similar clinical utility can be ascribed to mt-sDNA3y as the four RCTs of low sensitivity gFOBT2y provide for the clinical utility of hsFOBT2y^[8]. Using comparable clinical efficiency^[10] to allow clinical utility to be inferred from the RCTs of biennial FOBT obviates concern around small differences in specificity between the tests. In practical terms, even if patient uptake of mtsDNA is the same as that of FIT or hsFOBT, patients are more likely to see a greater net benefit from higher sensitivity mt-sDNA screening than from intermittent FIT/FOBT use, especially given the low rate of serious colonoscopy related complications.

CONCLUSION

CRC is the second leading cause of cancer mortality in

the United States with nearly 50000 deaths per year. mt-sDNA provides a colorectal cancer screening test with high sensitivity for the detection of CRC and the most significant pre-malignant lesions in a non-invasive format. It is approved as safe and effective for routine screening of asymptomatic individuals by the United States FDA, CE marked in Europe, and vetted and approved for coverage by the United States Centers of Medicare and Medicaid Services at three year intervals. mt-sDNA at three-year intervals is included in the American Cancer Society guidelines. Clinical experience demonstrates that patients formerly non-compliant with screening, ages 50-74, comprise a significant proportion (42%) of mt-sDNA users, which is consistent with patient screening preference studies.

Multiple studies support the superior point sensitivity of mt-sDNA over FIT, an important attribute of a screening test with limited harms that appeals to patients hesitant to pursue screening by other methods. The data

provided by the USPSTF technical report^[8] from three separate models supports the efficacy of mt-sDNA3y and demonstrates across 1000 screened individuals, age 50-74, that it yields a median of 226 life-years gained (range 215-250), averts 20 CRC deaths (range 19-22), reduces CRC mortality by 76% (range 68%-78%, and produces the most benefit (LYG) per complication (harm). The three CISNET models demonstrate that in terms of the number of colonoscopies per LYG, mt-sDNA3y (7-8) is equivalent to annual FIT (7-8) and lower than hsFOBT (9-10)^[8].

The USPSTF draft recommendation states "Screening for CRC is a substantially underused preventive health strategy in the United States... Accordingly, the best screening test is the one that gets done" and that maximizing the total proportion of the eligible population that receives screening will "result in the greatest reduction in deaths due to CRC"^[1]. As such, the clinical and modeling evidence and societal need for improved noninvasive screening strategies support a USPSTF recommendation for mt-sDNA for routine screening at three-year intervals, a conclusion consistent with the recommendations of others.

Failure to include a clear recommendation of mt-sDNA3y in the final USPSTF guideline may limit access to mt-sDNA for Americans not covered by Medicare. By only recommending the same tests as were recommended in 2008, the USPSTF draft recommendation limits significant progress in improving United States screening rates^[13,14] by affirming the current approaches only. In order to increase the screening rate, we must offer more efficacious choices. mt-sDNA3y for routine screening provides an opportunity to expand the pool of screened patients and to increase the quality of screening among those choosing non-invasive approaches.

Abstract

The diagnosis of gastrointestinal (GI) disorders is usually based on invasive techniques such as endoscopy. A key important factor in GI cancer is early diagnosis which warrants development of non- or less-invasive diagnostic techniques. In addition, monitoring and surveillance are other important parts in the management of GI diseases. Metabolomics studies with nuclear magnetic resonance and mass spectrometry can measure the concentration of more than 3000 chemical compounds in the urine providing possible chemical signature in different diseases and during health. In this review, we discuss the urinary metabolomics signature of different GI diseases including GI cancer and elaborate on how these biomarkers could be used for the classification, early diagnosis and the monitoring of the patients. Moreover, we discuss future directions of this still evolving field of research.

Key words: Metabolomics; Gastrointestinal diseases; Cancer; Inflammatory bowel disease; Metabolome; Urine

Core tip: Scientists are always searching for new disease biomarkers. An acceptable biomarker could help us in early diagnosis and classification of the diseases as well as the prediction of disease outcome. The diagnosis of gastrointestinal (GI) diseases is usually based on techniques such as upper or lower GI endoscopy, while highly sensitive and specific non-invasive diagnostic or screening tools are usually lacking. In this review, we have discussed the potentials of urinary metabolomics study as a future tool for the screening, diagnosis, classification and surveillance of GI diseases including inflammatory bowel disease and cancer.

INTRODUCTION

The rapid growth of high-quantity technologies and computational contexts allows the analysis of organic systems in distinctive details. New technologies such as DNA sequencing and mass spectrometry have permitted observing thousands of molecules concurrently instead of a few components that have been analyzed in old-fashioned research^[1].

By considering epigenetic ruling and posttranslational alterations, metabolites serve as direct signatures of biochemical activity in biological systems. Moreover, beyond genes and proteins, they are usually in direct association with disease phenotypes^[2]. Metabolomics or metabolic profiling is based on comprehensive and rapid analysis of thousands of metabolites simultaneously in biological samples including plasma and urine and is a feasible strategy for biomarker discovery^[3].

The routine urine analysis is often used for the diagnosis of diseases in the urinary tract. However, more than 3000 metabolites are detectable in the urine and their levels may be used as the signature of systemic diseases^[4]. These signatures are affected by energy and nutrient intake, body and cellular metabolisms and the environmental factors such as microbiota which have close cross-talk with the gastrointestinal (GI) system. Therefore, any disease in the GI tract may change the metabolic profile of the body that can be reflected in the bodily fluids including blood and urine.

This review provides an insight to the urinary metabolic profile of the GI diseases and its potential application in the clinical diagnosis and predicting their clinical as well as treatment outcome.

TECHNIQUES AND EVALUATION OF URINARY METABOLOMES

Assessment of some GI diseases requires the use of endoscopic methods which are not without risks. Determination of disease biomarkers in easily obtainable biofluids like urine, therefore, would be a valuable adjunct or even an alternative to conventional methods. Many serological markers for inflammatory bowel diseases (IBD) already exist, however, they are less helpful in determining disease subtypes (*i.e.*, Crohn's disease and ulcerative colitis) or forms of indeterminate colitis^[5]. Biomarkers or biomarker profiles that can predict and discriminate these subtypes with high probability are therefore desirable. Various studies pursuing this goal have been performed in the past couple of years and

have increased the list of metabolites found in higher or lower concentrations in body fluids, including urine, during IBD^[6]. These metabolites have been measured in IBD patients by highly sensitive techniques, for instance, by ¹H nuclear magnetic resonance (NMR) spectroscopy^[7-9], ion cyclotron resonance-Fourier transform mass spectrometry^[10] and by ultra-performance liquid chromatography coupled with electrospray ionization quadrupole time-of-flight mass spectrometry (MS) in rodents with experimental colitis^[11]. While the latter techniques are characterized as extremely sensitive, ¹H NMR spectroscopy is maybe less sensitive but known to produce highly reproducible results. A recent study compared different techniques for the detection of urine metabolites in humans and concluded that the NMR technique is the best method for identifying and quantifying urinary compounds^[4].

For the discrimination of IBD subtypes and the determination of severity and progress of GI diseases, many metabolites need to be identified. To organize and correctly interpret the large number of data, statistical methods, like multivariate analysis (*e.g.*, principal component analysis and orthogonal partial least squares projections) are applied. In the case of NMR, a method called "targeted or quantitative metabolic profiling" has been used to detect new possible sets of biomarkers^[12]. Here, the spectra of already characterized metabolites are stored in a database, and spectra measured in a new biofluid sample are compared with those from the database and thus identified and quantified. The determined metabolites not only may have importance as potential biomarkers but they can, at the same time, provide a link to the pathophysiology of the disease. In this respect, knowledge on the role of the determined molecule within the metabolic pathway is important. A urine metabolome database that allows researchers access to the types, structures and concentrations of urinary metabolites in different diseases has been therefore introduced by the Metabolomics Innovation Centre (<http://www.metabolomicscentre.ca/>; a platform hosted by the University of Alberta, Canada)^[4].

Taken together, urinary metabolites can be evaluated in GI diseases by different experimental methods of high or low sensitivity. Irrespective of the method used, detection of a unique metabolic fingerprint either for diagnosis, treatment, or detection of disease mechanisms is the primary goal.

URINARY METABOLOMICS IN IBD

IBD affecting over 1 million individuals in the United States and 2.5 million in Europe is a common chronic gastrointestinal disease with substantial costs for health-care. Moreover, it is estimated that the absolute number of IBD patients in newly industrialized countries may approximate that in the Western world until 2025^[13]. Despite this increase in the burden of IBD, gold standard tests for its diagnosis, monitoring and management are

usually invasive and sometimes inconclusive. Therefore, biomarkers including noninvasive methods such as urinary metabolomics studies might be useful for the management of patients with IBD^[14,15].

Urinary metabolomics has been studied in different mouse models of IBD. Interleukin-10 (*IL-10*) gene-deficient mice which are genetically susceptible to inflammation and colitis have shown different urinary metabolomics compared to non-inflamed animals. For instance, Murdoch *et al.*^[16] showed that several urinary metabolites such as trimethylamine (TMA) and fucose are changed dramatically in the *IL-10* gene-deficient mice after 8 wk of age which is the timeline for development of severe histological injury and colitis. These alterations in the metabolomics are majorly mediated by commensal microflora which play a key role in the disease process.

In another study on *IL-10* gene deficient mice, Lin *et al.*^[17] showed an association between 15 metabolites including fucose, xanthurenic acid, and 5-aminovaleric acid with intestinal inflammation. Elevated urinary xanthurenic acid in gene deficient mice was linked to increased plasma levels of kynurenine^[17]. In a further study, the same group validated these findings by showing that feeding *IL-10* gene-deficient and wild-type mice with Kiwifruit increases Kiwifruit-derived urinary metabolites more significantly in *IL-10* gene-deficient mice compared to wild-type mice without affecting urinary metabolites levels previously associated with inflammation^[18].

In another study, Otter *et al.*^[19] showed association between the concentrations of xanthurenic acid, α -CEHC glucuronide, and an unidentified metabolite m/z 495(-)/497(+) with inflammation in *IL-10* gene deficient mice.

Overall, studies on *IL-10* gene deficient mice generally agree with changes in urinary xanthurenic acid, a product of tryptophan catabolism through the kynurenine pathway. Bacterial lipopolysaccharides and pro-inflammatory cytokines are the activators of this pathway and its metabolites act as the moderators of T-cell tolerance to intestinal microbiota. As colitis does not usually develop in germ-free *IL-10* gene deficient mice, the role of intestinal microbiota looks considerable in the induction of urinary metabolomics alterations during colitis^[17,19-21].

Although, overall studies indicated that *IL-10* gene deficient mice have different urinary metabolomics profile compared to wild-type mice, Tso *et al.*^[22] showed that these differences are gender and age specific.

Schicho *et al.*^[23] expanded metabolomics study to an acquired model of chemical colitis induced by dextran sodium sulfate (DSS). After studying 69 urinary metabolites, they showed that urinary creatine, carnitine, and methylamines (including TMA and TMAO) were increased whereas antioxidant metabolites were decreased in DSS mice.

Another study on trinitrobenzene sulphonic acid-induced acute colitis in rats indicated that urinary tryptophan metabolites [4-(2-aminophenyl)-2,4-dioxobutanoic acid and 4,6-dihydroxyquinoline], gut microbial metabolites (phenyl-acetyl-glycine and p-cresol glucuronide), and the

bile acid 12 α -hydroxy-3-oxocholadienic acid which are associated with damage of the intestinal barrier function, microbiota homeostasis, immune modulation and the inflammatory response are altered during experimental colitis^[11].

Moreover, in a naïve T cell adoptive transfer experimental model of colitis, Martin *et al.*^[24] showed decrease in Krebs cycle intermediates in urine (succinate, α -ketoglutarate) indicating reduction in the glutaminolytic pathway related to overall loss of energy homeostasis during colitis.

Besides studies on animal models of colitis, studies on IBD patients have confirmed the diagnostic potentials of urinary metabolomics. By studying 206 Caucasian subjects [86 Crohn's disease (CD) patients, 60 ulcerative colitis (UC) patients, and 60 healthy controls], Williams *et al.*^[9] showed that urinary metabolites, which were in correlation with intestinal microbiota, were different in IBD patients compared to controls. In brief, urinary hippurate differed significantly between the three groups with the lowest level in CD patients. Moreover, 4-cresol sulfate levels were lower and formate levels were higher in CD patients compared to UC patients or controls. This study could significantly differentiate CD from UC^[9].

Another study compared the urinary metabolomic signature of patients with active UC, quiescent UC, and controls. In this study no significant difference in the urinary metabolomics profile of these 3 groups was observed^[8]. On the other hand, based on a recent study, a significant partial least squares discriminant analysis model was obtained through measuring urinary metabolomics in patients with active IBD vs a group with IBD in remission. Based on this study, glycine was increased in urine and acetoacetate decreased in urine during active IBD. Moreover, in active IBD, urinary citrate, hippurate, trigonelline, taurine, succinate and 2-hydroxyisobutyrate were decreased compared to the controls. Despite mentioned observations, this study could not clearly differentiate CD and UC patients based on the analysis of urine samples. Interestingly, contrary to the serum samples, up-regulation of acetoacetate and down-regulation of citrate, hippurate, taurine, succinate, glycine, alanine and formate in the urine samples of patients with IBD in remission could distinguish them from healthy controls^[25].

Another study showed that urinary metabolomics including tricarboxylic acid (TCA) cycle intermediates, amino acids, and gut microflora metabolites are different in patients with IBD compared to healthy controls. Comparison of CD and UC patients revealed different metabolomics fingerprints, but removal of patients with the surgical intervention revealed that CD could not be differentiated from UC^[26].

Schicho *et al.*^[23] expanded their findings in DSS mice by studying human subjects with IBD. Their study showed an increase in mannitol, allantoin, xylose, and carnitine in the urine and a decrease in urinary betaine and hippurate during IBD. However, the same as above mentioned studies^[25,26], they could not differentiate CD

and UC based on their metabolomics profile^[7].

Putting together, based on the metabolomics studies in IBD, the absolute urinary metabolomics signature of IBD is not yet clear. However, the body of literature supports the diagnostic role of urinary metabolites in IBD. More specifically, it seems that microbiota derivative metabolites are altered in IBD and are involved in the pathophysiology of this chronic inflammatory condition. Future multicenter studies on larger sample sizes and with considering confounders such as age, gender and medications should clarify whether urinary metabolomics could be used to: (1) Differentiate UC from CD; (2) predict outcome of the treatments; and (3) define the stage and severity of inflammation.

URINARY METABOLOMICS IN GI CANCERS

GI cancers are common and their burden is huge. Based on a global study in 2013, colorectal, stomach and esophageal cancer are ranked third, fifth and ninth for cancer incidence and fourth, second and sixth for cancer deaths, respectively^[27].

Despite available screening method for colorectal cancer which are usually costly and invasive, screening tests for upper GI cancers have not been well developed. Early detection of cancer or pre-cancerous lesions is always desirable. This could benefit from a urine-based cost-effective diagnosis and noninvasive screening assay whereby patients with undiagnosed cancer could be screened.

By analyzing urine samples from esophageal cancer patients and a control healthy group, Hasim *et al.*^[28] showed that mannitol, glutamate, γ -propanine, phenylalanine, acetate, allantoin, pyruvate, tyrosine, β -glucose and guinolate were higher in the urine of patients with esophageal cancer; however, N-acetylcysteine, valine, dihydrothymine, hippurate, methylguanidine, 1-methylnicotin- amide and citric acid were lower. Based on this study, urinary metabolomics could differentiate cancer and control groups. In addition, different pattern of metabolites were positively correlated with the rate of lymph node metastasis and clinical stages. Moreover, unsaturated lipids were a unique marker in differentiating late stages ($> 1b2$) and early stage ($\leq 1b2$) diseases^[28].

Based on another study, urinary metabolomics signatures clearly distinguished both Barrett's esophagus and esophageal cancer from controls. Although some overlaps were detected, the metabolomics profile of esophageal cancer was different than Barrett's esophagus^[29].

Metabolomics studies in gastric cancer are also promising. In a model of gastric adenocarcinoma-bearing mice, the urinary levels of TMAO and hippurate were significantly decreased, although the levels of 3-indoxylsulfate, 2-oxoglutarate, and citrate were significantly increased^[30].

Another animal study of implanted human gastric

cancer detected significant metabolic differences among normal, non-metastatic and metastatic groups. Based on this study, 10 selected metabolites were different between cancer and control groups. Briefly, the level of lactic acid, butanedioic acid, malic acid, citric acid and uric acid were higher in cancer indicating increase in aerobic glycolysis, respiration (mainly TCA cycle) and the impairment of mitochondrial enzymes. Moreover, glycerol and hexadecanoic acid as indicators of adipocyte lipolysis were higher in cancerous animals. Seven metabolites were also different between non-metastasis and metastasis groups. Alanine and glycerol (as substrates for glycolytic pathway) and L-proline were lower in cancerous animals with metastasis possibly due to a higher level of consumption. On the other hand, the level of myoinositol in the urine of metastasis group was higher^[31].

In a recently published article, the urinary metabolomics of gastric cancer patients was compared to healthy individuals. Based on this study, urinary metabolomics related to amino acids and lipid metabolism was significantly different in cancer vs control and could successfully discriminate both groups. Interestingly, the metabolomics signature of cancer showed much higher sensitivity compared to carbohydrate antigen 19-9 and carcinoembryonic antigen. 4-hydroxyphenylacetate, alanine, phenylacetylglutamine, mannitol, glycolate, and arginine levels were significantly correlated with cancer T stage. Together with hypoxanthine level, the above mentioned metabolites were tended toward control after surgical treatment^[32].

In a study by Chen *et al.*^[33], urinary lactic acid, arginine, leucine, isoleucine and valine were significantly higher, while citric acid, histidine, methionine, serine, aspartate, malic acid, and succinate were remarkably lower in the gastric cancer patients vs controls. In addition, the urinary valine and isoleucine levels were lower in advanced stages compared to early-stages of cancer^[33].

Another study also showed that urinary metabolomics could effectively differentiate gastric cancer patients from controls^[34]; however, the metabolites which were distinctive, were different than previously mentioned studies^[32,33], suggesting complexity in interpreting metabolomics results.

A study on urine metabolites of a colorectal cancer group of patients and their age-matched healthy controls as well as a rat model of chemically induced precancerous colorectal lesion revealed good separations between cancer patients or rats with pre-cancerous lesions and their healthy equivalents. Moreover, altered TCA cycle as well as gut microflora metabolisms were detected in cancer patients and the rat disease model. After surgery, the urinary metabolomic profile of cancer patients altered significantly compared to the preoperative stage since gut microflora metabolism and TCA cycle were down-regulated. In addition, 5-hydroxytryptophan significantly decreased after surgery suggesting an improvement of the tryptophan metabolism^[35].

The findings of the above mentioned study in colorectal

cancer were confirmed in a further study which also showed that a panel of urinary metabolite markers composed of citrate, hippurate, p-cresol, 2-aminobutyrate, myristate, putrescine, and kynurenate was able to discriminate colorectal cancer subjects from their healthy counterparts^[36].

Studies on the urinary metabolomics of GI cancers reveal alterations in microbiota, proteins and lipid mediated metabolites which are involved in the initiation and dissemination of cancer as well as the cellular overgrowth and proliferation, although no unique signature has been yet recognized. As a huge amount of variability is attributed to between-individual differences, future studies on larger sample sizes of GI cancer patients are required in order to detect associations with moderate effect sizes^[37].

URINARY METABOLOMICS IN OTHER GI CONDITIONS

Although many of the metabolomics studies have focused on GI conditions such as cancer and IBD, a few studies have assessed the roles of urinary metabolomics in other diseases.

Based on a study which compared the urinary metabolomics of 34 patients with celiac disease and 34 healthy controls, patients with celiac disease had a significantly lower levels of mannitol, glutamate, glutamine and pyrimidines, and higher levels of indoxyl sulfate, choline, glycine, acetoacetate, uracil, meta-hydroxyphenyl propionic acid, and phenylacetylglycine. This metabolomic signature is consistent with the hypothesis of small bowel dysbiosis in these patients^[38]. A further study hypothesized that the metabolomic signature of patients with potential celiac disease, defined as patients with the immunological abnormalities of celiac disease who lack jejunal biopsy findings consistent with their disease, is similar to those with overt celiac disease. Surprisingly, although these patients shared similar metabolomic profile in their serum, no clear joined signature was found in their urine, suggesting that defective small intestinal histology is needed for the development of a urinary metabolomic fingerprint of celiac disease^[39].

Studies on the urinary metabolomics of other GI diseases are limited. An animal study has shown the value of urinary metabolomics in the assessment of NSAIDs induced GI ulcer. Based on this study, a panel of urinary metabolites including 2-oxoglutarate, acetate, taurine and hippurate were significant biomarkers for the gastric damage induced by indomethacin in rats and could successfully predict the degree of GI damage, suggesting that NSAIDs induced gastric damage can be possibly screened in the preclinical stages by using urinary metabolomics^[40].

CONCLUSION

Urinary metabolomics studies show altered signature

in patients with GI disorders compared to healthy controls. The body of literature in this area has majorly focused on IBD and GI cancers. What is shared in all of these disorders is the alteration of urinary metabolites which are in association with GI microbiota and possibly dysbiosis in these chronic conditions. In addition, in cancer patients, the metabolomes which define cell proliferation and differentiation are altered. In IBD, differentiating UC and CD based on urinary metabolomic profile does not look simple at this stage, since confounders such as the clinical severity of the disease and medications may interfere with the metabolism in the body and the metabolomics profile of these patients. The most important use of urinary metabolomics in GI cancer is for early detection of pre-cancerous lesions. Whether the metabolomics signature in patients with pre-cancerous lesions such as Barrett's esophagus and colon polyps can predict the future outcome, *i.e.*, the possible chance of progressing to cancer is still under debate. Predicting the outcome of the diseases in response to medical or surgical therapies is also important in this area. In conclusion, although literature supports the role of urinary metabolomics in the diagnosis of some GI conditions, the fingerprints of these diseases are not unique and usually have overlaps.

LIMITATIONS OF URINARY METABOLOMICS IN GI DISORDERS

In 2009, Scalbert *et al.*^[41] extensively reviewed the limitations of mass-spectrometry-based metabolomics studies. Confounding effects of the diet, large Inter- and intra-individual variations, variations induced by sample collection, handling and storage and inconsistency in data extraction, interpretation and analytical methods were proposed as the major limitations of metabolomics studies. These limitations still affect the metabolomics studies. Moreover, the technology used for the measurement of metabolomics has limitations. For example, NMR is able to measure approximately 8% and gas chromatography MS is able to measure approximately 7% of the human urine metabolomes^[41]. For the urinary metabolomics, effects of the kidney function as well as the metabolic function of the body which may affect secretion and reabsorption of the circulating metabolites may confound the final results^[42].

FUTURE DIRECTION

Both organic and functional GI disorders usually lack well-defined noninvasive biomarkers which can help us with the diagnosis, treatment and the prediction of their outcome. In functional disorders like irritable bowel syndrome, the diagnosis is not usually definite and is based on exclusion. Moreover, the diagnosis of organic GI disorders usually relies on invasive techniques. Although, the urinary metabolomics signature shows alterations in different GI conditions compared to healthy subjects,

no unique signature has been yet defined. IBD, GI cancers and celiac disease have all shown alterations in the urinary metabolomics which are associated with possible GI dysbiosis, but to our knowledge, no study has systematically evaluated the GI microbiota profile concurrently. Studies on the urinary metabolomics profile of GI diseases have not usually considered confounding factors and the ways of analysis which have been used in these studies are not similar and sometimes cause different results in a single disease setting. Future studies should focus on the validation of the methods and should enhance our knowledge of metabolomic profiles which are in association with different metabolic pathways. The same as breath testing for helicobacter pylori and small bowel bacterial overgrowth, future urinary metabolomics studies may focus on metabolomic profiles induced through the consumption of labeled specific agents. Metabolomics of volatile vs non-volatile compounds is also an important area which should be considered. In addition, the effects of urinary diseases on GI system and microbiota as what has been recently observed in patients with chronic kidney diseases^[42] should be taken into account when interpreting urinary metabolomics studies.

Abstract

There are numerous factors which can affect the lymph node (LN) yield in colon cancer specimens. The aim of this paper was to identify both modifiable and non-modifiable factors that have been demonstrated to

affect colonic resection specimen LN yield and to summarise the pertinent literature on these topics. A literature review of PubMed was performed to identify the potential factors which may influence the LN yield in colon cancer resection specimens. The terms used for the search were: LN, lymphadenectomy, LN yield, LN harvest, LN number, colon cancer and colorectal cancer. Both non-modifiable and modifiable factors were identified. The review identified fifteen non-surgical factors: (13 non-modifiable, 2 modifiable) which may influence LN yield. LN yield is frequently reduced in older, obese patients and those with male sex and increased in patients with right sided, large, and poorly differentiated tumours. Patient ethnicity and lower socioeconomic class may negatively influence LN yield. Pre-operative tumour tattooing appears to increase LN yield. There are many factors that potentially influence the LN yield, although the strength of the association between the two varies greatly. Perfecting oncological resection and pathological analysis remain the cornerstones to achieving good quality and quantity LN yields in patients with colon cancer.

Core tip: Surgeons, pathologists and patients alike must appreciate that there are many factors which influence lymph node (LN) yield in resected colon cancer specimens. Clinicians must strive for the perfect oncological operation and pathological analysis. However, clinicians should be aware that despite optimal surgery and pathological analysis, other factors may influence the LN yield following colonic resection for cancer.

INTRODUCTION

The American Joint Committee on Cancer/Union Internationale Contre le Cancer utilises the TNM system to stage colon cancer. The stage of disease is dependent on the depth of penetration into the intestinal wall (T1-T4), the presence of localized lymph node (LN) metastases (N0-N2) and the presence of distant metastases (M0-M1). This system potentially lends itself to “understaging” of disease since accurate staging is closely linked to both adequate and high quality LN evaluation. Indeed, numerous studies have demonstrated an association between the number of LNs examined and patient survival, with the consistent finding that an increased number of evaluated LNs leads to improved survival^[1-9]. Furthermore, the decision to administer adjuvant chemotherapy is highly dependent on the presence or absence of LN metastases: When present, patients are classified as stage III and typically receive chemotherapy while those with stage II disease and no adverse features routinely undergo surveillance only.

The “gold” standard of at least a 12 LN examination following resection for colon cancer was initially proposed in 1990^[10]. The National Institute of Clinical Excellence suggested that when more nodes are examined the tumour is significantly more likely to be classified as node positive. Conversely, when few nodes are examined, there is a substantial risk of understaging^[11]. This standard has now been adopted in multiple guidelines for both colon and rectal cancer resection specimen analysis^[12-14]. More recently, the analysis of ≥ 12 LNs has been adopted as a standard quality indicator for colorectal resection specimens in the United States by the National Quality Forum^[13,15], the National Comprehensive Cancer Network (NCCN), the American Association of Clinical Oncology and the American College of Surgeons^[16-18]. However, the literature is variable on the subject with some groups suggesting that a harvest of 9 LNs is sufficient to stage node negative tumours^[19], others agreeing that harvesting more than 12 LNs is adequate for staging colon cancer^[4,6,20] and others still suggesting that there is no clear cut-off value and that as many LNs as possible should be harvested and analysed^[2,8].

Irrespective of the agreed and accepted LN cut-off, it should be appreciated that multiple factors may be influence nodal yield. Undoubtedly, surgical technique and pathological analysis are the cornerstones for adequate LN examination, however other, principally patient factors may be of relevance and lead to reduced LN yield despite optimal surgery and specimen analysis. This study aimed to review both modifiable and non-modifiable non-surgical factors that have been shown to influence colonic resection specimen LN yield and to summarise the pertinent published literature.

LITERATURE REVIEW

A literature review of PubMed for the period 1991-2015 was performed to identify the potential factors which may influence the LN yield in colon cancer resection specimens. The terms used for the search were: LN, lymphadenectomy, LN yield, LN harvest, LN number, colon cancer and colorectal cancer. Both non-modifiable and modifiable factors were identified (Table 1) and the individual papers reviewed. Further relevant publications were identified by cross reference of the reviewed papers.

NON-MODIFIABLE FACTORS

Ethnicity

There have been a number of studies which have assessed the influence of ethnicity on LN yield. The rationale as to why ethnicity would potentially affect the LN yield remains unclear.

In a large study Cone *et al.*^[21] interrogated the Surveillance Epidemiology and End Results (SEER)-Medicare database in the United States, evaluating all colonic cancer resections between the years 2000 and 2003. Their analysis included nearly 33000 patients, 62.5% of whom had less than 12 LNs in the resected specimen. Multivariate analysis showed that Hispanics were less likely than Caucasian patients to have ≥ 12 LNs resected (OR = 0.61, 95%CI: 0.5-0.74). Hispanic patients were younger (although all patients in the analyses were older than 65 years), lived in more populated areas and had a lower income status than their Caucasian counterparts. The reduced LN yield did not confer a negative outcome with no significant difference in survival between the groups.

Other smaller single institution studies such as that by Valsecchi *et al.*^[22] failed to show an association between LN yield and ethnicity.

Age

Numerous studies have assessed the influence of patient age on LN yield in resected colon cancer, the hypothesis being that younger patients are more likely to have a more aggressive oncological procedure, or conversely that older patients frequently undergo less aggressive lymphadenectomy. A national United Kingdom study from 2006 reported that increasing age was associated with a significant reduction in the number of harvested LNs ($P < 0.001$)^[23]. Moreover, for every 10 years increase in age in their cohort, there was an associated reduction in LN harvest by 0.9 nodes (95%CI: 0.7-1.1). The authors also noted that as the patient age increased there was also a significant increase in variability of LN harvest between the 79 participating centres ($P < 0.001$), which included both peripheral and tertiary referral centres. These findings were felt most likely to be due to a wider lymphadenectomy being performed in younger, medically fitter (and elective) patients as opposed to older patients with co-morbidities. An alternative

hypothesis is that LNs undergo a process of involution with increasing age^[23].

Stocchi *et al*^[24], in their study from the Cleveland Clinic, Ohio, also reported an association in 901 patients with stage II colon cancer between increasing age and fewer examined LNs ($P < 0.001$)^[24]. Patients younger than 65 years had a mean of 35.1 (range 15-44) nodes examined compared to a mean of 22.2 (range 12-28) nodes in patients older than 65 years.

Another population-based study by Chou *et al*^[15] analysed 127927 patients who underwent resection for stages I - III colon cancer between 1994 and 2005 in the United States. Of note, in 4.6% of patients, no regional LNs were examined and thus, these individual patients were not staged. Once again, age was shown to be a consistently important determinant of LN yield and for every 10-year incremental increase in patient age, there was an associated average reduction of 9% in the number of harvested LNs ($P < 0.01$). It should be noted that over the timeframe of the study, there was not only an increase in the average LN yield, but also a decrease in the mean age at diagnosis for patients with colon cancer - from 70.3 years in 1994 to 68.8 years in 2005. The rationale for this significant association between age and LN yield in this paper was thought to be as a result of a "complex interplay of patient and surgeon factors". The authors explained this by hypothesising that older patients are likely to be considered higher-risk operative candidates and thus a suboptimal surgical dissection (with resultant inadequate lymphadenectomy) may be performed with a view to reducing operative time. Nathan and colleagues also interrogated the SEER database for patients operated with curative intent for stage I - III colon cancer between 1998 and 2005^[25]. In the 27101 patients analysed, increasing patient age was again significantly associated with a decreased LN yield ($P < 0.001$). Finally, Baxter *et al*^[26] also interrogated the SEER database, specifically focusing on patient who had undergone colonic resection for pT3 lesions. They identified 11044 patients and once again were able to show that older patients had fewer LNs examined ($P < 0.001$). Several other studies have mirrored these

findings^[22,27-34], however, 2 smaller studies of 341 and 223 patients respectively, failed to demonstrate an association between colonic LN yield and patient age^[35,36].

Overall, it appears that increased patient age significantly influences LN yield in colon cancer.

Patient gender

A number of studies have shown a significant association between male sex and reduced LN yield^[25,28,36]. The largest of these included over three hundred thousand patients in a United States population based study analysing factors influencing LN yield in patients with gastrointestinal cancer^[28]. The reasons underlying this association are poorly understood. Dubecz *et al*^[28] suggested that men are more likely to be uninsured and thus may be less likely to receive "state-of-the-art" treatment which might include adequate lymphadenectomy as performed in a high-volume colorectal centre.

Socioeconomic class

It has been suggested that patients with lower socioeconomic class may be less likely to be treated in specialised centres and to receive the most up to date management with the result that their LN yield following resection for colon cancer is lower. A population-based analysis of all patients with gastrointestinal (GI) adenocarcinomas treated surgically in the United States between 1998 and 2009 ($n = 326243$) was performed by Dubecz *et al*^[28]. They aimed to evaluate time trends in lymphadenectomy for GI cancer and to identify factors associated with inadequate LN yield. Adequate lymphadenectomy was defined by the NCCN recommendations as a LN yield of > 12 in colon and rectal cancer. Throughout the study period it was found that the LN yield increased over time for all of the sub classifications of GI cancer. The median number of LNs retrieved for colon cancer increased from 9 in 1998 to 16 in 2009. However, only 49% of patients with a GI adenocarcinoma diagnosis underwent adequate lymphadenectomy. The rate of adequate evaluation was higher in colon cancer (77%) than in rectal cancer (42%). Patients living in areas with higher poverty rates were more likely to undergo inadequate lymphadenectomy. The socioeconomic data was based on county of residence which was linked to United States Census data. The first quartile, Q1 (most well off), had an adequate lymphadenectomy in 49% of cases, Q2 in 51% adequate while Q3 and Q4 (least well off) had adequate lymphadenectomy in 47% of cases. Patients of lower socioeconomic class were most likely to have an inadequate lymphadenectomy with the authors postulating that this finding most likely reflected a high proportion of uninsured patients who may be less likely to receive state of the art treatment. In a separate study, Rajput *et al*^[29], also showed that insurance status was associated with LN yield across patients identified from the NCCN and SEER databases. On multivariate analysis, patients with Medicare and Medicaid plans had lower yields than patients covered by commercial plans ($P = 0.007$). The authors' belief was that this finding

was secondary to the age profile of the patients, with those in the Medicare population tending to be older than those with private insurance coupled with a demonstrable decrease in LN yield with increasing age across all patients in the study.

In summary, lower SE status may be associated with reduced LN yield following resection for colon cancer, however there are multiple factors that may underlie this association.

Tumour location

There is consistent evidence that the location within the colon of the primary is strongly associated with the number of LN examined by the pathologist, with the length of the specimen often implicated as the causative factor. Stocchi *et al*^[24] reported that a 12 LN harvest was more likely with right sided as opposed to left sided carcinomas (85% vs 72%, $P < 0.001$). Similarly, in the study from Baxter *et al*^[26], patients with a left sided colon cancer (and rectal cancer) were less likely to have an adequate LN evaluation compared with patients with right sided lesions. In a separate study, Wright *et al*^[37] reported a median number of 12 LNs for right sided cancer and 9 LNs for left sided colonic tumours. Chou *et al*^[15] also reported a similar trend: In a sub-analysis of right and left sided colon cancers, tumours located in the ascending colon and hepatic flexure had, on average, 34% more LNs retrieved than those in the sigmoid and rectosigmoid. However, the authors acknowledged that the SEER data on which their study was based did not record the length of the resected specimen and speculated that the observed differences in LN yield may in fact be due to longer specimen lengths following right sided resection. The association between specimen length and LN yield has been repeatedly demonstrated. Stocchi *et al*^[24] showed that specimens less than 30 cm in length had a median LN harvest of 17 nodes whereas those longer than 30 cm had a median harvest of 24 nodes ($P < 0.001$)^[24]. Shen *et al*^[31] also reported variability in LN yield depending on both tumour site and specimen length. They studied 365 resected colon cancers and demonstrated an increased LN yield of 17.8 for caecal and ascending colon lesions vs 14.3 for sigmoid lesions ($P < 0.01$). Descending colon lesions were associated with the longest specimens at 29.2 cm and there was a clear association between the length of the specimen and LN yield, with an average of 11 LNs in specimens of 10 cm or less in length compared with 18.3 LNs when the specimens were over 30 cm in length. Numerous studies have shown similar patterns of decreased LN yield for left-sided vs right-sided colonic cancer^[22,27,29,33,34,38-40]. Two smaller studies, analysing 137 and 48 colon specimens respectively, failed to show an association between LN yield and primary tumour site^[41,42].

In summary, the published literature supports the hypothesis that tumour location influences LN yield in colon cancer.

Tumour size

It has previously been proposed that larger tumours elicit an intense antigenic response within the surrounding regional LN basin. This "response" may potentially make them more visible to pathologic examination and may thus lead to an increased LN yield^[37]. In a study by Chou *et al*^[15], for every 1 cm increase in tumour size, there was a corresponding average 2% increase in the number of examined LNs in colon cancer specimens. Tumour size was also shown to be a significant predictor of LN yield in univariate analysis in a study by Valsecchi *et al*^[22] ($P < 0.01$). There have been 2 recent studies from the Memorial Sloan Kettering group, both reporting a strong association between tumour size and the nodal yield^[27,43]. In the first study, tumour size of 4 cm or less resulted in a mean nodal harvest of 19.7 as compared to a mean nodal harvest of 23.3 when the tumour measured over 4 cm ($P = 0.02$)^[27]. In the second and more recent study, analysis of 256 colectomy specimens demonstrated a linear relationship between tumour size and LN yield ($P < 0.0001$)^[43]. Søreide *et al*^[39] also showed that LN harvest is related to tumour size. Tumours greater than 5 cm had adequate LN yield in 50% of cases, compared to 24%, when tumour size were less than 5 cm.

Colon cancer histological subtype and tumour differentiation

Tekkis *et al*^[23], in a study including more than 5000 patients, showed that the tumour differentiation was one of eight factors which had a significant influence on the number of LNs examined. Poorly differentiated tumours had significantly increased LN yield when compared to well or moderately differentiated lesions. In the same study, the tumour subtype was not shown to significantly influence nodal yield.

A number of other studies have reported an association between tumour differentiation subtype and LN yield, with the consensus being that the more poorly differentiated the tumour the greater the LN yield compared to well differentiated lesions^[25,27,35,37].

ASA grade

The evidence to support an association between American Society of Anesthesiologists (ASA) grade and LN yield is limited. The rationale behind linking ASA grade and LN yield is similar to that for increasing age. Patients with higher ASA are often older and may undergo emergent surgery, which may lead to less radical dissection in order to complete the operation in a timelier manner. A national United Kingdom study published in 2004^[23] did show that patients with higher ASA grade were less likely to have adequate LN harvesting when compared to patients with lower ASA grades: ASA III vs I ($P < 0.001$) and ASA IV-V vs I ($P = 0.036$).

LN positivity

The available literature shows conflicting findings with respect to the influence of LN positivity on LN yield. Any

association, positive or otherwise, should be interpreted with some caution due to the potential for underlying bias. An association between increased LN yield and nodal positivity, as shown by Tekkis *et al.*^[23] for example, may simply reflect a more comprehensive search for nodes. On the other hand, a finding of multiple involved nodes may lead to a less thorough search for further nodes leading to a lower overall nodal yield. In a study by Nash *et al.*^[27], no correlation was demonstrable between the total number of LNs examined and the number of LNs with metastatic disease ($P = 0.32$). However, there was a trend towards finding one fewer LN in each specimen for every 2 metastatic LNs.

Lymphovascular invasion

Lymphovascular invasion (LVI) is a surrogate marker for tumour aggressiveness and is associated with a poorer outcome. The limited available data shows no association between LVI and LN yield. Gelos *et al.*^[35] performed a retrospective analysis of 341 patients who underwent colorectal cancer resection with curative intent between 2000 and 2005 and investigated the impact of a number of factors including LVI on LN yield. There was a median of 15.17 LNs retrieved per patient, with 82.8% of the 341 patients having a LN harvest greater than 12, however the presence of LVI did not influence tumour LN yield. In another smaller study (48 patients) with a mean LN count of 14.1, no statistically significant relationship existed between the number of LNs and the presence of LVI ($P = 0.64$)^[42].

Microsatellite instability

An association between LN yield and microsatellite instability (MSI) has been put forward by a number of authors. MSI tumours are considered less aggressive than their microsatellite stable (MSS) counterparts and may demonstrate an enhanced host inflammatory reaction^[44-47].

An association between a high rate of MSI and a high total LN count in colorectal cancer has been demonstrated in a number of small studies. Higher LN retrieval may in part explain the improved survival seen in patients with MSI. Søreide *et al.*^[39] studied 121 patients under the age of 75 with the aim of determining whether proximal tumour location and MSI improved LN yield. One thousand two hundred (1200) LNs were retrieved from 121 patients and of these, 96 were positive (0.8%). Median LN harvest was 10 and only 36% of patients had an adequate harvest (*i.e.*, 12 or more LN). MSI was found in 33 out of the 121 patients (27%) and this was associated with a greater median LN yield of 12 vs 9 in the MSS group. Fifty-four percent of patients with MSI had adequate LN harvest vs 29% in the MSS group and 36% in the study as a whole [OR = 2.9 (1.3-6.5), $P = 0.011$]^[39].

Eveno *et al.*^[48] reported a smaller series of 82 patients with stages I and II colon cancer and also showed a significantly increased LN yield in the MSI group (mean 23.6 vs 13.7 LN).

A separate study investigated the association between MSI and LN yield but did not show a significant association^[49]. Of 168 patients with stage III colon cancer the mean total LN yield for MSI and MSS tumours was 15.9 and 16.9 respectively ($P = 0.664$). The authors concluded that increased survival in the MSI group ($P = 0.026$) could not be explained by differences in LN yield.

Body mass index

Studies performed in patients with gastric and rectal cancers have shown an association between obesity and reduced LN yield^[50,51]. Damadi *et al.*^[52] retrospectively reviewed 191 patients who underwent a resection for colon cancer between 1999-2006. They hypothesized that obese patients with a body mass index (BMI) > 30 kg/m² would have a smaller yield of LNs compared to non-obese patients with a BMI < 30 kg/m², however they found no significant difference between the groups (mean LN yield 12.7 in obese vs 12.4 in non-obese, $P > 0.2$).

Linebarger *et al.*^[53] performed a retrospective review of 401 patients, and stratified them into six groups based on BMI: Underweight (< 18.5 kg/m²), normal (18.5-24.9 kg/m²), overweight (25-29.9 kg/m²), stage I obesity (30-34.9 kg/m²), stage II obesity (35-39.9 kg/m²) and stage III obesity (> 40 kg/m²). They found no significant difference in the number of LNs harvested for each of the groups.

Kuo *et al.*^[54] retrospectively analysed 645 patients with stage III colon cancer from Taiwan who underwent colectomy. Patients were again placed into four groups based on their BMI: Obese (BMI > 27 kg/m²), overweight (BMI 24-27 kg/m²), normal (BMI 18.5-24 kg/m²) and underweight (BMI < 18.5 kg/m²). The mean BMI of the patients in the study was 23 kg/m². The authors showed a significantly increased mean LN yield in the underweight patient group (28.1 vs 23 in the normal BMI group, 19.5 in the overweight group and 19.8 in obese patient group respectively). A 2010 study analysed a cohort of 718 NCCN patients with stage I-III colon cancer and found three factors were associated with not meeting the quality standard of a 12 LN evaluation: Left-sided tumours, stage I disease and a BMI > 30 kg/m²^[28].

The impact of BMI on LN yield is overall unclear, with some studies pointing to a reduced in patients with a higher BMI.

MODIFIABLE FACTORS

Tumour tattooing

Endoscopic tattooing is frequently performed in order to facilitate tumour localisation during laparoscopic resection. Tumour tattooing may inadvertently map the sentinel node and associated draining nodes and thus make them more readily identifiable for pathological evaluation. A retrospective case controlled trial conducted between 2005 and 2009 aimed to determine if colonoscopic tumour tattooing could be utilised to increase staging accuracy by increasing the LN yield^[55]. The

authors assessed two groups of patients: The first group contained a series of 95 consecutively tattooed patients and the second group a series of 210 non-tattooed patients. All patients underwent surgery for colorectal cancer within the same time period. There was a higher LN yield in patients with pre-operative tattooing compared to the non-tattooed control group (median LN yield of 15 vs 12 nodes, $P = 0.014$). Multivariate analysis showed that the presence of carbon-containing LNs (with a detection rate of 71%) was an independent predictor for an increased LN yield ($P = 0.002$), although the reason for the lack of a predictive characteristic for the group in which tattooing did not result in carbon containing LNs was not clear.

The potential role of preoperative tattooing was also reported by Nash *et al.*^[27]. Their study was designed to develop a predictive model of LN yield in colon cancer. One hundred and fifty-two specimens from patients who had undergone resection for colon cancer were used, with detailed anatomical and surgical technique documentation on each specimen. A linear regression analysis was performed and this identified both predictors and confounders of the quantity of the LN harvest. Of the 15 variables analysed, it was found that tumour size, tumour location, number of resected pedicles and use of pre-operative tattoo had significant linear/quadratic relationships on the LN yield. When controlling for the 14 other variables, patients who underwent endoscopic tattooing had 3.1 more LNs harvested. This data further suggests that endoscopic tattooing may be used pre-operatively to maximise LN yield and increase the accuracy of disease staging. The authors acknowledged that as they did not record the proportion of LNs which harboured grossly apparent dye at the time of LN identification, they could not make a definitive conclusion as to the mechanism by which preoperative colonic cancer tattooing might increase LN yield Dawson *et al.*^[56] also hypothesised that pre-operative tattooing with India ink might increase the subsequent LN yield from the resected specimens. Their retrospective study included 174 patients who underwent surgery for colon cancer between 2006 and 2009. Sixty-two patients had pre-operative tattooing. The mean number of LNs harvested in the tattooed group was 23 compared to 19 in the non-tattooed group ($P = 0.03$). In the tattooed colon cancer group a 12 LN minimum was achieved in 87.1% patients vs 72.3% in the non-tattooed group. These results were mirrored in a separate analysis, within the same study, of 35 patients with rectal cancer. Once again, the results from this study suggest the routine utilisation of pre-operative colonoscopic tattooing may increase the LN yield in resected colonic malignancy.

Neoadjuvant chemotherapy

The role of neoadjuvant therapy in the setting of colon cancer remains in evolution. Data from studies performed in patients with rectal cancer has shown that neoadjuvant therapy may result in a decreased LN yield, however

this is in the context of both radiotherapy and chemotherapy. The initial data from the United Kingdom based FOxTROT trial reported on 150 patients in 35 centres^[57]. All patients had either T3 (with > 5 mm invasion into the muscularis propria) or T4 colon tumours and were randomised to either preoperative and postoperative chemotherapy or standard postoperative chemotherapy alone (2:1 randomisation). Overall, the authors reported that preoperative chemotherapy was a viable option with acceptable toxicity in this cohort. When the LN data were examined, 85 of 98 patients (87%) and 43 of 50 patients (86%) had 12 or more LNs examined in the combined preoperative and postoperative chemotherapy and postoperative chemotherapy groups respectively. Indeed, 46% and 54% of patients in both groups had greater than 20 LNs examined with median values of 21 and 22 nodes respectively ($P = 0.2$). The apical node was positive in 1 of 98 patients in the combined group (1%) and 10 of 50 patients in the postoperative chemotherapy only group (20%). Thus, in this study neoadjuvant chemotherapy did not result in a lower LN yield however more data is needed before definitive conclusions can be made.

CONCLUSION

There are many factors that can potentially influence the LN yield following resection for colon cancer and the relationship between these factors remains poorly understood. High quality oncological surgery and pathological analysis are the most important factors in ensuring optimal LN yield. However, the current review has highlighted a number of additional modifiable and non-modifiable factors that may also influence the number of LNs harvested. Older age, obesity, and male sex may be associated with reduced LN yield. Similarly, studies have shown an association between ethnicity and lower socioeconomic class and reduced LN harvest. Rather than being true associations, however, it is likely that these findings reflect, at least in part, external modifiable factors such as the surgeon's attitude to older patients undergoing surgery or the quality of care received by patients in lower SE groups. LN yield appears to be increased in patients with right-sided cancer, bulky tumours, or poor tumour differentiation. Again, these associations may reflect other factors known to influence nodal yield such as the length of the resection specimen. Nonetheless, these variables should be taken into consideration when evaluating the completeness of the LN harvest for individual patients.

Abstract

AIM: To evaluate impact of radiation therapy dose escalation through intensity modulated radiation therapy with simultaneous integrated boost (IMRT-SIB).

METHODS: We retrospectively reviewed the patients who underwent four-dimensional-based IMRT-SIB-based neoadjuvant chemoradiation protocol. During the concurrent chemoradiation therapy, radiation therapy was through IMRT-SIB delivered in 28 consecutive daily fractions with total radiation doses of 56 Gy to tumor and 5040 Gy dose-painted to clinical tumor volume, with a regimen at the discretion of the treating medical oncologist. This was followed by surgical tumor resection. We analyzed pathological completion response (pCR) rates its relationship with overall survival and event-free

survival.

RESULTS: Seventeen patients underwent dose escalation with the IMRT-SIB protocol between 2007 and 2014 and their records were available for analysis. Among the IMRT-SIB-treated patients, the toxicity appeared mild, the most common side effects were grade 1-3 esophagitis (46%) and pneumonitis (11.7%). There were no cardiac events. The R0 resection rate was 94% ($n = 16$), the pCR rate was 47% ($n = 8$), and the postoperative morbidity was zero. There was one mediastinal failure found, one patient had local failure at the anastomosis site, and the majority of failures were distant in the lung or bone. The 3-year disease-free survival and overall survival rates were 41% ($n = 7$) and 53% ($n = 9$), respectively.

CONCLUSION: The dose escalation through IMRT-SIB in the chemoradiation regimen seems responsible for down-staging the distal esophageal with well-tolerated complications.

Key words: Intensity modulated radiation therapy; Esophageal adenocarcinoma; Simultaneous integrated boost; Neoadjuvant chemoradiation; Dose escalation; Resection rate

Core tip: There are more data supporting neoadjuvant chemoradiation for locally advanced esophageal cancer. The best regimen of neoadjuvant chemoradiation remains to be defined, current available data using three-dimensional vs intensity modulated radiation therapy deliver modest dose to downstage the tumor. In this report, we reviewed our experience using dose escalation technique to Gross Tumor Volume with compromising dose to organ at risk, the high R0 resection rate results suggest the feasibility of using this approach for future prospective study.

INTRODUCTION

Distal esophageal cancer is a commonly lethal malignancy, with the annual death rate in the United States about 15590^[1]. Most single-modality treatment regimens provide poor cure rate. For example, surgical treatment alone has a 5-year survival of approximately 15% to 20%^[2,3]. Radiation therapy alone for resectable highly selected squamous cell cancer results in a 5-year survival

rate of approximately 34%^[4]. In recent decades, more data have emerged for locally regional esophageal cancer management. There are reports that suggest triple-modality treatment regimens provide better local control, better control of distant metastases, and better overall survival^[5]. Meta-analysis showed a survival benefit for patients treated with preoperative chemoradiotherapy (CRT) compared with surgery alone^[6]. We have been using triple-modality approach for locally advanced distal esophageal cancer. Although the results from CROSS studies demonstrated the triple-modality approach to be well-tolerated with survival benefit, the absolute benefit for adenocarcinoma remains small and the survival benefit for adenocarcinoma is not statistically significant^[7], with a 17% pathological complete response (pCR). There is clear evidence correlating pCR and better local control with improved survival^[8]. However, there are few reports regarding the role of radiation dose variation in triple-modality therapy. Understanding dose change and its impact on tumor response provides insight into the effectiveness of the combined treatment and may lead to improved survival. Therefore, we analyzed our experience with dose escalation through the intensity modulated radiation therapy with simultaneous integrated boost (IMRT-SIB) technique, with emphasis on the relationship of the site of pCR to the radiation dose escalation delivered to the gross tumor volume.

MATERIALS AND METHODS

Our Institutional Review Board approved this study. The patients included in this study were treated at our institution for locally advanced esophageal cancer between January 2007 and December 2014. The inclusion criteria were pathologically confirmed adenocarcinoma and no past or current history of malignancy or radiation treatment in the chest or abdomen. Written informed consent was obtained from all patients before starting treatment. All patients underwent staging and those with no distant disease and medically operable patients received neoadjuvant CRT for 5-6 wk. The resectable disease included stage cT1N1M0 or cT2-3N0-1M0 (Table 1)^[9].

Pretreatment staging included elaborate history taking, physical examination, routine blood studies, pulmonary function tests, an upper gastrointestinal endoscopy with biopsies, and computed tomography (CT) of chest, abdomen and neck. Endoscopic ultrasound was used routinely for staging of esophageal tumors if technically possible. All patients in this analysis underwent positron emission tomographic (PET) scanning as part of staging to better define gross tumor volume.

All treatment began with concurrent chemoradiation. Chemotherapy consisted of five cycles of concurrent platin-based weekly chemotherapy or 5-fluorouracil (5-FU)-based daily chemotherapy. The platin-based chemotherapy was given at a dose of 40-100 mg/m², starting on days 1, 8, 15, 22 and 29. The 5-FU-based chemotherapy was either continuous infusion CIV 5-FU (225 mg/m²) or oral capecitabine (capecitabine,

The radiation therapy could be delivered through four-dimensional (4D) plus IMRT with SIB. All patients who received radiation therapy started with CT-based 4D treatment simulations. The simulation was performed with the patient in the supine position using immobilization with the patient's arms over the head. The 4D simulations were performed if respiratory gating was feasible, otherwise, free-breathing 3D CT acquisition data would be obtained during simulation, the patients then were excluded from the IMRT-SIB protocol. All treatment planning in this series was performed by the same radiation oncologist. During the treatment planning, two target volumes were drawn gross tumor volume and clinical target volume, PET/CT imaging obtained within 1-3 wk prior to simulation data. Patients who did not have PET/CT data were excluded from the IMRT-SIB protocol. Clinical target volume and the clinical internal target volume reflected the microscopic sites of highest risk. The treatment planning target volume (PTV) for clinical target volume is about 5 mm beyond clinical target volume; the clinical target volume was contoured based on the Radiation Therapy Oncology Group consensus study protocol^[10]. The treatment PTV for gross tumor volume had no margins.

There are total 17 patients received SIB technique and included in this study, after resection the postoperative T stages of the analyzed tumors were as follows: ypT0 (n = 8, 47%); ypT1 (n = 4, 23.5%); ypT2 (n = 3, 17.6%); ypT3 (n = 2, 11.7%). Nodal disease was confirmed in three patients (17.6%) by pathological staging and the median number of assessed lymph nodes was 13 (range 3-27) (Table 2). There were five pulmonary complications (29%), one cardiac complication (5.8%), and six surgical

complications (35%). There were no treatment-related or operative deaths (Table 3).

The time required to finish radiation treatment ranged from 28-35 d. Clinical tumor volume (CTV) represents the conventional dose coverage, 5040 in 28 fractions and PET-positive alone target area will receive SIB to 5600 in 28 fractions, which is labeled as gross tumor volume (Figure 1). The PTV of 180 cGy per fraction provided a proximal and distal margin of 5 cm and a radial margin of 7 mm around the CTV volume except to the heart with approximately 3-5 mm margins. The average beam number was 6.3 (range, 5-9). All organs at risk met their dose constraints. The daily prescription dose of 2 Gy was specified at the International Commission on Radiation Units and Measurement reference point, and at least the 95% isodose had to encompass the entire PTV. The maximum dose to the PTV was not to exceed the prescription dose by 7%. Tissue density inhomogeneity correction was used. The 4D plan using respiratory gating technique applied to all patients.

Patients were followed routinely after finishing neoadjuvant chemoradiation. Surgical resection was performed between 6-8 wk after completion of CRT. The operative technique consisted of a transthoracic approach with a two-field lymph node dissection or a transhiatal approach, depending on tumor localization. A wide local excision of the N1 lymph nodes, including standard excision of the celiac nodes, was carried out in both techniques. Continuity of the digestive tract was restored by gastric tube reconstruction or colonic interposition procedure with cervical anastomosis.

For grading of the therapy response, the degree of histomorphologic regression was classified into four modified categories, as described by Mandard *et al*^[11]. Surgical margins were designated in accordance with the criteria of the AJCC staging manual. All resection margins, including circumferential margins, were evaluated for vital tumor with a cutoff point of 1 mm. Margin status was confirmed by frozen and permanent sections and the close distance to the nearest millimeter between cancer cells, and the margin was measured microscopically and recorded prospectively. The operation was defined as an R0 resection if there was no microscopic tumor found at the margin and as an R1 resection if a margin was positive microscopically.

Duration of follow-up was defined as the interval between the day of completed surgery, death, or the last follow-up visit or telephone call. The Kaplan-Meier method was used to calculate survival probabilities. Survival analyses were performed using Prism Graph Pad Version 5.00 (GraphPad Software, Inc., LaJolla, CA).

RESULTS

During the study period, 57 patients underwent neoadjuvant chemoradiation therapy followed by esophagostomy. After exclusion of patients with insufficient data, those who did not meet study criteria, and those without adequate follow-up ($n = 22$), the records of 35 patients were reviewed. Of the 35, 19 patients were eligible and enrolled in the IMRT-SIB treatment protocol and two patients without histological identification of adenocarcinoma were excluded from this analysis. Thus, 17 patients completed the IMRT-SIB treatment and were included in this study. There were 15 men and 2 women and the mean postoperative follow-up was 2.5 years (range from 0.22-6.5).

All staging was performed before any treatment began. The mean age at time of diagnosis was 65 years (range, 45-76 years) and 15 patients were men. Of all patients, 88% had a uT3 tumor. A microscopically radical (R0) resection was achieved in 94% of patients. One patient had an R1 resection due to persistent dis-

ease in the gastric cardia. Total pathologic complete response ypT0No is 47%. The node-negative patient after neoadjuvant chemoRT is 82% (Table 2). Table 2 shows the pathologic staging and effects of SIB-based neoadjuvant CRT. The pathologic stages of cancer were T0, T1, T2, T3, and T4 in 8 (47%), 4 (23%), 3 (18%), 2 (12%), and 0 (0%), respectively. A comparison of clinical and pathologic stages revealed that SIB-based neoadjuvant CRT resulted in down-staging of either the T or the N status of 13 (76.5%) patients.

Hematologic toxicity from neoadjuvant chemoradiation with SIB was mild for all patients. A few patients received granulocyte-colony stimulating factor for neutropenia that did not occur during CRT. Among non-hematologic adverse effects, esophagitis ($n = 10$, 58.8%) and pneumonia ($n = 3$, 17%) was more common than pneumonitis ($n = 2$, 11%). Surgical leak was the most common surgical-related complication ($n = 4$, 23.5%) (Table 3). No survivors had symptoms due to late toxicities such as accumulated pleural or cardiac effusions during long-term follow-up. There were no treatment-related deaths.

After a minimum follow-up of 22 mo and a mean survival of 29 mo, the local recurrence rate was 11% ($n = 2$). Most patients had distant failure (35%) or combined local/regional and distant failure (5%). The majority of local recurrences were within 2 years of follow-up. In addition, the anastomosis was the only recurrence site in 5.8% of patients. There was one mediastinal relapse associated with positive nodes that was treated with a full dose of IMRT-SIB. There was no peritoneal carcinomatosis found.

For the 17 patients analyzed, nine were alive and eight had died at the end of follow-up, for a 3-year overall survival rate of 52% (Figure 2). Among the pCR, the 3-year overall survival was 75%, and compared with pathological persistent disease (pPD) the survival was 33% (Figure 2A). The 3-year disease-free survival rate for the 17 patients analyzed was 41.2%. The disease-free survival for the pCR and pPD subgroups were 63.55% and 22.2%, respectively (Figure 2B). There is no statistical significance among the overall survival analysis ($P = 0.0523$) and disease-free survival analysis ($P = 0.0897$). However, there is trend toward improved

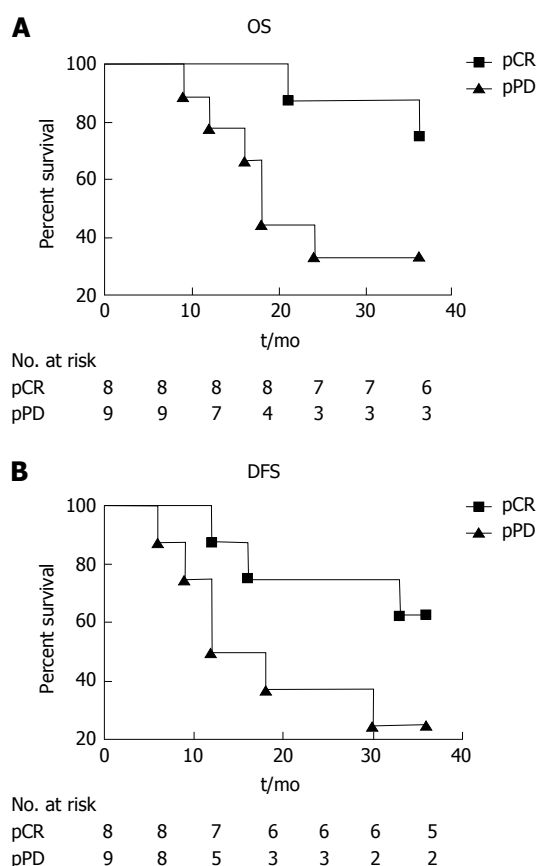

Figure 2 Kaplan-Meier survival curve. A: Overall survival for patients with pCR or without (pPD) ($P = 0.523$; $\chi^2 = 3.767$); B: Disease-free survival ($P = 0.897$; $\chi^2 = 2.879$). The disease-free survival represented from both local regional recurrences at anastomotic site, mediastinum, celiac trunk, or supraclavicular lymph nodes and distant metastases. OS: Overall survival; DFS: Disease free survival; pCR: Pathological completion response; pPD: Pathological persistent disease.

prognosis when comparing pCR vs not complete response, although this did not reach statistical significance.

In univariate survival analysis, among the various factors, post-triple modality node stages were a strong independent favorable predicting factor for survival ($P < 0.01$). Sex, the tumor size, the type of chemotherapy, the tumor location, and tumor configuration were not predicting factors for survival (Table 4).

Patients who had pCR to neoadjuvant treatment had a trend of benefit for the probability of survival compared to patients with pPD after neoadjuvant treatment. The 3-year overall survival rates were 75% vs 33% and the 3-year disease-free survival rates were 62.5% vs 22.2%, respectively. Interestingly, the analysis of histological regression after neoadjuvant showed improved survival rates if no or only rare residual tumor cells were found in the node specimen (Table 4).

DISCUSSION

Many reports show a consistent finding that response to preoperative therapy, particularly the absence of residual disease in the surgical specimen, is a good outcome indicator of better disease-free and overall survival^[8,12-14]. In a comprehensive literature review of 22 studies in

which patients with esophageal or esophagogastric junction cancer underwent esophagectomy after neoadjuvant CRT, patients with a pCR were two to three times more likely to survive than were those with residual disease in the esophagectomy specimen^[15]. These benefits translate into a 33% to 36% mean absolute survival benefit when a pCR is achieved than when it is not. These assumptions provide the rationale for intensification of preoperative treatment *via* a higher biological dose delivered to the tumor mass, without increasing the surrounding organs' risk of toxicity. The IMRT-SIB approach was based upon better radiographic findings of the biological target through PET scanning prior to CRT. This approach provides a better outline of the biological tumor within a mass, and allows RT dose intensity increase by 10% to the biological activity of tumor, without increasing the overall treatment time and the dose to the surrounding organs at risk^[16].

In the Cross study, although the improvement in overall survival is 14%, the improvement for adenocarcinoma is limited^[7]. The trend of improvement is not statistically significant. The greatest benefit was for squamous cell cancer. Few data were available on how to improve the outcome for esophageal adenocarcinoma and gastroesophageal cancers. Most reports had histology of adenocarcinoma and squamous cell cancer.

We reviewed our single-institute experience on adenocarcinoma using IMRT-SIB dose escalation technique, and found that the toxicity is low and local and that the incidence of distal recurrence is consistent with previous reports^[11,17,18]. Moreover, we found a possible association between that dose escalation with IMRT-SIB and the high pCR rate. The idea behind preoperative CRT in the treatment of esophageal and gastroesophageal junction cancer was to improve survival by reducing

locoregional failure^[13,18]. The high pCR rate through IMRT-SIB dose escalation to the tumor mass itself is a strong favorable prognostic factor for both locoregional and systemic recurrence and maybe even for overall survival^[19]. However, further studies are needed to explore the potential association between SIB-induced pCR and overall survival rate for adenocarcinoma.

The Cross study^[7] and the report by Hoepfner *et al.*^[20] used less than 4500 cGy dose protocol. In the Cross study, the low dose could explain the less favorable results for adenocarcinoma compared with squamous cell cancer histology^[7]. In the Hoepfner *et al.*^[20] report, the low-dose radiation could explain the less favorable results for neoadjuvant chemoradiation compared with perioperative chemotherapy for adenocarcinoma. At least, the suggestion of the low dose of radiation is one of factor contributed to low pCR was reported^[21]. In addition, whether predicting value of the SIB induced pCR and conventional dose resulted pCR are the same? Is there anything else be young dose response relationship between the gross tumor volume and delivered dose? Does dose escalation impact on risk of distant metastasis? More future studies need to explore above questions.

Since all cancers in the present study were in the lower distal esophagus, the radiation field was limited to the lower mediastinum and did not include in supraclavicular regions, and there were no recurrences in the supraclavicular areas. Strict dose constrains to the heart were used and no significant cardiac events were noted. Although some reports suggested that higher treatment morbidity and mortality were associated with neoadjuvant CRT^[20,22], the current cohort's patients had acceptable tolerance.

To our knowledge, ours is the first report of using IMRT-SIB with dose escalation resulting in high pCR in adenocarcinoma of esophagus. However, our study has limitations. First, this was a retrospective review that mostly consisted of the patients who were treated by a dedicated multidisciplinary team at a single institution. Selection biases from the study existed. Second, the sample size was small and only ypN was a positive predictive factor in univariate analysis; a larger size study will provide more reliable conclusions. Moreover, although we have reviewed all esophageal adenocarcinoma cases in our institute from the past 10 years, the IMRT-SIB has been implemented only recently and, as a result, the follow-up for this subgroup of patients was short. In a prospective setting, the patients could be stratified by different prognostic clinical variables in an effort to better elucidate the role of SIB dose escalation in certain patient groups.

In conclusion, the dose escalation through IMRT-SIB in the chemoradiation regimen seems responsible for the down staging of the distal esophageal or gastroesophageal junction tumors. The protocol is well-tolerated, postoperative complications were acceptable, and the complete resection rate is high. This radiation therapy dose escalation strategy warrants further

investigation.

ACKNOWLEDGMENTS

This report is in memory of Phillip D Price, MD, one of surgeons involved with the multidisciplinary pancreatic cancer committee at Zangmeister Cancer Center and Mount Carmel Health System, who passed away from malignancy. We thank Chris Tobolski for providing support for the treatment plan.

COMMENTS

Background

Improvement in resection rate is very important for advanced esophageal cancer, balance between toxicity and benefit from neoadjuvant treatment is always the focus of multidisciplinary oncology team. Neoadjuvant concurrent chemoradiation is becoming a standard of care for locally advanced esophageal cancer.

Research frontiers

The authors reported here a protocol that improved resection rate through simultaneous integrated boost (SIB) based dose escalation technique without comprising the toxicities. Few reports using this protocol.

Applications

Intensity modulated radiation therapy with SIB (IMRT-SIB) has much safe toxicity profile and less equipment restraint. This finding needs further large phase III clinical studies to confirm.

Terminology

IMRT-SIB is a novo radiation technique to deliver much higher dose to the biological gross tumor volume defined by positron emission tomographic positive area without increase radiation dose to all other area surrounding to it.

Peer-review

The authors present a retrospective analysis of an intensified regimen in neoadjuvant chemoradiation of advanced distal adenocarcinoma of the esophagus. This work is of interest for the oncology community.

TOPIC HIGHLIGHT

- 481 Colorectal cancer in the young, many questions, few answers
Deen KI, Silva H, Deen R, Chandrasinghe PC
- 489 On the road to standardization of D2 lymph node dissection in a European population of patients with gastric cancer
Yarema R, de Manzoni G, Fetsych T, Ohorchak M, Pliatsko M, Bencivenga M

REVIEW

- 498 Malignant biliary obstruction: From palliation to treatment
Boulay BR, Birg A
- 509 Genetic risks and familial associations of small bowel carcinoma
Shenoy S

ORIGINAL ARTICLE

Case Control Study

- 520 Genetic polymorphisms of *interleukin 1 β* gene and sporadic pancreatic neuroendocrine tumors susceptibility
Karakaxas D, Sioziou A, Aravantinos G, Coker A, Papanikolaou IS, Liakakos T, Dervenis C, Gazouli M

Contents

World Journal of Gastrointestinal Oncology
Volume 8 Number 6 June 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Yoshinori Marunaka, MD, PhD, Director, Head, Professor, Department of Molecular Cell Physiology, Department of Bio-Ionomics, Kyoto Prefectural University of Medicine, Kyoto 602-8566, Japan

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

At a time where the incidence of colorectal cancer, a

disease predominantly of developed nations, is showing a decline in those 50 years of age and older, data from the West is showing a rising incidence of this cancer in young individuals. Central to this has been the 75% increase in rectal cancer incidence in the last four decades. Furthermore, predictive data based on mathematical modelling indicates a 124 percent rise in the incidence of rectal cancer by the year 2030 - a statistic that calls for collective global thought and action. While predominance of colorectal cancer (CRC) is likely to be in that part of the large bowel distal to the splenic flexure, which makes flexible sigmoidoscopic examination an ideal screening tool, the cost and benefit of mass screening in young people remain unknown. In countries where the incidence of young CRC is as high as 35% to 50%, the available data do not seem to indicate that the disease in young people is one of high red meat consuming nations only. Improvement in our understanding of genetic pathways in the aetiology of CRC, chiefly of the MSI, CIN and CIMP pathway, supports the notion that up to 30% of CRC is genetic, and may reflect a familial trait or environmentally induced changes. However, a number of other germline and somatic mutations, some of which remain unidentified, may play a role in the genesis of this cancer and stand in the way of a clear understanding of CRC in the young. Clinically, a proportion of young persons with CRC die early after curative surgery, presumably from aggressive tumour biology, compared with the majority in whom survival after operation will remain unchanged for five years or greater. The challenge in the future will be to determine, by genetic fingerprinting or otherwise, those at risk of developing CRC and the determinants of survival in those who develop CRC. Ultimately, prevention and early detection, just like for those over 50 years with CRC, will determine the outcome of CRC in young persons. At present, aside from those with an established familial tendency, there is no consensus on screening young persons who may be at risk. However, increasing awareness of this cancer in the young and the established benefit of prevention in older persons, must be a message that should be communicated with medical students,

primary health care personnel and first contact doctors. The latter constitutes a formidable challenge.

Key words: Colon cancer; Young age; Rectal cancer; Colorectal cancer; Young patients; Survival; Early onset

Core tip: This review of colorectal cancer in the young focuses on new data that reveal CRC to be more a left sided cancer than previously thought and the predicted rise by the year 2030. The article outlines the genetics of colorectal cancer (CRC) and discusses limitation in current knowledge in establishing a fingerprint for sporadic CRC. Aside from diet in its aetiology, luminal alkalinity and the colonic microbiome may be contributory and require further research. The review discusses the need for increased awareness of CRC in the young and the need for global consensus on screening young people at risk.

Deen KI, Silva H, Deen R, Chandrasinghe PC. Colorectal cancer in the young, many questions, few answers. *World J Gastrointest Oncol* 2016; 8(6): 481-488 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i6/481.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i6.481>

INTRODUCTION

Colorectal cancer (CRC) is now the fourth most common cause of cancer deaths, with 600000 deaths reported worldwide annually - about 8% of all cancer deaths^[1,2]. It is the third most common cancer in men and the second most common cancer in women. The sporadic form, known to affect individuals in their fifth and sixth decades of life^[3], arises from a pre-existing polyp which progresses to cancer through the adenoma-dysplasia-carcinoma sequence; a pathological process which, in general, takes five to ten years^[4], and lends itself to prevention by screening^[5,6]. CRC is a disease of developed nations, and screening by faecal occult blood testing and colonoscopy has stemmed its incidence in those over 50 years^[6]. By contrast, CRC in the young, was a disease prevalent in the developing world^[7-14] compared with Australia, New Zealand and the West, where its prevalence in young individuals was low^[11,15,16]. However, more recently, there has been an increase in the number of reports of CRC in the young from the developed world^[17-19]. This is of concern because the incidence of rectal cancer has risen by 75% in the last 40 years^[20-22], contributing chiefly to the overall rise in cancer prevalence. Furthermore, this disease affects people in the prime of their life, and unlike cancer in older individuals, there is limited knowledge about the aetiology and pathogenesis of CRC in the young. The aim of this review is to present the current status of CRC in the young and to highlight areas for future research.

EPIDEMIOLOGY/PREVALENCE

Historically, CRC in young patients was highest in proportional prevalence from the Asian region. Studies have reported a high young cancer prevalence of 38% in Egypt^[7], 18% in Turkey^[8], 39% in India^[9], 29% in Nepal^[10], 23% from Saudi Arabia^[11], 19.7% from Sri Lanka^[12], 52% from a single institution in Pakistan^[13] and 10.1% from Taiwan^[14]. Most significantly, a recent study from the United States^[19], where the authors evaluated the records of 393241 patients over a 15-years period, revealed an overall decline in CRC by 0.92% - the effect attributed to screening. While this was true for those over 50 years old with CRC, the study observed an alarming increase in CRC in those less than 50 years, specifically, in young patients less than 35 years. Using statistical modelling, the authors predicted an increase in colon cancer by 90% in patients aged 20 to 34 years and 27.7% in those 35 to 49 years old by the year 2030. For rectal cancer, the predicted percentage increase in cancer prevalence for these two age groups was 124.2% and 46% respectively. Gender based analysis of CRC in young patients revealed an equal prevalence in young men and women^[22] contradicting the theory that female hormones are protective of colon and rectal cancer. Furthermore, a 1991 study of young patients in North America showed that the disease occurred in 34% more black men and 45% more black women compared with white Caucasian counterparts^[23]. Most young patients did not report a family history of CRC; O'Connell *et al*^[22] revealed that only 23% of young patients with CRC reported the presence of cancer in a family member.

FAMILY HISTORY

Contrary to previous knowledge, a current estimate of the proportion of CRC likely to have a major hereditary component is between 15% and 30%^[24]. The common heritable syndromes in CRC are either familial adenomatous polyposis (FAP) or hereditary non-polyposis colorectal cancer (HNPCC)^[25-27] known to be found in 2 to 5 percent of all patients with CRC. Familial adenomatous polyposis is defined by phenotype if an individual has multiple colonic polyps, usually over 100, in association with loss of the tumour suppressor gene -the adenomatous polyposis coli-APC gene-located on the long arm of chromosome 5 (5q21)^[25]. Most FAP patients will develop CRC by age 40 years, while in a minority, cancer will manifest in the fifth decade or after, due to the presence of the attenuated FAP gene. In contrast to FAP, HNPCC, first described by Henry Lynch, is characterised by the presence of fewer colonic polyps or cancer that is indistinguishable from sporadic CRC. In both conditions, which are of autosomal dominant inheritance, family history is of prime importance. For HNPCC, an affected member or members of a family should have had either CRC (Lynch type 1-site specific) or other extra-intestinal cancers (Lynch type 2), in association with

an index patient with CRC. In the absence of definitive genetic testing, a detailed family history was essential and formed the core of the Amsterdam and Bethesda criteria to make a diagnosis of HNPCC^[28,29]. Currently, we know that young patients with an underlying genetic syndrome are more likely to have a family history of cancer and present earlier compared with those with no known genetic syndrome, who presented with late stage metastatic disease^[30]. Thus, family history must continue to remain an essential component of clinical evaluation in patients with CRC, while it is essential to note that up to 20 percent of patients with a germline mutation in the study reported by Mork *et al.*^[30] had no family history of CRC.

ANATOMIC DISTRIBUTION

Several studies have reported that CRC in the young is a condition mostly confined to the left colon and rectum; in a retrospective study of young patients, Leff *et al.*^[31] revealed that 65% of cancers were in the rectum and that 83% of all colon and rectal cancers were distal to the splenic flexure. Kumar *et al.*^[32] reported that CRC was confined to the left colon and rectum in 67% of their study population. Furthermore, O'Connell *et al.*^[22] in a structured review of 55 studies comprising 6425 patients with young CRC, reported that cancer of the rectum was most frequent (54%). In the most recent publication of the Surveillance Epidemiology and End Result (SEER) study from the United States, dominance of cancer in the left colon and rectum was again mirrored^[19].

PRESENTATION

Studies have shown that CRC in young patients presents with three cardinal features of rectal bleeding, abdominal pain and alteration in bowel habit - constipation, altered stool diameter, mucoid rectal discharge^[33,34]. In general, CRC diagnosis in young patients was associated with a delay of approximately 6 mo^[33]. Physician related delay in diagnosis was chiefly because of a lack of understanding and suspicion of this disease in the young, where symptoms in young patients were considered due to such benign causes as haemorrhoidal disease by first contact physicians and patients alike. Some other factors that may contribute to delay are patients' preference in seeking non-traditional methods of symptom relief, such as Ayurvedha and Chinese medical treatment, in Asia, and because practitioners of allopathic medicine fail to perform a focused rectal examination at the point of first contact. With current worldwide reports of increasing prevalence of young CRC, it is important that we offer young symptomatic patients flexible sigmoidoscopy early, after comprehensive clinical examination, including focused digital rectal examination.

PATHOLOGY

In young patients, CRC is likely to be found in those

with a heritable syndrome^[28-30] such as FAP and HNPCC. In the Lynch Syndrome, tumours have been known to be predominant in the proximal colon^[35,36], but recent research revealed contradictory data where the most frequent site among early onset CRC patients was the distal colon^[37]. Of these, between 40 and 60 percent were in the rectum^[38,39]. In the WHO classification of tumours^[40], HNPCC and sporadic CRC with microsatellite instability have been classified based on the site and microscopic criteria. These are (1) proximally located mucinous adenocarcinomas which are commonly well circumscribed and are moderate-to-well differentiated; (2) proximally located poorly differentiated adenocarcinomas which show failure of gland formation with malignant epithelium arranged in small clusters, irregular trabeculae or large aggregates in well circumscribed tumours; and (3) adenomas in HNPCC indicating features of high cancer risk including villous and high grade intraepithelial neoplasia which display good circumscription and present as polypoid growths, plaques, bulky masses or ulcers rather than diffuse growths or strictures^[40]. In a single centre study, mucinous and signet-ring histological subtypes and poor to non-differentiated tumours were frequently seen among the young^[38,41,42], and accounted for 41.5% of all tumours^[38]. The incidence of tumour *in situ* (Tis) was lower in young patients compared with older patients and may indicate either failure of early detection or rapid progression from adenoma to carcinoma in the young compared with older patients^[43]. Other features that suggest more aggressive tumour biology in the young compared with older patients are the higher percentages of patients with lymph node metastasis (≥ 4 lymph nodes), distance metastasis and stage IV disease^[41,42].

GENETICS

All colorectal cancers occur from genetic mutations, which are part of a familial syndrome, hereditary syndrome or as sporadic cancer^[44]. Frequent among young patients are either FAP, variants of FAP or HNPCC. Historically, in the sporadic subtype, the origin of CRC was attributed to various common or rare genetic alterations that displayed variable penetrance, and remained largely unidentified^[45]. It is now estimated that up to 30% of CRC may have a hereditary component, with identifiable genetic aberration, especially if cancer occurs in the young^[23,24,30,46]. Next generation sequencing (NGS) is likely to further increase our knowledge of hitherto unidentified chromosome aberrations in association with cancer^[47] resulting in such diagnoses as the Li-Fraumeni syndrome, Cowden's disease, Juvenile polyposis and Peutz-Jegher syndrome^[46].

Different from germline mutations, somatic mutation, that may be spontaneous or follow contact with luminal carcinogens, may result in genetic alteration of a colonocyte in which control of apoptosis is lost in conjunction with a series of chromosomal changes that create microsatellite instability^[43]. In fact, the aetiology and range of hitherto unidentified germline and early onset somatic mutations is likely to be more extensive than

previously understood, which makes our understanding of the pathology in young patients with sporadic cancer even more complex. Essential to our understanding of tumourigenesis is knowledge of preservation of DNA integrity in the intestinal epithelial cell; deep within the base of the intestinal crypt lies the colonocyte stem cell that is covered in a thick layer of mucus. Each stem cell is designed to replicate into a transit amplifier stem cell and an inert stem cell that remains in the protected crypt base, remote from contact with carcinogens that may be present in the lumen of large bowel, thus preserving its DNA intact. In health, upward migration of the amplifier cell will give rise to a functional colonocyte that will shed in 5 to 7 d by genetically determined apoptosis, controlled by the *p53* gene located on chromosome 17 and the mitogen-activated protein kinase pathway (MAPK)^[43]. The MAPK pathway, of which KRAS and BRAF proteins are part, regulates cell proliferation, cell differentiation, cellular aging and apoptosis^[48]. Programmed colonocyte death prevents the propagation of mutagenic change, and constitutes yet another strategy of preserving intestinal cell DNA integrity^[43]. In the adenoma-carcinoma sequence, initialisation of neoplastic change occurs with silencing of the tumour suppressor genes located on chromosome 5 (*APC* gene), followed by serial changes in chromosome 17 (*p53* gene-mutated in colorectal cancer) and chromosome 18 (long arm deletion)^[49]. Furthermore, simultaneous activation of the proto-oncogene K-Ras will lead to uncontrolled cell growth^[49]. Hence, both germline mutations and somatic mutations may drive colorectal cancer in the young.

Currently, the genetic mechanisms that trigger CRC are grounded in three major pathways; chromosomal instability (CIN), microsatellite instability (MSI) and the cytosine-phosphate-guanine island methylator phenotype pathway (CIMP) pathway^[50,51] - mechanisms that create genomic instability, which together with a process that will selectively support mutagenic driver cells, produce colorectal cancer. It is essential in our understanding of this process that none of these pathways is mutually exclusive. However, CIN aberrations, by far, constitute the most common pathway in the development of CRC^[52].

CIN pathway

This describes the classical adenoma-dysplasia-carcinoma sequence in which it is thought that tumour formation is a result of progressive and sequential inactivation of tumour suppressor genes and, correspondingly, activation of tumour promoting oncogenes - mutation in the adenomatous polyposis coli (*APC*) gene being an important initial step in this pathway^[52]. Likewise, it is known that mutation of the KRAS oncogene contributes to CIN-associated sporadic CRC in up to a half of such sporadic cancer^[53]. Since RAS proteins control signaling in cell differentiation and apoptosis, disruption of such pathways will lead to neoplastic transformation. CIN-associated tumours comprise 75% to 80% of all tumours

found in Western populations^[54].

MSI pathway

It is known that formation of new strands of DNA may be interrupted by base pair mismatches, *i.e.*, mutations which may be either deletions or insertions. In health, the role of mismatch repair proteins is to bind, remove and repair the region of the mismatch error. In cells with malfunction of mismatch repair proteins, these mutations will tend to accumulate within areas of DNA coding called microsatellites. Such areas of microsatellite instability are the cause of sporadic CRC^[55].

CIMP pathway

This pathway of CRC differs fundamentally from CIN and MSI, in that, it causes mutation and epigenetic silencing of genes that control the cell cycle outside the APC control system. This pathway is chiefly associated with a group of protein kinases known as BRAF proteins, and usually occurs due to promoter methylation and silencing of the mut-L homologue 1 gene (MLH-1- short arm of chromosome 3), resulting in microsatellite instability. CIMP associated cancer is frequently found in patients of older age, has a slight female preponderance and is associated with right sided colon cancer, similar to the Lynch syndrome. However, it is rare for patients with Lynch syndrome-associated CRC to have BRAF mutations, which helps differentiate Lynch syndrome associated CRC from sporadic CRC^[56]. Thus, it becomes evident that no two colorectal cancers are likely to be the same, and that each will have its own unique characteristic genetic "fingerprint". It is also known that each cancer may have more than one of the aforementioned carcinogenic pathways^[57,58], which makes genetic imprinting of sporadic CRC all that more challenging. Furthermore, since CIN and MSI associated CRC is known to respond differently to chemotherapeutic agents and impact on cancer related survival, to enable tumour specific personalized treatments, future standard pathological tumour work-up may have to include such genetic "fingerprinting".

RISK FACTORS

A historic study of tumour genesis in the colon shed light on the alkaline environment in the lumen of the colon which, combined with secondary bile acids, is a promoter of tumour formation^[59]. N-nitroso compounds and ammonia, produced from bacterial action upon undigested protein products, and secondary bile acids alter the luminal environment, which affect colonocyte function and deplete oxygen levels in the colonic mucosa, thus favouring tumourigenesis. Furthermore, rapid urbanization with environmental pollution, lifestyle alterations such as reduction in physical activity and change in dietary patterns in young individuals^[9,60], may have also contributed to the rising incidence of CRC, although this alone does not explain its disproportionate rise in incidence in previously

low incidence parts of the world^[61].

SURVIVAL

Multiple studies of young patients with CRC from cancer registries have shown that, in young patients, 5-year survival did not differ from older patients despite a greater proportion of locally advanced cancer, regional lymph node involvement and less favourable histological types in the young^[61-63]. Ruiz *et al*^[64] showed an overall survival rate of 69.4% and 67.4% at 5 years for colon and rectal cancer respectively from a cancer registry database in Peru. Likewise, Parc *et al*^[63], reporting survival data from the central South Korean cancer registry, revealed a 5-year survival of 66% for young patients with cancer of the proximal colon, 70% for patients with distal colon cancer and 66% in patients with rectal cancer. However, if young patients with CRC present with concomitant metastasis, or in the case of a small proportion of patients with unfavourable histological features (poorly differentiated cancer, signet ring cancer), survival may be poor^[65]. Chan *et al*^[66] have shown that survival in young patients with a poor prognosis is predictable, and that maximum survival in this group of young patients after surgical intervention is no more than 20 mo.

SCREENING

CRC screening guidelines currently recommend routine screening of individuals from the age of 50 years. The screening tests range from invasive procedures such as flexible sigmoidoscopy and colonoscopy, through imaging investigations such as virtual colonoscopy, to minimally invasive procedures such as faecal occult tests^[67].

Although each test has its own different advantages and limitations, colonoscopy - widely regarded as the gold standard - has shown to decrease the incidence of CRC up to 80%. However, it is essential to note that colonoscopy is not a perfect test - studies have shown a miss rate of 6%-12% of adenomas > 1 cm and 5% for CRC^[67]. Faecal occult tests have shown promise too; an example being, the faecal immunochemical test which has shown high rates of detection of prevalent CRC in an asymptomatic population^[68].

With the rising incidence and mortality of CRC in young patients, effective screening methods must be able to detect these tumours early. Current guidelines suggest that individuals with a family history of CRC or adenomatous polyps, other than FAP, undergo screening earlier than at 50 years. That is, from the age of 40 or 10 years before the youngest cancer affected family member, while those with a family history of FAP undergo screening in adolescence^[68]. Population based early-onset CRC screening has not been justified due to low prevalence, cost and potential adverse procedural outcomes outweighing the benefits^[17]. To detect early onset CRC, suggestions have been to undertake routine screening from 40 years, instead of 50 years - however, decision

analysis models have shown no significant life-year gains for this change^[37].

To combat the rising incidence by screening of potential early onset CRC patients, awareness among physicians, primary healthcare workers and the lay public must increase. For the physician, this should begin at the stage of medical school by integration of preventive medicine and longitudinal cancer prevention modules into medical school curriculums - which have shown positive results^[69], and will improve the future physician's ability to identify young individuals at high risk.

In terms of young patient awareness, it is imperative that young adults are aware of screening for early onset CRC. A study revealed that university students had very poor knowledge of CRC screening, indicating the necessity for early-onset cancer awareness campaigns^[70]. Another feasible plan to improve screening rates is the employment of a well-trained lay cancer-screening navigator; this person's role would involve contacting individuals, discussing the importance of screening for CRC and implementing screening procedures such as faecal tests sent by mail. Although this was a feasible strategy for older patients aged 50 to 74 years^[71], it has yet to be determined how effective this strategy would be in younger individuals.

To avoid low screening rates, patients' screening method preferences require consideration. Studies have shown faecal aversion to be one of the chief hindrances to screening participation, and a survey revealed that 78% of participants would prefer to provide a blood sample instead^[72]. One such blood test to detect CRC, which requires further development, is the assessment of circulating methylated SEPT9 DNA, and although it is able to detect CRC in an asymptomatic individual, improved sensitivity is required for population screening^[73]. A highly sensitive and specific blood test for CRC could very well become the gold standard in the future, and thereby decrease incidence and mortality rates.

CONCLUSION

An epidemic of colorectal cancer in young patients is imminent. Based on better understanding of genetic mechanisms, currently it is estimated that genetic predisposition to colorectal cancer is 30% of all CRC. The figure is likely to be higher in young patients if all young patients with CRC were to have genetic assessment by NGS testing. While the MSI, CIN and CIMP pathways have been isolated and well defined, a number of germline and somatic mutations in CRC are likely to manifest from widespread use of NGS, multiple panel genetic tests. Furthermore, multiple permutations of genetic alterations are likely to show up in individual CRCs, with overlap of previously known syndrome based genetic changes, which will make individual genetic fingerprinting of CRC more complex and perhaps the age of onset of CRC, that is, whether young or older, irrelevant. In lifestyle assessment, populations, such as in Egypt, where consumption of red meat is high seem to have similar proportions of young

patients with CRC compared with predominantly non-meat eating populations, such as is found in India, which further complicates the search for a common lifestyle aetiology. What is common across the world in lifestyle is the growing fast food industry and childhood obesity; more thought and research needs to focus on its contributory role. For the present, the majority of cases of CRC remains sporadic and of multifactorial origin: Diet and nutrition, obesity, the colonic microbiome, smoking, alcohol consumption and hitherto unknown germline or somatic mutation. The role of screening for CRC in young patients is not likely to follow a "one test fits all" policy until we have worldwide genetic data in this group of patients. At present, mass screening by flexible sigmoidoscopy is expensive and may yield low productive rates. However, better education of medical students, primary healthcare personnel and first contact doctors, about the benefit of prevention and early detection of CRC in the young is likely to improve early detection rates in young persons. Whether early detection influences lead-time in such young patients with cancer remains unresolved, as some studies have shown a clear cut-off in survival at around 2 years. It is a formidable challenge to fight the rising incidence and mortality in early onset CRC patients, an effort that will require global co-operation and consensus.

Abstract

The amount of lymph node dissection (LD) required during surgical treatment of gastric cancer surgery has been quite controversial. In the 1970s and 1980s, Japanese surgeons developed a doctrine of aggressive preventive gastric cancer surgery that was based on extended (D2) LD volumes. The West has relatively lower incidence rates of gastric cancer, and in Europe and the United States the most common LD volume was D0-1. This eventually caused a scientific conflict between the Eastern and Western schools of surgical thought: Japanese surgeons determinedly used D2 LD in surgical practice, whereas European surgeons insisted on repetitive clinical trials in the European patient population. Today, however, one can observe the results of this complex evolution of views. The D2 LD is regarded as an unambiguous standard of gastric cancer surgical treatment in specialized European centers. Such a consensus of the Eastern and Western surgical schools became possible due to the longstanding scientific and practical search for methods that would help improve the results of gastric cancer surgeries using evidence-based medicine. Today, we can claim that D2 LD could improve the prognosis in European populations of patients with gastric cancer, but only when the surgical quality of LD execution is adequate.

Key words: Gastric cancer; D2 lymph node dissection; Evidence-based medicine; European patients; Regional lymph nodes

On the road to standardization of D2 lymph node dissection in a European population of patients with gastric cancer. *World J Gastrointest Oncol* 2016; 8(6): 489-497 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i6/489.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i6.489>

INTRODUCTION

Radical surgery for malignant tumors traditionally includes mandatory one-piece removal of regional lymph nodes (LNs). This approach was introduced over 100 years ago by an American surgeon, W.S. Halsted, and has been used to determine the extent of surgery in basic sites of neoplasia including tumors in the gastrointestinal tract. Despite its high clinical effectiveness and use as a standard treatment in Asia, extensive D2/D3 lymph node dissection (LD) has not been widely used in gastric cancer (GC) surgery in Europe and the Americas until recently.

Indeed until recently, European clinical recommendations for cancer treatment did not suggest D2 LD as a surgical standard of care^[1]. The relevance of this issue is also evident when considering the surgical standard of Western randomized trials on multimodal treatment for GC. The MAGIC trial set the standard for combined treatment of GC in the European Union, and D2 LD was performed in only 42.5% of patients^[2]. The US standard multimodal treatment for GC is based on the INT 0116 trial^[3] in which an extended LD was performed in only 10% of patients. In a large-scale clinical trial on perioperative chemoradiotherapy effectiveness (the CRITICS trial; ongoing in Europe), the planned extension of LD is more limited than D2^[4]. Thus, the issue of standardization in lymphadenectomy extension for GC in Western countries remains relevant.

DEFINITION AND LEVELS OF LYMPHNODAL DISSECTION IN GASTRIC CANCER

Lymphatic efflux from the stomach travels through a complex multidirectional network^[5]. Lymph from different sections of the stomach is drained into the para-aortal LN collector through one of four routes: (1) left subdiaphragmatic *via* the LN in the circulation of the left lower diaphragmatic artery; (2) abdominal *via* the LN along the left gastric, splenic, and common hepatic arteries and the celiac trunk; (3) upper mesenteric that receives lymph from the subpyloric LNs and runs along

the upper mesenteric artery; and (4) retropancreatic, which is associated with LNs of the hepatoduodenal ligament, upper mesenteric vessels and common hepatic artery. Both the left subdiaphragmatic and abdominal routes drain lymph from the upper third of the stomach. The lymphatic efflux from the gastric body drains primarily through the abdominal route, and lymph efflux from the distal stomach drains through abdominal, upper mesenteric and retropancreatic routes^[6].

Metastases to regional LNs are diagnosed in 37%-65% of patients with tumors in the gastric corpus, in 44%-80% of patients with tumors in the proximal stomach, and in 50%-59% of patients with tumors in the distal stomach^[7,8]. The involvement of regional LNs depends directly on the depth of primary tumor invasion. In intra- and sub-epithelial tumors, regional lymphogenous metastases are diagnosed in 0%-5.5% and 19%-31% of patients, respectively^[7,9]. In muscle or subserosal layer invasions, regional LN involvement increases to 30%-62%; in serous membrane tumors, regional LN metastases are found in 74% of patients, and 90%-91% in cases with infiltration of adjacent organs^[7].

The first one-piece tissue dissection of regional lymphogenous metastasis during the course of GC surgery was carried out in 1962 by Jinnai *et al*^[10]. Since then, the concept of extended radical LD has become an essential stage in the strategy of GC surgical treatment in Japan. Research in the field of lymph node (LN) topography and extended clinical efficiency formed the basis of the first edition of "General Rules for the Gastric Cancer Study", which was published in the early 1960s under the auspices of the Japanese Research Society for Gastric Cancer^[11]. The first English edition of these guidelines was published in Europe in 1995. Subsequently, research performed by the Japanese Gastric Cancer Association (JGCA) formed the basis for a second English edition based on the Japanese classification of gastric cancer by the JGCA^[12] as well as Japanese gastric cancer treatment guidelines^[13]. These guidelines describe the following groups of stomach LNs (Table 1, Figure 1).

According to the classification of gastric cancer by the JGCA (1998)^[12], the stomach lymphatic system consists of three LN compartments. Each of these is a temporary barrier that prevents tumor cells from entering the lymphatic system. Grouping stomach lymph collectors into compartments created the basis for determining the gradation of category "N" at staging and a theoretical basis for the extension of LD according to tumor site as reported in the following table (Table 2)^[12]. The LN groups 12b, p and above are classified as N3 - in the given classification-this is equivalent to distant metastases.

Of note, in the last version of tumor-node-metastasis (TNM) classification introduced by the Union for International Cancer Control (UICC)^[14], category "N" is determined not by the topography but rather by the number of affected regional LNs. Accordingly, in the last version of JGCA guidelines (2011)^[13], the extension of nodal dissection is defined according to the extension of

Table 1 The lymphatic system of the stomach^[12]

LN groups	LN topography
Nº1	Right paracardiac LNs
Nº2	Left paracardiac LNs
Nº3	LNs along the lesser curvature
Nº4sa	LNs along the short gastric vessels
Nº4sb	LNs along the left gastroepiploic vessels
Nº4d	LNs along the right gastroepiploic vessels
Nº5	Suprapyloric LNs
Nº6	Infrapyloric LNs
Nº7	LNs along the left gastric artery
Nº8a	LNs along the common hepatic artery (anterosuperior group)
Nº9	LNs at the celiac trunk
Nº10	LNs at the splenic hilum
Nº11p	LNs along the proximal splenic artery
Nº11d	LNs along the distal splenic artery
Nº12a	LNs in the hepatoduodenal ligament (along the hepatic artery)
Nº12b	LNs in the hepatoduodenal ligament (along the bile duct)
Nº12p	LNs in the hepatoduodenal ligament (behind the portal vein)
Nº13	Retro-pancreaticoduodenal LNs
Nº14a	LNs along the superior mesenteric artery
Nº14v	LNs along the superior mesenteric vein
Nº15	LNs along the middle colic vessels
Nº16	Para-aortic LNs
Nº17	LNs on the anterior surface of the pancreatic head
Nº18	LNs along the inferior margin of the pancreas
Nº19	Infradiaphragmatic LNs
Nº20	LNs in the esophageal hiatus of the diaphragm

LNs: Lymph nodes.

gastric resection as reported in the following figures.

During distal subtotal gastrectomy, the lymph node dissection levels are as follows: (1) D0: LD in a volume less than D1; (2) D1: Nº1, 3, 4sb, 4d, 5, 6, 7; (3) D1 +: D1 plus Nº8a, 9; and (4) D2: D1 plus Nº8a, 9, 11p, 12a (Figure 2).

In gastrectomy, the LD levels are as follows: (1) D0: LD in a volume less than D1; (2) D1: Nº1-7; (3) D1 +: D1 plus Nº8a, 9, 11p; and (4) D2: D1 plus Nº8a, 9, 10, 11p, 11d, 12a (Figure 3).

Levels of LD in proximal subtotal gastrectomy: (1) D0: LD in a volume less than D1; (2) D1: Nº1, 2, 3a, 4sa, 4sb, 7; and (3) D1 +: D1 plus Nº8a, 9, 11p (Figure 4).

LD extended beyond these definitions are classified as D2 +. Their effectiveness remains controversial; therefore, they are currently not recommended for routine use in clinical practice^[13].

Gastric cancer classification by JGCA (1998) has demonstrated its high efficiency in several clinical studies^[5,15,16]. LN staging based on topography laid the grounds for JGCA's classification. These are considered anatomical in contrast to the rather mechanistic quantitative approach of the UICC classification. This allows for consideration of disease propagation and for more accurate prognosis. In support of this thesis, the correlated survival of patients with lesions of various LN groups has been studied patients with the same number of regional lymphogenous metastases, survival

**Figure 1** Topography of stomach lymph node groups^[12].**Figure 2** Lymph node dissection levels in distal subtotal gastrectomy^[13].

differed depending on the LN collectors in which lesions were located^[17]. Thus, localization as well as the quantity of metastatically-affected regional LNs has a probable prognostic value. According to Y. Noguchi^[18], in N0, LN lesion groups 1-6 (N1 according to JGCA), LN lesion groups 7-12 (N2), and LN groups 13-16 (N3), the 5-year survival rate was 85%, 60%, 25% and 11%, respectively.

A significant advantage of the second JGCA gastric cancer classification in terms of practical application is its direct link with the volume of LD based on the staging principle of lymphogenous metastasis. Of note, the Japanese classification uses the term "regional lymph node". This is defined not only by the lymph node topography, but also by the site of the primary tumor in the stomach; the UICC classification does not provide this differentiation.

Another obvious advantage of the classification offered by JGCA^[12] lies in the possibility of extrapolating data about the regional LN condition into the UICC classification. The reverse conversion is not possible; therefore, it is not possible to conduct a comparative analysis of retrospective studies in a different series.

Western pathologists and surgeons criticize the Japanese GC classification mainly because of its complexity and also because precision mapping is laborious in practice. However, the Eastern and Western GC classifications are finally approaching each other. This tendency can be observed in the latest edition of the

DEBATE ON THE EXTENT OF LYMPHNODAL DISSECTION: EASTERN VS WESTERN POSITION

Results of a retrospective analysis of LD D2 were first published in Japan in 1970 by Mine *et al*^[19]. The authors reported a slight increase in the survival rate among

patients with pN0 and a probable increase in the 5-year survival rate from 10% to 21% in the group pN+. Similar results were reported in a study by Kodama *et al*^[20], who indicated an increase in the 5-year survival rate from 33% to 58% in the entire group of patients.

In the 1970s and 1980s, Japanese surgeons developed a doctrine of aggressive preventive GC surgery based on the extended (D2) and super-extended (D3) LD volumes^[21]. Concurrently, in Europe and the United States, the most common LD volume was D0-1. Due to the relatively lower GC incidence rates in the West,

European and American surgeons continued to reframe the ideology and master the techniques of extended interventions in GC cases until the end of the 1990s. This eventually caused a scientific conflict between the Eastern and Western schools of surgical thought. Japanese surgeons used D2 LD in surgical practice, whereas European surgeons insisted on repetitive clinical trials in the European patient population. They reasoned that certain biological differences in GC were present in the "Eastern" type^[22].

One of the most significant publications from that time was a study of a European population of patients with GC by Pacelli *et al.*^[23]. The authors reported a probable increase in the 5-year survival rate from 30% (D1, LD) to 49% (D2, 3 LD) for patients with stage III GC and from 50% to 65% in the entire group of patients.

Similar results were obtained by a group of German surgeons supervised by Siewert *et al.*^[24] during the course of a prospective multicentric trial of nearly 2500 patients. A probable increase in the survival rate was reported in patients with stages II - IIIA GC. However, in patients with pN2 (TNM UICC) or with extensive tumor invasion of the gastric serosa, D2 LD was not associated with increased survival.

Over time, researchers increasingly noted the low credibility of non-randomized studies. The results of the first randomized trials published by Dent *et al.*^[25] and Robertson *et al.*^[26] featured high rates of postoperative complications and mortality. However, the results did not provide high levels of credibility because of the small numbers of patients enrolled. The first large-scale randomized multicentric study of the efficacy of D2 LD in a population of European patients with GC was carried out in the 1990s.

This study, known as the Dutch trial^[27], involved 1078 randomized patients and was organized by the Dutch Gastric Cancer Group. At the same time, the British MRS (Medical Research Society) carried out its own trial^[28] with 400 randomized patients. The first results of these studies were preliminarily published in 1997 at the Second International Gastric Cancer Congress (IGCC) in Munich. However, the necessity of compliance with the full volume of D2 LD dramatically increased the frequency of splenectomies (up to 37% in the Dutch study and up to 65% in the British) and resections of the pancreas (30% in the Dutch study and 56% in the British) in all groups. These studies showed a dramatic increase in the number of postoperative complications after D2 LD (from 25% after performing D0-1 in the control group up to 43% in the Dutch trial and from 28% to 46% in the British trial). They also showed an increase in the postoperative mortality rate (from 4% to 10% in the Dutch trial and from 6.5% to 13% in the British trial)^[27,28]. In the Eastern Asian series however, the rate of postoperative complications was 17%-21%^[29,30]. The postoperative mortality rate after D2 LD in Eastern clinics was also significantly lower than in Europe-less than 2% in the Japanese nationwide registry^[31] and less than 1%^[30] or even zero^[29] in specialized centers.

After a 5-year follow-up of European randomized studies, the expected increase in survival of D2 LD group was not achieved; the 5-year survival in the Dutch trial was 45% in group D1 LD and 47% in group D2 LD. In the British trial, it was 35% in group D1 LD and 33% in group D2 LD^[32,33] (Figure 5).

Thus, the European oncology society preliminarily concluded that the extended LD volumes used in European GC patients were ineffective. This was based on evidence-based medicine and relied on the results of the two major Western randomized trials. However, a detailed analysis of this study and all potential reasons for the lack of a positive result were shown at the 1999 IGCC in Seoul. The summary of this analysis was later published in the *New England Journal of Medicine*^[34]. Despite a good design and detailed statistical analysis, the study had some serious shortcomings that made the results ambiguous. These included:

The large number of participating surgical centers (about 80 clinics), which resulted in surgeons obtaining an insufficient amount of practical experience in the surgical procedures required for the study. For instance, some surgeons performed fewer than 5 D2 LD surgeries per year. This not only potentially affected the level of postoperative complications and mortality, but also led to a reduction in LN removal in the course of D2 LD and consequently to a reduction in radical surgeries^[34].

There was a lack of surgery standardization (there were no clear criteria for splenectomy or spleen-saving dissection of the 10th LN group, instrumental or manual anastomosis, etc.).

Conversely, surgeons participating in the randomized trial in Taiwan performed a minimum of 80 D2 LD surgeries before the study began. The results of that study revealed a possible increase in survival rates when extended volumes of LD were performed^[35].

The median number of LNs removed is an important indicator of LD quality. Significant geographic fluctuations of this indicator in the performance of D2 LD have now been established. There are diametrically polar indicators in European randomized trials. In the British study, the median number of removed LNs was 17^[28]; in the Dutch study, the number was 30^[32]. There were 25-26 LNs removed in the Western retrospective studies^[36,37] and 54 LNs removed in Japanese specialized centers^[30]. The minimum adequate number of LNs to be removed in gastric cancer surgeries-according to the requirements of TNM UICC (2009)^[14]-is 15. This level of LD was provided in 86%^[36] to 95%^[37] of patients in the Western retrospective studies and in 100% of patients in the Japanese studies^[30]. According to Siewert *et al.*^[24], the efficiency of LD execution can meet the standards of D2 only when a minimum of 26 LNs are removed.

The average frequency of metastatic lesions in LNs of group N°10th (LNs of the splenic hilum) in various tumor sites in the stomach is 8.8%. Metastatic lesions in these LNs are likely to worsen the prognosis^[38]. The application of splenectomy on principle including for LN dissection of the 10th group was not effective in patients

Figure 5 Patient survival in the Dutch trial^[32].

with GC until recently. A small study conducted in Korea by Yu *et al.*^[39] demonstrated a tendency toward increased survival after splenectomy; however, this result was not statistically significant. A meta-analysis conducted in 2009 by Yang *et al.*^[40] also confirmed an increase in the 5-year survival rate of patients with GC after splenectomy. According to other authors^[38], unless the tumor has invaded the spleen, splenectomy is necessary only in case of LN lesions in group N^o4sa. Therefore, despite the fact that LN dissection of the 10th group is regulated by the JGCA guidelines (2011)^[13], the role of splenectomy as a standard stage of D2 LD remains controversial. The answer to this question will likely be clarified soon after the publication of the results of a large randomized trial investigating the efficacy of splenectomy in Japanese patients with cancer of the upper third of the stomach (JCOG 0110 that began in Japan in 2002)^[41].

Despite the previous pessimistic results, Hartgrink *et al.*^[42] conducted a second analysis of the "Dutch material" in 2001. They found a significant increase in survival in group D2 LD, especially in patients with metastases in LNs of the first stage of metastasis (N1 by JGCA). After 15 years of observation of patients during the Dutch trial, no significant difference in survival between groups under observation has not been noted. However, when the most controversial group of patients with splenectomies and resection of the pancreatic gland was excluded from the analysis, the 15-year survival rate increased dramatically from 22% in D1 LD to 35% in D2 LD ($P = 0.006$)^[43] (Figure 6).

In 2013, the results of meta-analysis obtained by 12 randomized controlled major European trials on LD D2 effectiveness were published. These clearly proved the thesis concerning an increased risk of postoperative complications with D2 LD and the possible increase in survival only in the group that did not have splenectomy and resection of the pancreatic gland^[44]. Therefore, in the latest European oncology guidelines, D2 LD is the standard surgical procedure but only in highly

Figure 6 Survival of patients in the Dutch trial after a 15-year observation^[43].

specialized centers with extensive experience in such surgeries as well as postoperative care^[45].

According to the Japanese guidelines on the gastric cancer treatment issued by JGCA (2011)^[13], the algorithm of surgical treatment in patients with GC is as follows (Figure 7).

The amount of LD required during surgical treatment of gastric cancer surgery has been quite controversial. Today, however, in light of evidence-based medicine, one can observe the results of this complex evolution of views: D2 LD is considered an unambiguous standard of GC surgical treatment in specialized centers according to national recommendations in Germany^[46], the United Kingdom^[47] and Italy^[48] as well as mutual recommendations of the European Society of Medical Oncologists, Surgical Oncologists and Radiation Therapists (ESMO-ESSO-ESTRO)^[45]. Such a consensus of the Eastern and Western surgical schools became possible due to the longstanding scientific and practical search for methods that would help improve the results of GC surgeries using evidence-based medicine^[49]. In Western surgical terminology, D2 LD is now called a standard volume of intervention, whereas D2 + LD is an extended operation.

This debate into the effectiveness of extended (D2 + LD) interventions in GC cases remains open. A well-known clinical study conducted by Sasako *et al.*^[34] did not demonstrate an increase in survival after D2 + para-aortic LD for patients with resectable GC. However, many recent studies have demonstrated the possibility of increased survival after the application of extended LD in a selected group of patients with a high risk of metastasis in LNs of the N^o16 station^[50,51].

Furthermore, the effectiveness of laparoscopic D2 LD in GC cases remains undetermined. Today, clinical research is underway in the KLASS-2 trial, which aims to determine the effectiveness of such interventions. The impact of interventions with D1 +, D2 and D2 + LD on the risk of intraperitoneal progression of GC after

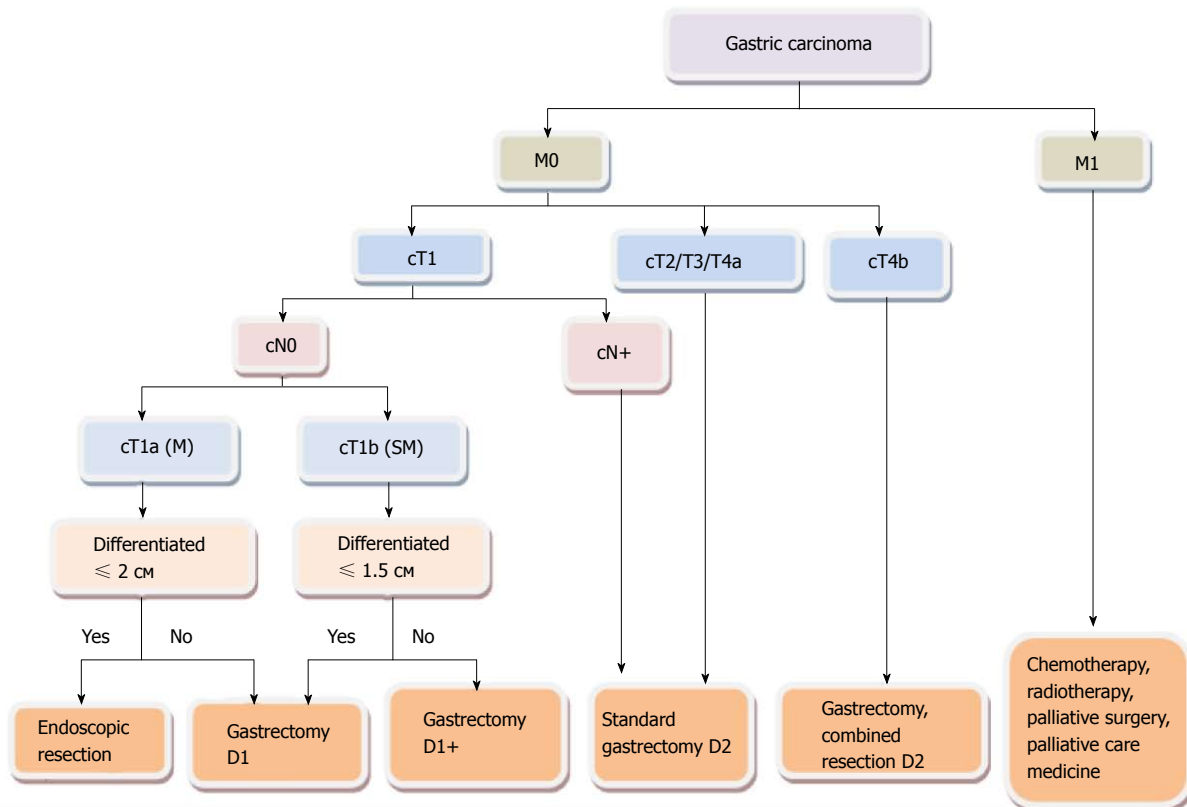

Figure 7 Algorithm of surgical treatment of patients with gastric cancer according to the guidelines provided by Japanese Gastric Cancer Association (2011)^[13].

surgery^[6] remains unknown.

CONCLUSION

The data show that D2 LD can improve the prognosis in European GC patients, but only when the surgical quality of LD execution is adequate. As part of the 10th IGCC in 2013 in Verona, Italy, the former president of the *European Society of Surgical Oncology*, Professor C. van de Velde, noted in his expert lecture that “the only way to improve the efficiency of surgical treatment of gastric cancer in Europe is to place patients in specialized surgical centers, provide training so that individual surgeons could specialize on the issue of LD D2 and an objective and permanent audit on quality of lymphadenectomy in each surgical center”.

Abstract

Malignant obstruction of the bile duct from cholan-

giocarcinoma, pancreatic adenocarcinoma, or other tumors is a common problem which may cause debilitating symptoms and increase the risk of subsequent surgery. The optimal treatment - including the decision whether to treat prior to resection - depends on the type of malignancy, as well as the stage of disease. Preoperative biliary drainage is generally discouraged due to the risk of infectious complications, though some situations may benefit. Patients who require neoadjuvant therapy will require decompression for the prolonged period until attempted surgical cure. For pancreatic cancer patients, self-expanding metallic stents are superior to plastic stents for achieving lasting decompression without stent occlusion. For cholangiocarcinoma patients, treatment with percutaneous methods or nasobiliary drainage may be superior to endoscopic stent placement, with less risk of infectious complications or failure. For patients of either malignancy who have advanced disease with palliative goals only, the choice of stent for endoscopic decompression depends on estimated survival, with plastic stents favored for survival of < 4 mo. New endoscopic techniques may actually extend stent patency and patient survival for these patients by achieving local control of the obstructing tumor. Both photodynamic therapy and radiofrequency ablation may play a role in extending survival of patients with malignant biliary obstruction.

Key words: Pancreatic neoplasms; Cholangiocarcinoma; Extrahepatic cholestasis; Stents; Catheter ablation

Core tip: Treatment of malignant biliary obstruction from cholangiocarcinoma or pancreatic cancer can be performed *via* endoscopic, percutaneous, or surgical means. The decision of when or how to achieve biliary decompression depends on the patient's condition, location of stricture, and stage of malignancy. Not all patients require biliary decompression, particularly with resectable tumors. Self-expanding metallic stents or plastic stents may be used for distal malignancy, depending on stage and prognosis. Stents, nasobiliary drainage, or percutaneous drains may

be used for hilar strictures. Endoscopic catheter-based therapies such as photodynamic therapy or radiofrequency ablation may prolong patient survival by achieving local tumor control.

INTRODUCTION

Obstruction of the extrahepatic bile ducts from a malignant process presents both a diagnostic and therapeutic challenge. It is a common problem, with as many of 70% of pancreatic cancer patients presenting with obstruction upon diagnosis^[1]. Obstruction may serve as the initial sign of disease - such as in the classic presentation of painless jaundice in pancreatic ductal adenocarcinoma - or may occur during progression of malignancy once the diagnosis is established. The two most common malignant neoplasms known to occlude the bile ducts are pancreatic ductal adenocarcinoma and primary bile duct cancer (cholangiocarcinoma). Other causes of malignant biliary obstruction can include ampullary carcinoma, primary duodenal adenocarcinoma, pancreatic neuroendocrine tumors, or occlusion of the hepatic hilum due to lymphadenopathy at the porta hepatis (as seen in metastatic colon cancer or lymphoma). Of note, some premalignant lesions such as biliary papillomatosis may cause an obstructive picture similar to malignancy. Benign conditions such as autoimmune cholangiopathy must also be ruled out, so obtaining tissue *via* endoscopic retrograde cholangiography (ERCP) with brush biopsy or core biopsy, or endoscopic ultrasound with fine needle aspiration (FNA) is paramount^[2]. Only once a firm diagnosis of malignancy is secured can the final choice of treatment be made.

Occlusion of the bile ducts may cause debilitating symptoms such as pruritus and malaise, and thus treatment is often recommended on that basis alone. This may come in the form of surgical resection if the patient presents with resectable disease. However, both pancreatic cancer and cholangiocarcinoma are notorious for presenting at an advanced stage in which immediate surgery is contraindicated. Treatment goals for these patients include downstaging of the tumor with chemoradiotherapy, or strictly palliative measures. Relief of biliary obstruction is recommended in either setting. Treatment of distal malignant biliary obstruction from pancreatic cancer is typically managed by an endoscopically placed single biliary prosthesis, whereas hilar strictures can be more challenging to manage due to the need to access the left and right systems of the biliary tree.

Within the past decade endoscopic techniques have been developed to treat tumor ingrowth into the bile duct with photodynamic therapy or radiofrequency ablation,

and recent studies show promise in expanding the role of endoscopic treatment. While the primary role at this time is to provide biliary decompression and relieve jaundice, the ability to provide therapy for these tumors represents a major shift in the role of the endoscopist. This review will consider the options for management based on the location of obstruction, as well as the stage of the underlying malignancy.

THE EFFECT OF JAUNDICE

The decision whether to decompress obstructed bile ducts in a patient with resectable disease has traditionally been quite controversial. Jaundice has long been recognized as an important preoperative risk factor in the setting of malignancy^[3,4]. Several mechanisms have been described through which jaundice exerts its negative effects. Jaundice is thought to impair cellular immunity, allowing tumor growth and metastatic progression if left untreated^[5]. In addition, obstruction to flow of bile decreases its availability in the enteric system for the absorption of lipid-soluble vitamins, including vitamin K, leading to coagulopathy and increased surgical bleeding risk. Even additional administration of oral vitamin K may be inadequate to reach appropriate levels of coagulation in obstructive cases^[6], which may further complicate any planned surgery. Bacterial and endotoxin translocation through the intestinal mucosa has also been demonstrated in jaundiced patients, making SIRS and sepsis a serious complication that can develop even prior to surgery^[6]. Jaundice has also been shown to increase the risk of infection if not treated before surgery^[7], as well as complications after surgery^[8]. Thus, there is a theoretical benefit to biliary drainage for relief of jaundice prior to surgical resection of these tumors.

It is thought the benefit of preoperative biliary drainage (PBD) may vary depending on the level of obstruction and planned surgery: Distal biliary obstruction from pancreatic cancer or distal cholangiocarcinoma may be treated surgically without the need for preoperative decompression, while hilar obstruction may require decompression to improve surgical outcomes. The differences in strategy likely stem from the need for partial hepatic resection in the treatment of hilar tumors, which may benefit from preoperative decompression.

MALIGNANT DISTAL BILIARY OBSTRUCTION

As many as 70% of patients with newly diagnosed pancreatic cancer have some degree of biliary tract obstruction at the time of diagnosis. Decompression *via* endoscopic stent placement can palliate jaundice and pruritus for symptomatic relief^[9]. Stent placement may also speed allow the patient to begin chemotherapy regimens by reducing the risk of chemotoxicity in a cholestatic liver^[10]. Endoscopic stent placement into the common bile duct is a fairly routine procedure (technically successful in over 90% of cases) and

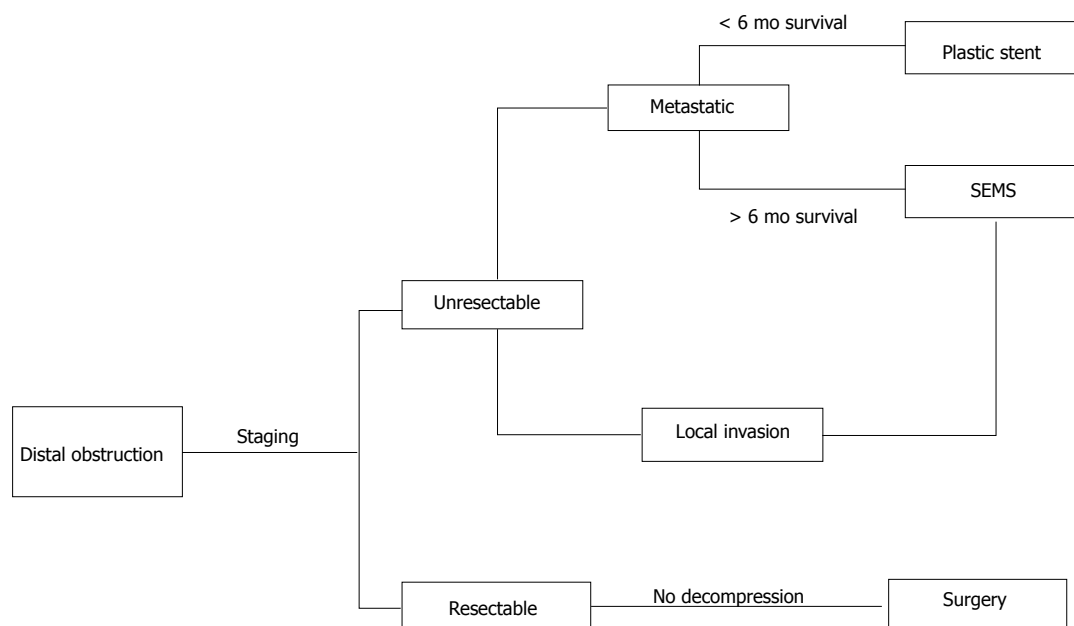

Figure 1 Algorithm for treatment of distal malignant biliary obstruction based on disease stage. Patients who are not candidates for ERCP with stent placement may undergo EUS-BD or percutaneous drainage. Adapted from Boulay BR, Parepally M. *World J Gastroenterol* 2014; **20**: 9345-9353. SEMS: Self-expanding metallic stent; ERCP: Endoscopic retrograde cholangiography; EUS-BD: Endoscopic ultrasound-guided biliary drainage.

has thus become the most common method of achieving biliary decompression^[11]. The choice of plastic or metallic stents depends on factors such as cost-effectiveness, expected length of survival, and diagnostic certainty. Over the past decade the use of self-expanding metal stents (SEMS) has become more common for treatment of both benign and malignant biliary strictures. While surgeons initially discouraged use of SEMS for pancreatic cancer due to concerns of increasing the difficulty of resection, SEMS do not interfere with planned pancreaticoduodenectomy as long as the stent does not involve the hilum^[12]. Thus the role for SEMS in treatment of obstruction from pancreatic cancer has grown in recent years.

Distal cholangiocarcinoma has a similar presentation, pattern of spread, and poor prognosis when compared to pancreatic ductal adenocarcinoma. At times the two diseases may be indistinguishable from each other upon initial presentation. Distal cholangiocarcinoma tends to infiltrate the adjacent pancreas, duodenum, and vasculature as well as nearby lymphatics, leading to locally advanced disease and eventually metastases. Thus, the same staging evaluation can be performed to assess for local invasion, with the goal of curative surgical resection when possible^[13]. Once the stage is known, similar principles of biliary decompression are applied as in pancreatic ductal adenocarcinoma. The management is based on disease stage as depicted in Figure 1.

RESECTABLE DISEASE

Surgical resection is the definitive treatment for patients who present with early-stage pancreatic cancer^[14]. PBD in resectable pancreatic cancer is not automatically recommended. Despite the beneficial effects of relieving

jaundice, PBD has been associated with increased complications including various types of infections as well as pancreatic fistulas^[15-17]. In 2010, van der Gaag *et al.*^[18] reported a randomized trial of 202 patients demonstrating that preoperative biliary drainage with stents was linked to increased complications compared to surgery alone in resectable pancreatic cancer. In this seminal study, rates of serious complications were 39% in the early-surgery group and 74% in the preoperative drainage group. Of note, the preoperative biliary drainage group waited 4 to 6 wk for surgery and were treated with plastic stents, both of which may have contributed to the poor performance of the biliary decompression group. However, based largely upon the experience noted by van der Gaag *et al.*^[18], preoperative biliary decompression for distal biliary obstruction is not recommended except to treat cholangitis or intractable pruritus.

LOCALLY ADVANCED DISEASE AND NEOADJUVANT THERAPY

Even those patients who undergo surgical resection of pancreatic cancer have poor long-term survival rates, so there is growing interest in the use of neoadjuvant therapy to boost outcomes, even for resectable pancreatic tumors^[19]. Neoadjuvant chemoradiotherapy has also been used for locally advanced tumors to downstage them and permit eventual surgical resection. Biliary stents are placed prior to neoadjuvant chemoradiotherapy, with the expectation of remaining patent until the time of surgery. Unfortunately, this expectation has not always been met when plastic stents are used during the preoperative period.

Numerous studies have now shown that SEMs are preferable to plastic stents in patients undergoing neoadjuvant therapy^[20-24]. Retrospective reviews of plastic stent performance during neoadjuvant therapy have demonstrated poor performance with the frequent need for unplanned stent exchange due to stent occlusion or cholangitis^[20,25]. Adams *et al*^[22] described a complication rate nearly 7 times higher with plastic stents, with a 3 times higher rate of hospitalization among a 52 patient cohort. SEMs are clearly more expensive than plastic stents, but their lower occlusion rates (and thus fewer unplanned stent exchanges) make them a more cost effective choice for patients undergoing neoadjuvant chemoradiotherapy with planned surgical resection^[26].

There are several choices of SEM type for use in patients with malignant distal biliary obstruction undergoing neoadjuvant therapy or in palliative cases. When considering uncovered (USEMSs) or covered stents (CSEMSs), the difference in design leads to a trade-off in adverse events between tissue ingrowth in USEMS and stent migration in CSEMS. One recent meta-analysis concluded that CSEMSs afforded an average of 61 d longer patency than USEMSs in palliative cases, with the cost of an increased incidence in migration (RR 8.11)^[27]. In contrast, a retrospective cohort study showed no difference in overall obstruction (CSEMSs 35% vs USEMSs 38%) among 749 patients, merely that the mechanisms of obstruction varied by stent design (tumor ingrowth vs debris)^[28]. Partially covered SEMs appear to have similar performance characteristics to fully covered SEMs and USEMS^[27,29].

Novel stent designs may further improve the performance of SEMs. A modified CSEMS with low axial force and uncovered flare ends has been developed with the goal of reducing stent migration, and when compared to USEMS had significantly longer patency (mean 219.3 d vs 166.9 d) and fewer unplanned procedures (23% vs 37%) compared to USEMSs^[30]. Drug eluting stents have been designed in an attempt to improve SEMs prevent tumor ingrowth and stent occlusion^[31]. An early multicenter prospective study using a paclitaxel-eluting stent did not show improved performance compared to conventional USEMS, though other stents are currently in development^[32]. Anti-reflux stents have been developed to limit duodenal contents into the bile ducts and limit stent occlusion^[23]. Initial experience with anti-reflux SEMs has yielded conflicting results, with one study showing long-term patency possibly exceeding conventional SEMs^[33] while a smaller study showed a disappointing rate of early occlusion^[34]. Further studies are needed to demonstrate the efficacy of anti-reflux and drug-eluting SEMs to determine their role in maintaining long-term stent patency.

Despite the wealth of data demonstrating the superiority of SEMs over plastic stents for malignant biliary obstruction, endoscopists may prefer to place a removable plastic stent if the diagnosis of malignancy is uncertain at that time of ERCP (such as in facilities where endoscopic

ultrasound with FNA and rapid on-site evaluation by cytopathologists is not available). In this situation, benign conditions such as chronic pancreatitis or autoimmune cholangiopathy may be suspected as the etiology of the biliary stricture, and a removable stent is preferable. The use of a fully covered SEMs is ideal when suspicion of malignancy is high and life expectancy exceeds 4 mo.

PALLIATIVE DECOMPRESSION IN DISTAL OBSTRUCTION WITH METASTATIC DISEASE

In the setting of incurable pancreatic cancer, patients may often present with advanced disease and limited life expectancy. SEMs may not be cost-effective for these patients, since their main advantage of durable patency is not applicable. SEMs cost 15-40 times more than most plastic stents, and are only cost effective if the patient survives > 4 mo^[26]. Some authors have suggested that SEMs should be used only in patients without distant metastases^[35]. The presence of liver metastases has been shown to predict mortality in pancreatic cancer, though the data is sparse and generally used only to determine operative risk^[36-38]. Although determination of life expectancy can be difficult and more research is needed to identify prognostic factors, endoscopists should be aware of the cost savings with plastic stents in patients with poor functional status and limited expected survival.

NON-ENDOSCOPIC BILIARY DRAINAGE IN MALIGNANT DISTAL OBSTRUCTION

In cases where ERCP fails or cannot be performed, percutaneous transhepatic biliary drainage (PTBD) has traditionally been used to create a tract for internal and external drainage. External drains have the potential downside of requiring emptying and flushing of the drain as well as routine drain exchange^[39]. Recent trials of percutaneous SEMs placement have also demonstrated good safety and effectiveness^[40-42]. An alternate second-line approach is endoscopic ultrasound-guided biliary drainage (EUS-BD), which has been increasingly shown to be both safe and effective when standard ERCP approaches fail. This technique can be used to achieve decompression *via* EUS-guided rendezvous procedure, EUS-guided choledochoduodenostomy, and EUS-guided hepatic gastrostomy^[43]. Complications can include bile leak, bleeding, or pneumoperitoneum. EUS-BD remains technically complex and limited to high-volume expert centers^[44].

Surgical biliary bypass remains an option, particularly when life expectancy exceeds 6 mo. Trials comparing surgical bypass to endoscopic therapy have shown similar mortality and fewer incidents of recurrent biliary obstruction when surgery was performed, though these

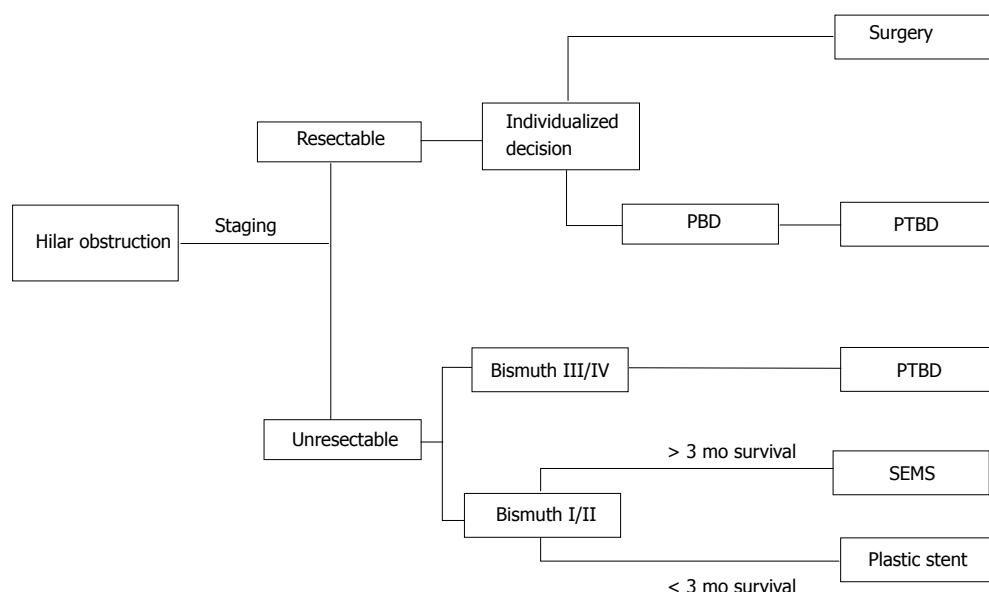

Figure 2 Algorithm for treatment of hilar malignant biliary obstruction. PBD is an individualized decision based on local expertise. PTBD: Percutaneous transhepatic biliary drainage; SEMS: Self-expanding metallic stent; PBD: Preoperative biliary drainage.

trials preceded the widespread use of SEMS and do not reflect current endoscopic practice^[45,46]. Surgical bypass can also relieve biliary and gastric outlet obstruction at the same time *via* creation of a surgical gastrojejunostomy and biliary bypass. However, biliary and gastroduodenal obstruction can also be relieved endoscopically during the same procedure, with placement of a duodenal SEMS followed by an endoscopic approach to the papilla for ERCP guided biliary stent placement or even EUS-BD^[47-50]. Thus, while ERCP is the preferred method for management of malignant distal biliary obstruction, a multidisciplinary team including interventional radiologists and surgeons is ideal for management of unusually difficult strictures when ERCP fails.

HILAR CHOLANGIOCARCINOMA: SURGICALLY TREATABLE DISEASE

Malignant obstruction of the extrahepatic bile ducts at the liver hilum can be much more difficult to treat, given the possible involvement of the left and right hepatic ducts and the need to decompress the left and right lobes individually. Complete resection is the only curative treatment for cholangiocarcinoma. Unfortunately, most patients will present with obstructive symptoms or frank jaundice later in the disease course^[51]. Resection modalities vary depending on the location of the malignancy: Intrahepatic tumors are treated with hepatic resection while extrahepatic tumors can be classified as hilar cholangiocarcinoma (Klatskin tumor) or distal cholangiocarcinoma. The level of the cystic duct demarcates hilar vs distal tumors. Hilar cholangiocarcinoma may still require partial hepatic resection as part of definitive management^[52]. In patients with Bismuth class 4 strictures involving the left and right hepatic duct, or vascular involvement of the hepatic

artery or portal vein, surgical resection is contraindicated and neoadjuvant or palliative techniques are indicated^[53]. Figure 2 depicts the overall management of hilar obstruction based on disease stage.

Several different imaging modalities can be used to determine the degree of proximal tumor extension. This is of critical importance in deciding on resectability and the optimal means of achieving biliary decompression. Computed tomography (CT) is the most commonly used type of imaging at the time of diagnosis, and multidetector CT (MDCT) has an accuracy of 86% in evaluating the ductal extent of hilar cholangiocarcinoma^[54]. Magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) provides detailed images of the biliary tree, though the presence of biliary stents can reduce the accuracy of staging^[55]. The accuracy of MRI in determining hilar involvement is estimated at 89%, similar to that of MDCT. Both types of imaging also provide information regarding lymph nodes and direct invasion of nearby structures. In contrast, direct cholangiography by either ERCP or percutaneous means may not allow imaging of the entire biliary tree due to complete obstruction of some segments by tumor. Direct cholangiography is also invasive and presents risks of bleeding or infection which are avoidable with cross-sectional imaging. Thus, MDCT or MRCP are both acceptable initial imaging strategies for treatment planning, though the presence of stents may favor the use of MDCT.

When a patient with hilar cholangiocarcinoma presents with resectable disease, the treatment team must consider whether to pursue PBD. As with pancreatic cancer, preoperative biliary drainage has long been a debated topic, though most authorities advocate against it in the absence of cholangitis^[56,57]. Drainage is recommended in

special situations such as cholangitis as well as patients with symptomatic jaundice (e.g., pruritus) or renal failure^[10]. In the absence of these factors, preoperative drainage has been previously discouraged on the basis that it confers no mortality benefit but may cause adverse events. Meta-analyses and systematic reviews of randomized controlled trials of preoperative biliary drainage have found increased complications and morbidity when PBD was performed, though overall mortality does not differ between the two groups^[58,59].

Nonetheless, it is standard practice to perform preoperative biliary drainage in countries such as Japan and South Korea, and there is reason to believe it can be helpful in optimizing surgical outcomes with proper patient selection. One reason for this enthusiasm has been increased recognition of the flaws in earlier studies which argued against preoperative drainage. A large number of studies from 1980s to early 2000s did not have standardized timing to clear obstruction and jaundice, with some prolonged periods that contributed to stent occlusions and associated complications^[60]. Even now, the optimal bilirubin level for surgery and optimal duration of PBD have not been established. The risk of drain occlusion or inflammatory change within the bile duct with prolonged drainage must be weighed against the risk of progressive obstruction on the outcome of liver resection during curative surgery. Thus preoperative biliary drainage is indicated when there will be a delay for surgery, such as in patients who undergo selective portal vein embolization in the setting of inadequate future liver remnant. In addition, the high-quality cholangiograms obtained in PBD can assist with treatment planning by delineating the extent of tumor involvement within the segmental bile ducts (though staging with MDCT or MRCP can provide adequate staging information without the risks of decompression).

It is possible that the benefit of PBD depends on the location of biliary obstruction within the hilum. Farges *et al.*^[61] performed a multicenter retrospective analysis of 366 patients undergoing extended right or left hepatectomy for hilar cholangiocarcinoma. PBD was not found to improve mortality overall, though a subgroup analysis revealed improved mortality in patients undergoing right hepatectomy (through reduced incidence of post-operative liver failure) while mortality was worse with left hepatectomy (through increased risk of sepsis)^[61]. This intriguing data will require confirmation with additional studies but may help guide the controversial decision whether to perform PBD in the future.

HILAR CHOLANGIOCARCINOMA: TECHNIQUES FOR PREOPERATIVE BILIARY DRAINAGE

Currently three techniques are available for preoperative biliary drainage of hilar malignancy: PTBD, endoscopic nasobiliary drainage (ENBD), and endoscopic retrograde biliary drainage (ERBD) with stent placement. No randomized controlled trial has been performed to compare these techniques. For hilar tumors, ERBD can be technically

challenging with the need to place multiple stents to drain obstructed biliary segments. The rate of complications is high, with reports showing morbidity of 25%-50% and mortality rates of 3%-5% with hilar tumors^[62]. The complications are mainly due to cholangitis with stent failure or inadequate drainage^[3,8].

ENBD has the advantage of providing drainage while allowing repeat cholangiography as needed prior to surgery with easy access to the drained intrahepatic segments^[7]. Nasobiliary drainage is also a safe technique with fewer complications than PTBD^[8]. However, nasobiliary tubes can be easily dislodged and may be poorly tolerated due to patient discomfort^[63]. The use of multiple nasobiliary tubes to provide bilateral drainage for Bismuth IV hilar tumors has been performed but is technically demanding.

Percutaneous transhepatic biliary drainage has become the preferred method for preoperative biliary decompression in some centers. This technique is attractive due to its low complication rate when compared to endoscopic stent placement. Kloek *et al.*^[3] reviewed 101 patients who had undergone PBD and found 48% infection rate with ERBD, while PTBD was associated with only 9% infection rate. The chief problem with PTBD is the risk of tumor seeding along the drain tract, which is estimated at 5%-20%^[7,8]. External transhepatic drains may cause patient discomfort and sometimes require additional oral intake of bile acid supplements, representing an uncomfortable nuisance to the patient^[8]. Despite these drawbacks, the safety and comparative ease of drain placement (compared to ENBD) make PTBD a reasonable option depending on the local expertise of the treatment team.

HILAR CHOLANGIOCARCINOMA: PALLIATIVE THERAPY FOR MALIGNANT BILIARY OBSTRUCTION

While preoperative treatment tends to employ ENBD or PTBD, these therapies are less practical in the setting of unresectable disease. For patients with Bismuth I or II tumors, ERBD has similar performance to PTBD while being less invasive. However, patients with more advanced hilar obstruction (Bismuth III or IV) are more difficult to palliate with biliary stents. A retrospective review of 126 patients with Bismuth III-IV obstruction demonstrated higher success rates with PTBD over SEMS (93% vs 77%), though median survival was similar between the two groups^[64]. Thus, PTBD is generally favored over endoscopic therapy even for palliation in advanced hilar obstruction.

The goal for palliative drainage is to relieve jaundice by draining an adequate liver volume (50% or more). This can be achieved with a single stent in Bismuth I tumors, though the strategy with more advanced hilar disease is more complex. Drainage of > 50% of the liver volume may require more than one catheter or stent, though the right lobe of the liver takes up 50%-60% of the liver volume and successful drainage of the right lobe with a single stent may be sufficient to relieve

jaundice. The question of whether to place a single or multiple drains can be answered by volume assessment of the liver (volumetry) using cross-sectional imaging by CT or MRI. MRI imaging can be used to guide the placement of a single stent to access the dominant lobe and provide adequate drainage with a single stent^[65].

Much like the treatment of distal obstruction with pancreatic malignancies, the past decade has seen increasing use of SEMS over plastic stents. There have been numerous studies that show significant advantages to metal stents vs plastic polyethylene stents^[56]. The length of patency for SEMS compared to plastic is much higher (as much as 12 mo vs 3 mo), owing to the 8-10 mm diameter of SEMS compared to the narrower 7, 8.5 or 10 French plastic stents. Complications from occlusion or migration are less common, though SEMS are notably much more expensive than plastic stents^[66]. Of course, patients with low performance status or advanced illness may not be expected to benefit from the prolonged duration of patency in SEMS; patients with life expectancy of < 3 mo would achieve the same benefit of palliation with lower costs using plastic stents. Cost analysis has demonstrated superiority of SEMS when patient survival is expected to exceed 3 mo^[56,66-68]. As with pancreatic cancer patients, the treating endoscopist must consider expected length of survival when choosing an appropriate and cost-effective stent for palliation.

When bilateral or multisegmental stents are required for adequate biliary drainage, various techniques are available to place SEMS and take advantage of the prolonged duration of patency relative to plastic stents. Not all patients will require multiple SEMS; a meta-analysis by Sawas *et al*^[69] shows no statistical difference in rate of failures or cholangitis between unilateral and bilateral SEMS placement for hilar tumors. Other retrospective data has favored the use of bilateral stents over unilateral stenting, with superior length of patency using multiple stents^[70]. The two main techniques for use of multiple stents for hilar tumors are the "side by side" method, in which both stents are placed in parallel, or the "stent-in-stent" or "Y" method, in which the second stent is placed through the mesh interstices of the first stent with their distal ends overlapping^[71]. There are no large studies indicating which method is superior in terms of technical or clinical success. Additional studies have looked at a 3-branch stent-in-stent to allow for better patency of stenting, with promising results but high degree of challenge for the endoscopist^[72,73]. It is generally recommended that endoscopic therapy of advanced hilar strictures be performed by experienced endoscopists in a tertiary center with available backup by interventional radiologists and surgeons.

ENDOSCOPIC ADJUVANT TREATMENT OF BILIARY OBSTRUCTION: MOVING BEYOND STENTING

Patients with cholangiocarcinoma and pancreatic cancer

continue to have notoriously poor prognoses when surgical cure is not an option. Meta-analyses have not shown significant improvement with standard chemoradiation regimens for biliary malignancies^[74], likely due to late presentation and aggressive nature on presentation. However, two endoscopic therapies aimed at providing local control of malignant biliary obstruction have shown some promise in early studies.

Over the past decade the use of photodynamic therapy (PDT) has been studied for palliation of unresectable cholangiocarcinoma. This technique employs a photosensitizing molecule such as porfimer sodium which accumulates in tissue with rapid turnover such as malignant cells. After 48 h laser irradiation is then used to treat the tumor, leading to selective apoptosis within the tumor mass *via* generation of oxidative radicals. The application of oxygen and light can be performed through a cholangioscope for precise phototherapy administration to limit damage on normal tissue^[75]. The first randomized controlled trial of PDT when compared to biliary stenting alone showed a dramatic increase in survival time from 98 d to 493 d^[76]. Another RCT also showed median survival increased from 210 to 630 d^[77]. Retrospective data also contributes to the body of information supporting increased survival and quality of life when PDT is used in addition to biliary stents as well as chemotherapy^[78,79]. Side effects from phototherapy are mainly related to photosensitivity, requiring patients to avoid direct sunlight for 4-6 wk. In addition, the high cost of PDT may be a factor preventing its widespread use for local control of unresectable cholangiocarcinoma.

Radiofrequency ablation, previously used for colonic or esophageal malignancies as well as hepatocellular carcinoma, has also been increasingly studied for local treatment of biliary obstructive malignancies. Compared to PDT, it offers low cost and is technically simple to perform. RFA induces ablative necrosis and can be used to palliate known biliary malignancies by using a bipolar probe placed at the site of obstruction^[75]. RFA can be performed percutaneously or *via* a catheter inserted *via* ERCP. Ablation uses 7-10 W bursts to create coagulative necrosis of the intraductal tumor mass and when performed *via* ERCP is followed by biliary stent placement^[51,75]. Plastic stents are applied when future ablations are planned, while SEMS may be used when a single session is planned. The risk of adverse events is low but includes hemobilia and biliary fistulas. The body of literature supporting RFA for biliary malignancies is not as robust as that for PDT, consisting mostly of retrospective series^[80]. A retrospective comparison by Strand *et al*^[81] compared results in 48 patients (16 RFA, 32 PDT) which demonstrated similar median survival (9.6 mo in RFA, 7.5 mo in PDT). Future studies will be required to determine the optimal techniques for RFA, as well as the patient populations who are most likely to benefit. European studies have also investigated the use of RFA therapy to treat occlusion of SEMS without the need for additional stent placement^[82].

The role of RFA in distal malignant biliary obstruction has

not been defined, though early experience is encouraging. In a retrospective study of 20 patients undergoing RFA of biliary strictures, 8 patients had distal obstruction due to pancreatic adenocarcinoma or intraductal papillary mucinous neoplasm. The study showed a median increase of 3.5 mm in bile duct diameter following RFA treatment, with maintenance of stent patency at 30 d^[83]. Similarly, a registry of 69 patients who underwent RFA for malignant biliary obstruction included 19 patients with pancreatic cancer. Again, the median diameter of the bile duct improved following RFA treatment. Interestingly, the pancreatic cancer patients responded better to RFA than cholangiocarcinoma patients, with RR 1.8 for stricture improvement^[84]. Other outcomes such as length of survival have not yet been studied in these patients. While further data is needed, including high-quality prospective data, the ability to achieve local control and prolong survival in these diseases using endoscopic therapies is an exciting prospect.

CONCLUSION

The management of malignant biliary obstruction requires consideration of several factors prior to the act of decompression *via* endoscopic or percutaneous means. The location of the stricture and underlying malignancy will affect the approach, as hilar stricture may be much more difficult to treat compared to simple strictures of the distal common bile duct. The stage of underlying malignancy also plays a role, as resectable disease may not typically require preoperative biliary drainage. For most cases, preoperative biliary drainage is discouraged due to the high incidence of infectious complications. In patients undergoing neoadjuvant therapy for locally advanced disease, SEMS appear to be the optimal approach for distal strictures while most data for hilar strictures appears to favor PTBD or ENBD. For palliation in advanced malignancy, SEMS are generally favored if life expectancy exceeds 3-4 mo, while plastic stents are favored in patients with particularly poor prognosis. The use of photodynamic therapy and radiofrequency ablation to achieve local control of these malignancies is an important step in prolonging survival, and presents an opportunity for endoscopists to have an increased role beyond stent placement in improving the quality and quantity of life for patients with cancer and biliary obstruction.

Abstract

Adenocarcinoma of small intestines (SBA) is a relatively rare malignancy with poor outcomes due to delayed diagnosis. Fifty percent of patients have metastases on presentation and therefore early detection and treatment offers the best long term outcomes. Certain genetic polyposis syndromes and familial diseases are associated

with increased risks for SBA. These include familial adenomatous polyposis (FAP), Lynch syndromes (LS), Juvenile polyposis syndrome, Peutz-Jeghers syndrome, Crohn's disease (CD) and celiac disease. Mutations in *APC* gene, Mismatch repair genes, *STK11* gene, and *SMAD4* gene have been implicated for the genetic diseases respectively. While there are no specific inherited genetic mutations for CD, genome-wide association studies have established over 140 loci associated with CD. CpG island mutations with defects in mismatch repair genes have been identified in celiac disease. Significant diagnostic advances have occurred in the past decade and intuitively, it would seem beneficial to use these advanced modalities for surveillance of these patients. At present it is debatable and no clear data exists to support this approach except for established guidelines to diagnose duodenal polyps in FAP, and LS. Here we discuss the genetic alterations, cancer risks, signaling mechanisms and briefly touch the surveillance modalities available for these genetic and clinical syndromes. English language articles from PubMed/Medline and Embase was searched were collected using the phrases "small-bowel adenocarcinoma, genetics, surveillance, familial adenomatous polyposis, lynch syndromes, Peutz-Jeghers syndrome, juvenile polyposis syndrome, CD and celiac disease". Figures, tables and schematic diagram to illustrate pathways are included in the review.

Key words: Small intestinal adenocarcinoma; Genetic risks; Mutations; Signaling pathways; Surveillance

Core tip: Adenocarcinoma of small intestine (SBA) is a relatively rare malignancy with poor outcomes due to delayed diagnosis. Certain genetic and familial diseases are associated with increased risks for SBA. These include Familial adenomatous polyposis, lynch syndromes, juvenile polyposis syndrome, Peutz-Jeghers syndrome, Crohn's disease and celiac disease. We discuss the clinical implications of

this aggressive cancer focusing on the genetic and familial associations, signaling mechanisms and available diagnostic modalities for surveillance.

Shenoy S. Genetic risks and familial associations of small bowel carcinoma. *World J Gastrointest Oncol* 2016; 8(6): 509-519 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i6/509.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i6.509>

INTRODUCTION

Small intestine comprises majority of the anatomical length and absorptive surface of gastrointestinal (GI) tract but accounts for less than five percent of GI tract malignancies^[1]. According to the seer's database an estimated 9410 new small bowel adenocarcinoma (SBA) cases and 1260 deaths may have occurred in the United States in 2015^[2].

Certain genetic syndromes and familial diseases are associated with SBA (Table 1). These are a heterogeneous group of familial polyposis and non-polyposis syndromes, inflammatory bowel diseases, and autoimmune diseases with distinct epidemiology, genetics, clinical presentation, treatment strategies, surveillance and outcomes.

These groups with inherent risk for both small bowel and colorectal cancers (CRC) have established surveillance recommendations for CRC but there are no clear guidelines for surveillance of small bowel cancers. Significant diagnostic advances have occurred in the past decade and patients may benefit for small bowel surveillance using these diagnostic modalities.

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is an autosomal dominant genetic disorder affecting approximately 1:10000 newborns caused by mutation of the APC gene on the long arm of chromosome 5. Multiple polyps of the colon and rectum are pathognomic of FAP. Polyps could be sessile or pedunculated and histology's may vary from tubular to villous adenoma. Most patients develop polyps by second decade and if untreated colon malignancy by the fourth decade (15% of gene carriers by age 10 years, 75% by 20 years, and 90% by 30 years)^[3].

The incidence of small intestinal cancers in FAP is not clear however the adenoma-carcinoma sequence for development of cancer is well established^[3-6]. In addition these patients are predisposed to multiple small bowel adenomatous polyps usually in the duodenum and periampullary region^[7,8].

The pathogenesis of these polyps is due to dysregulation of the canonical Wnt/ β -catenin pathway. The APC protein is a tumor suppressor, involved in cell adhesion, transduction and transcription, cell cycle control, maintenance of fidelity of chromosomal segregation and apoptosis. As part of a

scaffolding protein complex, it is a negative regulator of Wnt signaling pathway (Figure 1).

In the absence of Wnt signaling, cytosolic β -catenin that is not bound by cell-cell adherens junction is transferred to the degradation complex consisting of the proteins APC, axin, casein kinase 1 (CK1) and glycogen synthase kinase 3 (GSK3). CK1 and GSK3 phosphorylate and prime the unbound β -catenin targeting it for ubiquitination, and leads it to proteasome to be digested. This prevents translocation and accumulation of β -catenin into the nucleus.

Normally nuclear translocation of β -catenin leads to the expression of genes such as c-Myc and Wnt target genes: Promoting cell growth, division, proliferation and differentiation. It also regulates cell-cell adhesion and is important for tissue formation^[4,5].

More than 700 mutations of APC gene have been identified with the classic and attenuated types of FAP. APC gene mutation leads to production of truncated, nonfunctional version of this protein. This truncated APC protein fails to suppress the canonical Wnt/ β -catenin pathways even in the absence of Wnt signaling, results in unopposed translocation of β -catenin in the nucleus and stimulates transcription of c-Myc and other Wnt target genes that leads to the formation of polyps and predispose to cancers^[4,5]. In addition APC also interacts with microtubules, loss of APC may lead to mitotic spindle defects, leading to chromosome abnormalities when cells divide.

While colorectal polyps and cancer remains the primary tumors in FAP and advanced surgical techniques have reduced mortality from colorectal carcinoma, the leading second primary malignancy in these individuals is duodenal and small bowel carcinoma. The prevalence of duodenal adenomas is 50%-90% and these patients carry a relative risk of 330 for adenocarcinoma or up to 5% lifetime risk. The risk is highest in periampullary adenomas^[9]. The adenoma formation is not restricted to the duodenum but also noted in jejunum and ileum in 50%-75% of the patients. Studies using video capsule endoscopy (VCE) and balloon-assisted enteroscopy (BAE) confirm the presence of jejunal and ileal polyps frequently in FAP, especially with extensive duodenal polyposis^[10-12].

The increased risk for SBA appears to correlate between the severity of duodenal polyposis and presence of jejunal polyps^[10-13]. Scattered case series, report an association of marked duodenal polyposis, with higher stages of the disease on diagnosis and worse prognosis^[7]. Spigelman in 1989 developed an endoscopic scoring system (stage 1-4) to describe the severity of duodenal polyps in FAP. Predictors include the number, size, histology and the degree of dysplasia^[8]. The risk of progression to adenocarcinoma is associated with the size and histology of these polyps: 8.3% risk for sub centimeter polyps to 30% for polyps greater than 2 cm. Tubular adenoma carries a risk of (14%), increases to (23%) for tubulo-villous adenoma, and (36%) for villous

Table 1 Genetic risks and familial associations of small bowel carcinoma

Syndrome	Mode of inheritance	Mutated/associated gene	Relative risk (95%CI)	Lifetime risk for SBA	Polyps/pathway
FAP ^[7,29]	Autosomal dominant (AD)	APC	330 (132-681)	3%-5%	Adenoma-carcinoma
HNPCC/ LS ^[13,14,29]	AD	MMR (MSH2, MSH6, MLH1, PMS2)	291 (71-681)	1%-4%	Adenoma-carcinoma
PJS ^[31,36,37]	AD	STK11	500 (220-1306)	1.7%-13%	Hamartoma, adenoma-Ca
JPS ^[38,41]	AD	BMPRIA, SMAD4	Unknown	Unknown	Hamartoma, adenoma-Ca
Crohn's disease	Unknown (genome wide studies have associated 140 loci)	Unknown	30-60 ^[44-49] (15-609)	2.2% after/25 yr	Dysplasia-carcinoma
Celiac disease	Association with HLA-DQ2,HLA-DQ8	Unknown	60-80 ^[61-63] (7-240)	< 1%	Adenoma-carcinoma

FAP: Familial adenomatous polyposis; APC: Adenomatous polyposis coli; HNPCC: Hereditary nonpolyposis colorectal cancer; MMR: Mismatch repair gene; LS: Lynch syndrome; PJS: Peutz-Jeghers syndrome; STK11: Serine threonine kinase; JPS: Juvenile polyposis syndrome; BMPRIA: Bone morphogenetic protein receptor, type IA; SMAD4: Mothers against decapentaplegic homolog; HLA: Human leukocyte antigen complex.

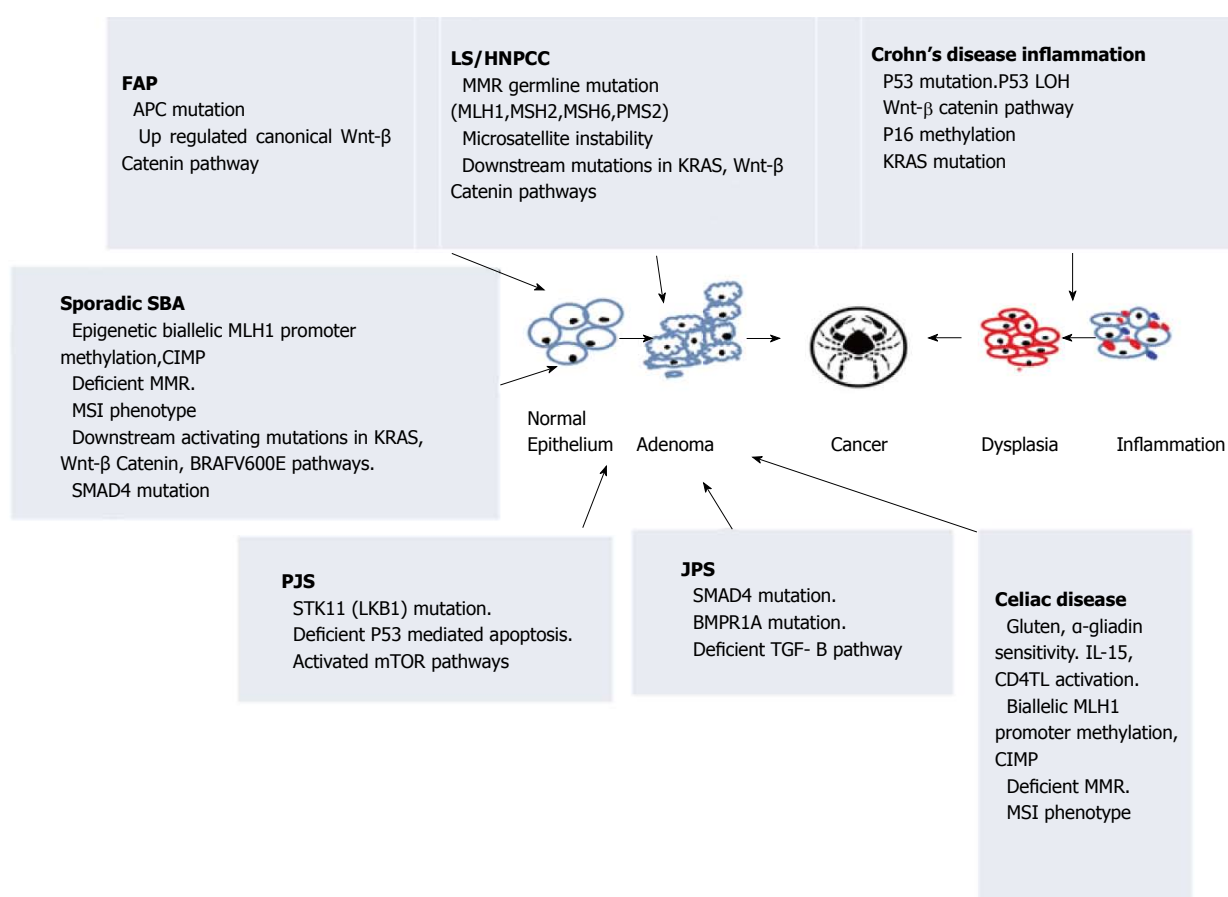

Figure 1 Schematic drawing of genetic and molecular pathways predisposing to small bowel carcinoma. Wnt: Wingless-type MMTV integration site family; KRAS: Kirsten rat sarcoma viral oncogene homolog; LOH: Loss of heterozygosity; CIMP: CpG island methylator phenotype; MSI: Microsatellite instability; BRAFV600E: V-raf murine sarcoma viral oncogenes homolog B; mTOR: Mammalian target of rapamycin; TGF-β: Transforming growth factor β; IL: Interleukin; CD4TL: CD4 T-lymphocytes.

adenomas^[1,14,15]. The significance of small bowel polyps beyond the duodenum is not defined given the fact that up to 44% of patients with FAP develop extensive (stage 4) duodenal polyps with aging but overall incidence of cancer is less than 5%^[13,16].

Due to this reason gastroduodenal surveillance with

endoscopy is generally limited for duodenal polyps^[7]. The exact age and interval to begin surveillance upper endoscopy is still debatable, some authors recommend annual endoscopy starting after colonic polyps are diagnosed or as early as 15 years of age^[17] while other authors suggest starting at age 25 years and interval

Figure 2 65-year-old male with familial adenomatous polyposis, previous total proctocolectomy 35 years ago with ileostomy adenocarcinoma: Polypoid growth at the ileostomy orifice.

based on severity as suggested by Spigelman grading system^[13,18].

Based on the existing data there are no recommendations or guidelines for surveillance of small bowel beyond the duodenum in FAP. Further research is required to identify what patients with FAP are at an increased risk for small bowel carcinoma^[13,19].

One unique subset of patients is FAP with ileostomy and ileoanal pouch carcinoma. Currently prophylactic restorative proctocolectomy with ileoanal pouch anastomosis (IPAA) is the preferred operation in FAP. Previously total proctocolectomy with end ileostomy was the operation most often performed for FAP^[20,21]. These patients with functioning ileostomies have an inherent risk for development of ileostomy adenocarcinoma (Figure 2). Adenomas frequently form in 35% of ileoanal pouches, examined in FAP who underwent restorative proctocolectomy^[22]. The risk of developing adenomas increases with the longevity of these functioning ileostomies. The estimated risks at 5, 10 and 15 years were 7%, 35%, 75% respectively. This predilection to form adenomas, may progress to adenocarcinoma. Positive immunostaining of β -catenin, p53 and frequent occurrence of KRAS mutations suggests adenoma-carcinoma sequence similar to colorectal cancers^[23]. The current recommendations for these patients is periodic clinical and endoscopic examination of their stomas and pouches with biopsies of any suspicious lesions^[21,24].

LYNCH SYNDROME

Lynch syndromes (LS) are an autosomal dominant genetic disorder with germline mutations of mismatch repair genes (MMR): MLH1, MSH2, MSH6 and PMS2. MLH1 and MSH2 mutation variants represent about 90% of families with LS; MSH6 variants in another 7%-10% and PMS2 mutation in less than 5%. Germline deletions in EPCAM (epithelial cell adhesion molecule) inactivate MSH2 in a small subset (< 1%) of patients with LS^[17].

Affected individuals carry the risk for colorectal, endometrial and ovary, genitourinary tract, stomach, hepatobiliary, pancreas and small bowel cancers (Figure 3).

The pathogenesis of these tumors involves microsatellites, which are short stretches of DNA with repetitive sequences of nucleotides and are susceptible to acquiring errors when MMR gene function is impaired. MMR genes present on different chromosomes coordinate the activities of other proteins such as DNA polymerase that maintain the fidelity of DNA replication and genomic integrity. MMR system encode for proteins that form DNA MMR complexes. These correct small insertions or deletions that may occur during somatic division. Thus MMR system proofreads and repairs defects that were overlooked by DNA polymerase.

Cancerous cells with defective MMR gene function exhibit microsatellite instability. This refers to an inconsistent number of microsatellite nucleotide repeats when compared to normal tissue. This phenotype with a markedly high rate of mutations involving cell-cycle regulation increases the risk of malignancy (Figure 1)^[17].

Immunohistochemistry of the tumor samples are used to detect the absence of the protein products of mismatch repair genes. These gene products function as dimers: MSH2 protein may complex with MSH6 or MSH3 protein, and MLH1 protein complexes with PMS2 or PMS1 protein. MSH6 and PMS2 proteins are unstable when unpaired. A pathogenic variant in MSH2 typically results in loss of expression of the proteins MSH2/MSH6 and a germline pathogenic variant in MLH1 results in loss of expression of the proteins MLH1/PMS2. Germline pathogenic variants in MSH6 and PMS2 typically do not result in loss of MSH2 or MLH1 expression because these proteins are still present in other pairings.

LS accounts for 3% to 5% of all CRC^[25] and it is the commonest inherited colon cancer syndrome. The average age of malignancy in LS is 44 years, vs 64 years in sporadic CRC^[3,17].

The risk factors for SBA in LS patient's increase with age, beginning at 40 years and a tenfold rise by the age of 60^[26]. Compared to sporadic SBA in general population, patients with LS present a decade earlier. About 10% of patients develop cancers before the age of 30^[27]. The lifetime risk for SBA is estimated as 1%-4% and is greater than 100 fold risk compared to general population^[13,14,28].

In 30%-70% patients with LS small bowel cancer may be the primary malignancy to manifest^[29]. The incidence appears higher in MLH1, and MSH2 carriers compared to MSH6^[13,29]. Further regional variations between various registries have been noted for the incidence of small bowel cancer. For instance Finnish and French (HNPCC/LS) patients have lesser incidence of small bowel cancer compared to Dutch (HNPCC/LS) patients^[28,29].

Most data from series of patients point to adenoma-carcinoma sequence comparable to colorectal neoplasia. Molecular data as described earlier indicate accumulation of mutations as an inciting event in the development of small bowel cancers similar to colorectal cancers. Some authors recommend that patients presenting with SBA routinely undergo analysis of the MMR phenotype

Figure 3 Sixty-nine-year-old male with family history of Lynch syndrome, jejunal adenocarcinoma, viewed on small bowel enteroscopy.

and screened for LS^[13,28,29]. This is especially true for histological findings of mucinous tumors infiltrated with lymphocytes and pushing tumor border suggestive of MSI phenotype in 75% patients^[29]. There are implications in choosing adjuvant chemotherapy regimen in this phenotype, as cancers deficient in MMR proteins may be resistant to 5-FU based chemotherapy^[30].

Upper endoscopic surveillance is recommended over the age of 30 years for gastric and duodenal polyps however at present there are no guidelines for small bowel cancer surveillance in LS^[13,14,17,26,28].

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is an autosomal dominant condition with mutation in the serine threonine kinase 11 (*STK11*) genes on the short arm of chromosome 19. The incidence of PJS is reported to be 1 in 50000 to 1 in 200000 live births. PJS is characterized by melanin spots on the buccal mucosa and predilection to form multiple gastrointestinal hamartomas and polyps. These are scattered throughout the small bowel, predominantly in the jejunum and ileum.

The *STK11* gene (also called *LKB1*) encodes for enzyme serine/threonine kinase 11^[31]. *STK11* is a tumor suppressor gene and associates with TP53 to regulate TP53-dependent apoptosis pathways^[32]. It also has a role in cell polarity, cell metabolism and energy homeostasis^[33]. Inactivation of *STK11* is an early event in the development of hamartoma and adenocarcinoma. In addition to loss of *STK11* function and altered TP53 expression, adenocarcinomas in PJS also demonstrate loss of heterozygosity (LOH) in 17p and 18q. These deletions are associated with an increased tendency of disease dissemination in colorectal cancer. *STK11* also exerts its inhibitory effects by phosphorylating and activating 14 protein kinases, all related to the AMP-activated protein kinases (AMPK)^[33]. AMPK is an evolutionally conserved serine threonine kinase and its activation by *STK11* leads to upregulation of signaling through the TSC (Tuberous sclerosis) complex. This in turn negatively regulates mTOR pathways. Loss of *STK11* activity leads to increased mTOR activity and characterized by an increased risk of malignancy (Figure 1)^[31,33,34].

Hamartomatous and adenoma polyps are scattered

throughout the small bowel, predominantly in the jejunum and ileum. Patients with PJS are predisposed to multiple GI tract and non GI tract malignancies which include breast, ovaries, testicular, pancreas, esophagus, stomach and non-small cell lung cancers^[34,35].

SBA has been known to occur in PJS. Meta-analysis of SBA in PJS compared to general population indicates a relative risk of 520^[36]. The life time incidence for adenocarcinoma is 1.7%-13% and rises rapidly in elderly^[36,37]. Adenocarcinoma originates from both adenomas and hamartomas. Intraepithelial neoplasia is observed in the hamartoma lesions^[29,36,37]. Due to the rarity of this condition, current surveillance protocols are not evidence-based. Endoscopies are performed more often to detect polyps which may pose a risk for intussusception, obstruction rather than cancers. Routine screening is recommended, beginning at age 18 with every 2-3 year interval^[31,35,36]. Recent study suggests surveillance with VCE beginning at the age 8 years and performed every three years if polyps are detected at initial examination. With a negative initial exam, surveillance should recommence at 18 years^[31].

JUVENILE POLYPOSIS SYNDROME

Juvenile polyposis syndrome (JPS) is an autosomal dominant disorder which is characterized by multiple hamartomatous polyps of the gastrointestinal tract and is the most common hamartomatous polyp syndromes with prevalence estimated to be between 1 in 16000 to 1 in 100000^[3,38]. Juvenile refers to the sporadic inflammatory hamartomatous polyps of childhood, rather than the age of onset. Most affected individuals have some polyps by age 20 years^[3]. Most are benign polyps, but malignant transformation may occur resulting in increased lifetime risk for colon (10%-40%) and stomach (21%) cancers and less commonly involving the small bowel and pancreas. The lifetime risk of SBA has been difficult to estimate due to the rarity of the disease and is also reduced by screening polypectomies. Malignant transformation occurs through traditional adenoma to cancer transformation sequence. Multiple genetic alterations similar to colorectal neoplasia also play a role in neoplastic transformation of juvenile polyps^[39].

Two genes, SMAD4, BMPR1A, have been implicated in

the pathogenesis of polyps in JPS. They encode proteins for either, transforming growth factor- β (TGF- β) or bone morphogenetic protein (BMP) signaling pathways. The *SMAD* gene on chromosome 18q21.1, adjacent to *DCC* (deleted in colon cancer) is a part of the TGF- β signal transduction pathway. SMAD4 proteins transmit TGF- β related growth-suppressing signals from cell membranes to nucleus mediating growth inhibition and apoptosis. The SMAD4 protein serves both as a transcription factor and as a tumor suppressor^[3]. More than 60 mutations in the *SMAD4* gene have been implicated in JPS. This results in the production of a truncated, nonfunctional protein thereby preventing transmission of TGF- β growth suppressing signals from the cell surface to the nucleus (Figure 1) leading to unregulated cell growth and susceptibility to polyp formation in JPS.

Mutations in *BMPR1A* on chromosome 10 are found in 20% to 25% of individuals with JPS^[40]. *BMPR1A* is a serine-threonine kinase (STK) type I receptor of the TGF- β superfamily, which when activated leads to phosphorylation of SMAD4 proteins. Mutations result in abnormal *BMPR1A* protein which cannot bind to ligands in the TGF- β pathway and interferes with the activation of the SMAD protein complex^[41].

Given the rarity of this disease there is no data on the incidence, relative risks, or life time risks of SBA and at present no guidelines exist for surveillance. Some authors do recommend upper endoscopy every 3-5 years from age 15, and repeated annually if polyps are diagnosed^[42].

CROHN'S DISEASE

Crohn's disease (CD) is an autoimmune inflammatory bowel disease affecting the GI tract with predilection for small intestine. The prevalence in North America ranges from 26.0 to 198.5 cases per 100000 persons. The incidence rates range from 3.1 to 14.6 cases per 100000 people per year^[43]. CD is characterized by transmural granulomatous inflammation of the small bowel in a discontinuous fashion and a tendency to form stenosis, strictures and fistulae. Adenocarcinoma of small intestines is a rare complication of CD with meta-analysis showing relative risks reported to be between 30 as 60 (95%CI: 15.9-60.9) compared to the general population^[44-48] and cumulative risk of 2.2% after 25 years of regional ileitis^[48,49]. The risk increases with chronicity of the disease, young age of onset, male sex, distal small bowel disease with strictures and fistulae.

CD results from abnormal mucosal immune response to environmental factors in genetically susceptible hosts. The granulomatous inflammation comprises of aggregates of macrophages, lymphocytes, plasma cells, and multinucleated giant cells that are formed in response to the release of inflammatory cytokines such as tumor necrosis factor^[15,50]. Etiologies in the pathogenesis of inflammatory bowel disease include genetic susceptibility, environmental, microbial factors and their interaction with intestinal epithelial cells and components of innate and adaptive immune system. Genetic susceptibility is confirmed with

higher prevalence in monozygotic twins and the familial clustering of the disease. A meta-analysis of six twin studies with a combined set of 112 MZ and 196 DZ twin pairs reported concordance rates of 30.3% and 3.6% respectively^[51]. Since 2006, genome-wide association studies have established over 140 loci associated with CD risk, however the significance and the contribution to the disease risk remains to be defined^[52].

The GI tract is continuously exposed to commensal internal flora and also pathogenic organisms and other environmental antigens. The integrity of the mucosal barrier is maintained by tight junctions occurring between adjacent epithelial cells and the relative impermeability of the apical villous epithelium which serves as an important function in the innate immune system. Complementing these are other cells such as Paneth cells which secrete antimicrobial substances such as, lysozymes, cysteine-rich defensins, and IgA and goblet cells which secrete mucus^[15,53]. These and other intrinsic defense mechanisms in the intestinal mucosa dilute, limit the adherence and invasion of commensal and pathogenic microorganisms and antigens. Alteration of this barrier leads to abnormal immune response by the effector lymphocytes and other proinflammatory cytokines leading to a state of chronic intestinal inflammation and its sequelae. Inflammatory cytokines produced by the immune system includes interleukins, chemokines, growth factors, and extracellular proteases. They interact with cell surface receptors and subsequently target genes which influence clonal neoplastic proliferation, angiogenesis and invasion through the basement membrane. In addition, excessive formation of reactive oxygen and nitrogen free radicals are potentially damaging to DNA and the integrity of cell surface membranes^[15].

Adenocarcinoma in CD is seen in the effected segments of the bowel which suggests inflammation-dysplasia-carcinoma sequence^[45,48,54,55]. Genetic alterations occur, which transform dysplastic mucosa to carcinoma. The prevalence of *MSI*, *APC*, *DCC* gene mutations are low, one study however showed 43% of patients with adenocarcinoma in CD carry K-RAS mutations, and overexpression of *p53* gene product in 71% of Crohn's associated carcinoma^[54]. Overexpression of *p53* is helpful to elucidate transformation from inflammation to dysplasia as inflammation does not overexpress *p53*^[55]. A mutational analyses of multiple areas of intestine from ten patients with CD and intestinal cancer, mutations in *KRAS*, *CDKN2A* (p16), and *TP53* that were observed in tumor cells was also present in non-tumor, and both nondysplastic and dysplastic epithelium suggestive of a field defect in CD^[56].

Another study on 41 patients with CD and small bowel cancer showed dysplasia association in 50% of the patients suggesting an inflammation-dysplasia-adenocarcinoma sequence in CD-related SBA, similar to what is observed in chronic colitis-related colorectal cancer (Figure 1)^[55,56]. The rarity of adenocarcinoma in CD makes mutation studies difficult. Perhaps analysis in multinational pooled data may reveal more information.

Symptoms highly suspicious for adenocarcinoma are development of a new small bowel stricture refractory to steroids or maximal medical management or a long standing quiescent disease with newly diagnosed small bowel obstruction. These warrant attention without delay. Compared to adenocarcinoma arising *de novo*, adenocarcinoma in CD present at a median age of 48 years, is more common in males, ileum as most common site and mucinous signet ring cell is more frequently seen^[57]. Early diagnosis and small bowel resection offers the best success for long term survival. Unfortunately majority of adenocarcinoma are diagnosed on post-operative specimens of resected bowel with metastatic nodal disease noted in 50% and distant metastases in 40% of patients. At present however there are no surveillance guidelines to detect SBA in patients with CD however study investigating the benefit of endoscopic surveillance of the small bowel lesions greater than 10 years duration is in progress^[55].

CELIAC DISEASE

Celiac disease is a chronic inflammatory autoimmune small intestinal disorder due to gluten sensitivity, an antigen in wheat, barley, rye and malt. It occurs in adults and children and affects 1% of the population. Celiac disease is associated with both human leukocyte antigen (HLA) and non-HLA genes and with other immune disorders, notably juvenile diabetes and thyroid disease. It is genetically associated with individuals positive for human leukocyte antigen-DQ2 or DQ 8. Familial aggregation is noted with 70% concordance in monozygotic twins^[58]. α -gliadin; a component of gluten is a 33 amino acid peptide sequence and is resistant to degradation by the proteases in the human intestines. Immune response to gliadin promotes inflammatory reaction in the small bowel. Infiltration of the lamina propria and the epithelium with chronic inflammatory cells (predominantly CD4 lymphocytes) triggers a cascade releasing cytokines, interferon- γ , interleukin-15 and metalloproteinases resulting in destruction of enterocytes, crypt hyperplasia and villous atrophy^[59,60].

Patients with celiac disease have an increased risk for enteropathy associated lymphomas as well as adenocarcinoma of the small intestine compared to the general population^[59,61]. Given the rarity of celiac disease and adenocarcinoma the true incidence is difficult to ascertain, however the reported relative risk is increased between 60-80 compared to the general population^[61-63]. Most commonly seen in jejunum, the natural history seems to follow the adenoma-carcinoma sequence as seen in colorectal neoplasms. Small bowel mucosa in celiac disease does not show any premalignant field defect or dysplasia in mucosa adjacent to the adenocarcinoma. However the mechanism for formation of adenomas in celiac disease has not yet been elucidated^[64].

Recent molecular studies have shown that celiac disease associated adenocarcinomas in the elderly are characterized by high level of CpG island methylation

(CIMP), MLH1 inactivation, microsatellite instability (MSI) and defect in the MMR pathways (Figure 1)^[65-67]. Methylation of CpG sites within the promoters of genes can lead to their silencing. This feature is found in a number of human cancers. Similar to LS as described earlier, celiac disease should be considered in the differential diagnosis in patients presenting with sporadic SBA, in the elderly, especially with MSI positivity^[65-67]. These sporadic and celiac associated tumors however show CIMP (CpG island methylator phenotype) and BRAFV600E hotspot mutations that serve to distinguish them from LS cases.

The risk for adenocarcinoma rises in longstanding, untreated celiac disease. Symptoms of celiac disease diagnosed in children and treated with gluten free diet often improve. This may create a false notion of having overcome the disease, with resurgence later in life. Development of new symptoms of weight loss, abdominal pain, anemia, blood loss, and fever in patients who were on a gluten free diet should raise suspicion of neoplastic transformation and should be thoroughly evaluated^[59]. At present there are no guidelines for small bowel surveillance for adenocarcinoma or lymphoma in asymptomatic patients with celiac disease.

SURVEILLANCE MODALITIES FOR SMALL BOWEL

The manifestations of small bowel malignancy are generally nonspecific and often diagnosed in advanced stages. Fifty percent of patients have metastases at diagnosis. Mean duration of symptoms before diagnosis is 10 mo^[68]. Diagnosis is often made with a combination of diagnostic tests which includes both endoscopy and radiography. Considerable advances have occurred in endoscopic techniques with introduction of capsule endoscopy and balloon assisted endoscopy. Also advances in both computed tomography (CT) and magnetic resonance imaging (MRI) enterography and enteroclysis are playing an increasing role in evaluation of small bowel diseases.

Endoscopy

Esophagogastroduodenal (EGD) endoscopy with front and side viewing camera is the standard diagnostic procedure and is accurate in identifying, biopsy of lesions proximal to the ligament of Trietz. Push enteroscopy can visualize the duodenum, proximal jejunum while balloon assisted enteroscopy (BAE) can visualize the entire small bowel (Figure 3). However the latter techniques are time consuming, technically challenging and often requires deep sedation or general anesthesia^[69]. BAE encompasses both single and double balloon techniques and can be performed through the oral or anal route. A complete small bowel examination can be accomplished in up to 80% of the patients. It carries the advantage of ability to perform endoscopic interventions such as biopsy, polypectomy and marking the lesion^[69-71]. A fewer studies

utilizing BAE techniques have confirmed the presence of small bowel polyps in patients with FAP^[10,71,72].

Video capsule endoscopy

Video capsule endoscopy (VCE) has become one of the most important investigational tools for small bowel mucosal evaluation. Due to ease of the procedure it has become a first line tool to detect small bowel abnormalities in non-obstructed patients for evaluation of small intestinal diseases such as occult GI bleeding, suspected CD, celiac disease, small bowel tumors, and motility disorders^[73]. Most VCE studies show the presence of small bowel polyps ranging 50%-87% in patients with FAP^[11,12] and there are a few case series suggesting the role of VCE in LS^[74,75]. A study comparing VCE to MRI showed the advantage of VCE to detect smaller polyps. Polyps larger than 15 mm were detected equally in both groups, whereas smaller polyps were seen much more often with capsule endoscopy. Polyps that were smaller than 5 mm were exclusively seen with capsule endoscopy. However, location of the detected polyps and determination of their exact sizes was more accurate by MRI^[76,77].

Drawback for VCU include capsule retention, missed polyps < 1 cm, especially duodenal polyps (due to rapid transit)^[73,78]. Using combination of VCE and subsequent BAE for endoscopic intervention offers an ideal method of surveillance and treatment in these polyposis syndromes, avoiding a laparotomy. The value of such approach is yet to be demonstrated^[13].

CT and MRI enterography and enteroclysis

Advances in temporal and spatial resolution offered by CT scan and MRI scan with newer enteric agents used to distend the small bowel have replaced barium radiography as the preferred diagnostic tests. Both CT and MRI scan provide details of the bowel wall and the mesentery and the surrounding viscera. Enterography entails using oral contrast while for enteroclysis a nasojejunal tube need to be inserted to deliver the contrast. Enteroclysis provides better bowel distension offers improved mucosal details. MRI enteroclysis has been shown to be a more dynamic and sensitive than CT enteroclysis for mucosal details. These are due to better soft tissue contrast that is achieved with MRI^[79,80]. A study on 150 patients with MRI enteroclysis showed sensitivity, specificity of 86% and 98% respectively^[81]. A recent study compared VCE to MRI enteroclysis with results showing higher specificity of MRI images in detecting small bowel lesions^[82]. The authors attributed this to the distension of the small bowel with enteroclysis and a three dimensional views compared to a uni-directional view of the VCE. Secondly MRI enteroclysis may be beneficial in stenosis or strictures in small bowel disease as the risk of capsule retention are eliminated.

CONCLUSION

Certain genetic and familial diseases are associated

with increased risks for SBA. The pathogenesis and molecular mechanisms for some of these syndromes are described and the risk varies according to the types of polyps and polyposis syndromes. Although the overall incidence of SBA is low the prognosis remains dismal due to nonspecific symptoms and often a delay in diagnosis. Intuitively it would seem that use of surveillance modalities may benefit these patients at higher risk for SBA. At present it is debatable and there is no data to support this approach except for established guidelines to diagnose duodenal polyps in FAP, and LS. Further research, perhaps multi-institutional study is warranted focusing on identifying patients who are at risk for small intestinal adenocarcinoma and on optimal surveillance strategies.

Abstract

AIM: To evaluate the association between the interleukin 1 β (IL-1 β) polymorphisms and the pancreatic neuroendocrine tumor (pNET) development.

METHODS: A case-control study was conducted analyzing IL-1 β polymorphisms using germline DNA collected in a population-based case-control study of pancreatic cancer (51 pNET cases, 85 pancreatic ductal adenocarcinoma cases, 19 intraductal papillary mucinous neoplasm and 98 healthy controls).

RESULTS: The distribution of genotypes for the -511

C/T polymorphism in the pNET patient groups showed significant difference compared to the control group. It is known that the carriers of the IL-1 β -511T allele have increased concentrations of IL-1 β . The -511 CT and TT high-expression genotypes were over-represented in pNET patients.

CONCLUSION: The findings of this study suggested a possible role of IL-1 β -511 C/T genotypes in the pathogenesis of pNETs since the presence of the IL-1 β -511 CT and TT genotypes and the T allele was associated with an increased risk of pNET only.

Key words: Interleukin 1 β ; Neuroendocrine tumors; Pancreas

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Pancreatic neuroendocrine tumors (pNETs) are a heterogeneous group of rare neoplasms derived from pancreatic endocrine cells and have significantly different tumor biology and present better prognosis compared with tumors of the exocrine pancreas, like pancreatic adenocarcinomas. It is widely accepted that chronic inflammation contributes to pathogenesis of many pancreatic diseases, including pancreatic carcinogenesis. Interleukin 1 β (IL-1 β) is a highly active pro-inflammatory cytokine with multiple biological effects, such as directing cancer cells to either neuroendocrine differentiation or to development of adenocarcinoma. The purpose of the study was to evaluate the association between the IL-1 β polymorphisms and the pNET development.

INTRODUCTION

Pancreatic neuroendocrine tumors (pNETs) are a heterogeneous group of rare neoplasms derived from pancreatic endocrine cells^[1-5]. The annual incidence of pNETs is estimated to be approximately 3.65 per 100000 individuals in the United States and occur sporadically or may be associated with genetic syndromes such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel-Lindau syndrome (VHL), von Recklinghausen disease (neurofibromatosis NF-1), and tuberous sclerosis complex (TSC)^[6-8].

pNETs are mainly considered functionally inactive tumors, but when related with hormone or peptide over-production, such as insulin, gastrin, glucagon, vasoactive intestinal polypeptide (VIP) and somatostatin they are responsible for many characteristic clinical syndromes, with insulinoma being the most common pNETs are usually

asymptomatic^[9,10], have significantly different tumor biology, and present better prognosis compared with tumors of the exocrine pancreas, like pancreatic adenocarcinomas (PDACs)^[11].

The molecular basis of pNETs pathogenesis is poorly characterized but several recent reports have been conducted in order to clarify their etiology^[12].

It is widely accepted that chronic inflammation contributes to pathogenesis of many pancreatic diseases, including pancreatic carcinogenesis^[13,14]. However, the exact mechanism by which chronic inflammation promotes carcinogenesis is still unknown. During carcinogenesis the host-mediated anti-tumor activity is suppressed, whereas pro-inflammatory events support tumor growth, angiogenesis, invasion and metastasis^[15]. The inflammatory response is mediated by cytokines, which are glycoproteins or soluble proteins and their role in cancer immunity and carcinogenesis has been well established^[16-18].

Neuroendocrine tumors express various cytokines and growth-factors. Several pro-inflammatory cytokines have been found in pNETs tissue suggesting their involvement in pNET development^[19-21]. Additionally, numerous studies suggested that gastroenteropancreatic-NETs occur more frequently in the environment of chronic inflammation^[22-24]. Thus, cytokines such as interleukin 1 (IL-1) poses an important role in neuroendocrine tumors since direct cancer cells to either neuroendocrine differentiation or to development of adenocarcinoma, while exogenously added IL-1 results in a decrease of chromogranin A (CgA) and simultaneous increase in carcinoembryonic antigen (CEA) secretion^[25].

IL-1 β is a highly active pro-inflammatory cytokine with multiple biological effects^[26]. IL-1 β protein levels are related to the intensity of the inflammatory response, and regarding to pancreas, IL-1 β is implicated in cancer progression, especially tumor invasiveness, metastasis and angiogenesis^[27,28].

The IL-1 β gene is located in the IL1 cluster on chromosome 2q and several single nucleotide polymorphisms (SNPs) of this gene influence the regulation of its expression and function have been studied^[29-32]. There are two SNPs in the proximal promoter region of the IL-1 β gene, -511 C/T and +3954 T/C, which both have been correlated with gastrointestinal cancers, such as gastric, hepatocellular cancer (HCC) and pancreatic cancer^[33-36]. Recently, Cigrovski Berković *et al.*^[37] reported that the IL-1 β -511 SNP contributes to the pNET susceptibility.

We conducted a case-control study to analyze IL-1 β polymorphisms as risk factors for pNETs using germline DNA collected in a population-based case-control study of pancreatic cancer [51 pNET cases, 85 PDAC cases, 19 intraductal papillary mucinous neoplasm (IPMN) and 98 healthy controls] conducted in the Athens, Greece and Izmir, Turkey areas.

MATERIALS AND METHODS

Patients

The case-control study included 51 pNET cases (22

Table 1 Characteristics of the patients and controls *n* (%)

nonfunctional and 29 functional), 85 PDAC cases, 19 IPMN and 98 healthy controls (Table 1). None of the cases had a history of chronic pancreatitis. For subsequent analysis, we excluded cases and controls with known genetic syndromes (*e.g.*, MEN1, MEN2, VHL or TSC). Controls were healthy blood donors with no evidence of inflammation. The diagnosis in all cases was established by standard procedures and confirmed histopathologically either from operatively resected tumors or biopsy tissues, in cases of unresectable tumors. Before commencement of the study, the Ethical committee at the participating centers approved the recruitment protocols. All participants were informed regarding the study, and their written consent was provided.

Genotyping

Genomic DNAs were isolated from peripheral ethylenediaminetetraacetic acid-treated blood of patients and healthy controls using the NucleoSpin Blood Kit (Macherey-Nagel, Germany). The *IL-1 β* -511 C/T (rs16944) polymorphism was detected by PCR-RFLP using the set of primers: 5'-TGGCATTGATCTGGTTCATC-3' and 5'-GTTTAGGAATCTTCCCACTT-3'. The 35 cycles of PCR were carried out at 94 °C for 5 min, 94 °C for 1 min, 58 °C for 40 s and 72 °C for 1 min and the final cycle of 72 °C for 5 min. Amplified PCR products were digested with *Ava*I for 2 h at 37 °C. The fragments of 189- and 116-bp revealed homozygosity for the C allele, and 305-bp indicated homozygosity for the T allele. The +3954 C/T (rs 1143634) polymorphism was detected with the 5'-TCAGGTGTCCTCGAAGAAATCAAA-3' and 5'-GGTTTTTGTCTGTGAGTCCC-3' set of primers and the cycling parameters for that was 94 °C for 5 min, 94 °C for 45 s, 56 °C for 45 s and 72 °C for 45 s and the final cycle

of 72 °C for 5 min. After 35 cycles the PCR product were digested for 2 h at 65 °C with *Taq*I. The fragments of 97- and 85-bp revealed homozygosity for the C allele and on the other hand 182-bp fragments showed homozygosity for the T allele.

Statistical analysis

Genotype frequencies were compared with the χ^2 with Yate's correction using S-Plus (v. 6.2, Insightful, Seattle, WA). Odds ratios (ORs) and 95% CIs were obtained with GraphPad (v. 3.00, GraphPad Software, San Diego, CA). The *P* values are all two-sided, and *P* values of < 0.05 were considered to be significant. Hardy-Weinberg equilibrium was verified by calculating the expected frequencies and numbers and was tested separately in patients and in controls using the goodness-of-fit χ^2 test. Haplotype analysis was performed using the <http://bioinfo.iconcologia.net/SNPstats> software.

RESULTS

The clinicopathological characteristics of the studied population are summarized in Table 1. The genotype frequencies of the *IL-1 β* -511 C/T and +3954 C/T polymorphisms between PDAC, pNET, IPMN patients and controls are given in Table 2. All genotype distributions were in Hardy-Weinberg equilibrium. The distribution of genotypes for the -511 C/T polymorphism in the pNET patient groups only showed significant difference compared to the control group. It is known that the carriers of the *IL-1 β* -511T allele have increased concentrations of IL-1 β ^[38]. The -511 CT and TT high-expression genotypes were over-represented in pNET patients (Table 2). However, the presence of the +3954T

allele seems to have a protective role in the pNET development since it is found to be over-represented in healthy controls. The haplotype analysis did not reveal any significant association. No significant association was found between genotypes, haplotypes, and clinico-pathological data of the patients.

DISCUSSION

PNETs are a rare, heterogeneous group of neuroendocrine tumors. They usually have a better prognosis than the PDACs. The cause of these tumors is not fully understood, but differential expression of proinflammatory cytokines were found in pNET tissues^[19-21]. The findings of this study suggested a possible role of IL-1 β -511 C/T genotypes in the pathogenesis of pNETs since the presence of the IL-1 β -511 CT and TT genotypes and the T allele was associated with an increased risk of pNET only. None significant correlation was found with PDAC and IPMN cases. Although Barber *et al.*^[36], reported that the +3954 C/T polymorphism of the IL-1 β gene predisposes to pancreatic cancer; our findings did not reveal any significant association. Additionally, they are partly in agreement with the findings of Cigrovski Berkovic *et al.*^[37], which suggest that there is an association between the IL-1 β -511 C/T genotype and the susceptibility to pNET, especially functional pNETs. In our study we did not find any haplotype combination to be statistically associated with the susceptibility to pNETs, neither PDAC nor IPMN cases, but we observed that the +3954T allele is over-represented among healthy controls compared to pNET cases suggesting that this allele might have a protective role in pNET development.

Carcinogenesis in the gastrointestinal tract and pancreas is often associated with chronic inflammation^[39-42]. It is known that the carriers of the -511T allele associated with high IL-1 β serum levels^[38], and in different type of cancers IL-1 β levels correlate with inflammation, worse prognosis and carcinoembryonal antigen (CEA) levels, a well-known

biomarker of tumor exocrine differentiation^[25,43].

Our previous results suggested that TNF- α -1031 polymorphism is associated with the development of pNET and IPMN^[41], and several studies supported that pro-inflammatory cytokines were detected in pNET tissues signifying their etiological involvement^[19,44]. Taken these into consideration future studies in larger populations are needed to elucidate the role of cytokines and inflammatory pathway in the sporadic pNET development.

COMMENTS

Background

Carcinogenesis in the gastrointestinal tract and pancreas is often associated with chronic inflammation. The study provides evidence of a role of interleukin 1 β (IL-1 β) -511 C/T genotypes in the pathogenesis of pancreatic neuroendocrine tumors (pNETs).

Research frontiers

PNETs are a rare, heterogeneous group of neuroendocrine tumors. They usually have a better prognosis than the pancreatic adenocarcinomas. The cause of these tumors is not fully understood, but differential expression of proinflammatory cytokines were found in pNET tissues. Identifying genetic factors associated basically with pNET incidence may help in the primary prevention of pNET across the globe.

Innovations and breakthroughs

The study suggested a possible role of IL-1 β -511 C/T genotypes in the pathogenesis of pNETs since the presence of the IL-1 β -511 CT and TT genotypes and the T allele was associated with an increased risk of pNET only.

Applications

The study contributes to elucidate the role of cytokines and inflammatory pathway in the sporadic pNET development.

Terminology

PNETs: Pancreatic neuroendocrine tumors; PDACs: Pancreatic adenocarcinomas; IPMN: Intraductal papillary mucinous neoplasm.

Peer-review

This is an interesting study that looks at IL-1 β as a potential inflammatory

cytokine stimulus for tumour formation in pNETs. While chronic inflammation is known to contribute to carcinogenesis, in the pancreas, this is peculiar to PDAC where association with chronic pancreatitis is not uncommon.

World Journal of Gastrointestinal Oncology
Volume 8 Number 7 July 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Han-Xiang An, MD, Doctor, Department of Radiation Oncology, University Hospital Marburg, Marburg D-35043, Germany

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Sepsis and septic shock are life threatening condition associated with high mortality rate in critically-ill patients. This high mortality is mainly related to the inadequacy between oxygen delivery and cellular demand leading to the onset of multiorgan dysfunction. Whether this multiorgan failure affect the pancreas is not fully investigated. In fact, pancreatic injury may occur because of ischemia, overwhelming inflammatory response, oxidative stress, cellular apoptosis and/or metabolic derangement. Increased serum amylase and/or lipase levels are common in patients with septic shock. However, imaging test rarely reveal significant pancreatic damage. Whether pancreatic dysfunction does affect the prognosis of patients with septic shock or not is still a matter of debate. In fact, only few studies with limited sample size assessed the clinical relevance of the pancreatic injury in this group of patients. In this review, we aimed to describe the epidemiology and the physiopathology of pancreatic injury in septic shock patients, to clarify whether it requires specific management and to assess its prognostic value. Our main finding is that pancreatic injury does not significantly affect the outcome in septic shock patients. Hence, increased serum pancreatic enzymes without clinical features of acute pancreatitis do not require further imaging investigations and specific therapeutic intervention.

Key words: Septic shock; Pancreas; Lipase; Amylase; Prognosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Pancreatic injury is common in septic shock patients. Tissue hypoperfusion is the main leading cause of pancreatic insult. Other factors such as oxidative stress

and cellular apoptosis have been reported to enhance the pancreatic damage. The clinical relevance of increased level of pancreatic enzymes is not well established. In fact, hyperamylasemia and/or hyperlipasemia are not associated with higher mortality. Moreover, most of the imaging investigations do not show significant morphological changes of the pancreas. Hence, disturbed serum pancreatic enzymes without clinical evidence of acute pancreatitis should not trigger any specific therapy.

Pancreatic injury in patients with septic shock: A literature review. *World J Gastrointest Oncol* 2016; 8(7): 526-531 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i7/526.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i7.526>

INTRODUCTION

Severe sepsis and septic shock are common life-threatening conditions in critically-ill patients^[1-3]. Despite recent therapeutic advances and the establishment of internationally accepted guidelines regarding the management of patients suffering from septic shock, the overall mortality in these patients ranges from 30% to 60%^[2,4,5]. This high mortality is usually associated with the onset of multiple organ dysfunction. In fact, a few studies have reported that the worsening of organ function as well as the increase in the number of the failing organs is significantly associated with poor outcome in both adult and pediatric patients^[6,7]. Accordingly, it has been reported that the onset of acute kidney injury is associated with a significant rise in the intensive care unit (ICU) mortality up to 50%-70% and that the highest mortality has been in patients with a high score on the severity of illness scale and/or in those who require renal replacement therapy^[2,8-10]. Similarly, hypoxic liver injury in patients with septic shock has been reported to be associated with a mortality as high as 50%^[11,12]. Experimental and clinical studies also suggest that gut ischemia is one of the hallmarks of septic shock^[13-15]. However, whether pancreatic exocrine function is also impaired in septic shock patients has not been fully investigated. Moreover, there is still debate regarding the optimum modality for management of pancreatic insult as well as its prognostic value.

The aim of this review is to describe the epidemiology and the physiopathology of pancreatic injury in septic shock patients, to clarify whether it requires specific management and to assess its prognostic value.

RESEARCH

A systematic literature search was conducted through Pubmed by using the following Medical Subheadings terms: Septic shock, sepsis, lipase, amylases and acute pancreatitis. Different Boolean operator combinations

(AND/OR) were attempted. Overall, 97 articles were selected for this review. We didn't proceed to any language restriction and only the studies published between 1996 and 2016 were considered.

EPIDEMIOLOGY OF PANCREATIC INJURY IN SEPTIC SHOCK

The incidence of pancreatic injury in critically-ill patients is extremely variable according to the used definition. High levels of amylase levels have been reported in 32% to 79% of patients admitted in medical or surgical ICUs^[16-19]. However, most of these studies have concluded that this elevation is not always due to pancreatic insults^[16,18]. In fact, the proportion of non-pancreatic isoamylase in patients with hyperamylasemia has been reported to range from 30% to 74% of the total serum amylase^[16,18]. Hence, other markers have been used to assess the exocrine pancreatic dysfunction in critically-ill patients. Lipase is one such marker which is more specific for the diagnosis of pancreatitis^[20]. Similar to hyperamylasemia, increased lipase serum level is also common in critically-ill patients. In fact, Manjuck *et al.*^[21] reported that hyperlipasemia is found in 40% of the patients requiring ICU admission. Similarly, Denz *et al.*^[19] reported increased serum lipase levels in 57% of critically-ill patients. Recent guidelines have highlighted that the rise of one or both of these two enzymes should be higher than three times the upper limit of normal range to be considered as a useful criterion for acute pancreatitis^[22]. However, only a limited number of patients admitted to the ICU with a diagnosis other than pancreatitis fulfill this definition^[23] and/or have significant morphological changes in pancreatic anatomy on imaging tests^[19,21]. Only a few studies have focused on the exocrine pancreatic dysfunction in the subgroup of critically-ill patients with septic shock^[23-25]. Hence, epidemiological data regarding the pancreatic function impairment in this group of patient is lacking.

PHYSIOPATHOLOGY OF PANCREATIC INJURY IN SEPTIC SHOCK

The pathophysiology of pancreatic injury in septic shock patients is not fully understood. The most commonly accepted hypothesis is pancreatic ischemia^[26,27]. However, few experimental and human studies have suggested that other mechanisms might also be involved such as cell apoptosis^[28,29], increased release of nitric oxide by the endothelial cells^[30], platelets activation^[31], ischemia - reperfusion phenomenon^[32], elevated triglyceride levels and the development of biliary sludge^[33].

Pancreatic ischemia

Severe hypotension and tissue hypoperfusion are the main hallmarks of septic shock^[34,35]. Experimental studies have shown that gut perfusion is severely impaired in the early stages of septic shock^[14,36]. In a porcine model of septic shock caused by fecal peritonitis, Ijungdahl *et al.*^[14]

have reported that the oxygen consumption of the gut, including that of pancreas, is markedly increased in this condition. This is accompanied by a significant decrease in the gut intramucosal pH which occurs even before the lactate rises in the arterial blood. The pancreas is particularly sensitive to hypotension. In fact, a temporary ischemia for 40 min has been shown to be sufficient to cause significant pancreatic injury on histological examination, presenting mainly as peripheral necrosis of the lobules^[37]. Several studies have suggested that the impairment of pancreatic perfusion is more pronounced in septic shock. In fact, in an experimental animal model study, Raper *et al.*^[26] reported that the cardiac output is increased during the hyper dynamic phase of septic shock. Concomitantly, the systemic blood flow is increased in the gallbladder and the colon whereas it is markedly decreased in the pancreas. This demonstrates that the oxygen delivery to the pancreatic cells is significantly decreased despite the considerable increase of their oxygen requirement^[26].

Beside these macro-circulatory abnormalities, pancreatic injury related to septic shock can also be explained by micro-circulatory and cellular dysfunctions^[38]. In fact, severe sepsis and septic shock are commonly associated with coagulation abnormalities, usually manifested as disseminated intravascular coagulation^[39,40]. Several forensic studies have reported ischemic and necrotic changes in various organs. These include occlusion and fibrin deposition in small and mid-size vessels, observed in patients who die from septic shock^[41]. These abnormalities are triggered mainly by an overwhelming inflammatory reaction which is orchestrated by the immune host defense in response to the endotoxin aggression^[34,39]. The expression of the tissue factor by the mononuclear, polymorphonuclear and endothelial cells activates the coagulation cascade^[42,43]. Activation of platelets, down-regulation of anticoagulant pathways and reduced fibrin removal due to inhibition of fibrinolysis enhances microvascular thrombosis^[39]. Experimental studies have shown that the pancreatic microcirculation is deeply disturbed in septic shock. In fact, in a model of fecal peritonitis, Hildebrand *et al.*^[27] reported that the microcirculatory flow is reduced by 50% in various splanchnic organs within 240 min. The flow normalizes after fluid resuscitation in all the organs, except in the pancreas.

Although the most widely accepted hypothesis used to explain pancreatic dysfunction in patients with septic shock is pancreatic ischemia, significant pancreatic injury has also been reported in normotensive sepsis model. This suggests that other mechanisms may also be responsible for causing pancreatic ischemia^[44].

Cellular apoptosis

Delayed and inappropriate management of septic shock is associated with a worse outcome due to multiple organ dysfunction syndrome (MODS)^[45-48]. The main cause of MODS in this condition is the uncontrolled inflammatory storm caused by overwhelming host

immune response^[49]. Beside the deleterious effect of this reaction on the macrocirculation and microcirculation, as described above, the pro-inflammatory cytokines—mainly interleukine (IL)-1 β , IL-6 and tumor necrosis factor (TNF)- α - also activate the NF- κ B pathway. This causes cellular self-destruction and apoptosis^[50]. This has been demonstrated in the hepatocytes and the immune cells with severe Gram-negative bacterial infection^[50,51]. Experimental studies have shown that the exposure of pancreatic cells to lipopolysaccharide is associated with apoptosis and increased release of TNF- α , IL-1 β and IL-8. Damage to the Acinar cells consists of nuclear fragmentation, abnormal cytoplasmic vacuoles and cellular swelling^[28,29,52,53]. Unlike these experimental studies, there is no evidence to suggest that apoptosis is a major cause of exocrine pancreatic dysfunction in patients suffering from septic shock. In fact, histological studies performed in patients who died from septic shock and multiorgan failure have shown that the apoptosis of acinar cells is seen only in a scattered manner^[54].

Other mechanisms

Other hypothesis that may explain pancreatic injury in patients suffering from septic shock.

The oxidative stress: Oxidative stress has been demonstrated in patients suffering from septic shock patients^[55]. The main causes of mitochondrial dysfunction and increased release of reactive oxygen species are ischemia/reperfusion phenomenon and inflammation^[55,56]. Other factors, such as the activation of the phagocytic cells and the production of nitric oxide by the endothelial cells, have been shown to aggravate the oxidative stress^[57]. The cellular damage in sepsis is enhanced by the depletion of antioxidants and scavenger enzymes such as glutathione and thiamine in the plasma^[56,58]. Several studies have suggested that the oxidative stress can induce pancreatic damage in septic shock^[32,59].

Triglycerides: Serum triglyceride level has been reported to be significantly increased in septic shock^[60,61]. Moreover, compared to those patients who survived septic shock, patients who died from it have been found to have a higher serum triglyceride level over the first 7 d of their illness^[62]. Whether the high level of serum triglyceride seen in patients with septic shock is enough to induce pancreatic cell damage need to be investigated.

CLINICAL RELEVANCE OF PANCREATIC INJURY

The clinical relevance of increased amylase and/or lipase in patient with septic shock has been poorly investigated. Whether pancreatic injury is only a satellite phenomenon or a major condition affecting the prognosis of this group of patients is still a matter of debate. In fact, only a few studies, most of them with a small number of patients, have investigated pancreatic dysfunction in critically-

ill patients^[19,21,23-25,44]. Pezzilli *et al.*^[23] have reported that amylase and lipase levels are significantly increased in patients with septic shock in comparison to a control group. However, none of the included patients met the criteria of acute pancreatitis and no significant correlation was found with mortality. These findings have been corroborated by post-mortem pancreatic tissue sample examination which has not shown significant morphological changes^[24].

Available data suggest that imaging tests should not be requested for all critically-ill patients with deranged pancreatic enzymes as long as the clinical assessment does not suggest acute pancreatitis. In fact, Denz *et al.*^[19] reported that contrast enhanced computed tomography performed for all patients with a serum lipase level higher than 450 U/L was positive only in 35% of the patients. None of these patients had severe necrotizing pancreatitis which required specific management. However, the authors have reported that imaging abnormalities are more common in patients with increased blood levels of pancreatitis-associated protein. This raises the question: Which marker can be considered as a reliable test to assess the pancreatic dysfunction?

Even though the available data shows that the increase in the levels of pancreatic enzymes does not affect the mortality in critically-ill patients, the pancreatic dysfunction may cause malnutrition in patient with prolonged stay in intensive care units. In fact, the pancreatic secretory function is important for the digestion and absorption of fats, protein and carbohydrates^[63]. In a prospective cross-sectional study of 563 critically-ill patients, Wang *et al.*^[64] reported that the prevalence of exocrine pancreatic insufficiency in these patients is 52.2% although only 34.9% of these patients had increased serum lipase levels and only 30.2% had increased serum amylase levels. The definition of exocrine pancreatic insufficiency in their study was based on decreased fecal elastase-1 concentration (< 200 mcg/g). The authors have also found that both shock and sepsis are independent factors which predict exocrine pancreatic insufficiency. Tribi *et al.*^[25] have reported similar results as they found that the concentration of amylase and chymotrypsin in the duodenal juice is significantly lower in patients with sepsis or septic shock than in healthy volunteers. Moreover, the concentration of trypsin is significantly lower in septic shock patients than sepsis patients without shock. The therapeutic implications of these findings need to be investigated by further studies.

CONCLUSION

Pancreatic injury is common in patients suffering from septic shock. Increase in levels of pancreatic enzymes does not significantly affect the outcome. Only those patients who show clinical features of acute pancreatitis need to undergo further radiological investigations. However, pancreatic dysfunction may affect the nutritional state of patients receiving enteral feeding and requiring prolonged ICU stay. Whether specific treatment should be considered to avoid malnutrition in these patients need to

be investigated further.

Abstract

AIM: To investigate the microRNA (miRNA) expression during histological progression from colorectal normal mucosa through adenoma to carcinoma within a lesion.

METHODS: Using microarray, the sequential changes in miRNA expression profiles were compared in colonic lesions from matched samples; histologically, non-neoplastic mucosa, adenoma, and submucosal invasive carcinoma were microdissected from a tissue sample. Cell proliferation assay was performed to observe the effect of miRNA, and its target genes were predicted using bioinformatics approaches and the expression profile of SW480 transfected with the miRNA mimics. mRNA and protein levels of the target gene in colon cancer cell lines with a mimic control or miRNA mimics were measured using qRT-PCR and Western blotting. The expression levels of miRNA and target gene in colorectal tissue samples were also measured.

RESULTS: Microarray analysis identified that the miR-320 family, including miR-320a, miR-320b, miR-320c, miR-320d and miR-320e, were differentially expressed in adenoma

and submucosal invasive carcinoma. The miR-320 family, which inhibits cell proliferation, is frequently downregulated in colorectal adenoma and submucosal invasive carcinoma tissues. Seven genes including CDK6 were identified to be common in the results of gene expression array and bioinformatics analyses performed to find the target gene of the miR-320 family. We confirmed that mRNA and protein levels of CDK6 were significantly suppressed in colon cancer cell lines with miR-320 family mimics. CDK6 expression was found to increase from non-neoplastic mucosa through adenoma to submucosal invasive carcinoma tissues and showed an inverse correlation with miR-320 family expression.

CONCLUSION: MiR-320 family affects colorectal tumor proliferation by targeting CDK6, plays important role in its growth, and is considered to be a biomarker for its early detection.

Core tip: We investigated for the first time the sequential changes of miRNA expression profiles in colonic lesions from matched samples; histologically, non-neoplastic mucosa, adenoma, and submucosal invasive carcinoma were microdissected from a tissue sample. We have shown that the miR-320a, miR-320b, miR-320c, miR-320d are downregulated from colorectal adenoma and miR-320e is downregulated from colorectal submucosal carcinoma tissue and the miR-320 family suppresses tumor proliferation by targeting CDK6. The miR-320 family may play an important role in the growth of colorectal tumors and can be considered as a biomarker for the early detection of colorectal tumors.

MicroRNA-320 family is downregulated in colorectal adenoma and affects tumor proliferation by targeting CDK6. *World J Gastrointest Oncol* 2016; 8(7): 532-542 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i7/532.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i7.532>

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies resulting in cancer-related deaths in the world^[1]. The adenoma-carcinoma sequence, which involves a series of changes from normal colorectal epithelium through an adenoma to an invasive and metastatic tumor, has been widely recognized as an important developmental mechanism in CRC^[2]. According to this theory, the colorectal adenoma (CRA) is considered

to be a precursor lesion of CRC; the removal of CRAs by polypectomy has been shown to reduce the incidence and mortality due to CRCs^[3]. Endoscopic mucosal resection and endoscopic submucosal dissection (ESD) enable resection of almost all intramucosal neoplasia with submucosal invasion of less than 1000 μ m in the colon^[4]. Thus, detection of colorectal tumors in the early stages has become increasingly important in treatment and prognosis.

The adenoma-carcinoma sequence is accompanied by several genetic and epigenetic alterations, such as mutations of cancer-associated genes and epigenetic modifications, including changes in DNA methylation, histone modifications, and microRNAs (miRNAs)^[5,6]. However, the involvement of miRNAs in the mechanism of this sequence remains undetermined. miRNAs are small (19-23 nucleotide) endogenous non-coding RNAs that regulate gene expression by targeting the 3' untranslated region (UTR) of mRNA. miRNAs play fundamental roles in various biological processes^[7]. Accumulating evidence indicates that miRNAs are frequently dysregulated in human cancers^[8], and alterations of miRNA expression in colorectal tumors have been well documented. For example, miRNA profiles of CRC compared with those of normal mucosa^[9] and adenoma^[6,10] have been reported. However, limited reports exist on the sequential changes in miRNA expression during histological progression from normal colonic mucosa through colorectal adenoma to early carcinoma in a lesion from a patient.

Furthermore, according to the Paris and Japanese classification^[11,12], a flat colorectal lesion exceeding 10 mm in diameter is classified as a "laterally spreading type (LST)" and subclassified into a granular (G) or a non-granular (NG) type. The percentage of gene mutation in the protruded tumor is hypothesized to be different from that of the LST^[13]. When we focused on miRNA, expression changes of some miRNAs in exophytic and flat elevated tumors were reported^[14]; however, there is no analysis comparing miRNA expressions of the LST with those of the protruded tumor.

Therefore, we analyzed miRNA expressions of both LSTs and protruded tumors as a specific feature of the stepwise progression from adjacent non-neoplastic mucosa to adenoma and submucosal invasive carcinoma using matched samples to compare accurate miRNA expression in each phase.

MATERIALS AND METHODS

Tissue samples

Formalin-fixed, paraffin-embedded (FFPE) colorectal tissue samples that included carcinoma, adenoma, and adjacent non-neoplastic mucosa were obtained from patients who underwent ESD at Tohoku University between January 2011 and December 2014 and provided written informed consent for study participation. All the cancers were limited to submucosal carcinomas, which were classified as T1MON0 (American Joint Committee on Cancer Staging

Manual) in this study. The 18 colorectal samples were LST (15 carcinoma with adenoma and 3 carcinoma without adenoma) and the 3 colorectal samples were protruded-type carcinoma with adenoma.

A senior pathologist reviewed the histopathological grades and types of all cases. Regions of colorectal carcinoma, pre-existing adenoma, and adjacent non-neoplastic mucosa in a resection specimen were microdissected using a laser microdissection (LMD) system (Leica Microsystems, Wetzlar, Germany). This study was reviewed and approved by the ethics committee and the institutional review board at the Tohoku University Hospital.

Cell lines and transfection

Human colon cancer cell lines HT29 and SW480 were obtained from the American Type Culture Collection (Manassas, VA) and then grown in Dulbecco's Modified Eagle's Medium supplemented with 10% (v/v) fetal bovine serum at 37 °C in a humidified atmosphere of 5% CO₂. The human intestinal epithelial cells (InEpC) were obtained from Lonza, Japan.

We used mirVana™ miRNA 320a, b, c, d, and e mimic; mimic control; inhibitor; and inhibitor control (Life Technologies, Carlsbad, CA). These RNA oligonucleotides were transiently transfected into SW480 and HT29 cells using the Lipofectamine RNAiMAX Reagent (Invitrogen, United States) according to the manufacturer's instructions.

RNA isolation

Total RNA from microdissected FFPE samples was purified using a miRNAeasy FFPE kit (QIAGEN, Hilden, Germany). Total RNA isolated from cultured cells using TRIzol reagent (Invitrogen) was purified with an RNeasy Mini kit (QIAGEN).

miRNA microarray analysis

The RNA from FFPE samples was labeled with a miRNA complete labeling and Hyb kit (Agilent Technologies, Santa Clara, CA, United States), and the labeled probes were hybridized onto Agilent Human miRNA Microarray Rel 19.0 according to the manufacturer's instructions. The arrays were scanned and the data were extracted and analyzed using the Agilent Feature Extraction software and Agilent GeneSpring software.

Quantitative real-time polymerase chain reaction

RNA samples were reverse transcribed into cDNA using QuantiTect Reverse Transcription Kit and miScript II RT Kit (QIAGEN). Each cDNA sample was analyzed in triplicate using the QuantiFast SYBR Green PCR kit (QIAGEN) with the StepOnePlus real-time PCR system (Life Technologies). A comparative $\Delta\Delta C_t$ method was used for the quantification of the miR-320 family and CDK6 expression; expression levels of the hsa-miR-320 family and CDK6 were normalized by those of U6 and GAPDH, respectively. A miScript Primer Assay (QIAGEN) was used for the miR-320 family and U6. The following primer sets were used for other quantitative reverse transcription (qRT)-PCR assays:

CDK6 Forward: 5'-GGATAAAGTTCCAGAGCCTGGAG-3';
CDK6 Reverse: 5'-GCGATGCACTACTCGGTGTGAA-3';
and GAPDH Forward: 5'-ATCAGCAATGCCTCCTGCAC-3';
Reverse: 5'-ATGGCATGGACTGTGGTCAT-3'.

Cell proliferation assay

Human colon cancer cell lines SW480 were seeded in 96-well plates, and cell proliferation was measured 24, 48, 72, 96, and 120 h later using the CellTiter96 Aqueous One Solution Cell Proliferation Assay (MTS assay; Promega, Madison, WI, United States) according to manufacturer's instructions.

Gene expression analysis and miRNA target prediction

Gene expression profiling of SW480 transfected with a mimic control or miR-320a mimics was performed using the SurePrint G 3 Human Gene Expression 8x60K v2 Microarray Kit (Agilent Technologies) according to the manufacturer's instructions. Candidates of miRNA target genes were selected according to the results of these mRNA expression analysis and two different bioinformatics algorithms-TargetScan (<http://www.targetscan.org>) and Pic tar (<http://pictar.mdc-berlin.de/>).

Protein extraction and Western blot

Total cell lysates were prepared using a mammalian cell extraction kit (BioVision, Mountain View, CA, United States). Protein concentrations in the lysates were measured using the BCA Protein Assay kit (Pierce Chemical Co., Rockford, IL, United States). Equal amounts of proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred onto polyvinylidene difluoride membranes. After incubation with Tris-buffered saline and Tween-20 containing an ECL blocking agent, the membranes were incubated with primary antibodies against CDK6 (Cell Signaling Technology, Inc., Danvers, MA, United States) or α -tubulin (B512, Sigma) at 4 °C overnight and further incubated with secondary antibodies for 1 h at room temperature. Reactive bands were detected using the ECL Prime Western Blotting Detection Reagent (GE Healthcare, Bucks, United Kingdom).

Statistical analysis

Data from at least three independent experiments were analyzed. Statistical analysis was conducted using Excel (Microsoft). The difference between two groups was analyzed using the paired *t*-test for miRNA array data and the Student's *t*-test for qRT-PCR data. The statistical significance of correlations between the expressions of the miR-320 family and CDK6 mRNA was evaluated using Pearson's correlation analysis. *P* < 0.05 was considered statistically significant.

RESULTS

Most miRNAs associated with the adenoma-carcinoma sequence were common to LSTs and protruded tumors

Sequential changes of miRNA expression profiles from matched samples, histologically non-neoplastic mu-

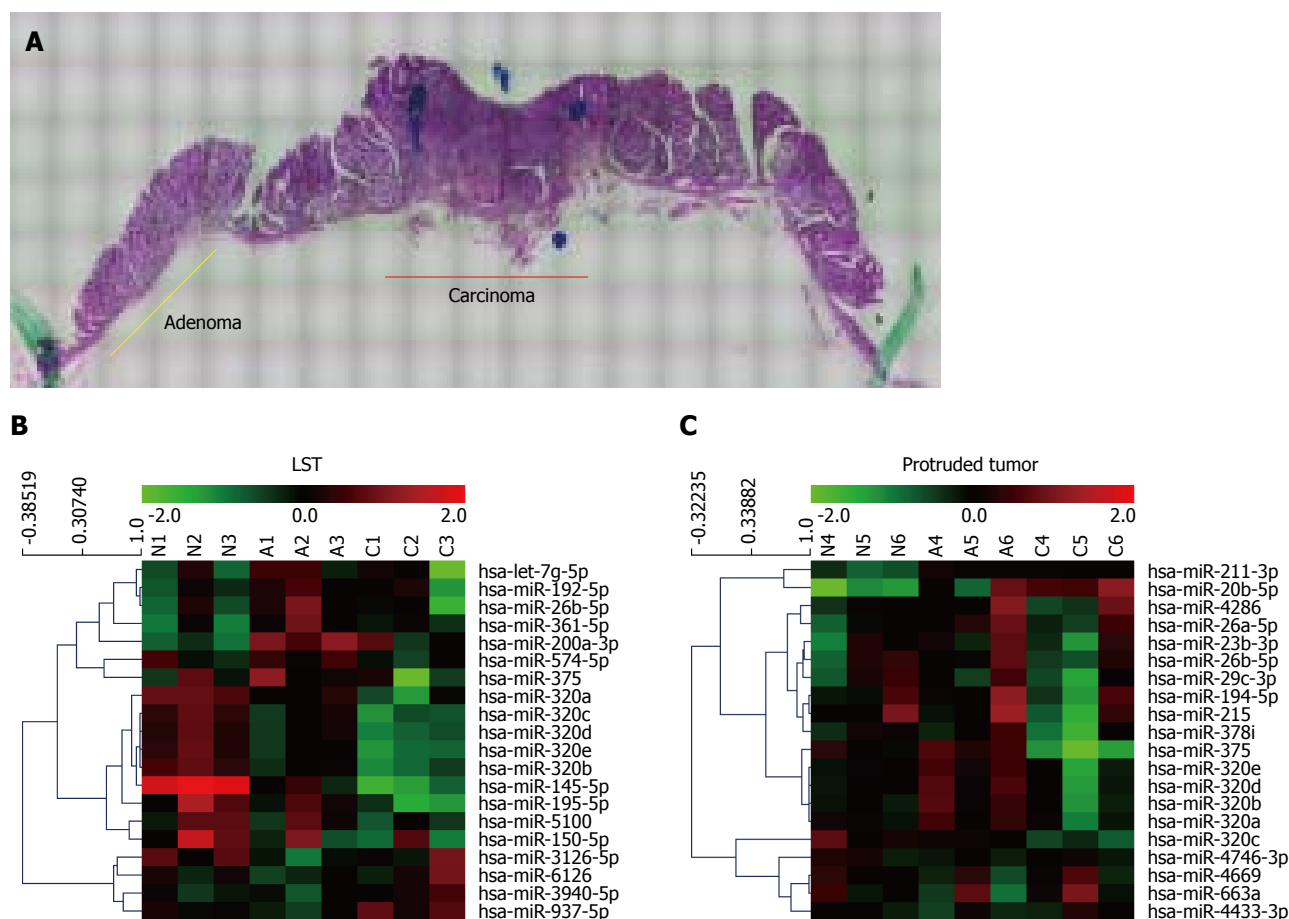

Figure 1 MiRNA expression profiles of matched samples. A: Regions of colorectal carcinoma, pre-existing adenoma, and adjacent non-neoplastic mucosa in a resection specimen were microdissected using laser microdissection (LMD); B and C: The miRNA expression profiles were compared with three matched regions from LSTs ($n = 3$) and protruded tumors ($n = 3$). For each miRNA, red represents higher expression and green represents lower expression than the average expression. LST: Laterally spreading type; C: Carcinoma; A: Adenoma; N: Adjacent non-neoplastic mucosa.

cosa, adenoma, and submucosal invasive carcinoma microdissected by LMD from a tissue sample (Figure 1A), were assessed. To differentiate tumor forms, these analyses were conducted in each of the LSTs ($n = 3$) and protruded tumors ($n = 3$) (Figure 1B and C). All three LSTs were of the granular type. Seven miRNAs in LSTs and 23 miRNAs in protruded tumors showed significantly higher or lower expression in early carcinomas than that in adenomas, with expression in non-neoplastic mucosa as the baseline. The top 10 miRNAs in each form are summarized in Table 1. Comparing these results, six of the 10 miRNAs, including five belonging to the miR-320 family (320a, b, c, d, and e) were identical. In addition, we confirmed the downregulation of miR-195 (LST), miR-375, miR-378 (protruded tumor), and miR-26b (both forms) in early cancer, which has been previously reported in several studies of CRCs^[9,15,16]. Decreased expression of miR-320a and 320b in CRC has also been reported previously^[6,17,18]. It is interesting that these changes in miR-320 family expressions are common in early carcinomas both in LSTs and protruded tumors; therefore, we focused on

the miR-320 family in the subsequent analysis.

miR-320 family is significantly downregulated in colorectal adenoma and submucosal invasive carcinoma

To confirm the downregulation of the miR-320 family in early carcinoma, we conducted qRT-PCR of the miR-320 family using 18 matched colorectal submucosal invasive carcinoma specimens in LSTs (Figure 2A). Expressions of all members of the miR-320 family except miR-320e in adenoma were significantly decreased not only in submucosal invasive carcinomas but also in adenomas compared with those in the non-neoplastic mucosa ($P < 0.05$ and $P < 0.01$, respectively). On comparing adenomas and carcinomas, expression levels of the miR-320 family, except for 320d, in carcinomas were lower than that in adenomas; however, differences were not statistically significant. These findings were confirmed in human colon cancers cell lines by qRT-PCR, and expression of the miR-320 family was found to be decreased in HT29 and SW480 compared with that in InEpc (Figure 2B).

These results indicated that the expression of the miR-320 family decreased from the early stages of the

adenoma-carcinoma sequence.

miR-320 family, except miR-320e, inhibits cell proliferation

To reveal the role of the miR-320 family in CRC, cell proliferations in SW480 transfected with the miR-320 family were analyzed by MTS assay for 5 d. Overexpression of miR-320a, 320b, 320c, or 320d significantly inhibited the cell growth of SW480 (Figure 3), and inhibition of these miRNA significantly promoted proliferation of SW480 (data not shown). However, these findings were not observed with miR-320e.

miR-320a targets CDK6

To find a target gene of the miR-320 family, we used miR-320a as a representative of the miR-320 family in microarray gene expression analysis and miRNA target prediction. Before the gene expression analysis, we confirmed that the expression of miR-320a in SW480 cells transfected with miR-320a mimics was increased by approximately 1600-fold compared with that in controls. Next, the gene expression analysis of SW480 with a mimic control or miR-320a mimics was conducted using microarray, and the expressions of 497 genes were found to be decreased in SW480 with miR-320a mimics (fold-change < 0.67). In addition to these tests, we conducted TargetScan and Pic tar analyses to detect potential targets of miR-320a; seven genes (BLCAP, HOXA10, KCNS3, RASA1, NPAS2, ARPC5, and CDK6) were identified to be common in the results of these three different analyses (Figure 4A). In seven candidate genes, CDK6 expression was shown to be associated with prognosis in patients with CRC^[19]; moreover, the results of miRNA binding-site prediction analyses using bioinformatics tools (Target scan

and microRNA.org) indicate that CDK6 has a putative miR-320 family's binding site that is mapped to the 3' UTR (Figure 4B). From these results, we selected CDK6 as a novel candidate target of the miR-320 family.

mRNA and protein levels of CDK6 suppressed by miR-320 family in colon cancer cell lines

To examine whether the miR-320 family influences both mRNA and protein levels of CDK6, these were analyzed in colon cancer cell lines (HT29 and SW480) with a mimic control or miR-320 family mimics. Both mRNA and protein levels of CDK6 were significantly suppressed in cells with miR-320 family mimics (Figure 4C and D).

Increased CDK6 expression from non-neoplastic mucosa through adenoma to submucosal invasive carcinoma with inverse correlation to the miR-320 family expression

To confirm the changes of CDK6 expression in colorectal tissues, we investigated CDK6 expression in FFPE tissues of 18 matched samples. Two samples were excluded because of difficulty in detecting CDK6 expression. CDK6 expression in submucosal invasive carcinoma compared with non-neoplastic mucosa was significantly increased (*P* < 0.05, Figure 4E) and that in adenoma was also increased but without statistical significance (*P* = 0.10). Finally, we found that there is an inverse correlation between the expression levels of the miR-320 family, except miR-320c, and CDK6 in the 16 matched samples studied (*P* < 0.05, Figure 4F).

DISCUSSION

The main aim of this study was to investigate changes

Figure 2 The relative expression levels of the miR-320 family in formalin-fixed, paraffin-embedded samples and cell lines. A: The expression of the miR-320 family in 18 samples (15 colorectal carcinoma with adenoma and 3 colorectal carcinoma without adenoma); B: The expression of the miR-320 family in human colon cancers cell lines (HT29 and SW480) compared with that in human intestinal epithelial cells (InEpC). (^a $P < 0.05$, ^b $P < 0.01$). C: Carcinoma, A: Adenoma, N: Adjacent non-neoplastic mucosa.

in miRNAs corresponding to the adenoma-carcinoma sequence and to clarify the functions of these miRNAs in carcinogenesis. We showed that the miR-320 family (a, b, c, d and e) were important factors in the progression of the early stages of colorectal tumors and found a novel target of the miR-320 family, CDK6. From the results of our comprehensive microarray miRNA analysis, miR-320a, b, c, d and e were downregulated from adenoma to submucosal invasive carcinoma in both LSTs and protruded tumors. It has been previously reported that miR-320a regulates tumor occurrence^[20], progression^[21], and metastasis^[22] in CRC; therefore, we inferred that the miR-320 family may play an important role in colo-

rectal carcinogenesis^[23]. Moreover, 6 of the 10 miRNAs, including the miR-320 family, were identical between the LST-G type and protruded tumors; therefore, there is a possibility that the carcinogenic mechanisms of these two different forms share similar pathways. In contrast, the LST-NG type has been reported to show a significantly higher frequency of submucosal invasion than the LST-G type^[24]; thus, their carcinogenic mechanisms might be different. Further verification of the carcinogenic mechanisms of the LST-NG type is warranted.

To investigate the expression of the miR-320 family in the colorectal tissue, we conducted expression analysis of the miR-320 family in 18 FFPE samples by RT-PCR.

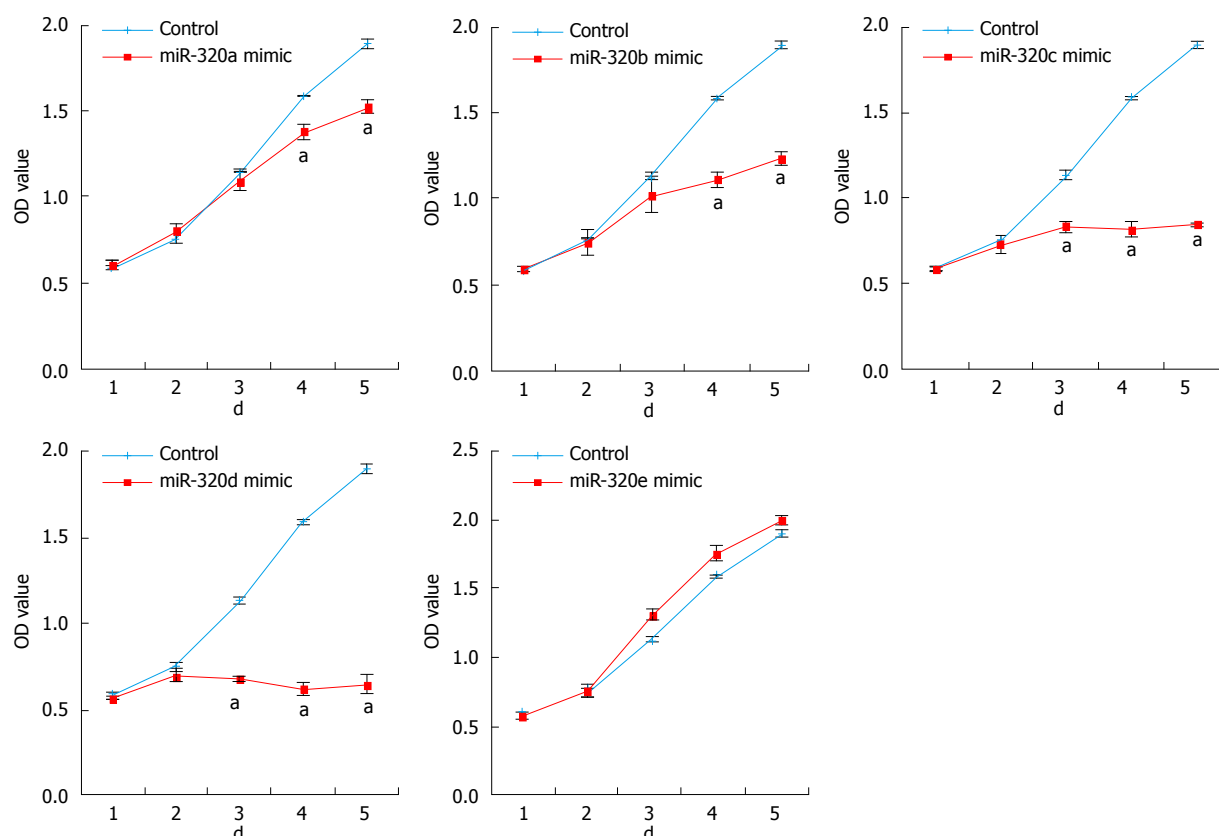

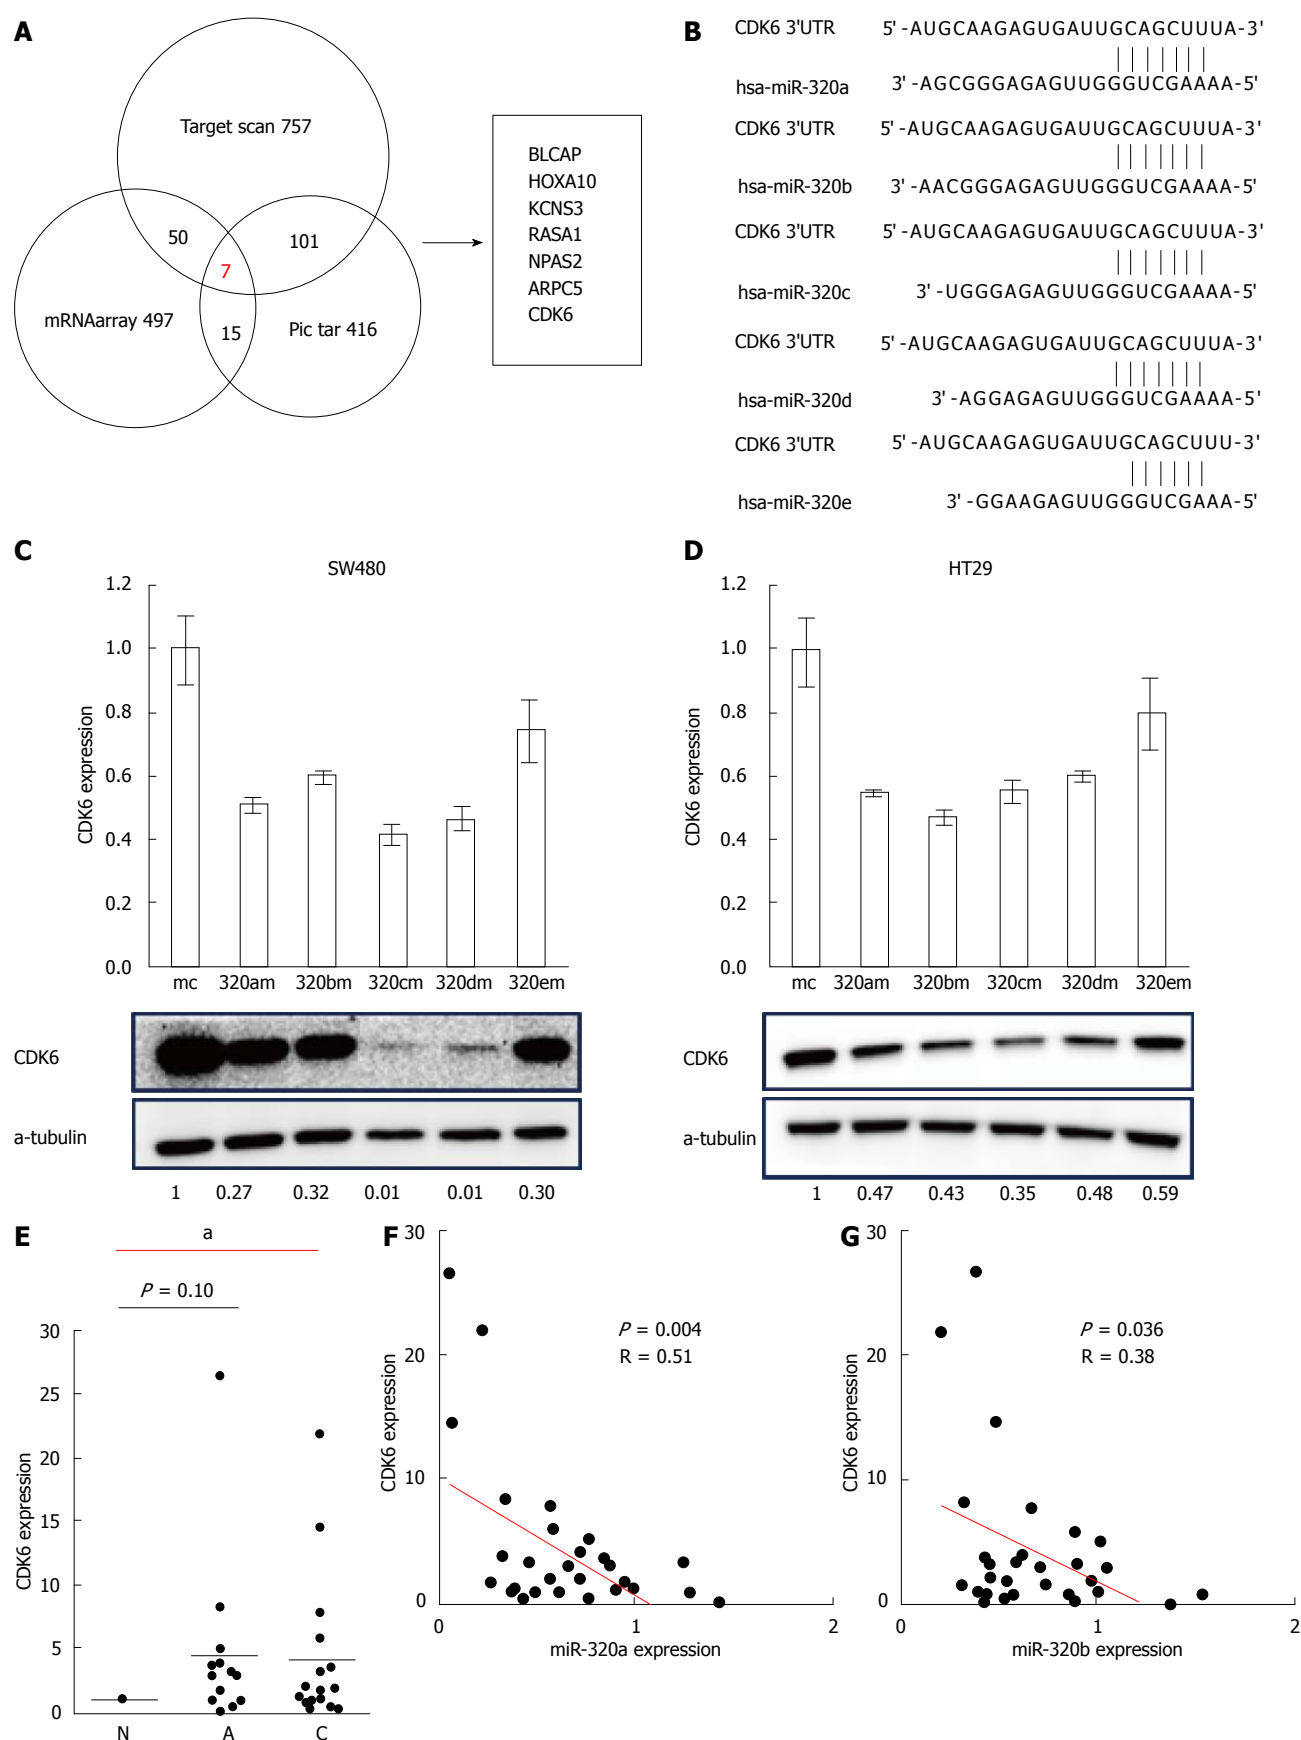

Figure 3 The miR-320 family inhibits colon cancer cell proliferation. Cell proliferation in SW480 transfected with the miR-320 family was assessed by the MTS assay, each day, for up to 5 d ($^aP < 0.05$).

In addition to the results from our miRNA microarray analysis, which showed differences of the miR-320 expression between colorectal adenoma and carcinoma, qRT-PCR analyses showed progressively decreasing expression of the miR-320 family, except miR-320d, from non-neoplastic mucosa through adenoma to submucosal invasive carcinoma. There are some reports of a relationship between miRNA and colorectal adenoma^[6,25], and miR-320a was downregulated from colorectal mucosa to low-grade dysplasia to high-grade dysplasia to adenocarcinomas in the same sample^[6]. Our results support these previous findings, and this article presents the first report of the downregulation of miR-320b in CRA, miR-320c and d in CRA and CRC, and miR-320e in CRC. miR-320a has been shown to effectively regulate proliferation, cell cycle, invasion, migration, and epithelial-mesenchymal transition of CRC, particularly in advanced stages, and is a novel tumor and metastasis suppressor acting by directly targeting mRNAs of neuropilin 1, β -catenin, and other genes^[17]. We confirmed that miR-320a inhibited cell proliferation in cancer cell lines but not how it affects tumor progression in earlier stages of the tumor. Further, the carcinogenic mechanisms of miR-320b, c, d, and e are poorly understood, particularly in CRC. Therefore, we first tried to identify novel targets of the miR-320 family to identify the carcinogenic mechanism in the early stages of the adenoma-carcinoma sequence.

The most commonly used approach to find the target genes of miRNA is through bioinformatics algorithm. Recent reports have provided evidence that miRNAs may downregulate a greater number of transcripts than previously appreciated^[26]; we adopted the results of the mRNA expression array analysis to narrow down the candidates. Finally, we selected seven target genes as common to two bioinformatics algorithms and our results of the mRNA array.

Carcinogenesis is believed to be caused by the dysregulation of the cell-cycle machinery. CDK6, a cyclin-D1-dependent kinase, plays an important role in G₁/S phase transition of the cell cycle and sends signals modulating the control of cell development^[27]. The function of CDK6 in CRC has been shown previously^[19], and there are several reports on the relationships between CDK6 and miRNA in some types of cancers^[28]. Moreover, it was reported that miR-320c inhibited tumor-like behaviors of bladder cancer by targeting CDK6^[29]. However, no studies have examined the relationship between the expression of the miR-320 family and CDK6 expression in CRC.

We confirmed the decreased expression of mRNA and CDK6 in CRC cell lines transfected with the miR-320 family. In addition, we confirmed that CDK6 expression was downregulated in colorectal tumor tissues and that the expressions levels of the miR-320 family, except miR-320c, were negatively correlated with the mRNA expression levels of CDK6. These results suggested that

Figure 4 The miR-320 family targets CDK6. A: Seven candidate target genes of miR-320a were identified as being common from the results of expression profiling and two bioinformatics algorithms. The decreased expression of 497 pieces was observed in gene expression profiling of SW480 transfected with an miR-320a mimic and a mimic control (fold-change: < 0.67), and target genes of miR-320a were predicted by TargetScan and Pic tar; B: CDK6 has a putative miR-320 family-binding site mapped to the 3' UTR; C and D: mRNA and protein levels of CDK6 in colon cancer cell lines (HT29 and SW480) transfected with miR-320 family mimics and a mimic control; E: The relative CDK6 expression level compared with that in non-neoplastic mucosa in 16 matched samples; F-J: Pearson's correlation analysis between the expression levels of the miR-320 family and CDK6 in 16 matched samples ($^*P < 0.05$). UTR: Untranslated regions; 320am: miR-320a mimics; 320bm: miR-320b mimics; 320cm: miR-320c mimics; 320dm: miR-320d mimics; 320em: miR-320e mimics; mc: Mimic control; C: Carcinoma; A: Adenoma; N: Adjacent non-neoplastic mucosa.

the miR-320 family is targeted to CDK6 in CRC and has an influence on cell cycle. We report that the miR-320 family suppresses colorectal tumor progression by targeting CDK6.

In our study, the effects on tumor proliferation by overexpression of miR-320e were not observed, whereas overexpression of miR-320c and miR-320d resulted in a particularly strong reduction of tumor proliferation. CDK6 expression after introduction of miR-320e mimics in colon cancer cell lines indicated a similar tendency to be decreased at the mRNA and protein levels, but these were not as significant as the marked changes observed in other members of the miR-320 family. Targets of miRNAs can be predicted by requiring conserved Watson-Crick pairing to the 5' region of the miRNA, known as the miRNA seed^[30]. The seeds of miR-320e for CDK6 were maximum 6 mer. As the seeds of other members of the miR-320 family were maximum 8 mer, this difference in the structure of the miR-320 family might lead to differences in the effects on CDK6 expression. We believe that this results give support the relationship between miR-320 family and CDK6. Further validations of these are required.

In conclusion, we have shown that the miR-320 family, which suppresses tumor proliferation by targeting CDK6, is downregulated in colorectal adenoma and early colorectal carcinoma tissue. The miR-320 family may play an important role in the growth of colorectal tumors and can be considered a biomarker for the early detection of colorectal tumors.

COMMENTS

Background

According to the adenoma-carcinoma sequence, colorectal adenoma (CRA) is considered to be a precursor lesion of colorectal cancer (CRC); the removal of

CRAs by polypectomy has been shown to reduce the incidence and mortality due to CRCs. Thus, detection of colorectal tumors in the early stages has become increasingly important in treatment and prognosis. The adenoma-carcinoma sequence is accompanied by several genetic and epigenetic alterations, such as mutations of cancer-associated genes and epigenetic modifications, including changes in microRNAs (miRNAs). However, the involvement of miRNAs in the mechanism of this sequence remains undetermined.

Research frontiers

miRNAs are frequently dysregulated in human cancers, and alterations of miRNA expression in colorectal tumors have been well documented. For example, miRNA profiles of CRC compared with those of normal mucosa and adenoma. However, limited reports exist on the sequential changes in miRNA expression during histological progression from normal colonic mucosa through colorectal adenoma to early carcinoma in a lesion from a patient. miR-320a has been shown to effectively regulate proliferation, cell cycle, invasion, migration, and epithelial-mesenchymal transition of CRC. However, the carcinogenic mechanisms of miR-320b, c, d, and e are poorly understood, particularly in CRC, and needed further exploration.

Innovations and breakthroughs

The authors investigated for the first time the sequential changes of miRNA expression profiles in colonic lesions from matched samples; histologically, non-neoplastic mucosa, adenoma, and submucosal invasive carcinoma were microdissected from a tissue sample. They have shown for the first time that the miR-320b, miR-320c, miR-320d are downregulated from colorectal adenoma and miR-320e is downregulated from colorectal submucosal carcinoma tissue and the miR-320 family suppresses tumor proliferation by targeting CDK6.

Applications

This study suggests that the miR-320 family affects colorectal tumor proliferation by targeting CDK6, plays an important role in the growth of colorectal tumors. From these results, miR-320 family is considered as a biomarker for early detection of colorectal tumor.

Terminology

The adenoma-carcinoma sequence is accompanied by several genetic and epigenetic alterations, such as mutations of cancer-associated genes and epigenetic modifications, including changes in DNA methylation, histone modifications, and miRNAs. miRNAs are small (19-23 nucleotide) endogenous non-coding RNAs that regulate gene expression by targeting the 3' untranslated

region of mRNA. miRNAs play fundamental roles in various biological processes.

Peer-review

The manuscript by Tadano *et al* investigated the expression of miRNA in colorectal adenoma and submucosal invasive carcinoma and revealed miR-320 family affects colorectal tumor proliferation by targeting CDK6. This article is overall interesting and gives new insight in the field of dysregulation of miRNAs and colorectal cancer.

Abstract

AIM: To evaluate the opioid-sparing effect of selective cyclooxygenase-2 (COX-2) inhibitors on short-term surgical outcomes after open colorectal surgery.

METHODS: Patients undergoing open colorectal resection within an enhanced recovery after surgery protocol from 2011 to 2015 were reviewed. Patients with combined general anesthesia and epidural anesthesia, and those with acute colonic obstruction or perforation were excluded. Patients receiving selective COX-2 inhibitor were compared with well-matched individuals without such a drug. Outcome measures included numeric pain score and morphine milligram equivalent (MME) consumption on postoperative day (POD) 1-3, gastrointestinal recovery (time to tolerate solid diet and time to defecate), complications and length of postoperative stay.

RESULTS: There were 75 patients in each group. Pain score on POD 1-3 was not significantly different between two groups. However, MME consumption and MME consumption per kilogram body weight on POD 1-3 was significantly less in patients receiving a selective COX-2 inhibitor ($P < 0.001$). Median MME consumption per kilogram body weight on POD 1-3 was 0.09, 0.06 and nil, respectively in patients receiving a selective COX-2 inhibitor and 0.22, 0.25 and 0.07, respectively in the comparative group ($P < 0.001$), representing at least 59% opioid

reduction. Patients prescribing a selective COX-2 inhibitor had a shorter median time to resumption of solid diet [1 (IQR 1-2) d vs 2 (IQR 2-3) d; $P < 0.001$] and time to first defecation [2 (IQR 2-3) d vs 3 (IQR 3-4) d; $P < 0.001$]. There was no significant difference in overall postoperative complications between two groups. However, median postoperative stay was significantly 1-d shorter in patients prescribing a selective COX-2 inhibitor [4 (IQR 3-5) d vs 5 (IQR 4-6) d; $P < 0.001$].

CONCLUSION: Perioperative administration of oral selective COX-2 inhibitors significantly decreased intravenous opioid consumption, shortened time to gastrointestinal recovery and reduced hospital stay after open colorectal surgery.

Core tip: This comparative study validates the effectiveness of perioperative administration of oral selective cyclooxygenase-2 (COX-2) inhibitors as a part of multimodal analgesia in an enhanced recovery after surgery protocol to significantly reduce opioid requirement (but not pain score) after open colorectal surgery. Our findings also indicate that opioid-sparing effect of selective COX-2 inhibitor has some important clinical benefits including quicker gastrointestinal recovery and shorter hospitalization.

Lohsiriwat V. Opioid-sparing effect of selective cyclooxygenase-2 inhibitors on surgical outcomes after open colorectal surgery within an enhanced recovery after surgery protocol. *World J Gastrointest Oncol* 2016; 8(7): 543-549 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i7/543.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i7.543>

INTRODUCTION

Effective pain control for open colorectal surgery plays a crucial role in improving patient's recovery. Various analgesic modalities have been utilized to reduce postoperative pain including epidural analgesia and administration of selective cyclooxygenase-2 (COX-2) inhibitors. However, a recent nationwide analysis of the outcomes of epidural analgesia in open colorectal surgery in the United States has shown that epidural analgesia does not add major clinical benefits over conventional analgesia, but it is associated with longer hospital stay and a higher incidence of ileus^[1]. In a large international registry of the enhanced recovery after surgery (ERAS) Compliance Group, prolonged hospitalization was also observed in patients with epidural analgesia^[2]. Moreover,

epidural analgesia needs to be performed by a qualified anesthesiologist and it could lead to some serious complications such as epidural hematoma and epidural abscess^[3]. As a result, the application of epidural analgesia in clinical practice has been limited^[1,4,5].

On the other hand, a selective COX-2 inhibitor, a nonsteroidal anti-inflammatory drug (NSAID) directly targeting COX-2 which is an enzyme primarily responsible for inflammation and pain, are widely available in both oral preparation and injectable form^[6]. Having little or no effect on platelet aggregation, a selective COX-2 inhibitor has currently been used as a part of multimodal analgesia for several surgical procedures including colorectal surgery - which prefers a non-opioid analgesic regimen^[7-9]. Perioperative administration of selective COX-2 inhibitors can reduce opioid requirement^[10], facilitate gastrointestinal recovery and shorten hospital stay after colorectal surgery^[11]. However, there are a limited number of studies examining these outcome benefits in the setting of an ERAS protocol^[10].

In Thailand, an ERAS protocol for colorectal surgery has been introduced into a daily practice since 2011^[9,12]. Regarding perioperative analgesia in our ERAS protocol, selective COX-2 inhibitors will be provided based on patient's comorbidities and their healthcare coverage scheme. Meanwhile, thoracic epidural analgesia is seldom applied due to its technical demand and a limited number of physician anesthesiologists^[4]. Like many developing and underdeveloped countries, a majority of colorectal procedures in Thailand remains an open surgery because of limited resources and the expense of laparoscopic surgery^[13]. The objective of this study was therefore to examine the clinical outcomes of perioperative administration of an oral selective COX-2 inhibitor for open colorectal surgery within an ERAS protocol (without the need of epidural analgesia).

MATERIALS AND METHODS

This non-randomized, comparative, prospective study included adult patients undergoing elective laparotomy for colorectal resection from January 2011 to September 2015 at the Faculty of Medicine Siriraj Hospital. The study was approved by the Siriraj Institutional Review Board (SIRB COA No. Si014/2013). Patients with combined general anesthesia and epidural anesthesia, and those with acute colonic obstruction or perforation were excluded. Clinical outcomes of patients receiving a selective COX-2 inhibitor were compared with those without such a drug, with a ratio of 1 to 1. They were matched for age, gender, body mass index (BMI), the ColoRectal Physiological and Operative Severity Score for the enUmeration of Mortality and Morbidity (CR-POSSUM)^[14], and type of surgical procedure. Of note, all operations were performed by the author under an ERAS protocol. The ERAS protocol has been previously described^[9,12,15]. In brief, only patients with left-sided colon or rectal resection received preoperative mechanical bowel preparation. Right-sided colon resection was preferentially

Table 1 Perioperative pain control regimen

Preoperative period	1 tablet of acetaminophen 500 mg ± 1 tablet of a selective cyclooxygenase-2 inhibitor (either celecoxib 400 mg, etoricoxib 90 mg or etoricoxib 120 mg)
Intraoperative period	Balanced general anesthesia Application of atraumatic O-ring wound retractor (if available)
Postoperative period	Infiltration of 0.5% bupivacaine into fascial layer and muscle around the wound edge 1 tablet of acetaminophen 500 mg every 6 h in the first 3 d ± 1 tablet of a selective cyclooxygenase-2 inhibitor daily for 5-7 d Intravenous patient-controlled morphine (or tramadol) or intermittent intravenous morphine if pain score > 3

done through a transverse incision. Otherwise, a midline laparotomy was performed. No intraabdominal drain or nasogastric tube was used. A diverting stoma was selectively fashioned in cases of coloanal anastomosis and neoadjuvant chemoradiation. Medication for prophylaxis of postoperative nausea and vomiting was administered based on patient's risk factor^[16]. Standard postoperative care was provided including early feeding and scheduled ambulation.

Perioperative analgesia

Approximately 3 h prior to surgery, one tablet of acetaminophen 500 mg with or without one tablet of an oral selective COX-2 inhibitor (either celecoxib 400 mg, etoricoxib 90 mg or etoricoxib 120 mg) were given. Of note, the administration of a selective COX-2 inhibitor was based on patient's co-morbidities, contraindication (i.e., coronary artery disease, ischemic stroke, peripheral arterial disease, uncontrolled hypertension) and their healthcare coverage scheme. An operation was performed under a balanced general anesthesia. An atraumatic O-ring wound retractor was applied during the operation if available^[17]. After a closure of abdominal wall muscle, 0.5% bupivacaine (3-4 mg/kg) was infiltrated into fascial layer and muscle around the wound edge. The wound was then closed primarily. Standard protocol for postoperative pain control was followed in all cases. Basically, intravenous morphine (0.03-0.05 mg/kg per dose every 1-2 h) was administered if pain score was > 3 (using a numeric rating scale of 0-10 with 0 = no pain 10 = worst possible pain). Intravenous patient-controlled morphine or intravenous tramadol (an equivalent of 10 mg tramadol to 1 mg morphine) may be used in some cases^[18]. During the postoperative period, one tablet of acetaminophen 500 mg was given every 6 h in the first 3 d, with or without daily oral selective COX-2 inhibitor for 5-7 d. Perioperative analgesia protocol was summarized in Table 1.

Outcome measures

Primary outcome measures included average pain score on postoperative day (POD) 1-3, intravenous opioid requirement on POD 1-3, gastrointestinal recovery (time to tolerate solid diet and time to defecate), complication according to the Clavien-Dindo classification system^[19], prolonged postoperative ileus^[20], and length of postoperative stay. Pain scores were recorded every 4 h by nursing staff. All pain assessments were noted after

patients were asked to take a deep breath. Should the patients slept at night during the scheduled time for pain assessment, they were not awakened and the actual time the patients were assessed was noted. Unless intravenous patient-controlled opioid was applied, intermittent intravenous morphine was given if pain score was > 3 as in the aforementioned regimen. Total daily intravenous opioid requirement was reported as morphine milligram equivalent (MME).

All patients were offered a clear liquid diet immediately after surgery providing that they were clinically stable. Once the oral intake exceeded 20 mL/kg body weight without nausea and vomiting, the diet was advanced to a low-residual solid diet. Prolonged postoperative ileus was defined as at least two times of nausea/vomiting, inability to tolerate oral diet and absence of flatus over 24 h, and abdominal distension with radiologic confirmation occurring on or after POD 4^[20]. Patients were discharged from the hospital when they had no fever, adequate pain control with oral analgesics, good ambulation, and satisfactory recovery of gastrointestinal function. All patients were scheduled for follow-up at 30 d postoperatively.

Statistical analysis

All data were prepared and compiled using Statistical Package for the Social Sciences (SPSS®) program version 18.0 for Windows (SPSS Inc., Chicago, IL). Values are expressed as median (interquartile range: IQR), mean (SD) or number (%). Continuous variables were compared using the *t*-test or Mann-Whitney *U* test. Categorical variables were compared using the χ^2 test. A *P*-value of less 0.05 was considered statistically significant.

RESULTS

This study included 150 patients (57% male) with the average age of 65 years (range 30-87). There were 75 patients in each group. There was no significant difference in patient's characteristics, intraoperative detail, type of operation and percentage of adherence to the ERAS protocol between the two groups, except patients receiving a selective COX-2 inhibitor had a higher level of preoperative hematocrit and serum albumin (Table 2).

Pain score on POD 1-3 was not significantly different between the two groups. However, MME requirement on POD 1-3 was significantly less in patients receiving

a selective COX-2 inhibitor (Table 3). Median MME consumption per kilogram body weight on POD 1-3 was 0.09, 0.06 and nil, respectively in patients receiving a selective COX-2 inhibitor and 0.22, 0.25 and 0.07, respectively in the comparative group (*P* < 0.001), representing at least 59% opioid reduction.

Patients receiving a selective COX-2 inhibitor had a shorter median time to resumption of solid diet [1 (IQR 1-2) d vs 2 (IQR 2-3) d; *P* < 0.001] and time to first defecation [2 (IQR 2-3) d vs 3 (IQR 3-4) d; *P* < 0.001]. There was no significant difference in the rate of overall postoperative complication and prolonged postoperative ileus between the two groups (Table 4). Of note, there were 1 non-fatal acute myocardial infarction and 1 colorectal anastomotic leakage requiring an operation in patients without selective COX-2 inhibitor. Median and average postoperative stay was significantly 1-d shorter in patients prescribing a selective COX-2 inhibitor; [4 (IQR 3-5) d vs 5 (IQR 4-6) d; *P* < 0.001] and [4.3 (SD 3.0) d vs 5.3 (SD 2.5) d; *P* = 0.023], respectively. Three patients (4%) in the selective COX-2 inhibitor group and 1 patient (1%) in the comparative group required readmission within 30 d after the operation (*P* = 0.62). No 30-d death was observed in this study.

DISCUSSION

The main findings of this comparative study are that perioperative administration of an oral selective COX-2 inhibitor - as a part of multimodal analgesic regimen - reduces intravenous opioid requirement, shortens time to gastrointestinal recovery and decreases the length of hospital stay after open colorectal surgery within an ERAS protocol. These results were consistent with a report from a prospective randomized, double-blind, placebo-controlled study examining the influence of pre- and post-administration of a selective COX-2 inhibitor (valdecoxib 40 mg) in major colorectal surgery within a non or partial ERAS protocol^[11]. The randomized clinical trial indicated that patients treated with valdecoxib had a one-third opioid reduction, a 12-h quicker time to first bowel movement and a 2-d shorter hospital stay. However, valdecoxib has been off the market since 2005 due to its potentially life-threatening skin reaction and lack of adequate data on its long-term cardiovascular safety^[21].

Many studies have shown that preemptive analgesia is more effective than postoperative analgesia^[22-24]. A combination of preoperative and postoperative admini-

stration of analgesics would have a better pain control. A beneficial outcome effect of perioperative administration of currently available selective COX-2 inhibitors including celecoxib and etoricoxib may be attributed to adequate perioperative nociceptive afferent blockage and to minimize central sensitization (as a preoperative use), and to maintain anti-inflammatory effect after an operation (as a postoperative use). Unlike conventional NSAIDs, a selective COX-2 inhibitor has little or no effect on platelet aggregation and gastrointestinal irritation^[25,26]. These characteristics of selective COX-2 inhibitors are therefore favorable to perioperative administration.

Although there was no difference in postoperative pain score between the two groups, this study showed that a regimen of perioperative pain control in both groups was very effective - which achieved a reasonable level of comfort in the postoperative period (with a median pain score of < 2). However, patients receiving a selective COX-2 inhibitor required less parenteral opioid. Since opioid is well known to cause postoperative nausea/vomiting and gastrointestinal dysfunction^[27], as a result, in part, shorter gastrointestinal convalescence was observed in patients prescribing a selective COX-2 inhibitor. While a reduction in opioid consumption may be responsible for shorter time to gastrointestinal recovery, a selective COX-2 inhibitor alone was shown to diminish a local inflammatory response of the small bowel to surgical manipulation, thus leading to quicker recovery of postoperative intestinal dysfunction^[28]. In animal studies, selective COX-2 inhibitors induced duodenal motility and improved small bowel propulsion in rats subjected to abdominal surgery^[29,30].

In this study, there was a non-significant trend in decreased rates of overall complication and prolonged postoperative ileus in patients receiving a selective COX-2 inhibitor. The clinical relevance of NSAID-induced opioid sparing on favorable postoperative outcomes, including less incidence of postoperative gastrointestinal dysfunction and other complications, has been shown in several studies of non-colorectal surgery^[31-35] and colorectal surgery^[11]. Apart from its opioid-sparing effects,

selective COX-2 inhibitors may be associated with a reduction in postoperative complication by minimizing both inflammatory response and endocrine-metabolic response to surgery^[36].

While it seems clear that a selective COX-2 inhibitor has a positive impact on opioid consumption and gastrointestinal recovery in this study, patients prescribing a selective COX-2 inhibitor are generally at a higher risk for cardiovascular and thromboembolic events compared with a control or placebo drug^[37]. Therefore, selective COX-2 inhibitors should not be used in individuals at increased risk for vascular thrombosis, *e.g.*, coronary artery disease, cerebrovascular disease and peripheral arterial disease. The physicians are also encouraged to use the lowest effective dose for the shortest duration of a selective COX-2 inhibitor. In surgical point of view, the use of any NSAIDs including selective COX-2 inhibitors in the setting of gastrointestinal anastomosis has been concerned because some studies have suggested that NSAIDs may impair anastomotic healing^[38-40]. Recently, a meta-analysis of clinical and experimental studies in 2014 has indicated a strong link between anastomotic leakage and the use of non-selective NSAIDs, but not the use of selective COX-2 inhibitors^[41]. So far, the ERAS society guidelines include NSAIDs and selective COX-2 inhibitors as a component of multimodal analgesia in elective colorectal surgery^[7,8].

Limitations of this study include the fact that it is a non-randomized study. Selective bias and performance bias could occur in the study. However, all patients were operated on by the same surgeon with a relatively high adherence to the ERAS protocol (> 80% compliance in both groups). Moreover, the patients were systematically assessed with a pre-defined objective measurement. It should be noted that not all patients received intravenous patient-controlled analgesia due to a limited number of equipment. To overcome this problem, a standardized protocol for postoperative pain control has been adopted in our institute since 2004. Another limitation is that only patients undergoing open colorectal surgery were included in this study. Whether patients undergoing minimally

invasive surgery, who will have a less inflammatory and metabolic response to surgery compared with open surgery^[42], will be beneficial to the administration of selective COX-2 inhibitors are not investigated.

In conclusion, this study validates the effectiveness of perioperative administration of currently available oral selective COX-2 inhibitors as a part of multimodal analgesia in an ERAS protocol to significantly reduce opioid requirement (but not pain score) after open colorectal surgery. Our findings also indicate that opioid-sparing effect of selective COX-2 inhibitor has some important clinical benefits including quicker gastrointestinal recovery and shorter hospitalization.

COMMENTS

Background

Effective perioperative pain control plays a crucial role in improving patient's recovery especially for an open abdominal surgery. Opioid is very effective analgesia but it has several undesired side effects such as sedation, itching, nausea, vomiting and constipation. Non-opioid analgesia has been recommended as a part of multimodal analgesia in an enhanced recovery after surgery (ERAS) protocol. Selective cyclooxygenase-2 (COX-2) inhibitors have some advantages over conventional non-steroidal anti-inflammatory drugs because they have little or no effect on platelet aggregation and gastrointestinal irritation.

Research frontiers

Several studies have shown perioperative administration of selective COX-2 inhibitors can reduce opioid requirement, facilitate gastrointestinal recovery and shorten hospital stay after colorectal surgery. However, there are a limited number of studies examining these outcome benefits in the setting of an ERAS protocol.

Innovations and breakthroughs

The present study validates the effectiveness of perioperative administration of currently available oral selective COX-2 inhibitors as a part of multimodal analgesia in an ERAS protocol to significantly reduce opioid requirement (but not pain score) after open colorectal surgery. This study also indicates that opioid-sparing effect of selective COX-2 inhibitor has some important clinical benefits including quicker gastrointestinal recovery and shorter hospitalization.

Applications

The study results suggest that perioperative administration of selective COX-2 inhibitors is an effective perioperative pain control regimen - which could be used as a part of multimodal analgesia for open colorectal surgery if no contraindication.

Abstract

AIM: To report our experience on management of colorectal neoplasia during pregnancy and in the postpartum period.

METHODS: Patients who were diagnosed with colorectal cancer during pregnancy or in the postpartum period (< 6 mo), between 8/1997 and 4/2013, in our department were reviewed. Patient characteristics, operations, fetal health and follow-up during pregnancy, type of delivery and oncologic outcomes were analyzed.

RESULTS: Eight patients met our study criteria. Median age at the time of diagnosis of colorectal cancer was 31 years. Median follow-up after surgery was 36 mo. Median duration of symptoms before diagnosis was 16 wk. Three patients were diagnosed with colorectal cancer during pregnancy and underwent surgery prior to delivery. None of the patients received adjuvant treatment during pregnancy. Five patients were diagnosed with colorectal cancer within a median of 2.1 mo after delivery and underwent surgery. No adverse neonatal outcomes were noted. All deliveries were at term (2 cesarean sections) except for one preterm delivery following low anterior resection on the 34th week of pregnancy.

CONCLUSION: There has been a significant delay in the diagnosis of colorectal cancer which is probably due to overlap of symptoms and signs between these tumors and a normal pregnancy. Surgery for colorectal cancer during pregnancy can be performed safely without compromising

maternal and fetal outcomes.

Key words: Colorectal cancer; Pregnancy; Postpartum; Neoplasia

Core tip: This paper summarizes the experience of a tertiary referral colorectal center in the United States on the management of colorectal neoplasia during the pregnancy and postpartum period. Eight patients who were diagnosed with colorectal cancer during pregnancy or in the postpartum period between 8/1997 and 4/2013 were reviewed. No maternal and neonatal mortality occurred related to surgical treatment. While surgery for colorectal cancer during pregnancy can be performed safely and may not affect maternal and fetal outcomes adversely, there has been a significant delay in the diagnosis of colorectal cancer which is probably due to overlap of symptoms and signs between these tumors and a normal pregnancy.

Management of colorectal neoplasia during pregnancy and in the postpartum period. *World J Gastrointest Oncol* 2016; 8(7): 550-554 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i7/550.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i7.550>

INTRODUCTION

While the incidence of colorectal cancer is steady or falling, some studies report an increased incidence of colorectal cancer in younger patients (< 40 years)^[1], which may occur during the reproductive age and therefore interfere with pregnancy. Around 0.1% of pregnant women develop a malignancy and there is limited experience on the management of colorectal cancer diagnosed during pregnancy or in the postpartum period^[2]. When colorectal cancer is detected in this period, treatment options may be limited. As two patients with possibly conflicting interests need to be managed, many ethical, psycho emotional and medical issues need to be simultaneously addressed. In this study, we analyzed management, complications, maternal and fetal outcomes in patients who were diagnosed with colorectal cancer during pregnancy or in the immediate postpartum period.

MATERIALS AND METHODS

After obtaining the institutional review board approval (IRB), patients who were diagnosed with colorectal cancer during pregnancy or in the postpartum period and treated at the Department of Colorectal Surgery Cleveland Clinic Ohio, from August 1997 to April 2013, were analyzed in the study. The postpartum period is defined as first 6 mo after delivery^[3]. Patient characteristics, cancer

follow-up, history of previous pregnancies, medications used during pregnancy, indication for surgery, operations performed, outcomes after surgery, complications, maternal and fetal morbidity and mortality during perinatal period and type of delivery were analyzed. Data were retrieved from the IRB approved prospectively maintained databases with supplemental information from patient charts. A multidisciplinary team including gastroenterologists, oncologists, obstetricians and colorectal surgeons followed up all patients.

Quantitative data were reported as median (range) and categorical data as numbers.

RESULTS

Eight patients met our study criteria. Median age at the time of diagnosis of colorectal cancer was 31 (24-38) and median body mass index was 24 (19-27) kg/m². Median follow-up after surgery was 36 mo (0.2-192). Two patients had a family history of hereditary non-polyposis colorectal cancer and one had juvenile polyposis syndrome. Four patients were nulliparous, the remaining 4 patients had a history of previous successful pregnancies. The presenting symptoms, duration of symptoms, tumor location and treatment strategy are listed in the Table 1. Median duration of symptoms before diagnosis was 16 (4-43) wk. Three patients were diagnosed with colorectal cancer during pregnancy and underwent surgery prior to delivery. These cases included 1 anterior resection with an end colostomy in the 18th week, 1 low anterior resection in the 24th week and 1 subtotal colectomy during the 8th week of pregnancy. Five patients were diagnosed with colorectal cancer within a median of 2.1 (1-4.2) mo after delivery. One synchronous low anterior resection and liver resection, 1 extensive left colectomy, 1 transanal resection, 1 ileocecal resection, and 1 right colectomy were performed on those patients. No adverse neonatal outcomes were noted. All deliveries were at term, except for one patient who underwent low anterior resection during pregnancy (34th week) and delivered preterm. Two patients underwent a cesarean section. Median APGAR score was 9 (8-9). Median birth weight was 3100 (3000-3800) g.

Adjuvant or neoadjuvant treatments were administered exclusively after delivery. In particular, one patient received neoadjuvant chemoradiotherapy whereas adjuvant chemotherapy was given to 5 patients. The specific chemotherapeutic regimens were 5-fluorouracil with leucovorin (*n* = 2), FOLFOX (*n* = 2) and FOLFIRI (*n* = 1). In long-term follow-up, two patients had further successful pregnancies. One of these patients had a ventral hernia repair. The patient initially treated with transanal excision of a T1 rectal lesion opted in favor of radical surgery after delivery and underwent low anterior resection.

DISCUSSION

Our study shows that surgical intervention can be safe and feasible in patients who are diagnosed with

Table 1 Treatment strategy and patient status at last follow-up

	Stage	Start of symptom (pregnancy week)	Duration of symptoms until diagnosis (wk)	Symptom	Tumor location	NCRT	Postoperative chemotherapy	Postoperative radiotherapy	Status at last follow-up
1 ^{1,2}	I	4	10	Rectal bleeding	Sigmoid colon	-	-	-	Alive (NED)

colorectal cancer during pregnancy or in the postpartum period. All of our patients who were diagnosed with colorectal cancer after delivery, had symptoms during pregnancy. Normal pregnancy can mask the symptoms and signs associated with colorectal malignancy^[2,4,5]. For example, abdominal pain, intermittent rectal bleeding and anemia can occur during the course of pregnancy^[6]. Occasional abdominal pain can be related to an enlarging uterus and uterine cramps. Hemorrhoids or anal fissure can be common causes of rectal bleeding in pregnant women^[7]. Pregnancy can limit the utilization of standard diagnostic and therapeutic tools due to a gravid uterus and a potentially vulnerable fetus^[8], which in particular can hamper the liberal use of colonoscopy and computed tomography. However, all patients in our study group underwent complete colonoscopic evaluation before surgery. The age of diagnosis and tumor characteristics in our patients are similar to other series^[5].

Ultrasonography (USG), magnetic resonance imaging (MRI) or computed tomography (CT) were used for disease staging in our series. USG, MRI and CT can be used during pregnancy after consenting the patients about the associated risks and benefits. Heat effects of the magnetic field can be risky for the fetus, especially in the first trimester^[9,10]. CT scan has a limited role in pregnancy due to radiation and contrast^[11]. Proctosigmoidoscopy may be very helpful for differential diagnosis since more than 85% of colorectal tumors diagnosed during pregnancy appear to develop below the peritoneal reflection^[12]. In addition, common anorectal problems can be excluded with a careful anorectal exam. In our series, 5 patients had rectal and 1 patient had a sigmoid colon cancer. Diagnosis of colorectal cancer at an early stage would result in better outcomes. Gastrointestinal symptoms should not be overlooked in a pregnant woman and should be evaluated with proper diagnostic modalities.

According the American Society of Gastrointestinal Endoscopy guidelines, an endoscopic intervention is safer than radiologically guided or surgical operations^[13]. It is preferable to postpone endoscopy to the second trimester^[12]. However, patients should be informed about the potential side effects including over sedation leading to hypoventilation or hypotension, teratogenic effects of medications used for sedation and premature birth^[13]. We did not experience any complications patient or fetus related in our diagnostic work-up. Familial adenomatous polyposis is a known risk factor for colorectal cancer during pregnancy^[14]. In our cohort, 2 patients had a family history of HNPCC and both of these patients were later confirmed with positive genetic testing. One of our patients had juvenile polyposis syndrome and diagnosed with a right colon cancer but later expired due to metastatic disease. In this particular patient diagnosis was delayed 43 mo and was diagnosed in the postpartum period.

The treatment strategy for colorectal cancer should be no different for pregnant and non-pregnant patients in terms of the aim which is potential curative treatment of the disease. However, the well-being of the fetus should be considered. Termination of ongoing pregnancy or delay of required treatment should be discussed with the patient according to time of pregnancy and patient's preference^[2,6,15]. The first trimester of pregnancy is not appropriate for chemotherapy because of high risk of fetal malformations^[16]. While it is generally recommended that chemotherapy should be given only after delivery, there are some reports suggesting that chemotherapy can be given in the second trimester without causing significant long-term complications^[6,17,18]. However, it has been reported that the administration of 5-fluorouracil during pregnancy may cause spontaneous abortion^[12]. If maternal and/or fetal healths are threatened, pre-

term delivery can be considered^[6]. Walsh *et al.*^[19] have proposed an algorithm to manage colorectal cancer diagnosed during pregnancy and recommend individualized treatment based on the disease stage and time of diagnosis during pregnancy. Acting as a team during follow-up and including the patient in decision making are advised.

While low patient number and retrospective design are the major drawbacks of the study, our study is one of the largest single center experiences on this topic. In our limited experience with three patients who have undergone surgery during pregnancy, no adverse maternal and fetal outcomes were observed. There has been a significant delay in the diagnosis of these tumors which is probably due to overlap of symptoms and signs between colorectal malignancy and a normal pregnancy.

Poster presentation at the meeting of the American Society of Colon and Rectal Surgeons, 2014. Erman Aytac is an assistant professor of surgery at the Acibadem University in Istanbul, Turkey.

COMMENTS

Background

Colorectal cancer in pregnancy is a rare condition and the literature on this subject is scant with fewer than 300 cases reported. The diagnosis of colorectal cancer in pregnancy is usually delayed because the individuals are young and the diagnosis is not entertained. As two patients with possibly conflicting interests need to be managed, many ethical, psycho emotional and medical issues need to be simultaneously addressed. In this study, they analyzed management, complications, maternal and fetal outcomes in patients who were diagnosed with colorectal cancer during pregnancy or in the immediate postpartum period.

Research frontiers

Around 0.1% of pregnant women develop a malignancy and there is limited experience on the management of colorectal cancer diagnosed during pregnancy or perinatal period. When colorectal cancer is detected in this period, treatment options may be limited.

Innovations and breakthroughs

In the authors' experience with three patients who have undergone surgery during pregnancy, no adverse maternal and fetal outcomes were observed. There has been a significant delay in the diagnosis of these tumors which is probably due to overlap of symptoms and signs between colorectal malignancy and a normal pregnancy.

Applications

The treatment strategy for colorectal cancer should be no different for pregnant and non-pregnant patients in terms of the aim which is potential curative treatment of the disease. Considering the significant delay in the diagnosis of these tumors during pregnancy, new diagnostic modalities with reduced fetal side effects would facilitate diagnosis of colorectal cancer.

Terminology

Patients who were diagnosed with colorectal cancer during pregnancy or in the postpartum period were analyzed in the study. The postpartum period is defined as first 6 mo after delivery.

Peer-review

In this retrospective study by Aytac *et al* the authors are presenting their experiences in the management of colorectal neoplasia during pregnancy and in the postpartum period. This is a well written paper with insightful, thoughtful and helpful observations which are a result of serious and hard work from an experienced team of experts in the field of colorectal surgery.

Abstract

AIM: To evaluate the value of systemic inflammation-based markers as prognostic factors for advanced pancreatic cancer (PC).

METHODS: Data from 82 patients who underwent combination chemotherapy with gemcitabine and erlotinib for PC from 2011 to 2014 were collected retrospectively. Data that included the neutrophil-to-lymphocyte ratio (NLR), the platelet-to-lymphocyte ratio, and the C-reactive protein (CRP)-to-albumin (CRP/Alb) ratio were analyzed. Kaplan-Meier curves, and univariate and multivariate Cox proportional hazards regression analyses were used to identify the prognostic factors associated with progression-free survival (PFS) and overall survival (OS).

RESULTS: The univariate analysis demonstrated the prognostic value of the NLR ($P = 0.049$) and the CRP/Alb ratio ($P = 0.047$) in relation to PFS, and a positive

relationship between an increase in inflammation-based markers and a poor prognosis in relation to OS. The multivariate analysis determined that an increased NLR (hazard ratio = 2.76, 95%CI: 1.33-5.75, $P = 0.007$) is an independent prognostic factor for poor OS. There was no association between the PLR and the patients' prognoses in those who had received chemotherapy that comprised gemcitabine and erlotinib in combination. The Kaplan-Meier method and the log-rank test determined significantly worse outcomes in relation to PFS and OS in patients with an NLR > 5 or a CRP/Alb ratio > 5.

CONCLUSION: Systemic inflammation-based markers, including increases in the NLR and the CRP/Alb ratio, may be useful for predicting PC prognoses.

Core tip: This retrospective study validates the value of systemic inflammation-based markers as prognostic factors for pancreatic cancer (PC). The neutrophil-to-lymphocyte ratio and the C-reactive protein-to-albumin ratio, which can be determined from routine blood tests before chemotherapy, can be used as useful biomarkers in PC to predict a patient's response to chemotherapy.

Prognostic value of inflammation-based markers in patients with pancreatic cancer administered gemcitabine and erlotinib. *World J Gastrointest Oncol* 2016; 8(7): 555-562 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i7/555.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i7.555>

INTRODUCTION

Pancreatic cancer (PC) is a devastating malignant tumor that has a poor prognosis^[1]. Although surgical resection offers a good prognosis and prolongs survival, only 10%-20% of patients are eligible for a curative resection at the time of diagnosis^[2,3]. Systemic chemotherapy is a major treatment modality for unresectable PC, and the National Comprehensive Cancer Network recommends gemcitabine-based chemotherapy as standard therapy for advanced or metastatic PC. The findings from recent studies have demonstrated that gemcitabine and erlotinib (Tarceva®) administered in combination improve therapeutic response rates and overall survival (OS)^[4-6]. However, the PC prognosis remains extremely poor, and it is difficult to predict in advanced PC before chemotherapy. Hence, to administer effective treatment, better prognostic predictors are required than those that are currently available.

Evidence is accumulating that supports the relationship between the inflammatory response and cancer development^[7,8]. Bhatti *et al.*^[9] proposed that hematologic inflammation-based markers could be used as prognostic markers in resectable PC. C-reactive protein (CRP) levels, and leukocyte, neutrophil, lymphocyte, and platelet counts, as well as the neutrophil-to-lymphocyte ratio (NLR) and the platelet-to-lymphocyte ratio (PLR), could be prognostic markers for patients with PC^[10,11]. Recently, an increase in the CRP/albumin (CRP/Alb) ratio has been reported to correlate with poor prognoses in patients with malignant tumors^[12-14]. However, the relationship between the CRP/Alb ratio and the PC prognosis has not been studied. Since cancer progression depends on the systemic inflammatory response^[15], we hypothesized that the status of the peripheral blood at the time of diagnosis reflects the inflammatory response and the disease activity associated with PC.

This study aimed to evaluate the prognostic value of systemic inflammation-based markers within the peripheral blood of patients with advanced or metastatic PC, and to determine their usefulness in predicting patients' responses to chemotherapy.

MATERIALS AND METHODS

Patients and study design

We retrospectively collected data from patients with PC who were admitted to two tertiary hospitals, namely, Anam Hospital and Ansan Hospital in South Korea, between January 2011 and December 2014. Only consecutive patients with primary PC were included in the study. All of the patients met the following criteria: (1) the presence of a pathologically confirmed pancreatic adenocarcinoma; (2) receipt of first-line chemotherapy comprising gemcitabine and erlotinib administered in combination; and (3) the presence of locally advanced or metastatic PC. Gemcitabine was administered at 1000 mg/m² three times per week, which was followed by rest for 1 wk. Erlotinib was administered as a single oral 150 mg dose during chemotherapy. Patients who had undergone previous curative resections of their primary pancreatic tumors, or who had undergone first-line chemotherapy that involved other chemotherapeutic agents, including 5-fluorouracil, were excluded from this study.

The patients' demographic, clinical, and laboratory data, including the WBC and differential counts, the platelet count, and information about tumor markers, were collected and analyzed. All of the laboratory data were obtained on the day of or on the day that followed hospital admission. The NLR was calculated by dividing the neutrophil count by the lymphocyte count, and the PLR was calculated by dividing the platelet count by the lymphocyte count. The CRP/Alb ratio was determined as the CRP level divided by the serum albumin level. The follow-up duration was defined as the period from the first day of treatment to the day of death or August 2015.

Statistical analysis

An increased NLR was defined as > 5 , and an increased PLR was defined as > 150 ^[14]. The CRP/Alb ratio cutoff value was 0.5, which was based on a previous study^[13]. Progression was defined as a 25% or more increase in total tumor size and/or the appearance of new lesions at any site. Progression-free survival (PFS) was defined as the time from treatment to the first observation of progression. OS was defined as the date of the first treatment to the date of death. The Kaplan-Meier method and the log-rank test were used to compare the PFS and OS rates, and the 95%CI were calculated. The univariate and multivariate analyses were carried out using the Cox proportional hazards model, and student's *t*-test was used to analyze the response and survival time results. A *P* value < 0.05 was considered statistically significant. The statistical analyses were conducted using IBM® SPSS® software version 20.0 (IBM Corporation, Armonk, NY, United States).

RESULTS

Patient characteristics

Table 1 presents the characteristics of the 82 patients who met all of the study's eligibility criteria. The mean age of the patients when they were diagnosed with PC was 63.5 ± 10.7 years, and 60% of the patients were men. Most of the patients (85%) had favorable performance statuses with Eastern Cooperative Oncology Group (ECOG) scores of 0 or 1. The median values for the inflammatory

markers were as follows: NLR: 3.1 (range, 1-48); PLR: 141 (range, 44-921); and CRP/Alb ratio: 0.5 (range, 0-38). All of the patients were finally diagnosed with pancreatic adenocarcinoma based on pathologic examinations. Fourteen patients (17%) had locally advanced PC and 68 patients (83%) had metastatic lesions when they were diagnosed with PC.

Prognostic value of the factors associated with PC

Univariate analyses were performed using sex, age, the tumor stage, the ECOG performance status score, the tumor markers, and the inflammatory markers as possible variables for PFS (Table 2), and it determined that an NLR > 5 ($P = 0.049$) and a CRP/Alb ratio > 0.5 ($P = 0.047$) were significant predictors of a poor prognosis. Univariate and multivariate analyses were also performed in relation to OS (Table 3). The univariate analysis revealed that the presence of distant metastasis ($P = 0.017$), an ECOG performance status score of 2 ($P = 0.002$), an NLR > 5 ($P = 0.008$), and a CRP/Alb ratio > 0.5 ($P = 0.011$) were significantly associated with poor OS. The multivariate analysis showed that an ECOG performance status score of 2 [hazard ratio (HR) = 2.94, 95%CI: 1.42-6.08, $P = 0.004$] and an NLR > 5 (HR = 2.76, 95%CI: 1.33-5.75,

ECOG: Eastern Cooperative Oncology Group; CA19-9: Carbohydrate antigen 19-9; CEA: Carcinoembryonic antigen; NLR: Neutrophil-to-lymphocyte ratio; PLR: Platelet-to-lymphocyte ratio; CRP: C-reactive protein; HR: Hazard ratio.

$P = 0.007$) were independent factors associated with the prognosis of PC.

Inflammation-based factors and PC outcomes

By the time this study was completed, 57 patients had died because of disease progression. The patients were categorized according to the NLR and the CRP/Alb ratio and subgroup analyses were performed. The groups were compared with respect to the duration of chemotherapy and the time until death (Table 4). Patients with initial NLRs ≤ 5 continued chemotherapy with gemcitabine and erlotinib for longer. The time to disease progression was significantly longer when the patients' NLRs did not increase. The mean time until death was longer in patients who had NLRs ≤ 5 compared with patients who had NLRs > 5 . The mean time until death was shorter in patients with CRP/Alb ratios > 0.5 compared with patients with CRP/Alb ratios ≤ 0.5 .

Prognostic comparisons based on the NLR and the CRP-to-albumin ratio

The NLR has been identified as a prognostic indicator in patients with PC who are undergoing gemcitabine-based chemotherapy; therefore, we compared the cancer prognosis in a group of patients with NLR ≤ 5 with that in a group of patients with NLR > 5 . Kaplan-Meier analyses determined that PFS was significantly better in patients

with NLRs ≤ 5 (4.9 ± 0.5 mo) compared with those with NLRs > 5 (3.1 ± 0.7 mo) ($P = 0.043$) (Figure 1A), and that OS was significantly better in patients with NLRs ≤ 5 (11.1 ± 1.2 mo) compared with those with NLRs > 5 (5.8 ± 0.9 mo) ($P = 0.005$) (Figure 1B). PFS for patients with CRP/Alb ratios > 0.5 (3.2 ± 0.4 mo) was significantly worse compared with those with CRP/Alb ratios ≤ 5 (5.3 ± 0.7 mo) ($P = 0.034$) (Figure 2A), and OS for patients with CRP/Alb ratios > 0.5 (7.9 ± 1.2 mo) was significantly worse compared with those with CRP/Alb ratios ≤ 5 (12.7 ± 1.2 mo) ($P = 0.007$) (Figure 2B).

DISCUSSION

Systemic chemotherapy is recommended as palliative therapy for PC^[16], but only a limited number of patients benefit from chemotherapy. Gemcitabine-based combination therapy is considered an effective first-line treatment for advanced PC^[4,17-19]. While the tumor stage and the carbohydrate antigen 19-9 levels have been used to predict patients' prognoses^[20-22], predicting the therapeutic effect of or a patient's response to chemotherapy is difficult.

Findings from recent studies of different malignant tumors have suggested that increases in the levels of systemic inflammation are indicative of poor survival^[23,24]. Inflammatory cells within the tumor microenvironment play important roles in tumor development and in the

survival of malignant cells^[25,26]. Therefore, systemic inflammation-based markers may be indicators of cancer prognosis and of patients' responses to therapy. Since these markers can be readily measured in peripheral blood samples, its usefulness would be greatly expectable in practice. Indeed, some investigators have described the prognostic value of these systemic inflammatory response markers in advanced PC^[11,27-29].

The current investigation scrutinized the value of a number of clinical parameters, including the NLR, PLR, and the CRP/Alb ratio, as prognostic predictors in patients with PC who received combination chemotherapy that comprised gemcitabine and erlotinib. The univariate and multivariate analyses determined that a higher

ECOG performance status score, metastatic disease, a higher NLR, and a higher CRP/Alb ratio were associated with poor outcomes. A multivariate analysis of the significant inflammation-related factors determined that the NLR was independently associated with OS. In the patients with PC, a higher NLR was associated with significantly worse OS (2.6 mo) compared with a lower NLR (8.5 mo), but the PLR was not determined to be an independent prognostic factor. A higher CRP/Alb ratio was associated with a poor prognosis according to the univariate analysis, but the multivariate analysis did not show that it was an independent prognostic factor.

The mechanism that underlies the association between inflammation-based markers and poor PC outcomes

has not been clarified. Systemic inflammatory changes would be reflected in increases in the neutrophil levels, and these could be induced by tumor invasion and disease progression, despite the administration of chemotherapy. Inflammatory responses can inhibit the immune system by suppressing the cytolytic activity of the immune cells, including that associated with the lymphocytes, activated T cells, and natural killer cells^[30]. Furthermore, inflammatory responses can promote tumor angiogenesis, invasion, and metastasis by recruiting regulatory T lymphocytes and activating cytokine production^[31,32]. Since an increase in the neutrophil count or a decrease in the lymphocyte count within the WBC count will present as a higher NLR, the NLR will be strongly associated with the prognosis for a patient with a malignant tumor. Moreover, cancer progression against chemotherapy activates inflammatory processes within the tumor microenvironment^[33], and the WBC ratios may change under these conditions.

The prognostic value of the preoperative NLR has been described in patients with resectable PC^[34-36], but the response of the NLR to chemotherapy and its value as a prognostic marker have not been established. We observed that the mean times until disease progression or death were significantly shorter in patients with NLRs > 5 compared with those whose NLRs were not elevated. Elevated neutrophil counts may aid cancer progression by providing a favorable environment for tumor growth. Furthermore, lymphocytopenia, which can be induced by many of the inhibitory immunologic mediators that are released by tumor cells, results in a weakened immune system that would contribute to poor patient outcomes during systemic chemotherapy.

To the best of our knowledge, this is the first study to evaluate the value of the CRP/Alb ratio in advanced PC. Another strength of our study is that the data were only collected from patients who were receiving a unified chemotherapy regimen that comprised gemcitabine and erlotinib. While other studies of PC have included both resectable and unresectable tumors^[9,37], we excluded patients with PC who had undergone surgery from the analysis. However, there are several limitations to our study. First, this was a retrospective study that involved a relatively small number of patients. While an elevated NLR was related to the PC prognosis, we could not validate the prognostic value of the PLR in this study. More data obtained from larger numbers of patients will be required to determine the true value of the PLR for predicting PC prognoses. Second, while we excluded those patients who had been diagnosed with acute pancreatitis or other infections, patients with early infections may have been included during the selection process. Since pancreatic duct obstruction and biliary tract invasion are relatively frequent in PC, patients with potentially aggressive disease may have been allocated to the group containing patients with higher NLRs. Finally, this study only evaluated patients who received combination chemotherapy with gemcitabine and erlotinib; hence, it is difficult to extrapolate the data to

all patients with PC. The therapeutic strategy for PC may differ considerably in relation to a patient's socioeconomic status, comorbidities, and other factors. However, since gemcitabine-based chemotherapy is widely recommended as first-line palliative chemotherapy for PC throughout the world, the NLR, which is easily calculated, would assist clinicians to predict patients' therapeutic responses and PC prognoses.

In summary, our results strongly support the idea that systemic inflammation-based parameters may be useful prognostic markers for patients with advanced PC. The NLR when determined at the time of a diagnosis of PC could be a valuable marker for predicting a patient's response to chemotherapy with gemcitabine and erlotinib. Furthermore, the CRP/Alb ratio may be valuable as a prognostic factor in PC. More prospective studies are needed to verify the usefulness of these inflammation-based markers in patients with PC.

COMMENTS

Background

Inflammation based markers have been known to have a prognostic value predicting the outcome of various cancers. Since the status of the peripheral blood reflects the inflammatory response at the time of diagnosis, it could be used the systemic inflammation based markers [neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio, C-reactive protein (CRP)-to-albumin ratio, etc.] as a prognostic biomarker in advanced pancreatic cancer (PC).

Research frontiers

It is important to be able to predict the outcome and response to chemotherapy in advanced PC. This study assessed the prognostic value of systemic inflammation based markers in patients with palliative chemotherapy due to inoperable PC.

Innovations and breakthroughs

Although prior investigators had studied about the prognostic value of NLR in malignancy, there was no study about the CRP-to-albumin ratio in PC. The present study showed that both NLR and CRP-to-albumin ratio can be useful and easy biomarkers to predict the response and outcome of PC.

Applications

It can be easily calculated NLR or CRP-to-albumin ratio from routine blood tests. The systemic inflammation-based markers can be useful tool to predict the outcome in patients with PC.

Terminology

The NLR was calculated by dividing the neutrophil count by the lymphocyte count, and the PLR was calculated by dividing the platelet count by the lymphocyte count. The CRP/Alb ratio was determined as the CRP level divided by the serum albumin level.

Peer-review

The manuscript by Lee *et al* aims to identify inflammation-based markers in patients with pancreatic cancer treated with gemcitabine and erlotinib. Eighty-two pancreatic cancer patients were enrolled in this retrospective study. Patients received combination chemotherapy with gemcitabine and erlotinib. Multivariate analysis demonstrated that an increased neutrophil-to-lymphocyte ratio (hazard ratio = 2.76, 95%CI: 1.33-5.75, $P = 0.007$) was an independent prognostic factor for poor overall survival. CRP/albumin ratio was related to progression free survival. The manuscript is in general well written and the topic is of interest.

Abstract

AIM: To investigate the prevalence of undernutrition, risk of malnutrition and obesity in the Italian gastroenterological population.

METHODS: The Italian Hospital Gastroenterology Association conducted an observational, cross-sectional multicenter study. Weight, weight loss, and body mass index were evaluated. Undernutrition was defined as unintentional weight loss > 10% in the last three-six months. Values of Malnutrition Universal Screening Tool (MUST) > 2, NRS-2002 > 3, and Mini Nutritional Assessment (MNA) from 17 to 25 identified risk of malnutrition in outpatients, inpatients and elderly patients, respectively. A body mass index ≥ 30 indicated obesity. Gastrointestinal pathologies were categorized into acute, chronic and neoplastic diseases.

RESULTS: A total of 513 patients participated in the study. The prevalence of undernutrition was 4.6% in outpatients and 19.6% in inpatients. Moreover, undernutrition was present in 4.3% of the gastrointestinal patients with chronic disease, 11.0% of those with acute disease, and 17.6% of those with cancer. The risk of malnutrition increased progressively and significantly in chronic, acute and neoplastic gastrointestinal diseases in inpatients and the elderly population. Logistical regression analysis confirmed that cancer was a risk factor for undernutrition (OR = 2.7; 95%CI: 1.2-6.44, $P = 0.02$). Obesity and overweight were more frequent in outpatients.

CONCLUSION: More than 63% of outpatients and 80% of inpatients in gastroenterological centers suffered from significant changes in body composition and required specific nutritional competence and treatment.

Key words: Obesity; Malnutrition; Risk of Malnutrition; NRS2002; Gastrointestinal disease

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The relevance of this study concerns the finding that in patients with gastroenterological disease, both prevalence of undernutrition and risk of malnutrition were higher in patients admitted to the hospital and in patients with cancer disease, while obesity and overweight were more frequently detected in outpatients. In conclusion, we can attest that two-thirds of gastroenterological patients suffered from abnormalities in body composition and required targeted nutritional treatments.

INTRODUCTION

Malnutrition is defined as a structural and functional alteration of the body composition. Although the term malnutrition is commonly used in the sense of undernutrition, it encompasses both weight loss (undernutrition) and weight gain (overweight and obesity). The physiological basis of undernutrition and obesity is the deficit (undernutrition) or the excess (obesity) of calories that results in measurable adverse effects on clinical outcomes^[1-5]. The equilibrium between the total energy requirements, nutrient intake and utilization is mediated by hormonal and cytokine stimuli that induce the activation of intracellular metabolic pathways.

Previous papers have found that the prevalence of hospital undernutrition varies between 27% to more than 50% depending on the identification criteria, the medical or surgical setting and the age of the patients^[6-10].

It is important to identify and treat undernutrition because it has been associated with a higher likelihood of hospitalization, a prolonged (by 29%-65%) hospital stay^[11-15] and an increase in costs of up to 68%^[16,17]. Moreover, it must be emphasized that hospital undernutrition worsens if untreated^[18]. Today, many health care workers do not recognize malnutrition and do not consider nutrition as one of the more relevant aspects of the clinical management of patients^[19].

The risk of undernutrition can be identified using different validated nutritional screening tools, such as the NRS-2002, MUST, and the MNA^[20-22].

Of note, the prevalence of overweight and obesity has been steadily growing in the general population and among inpatients and represent important risk factors of morbidity and mortality^[23-27].

Currently few data are available in the literature about the prevalence of undernutrition and the risk of malnutrition among Italian inpatients and outpatients, particularly in the gastroenterological setting. The Italian multicenter HOMIS study identified undernutrition in 19.1% and obesity in 24.8% of its patients^[28]. Another Italian multicenter study, PIMAI, reported a prevalence rate of undernutrition of 30.7%, a risk of malnutrition, evaluated by the NRS-2002, of 28.6% and a rate of obesity of 21%^[29,30].

The nutritional state of Italian gastroenterological patients has been described in an Italian multicenter study^[31] that involved twenty-seven gastroenterology units. The study highlighted a mean of 27% of undernourished patients with a wide range (4% to 55%), probably due to the lack of appropriate nutritional assessment.

Consistent data on the prevalence of malnutrition in gastroenterology units have been limited to a few subsets of patients such as those with cirrhosis^[32-36] and Crohn's disease^[37-39].

Similarly, the prevalence of obesity in Italian gastroenterology centers has not been adequately studied, although it is an important risk factor for many gastroenterological diseases^[40-42], and it seems to affect approximately 12% of discharged patients^[43].

The aim of this study is to measure the prevalence rate of undernutrition, risk of malnutrition and obesity in the Italian gastroenterological population suffering from acute, chronic and neoplastic disease.

MATERIALS AND METHODS

Study design

This was an observational, cross-sectional and prospective multicenter study that was urged and supported by the Italian Hospital Gastroenterology Association (AIGO).

Nineteen Italian Gastroenterological Units and Services participated in the study, as disclosed by the AIGO website.

Inclusion criteria

All inpatients and outpatients (day hospital and ambulatory) admitted between January 14 and 20, 2013 were consecutively enrolled in the study and submitted to nutritional assessment. As this was an observational study, the sample size was determined by the number of inpatients and outpatients who visited the various centers during the study week.

Patient population

In this study, we enrolled three different categories of patients with gastrointestinal disease: (1) subjects with a diagnosis of acute gastrointestinal disease: Dysphagia, dyspepsia, heartburn, other abdominal pains, acute diarrhea, exacerbation of chronic diarrhea, acute constipation, digestive hemorrhage, acute hepatitis, cholangitis, rectum hemorrhage, inflammatory bowel disease (IBD) exacerbation, or acute pancreatitis; (2) patients with chronic gastroenterological disease: Reflux disease, achalasia, chronic gastritis, chronic viral hepatitis, chronic alcoholic hepatitis, non-alcoholic fatty liver disease, other chronic hepatitis, cirrhosis, chronic pancreatitis, Crohn's disease and ulcerative proctocolitis, other chronic enteropathy, or chronic constipation; and (3) patients with gastrointestinal cancer: Esophagus, gastric, small bowel, colon, pancreatic, or biliary cancer and hepatocarcinoma. Patients were categorized as having (1) chronic disease, if the symptoms, signs and diagnosis had persisted for ≥ 6 mo; (2) acute disease, if the symptoms, signs and diagnosis had recently appeared, regardless of the presence of chronic disease; or (3) cancer, if affected by gastroenterological neoplastic disease, regardless of the presence of acute and/or chronic disease, as it was assumed that the presence of neoplastic disease itself was sufficient to determine further deterioration of a patient's nutritional status.

Nutritional parameters

Weight (kg) and height (centimeters) were measured in the morning in fasting patients dressed in their underwear and without shoes.

The body mass index (BMI) was calculated by dividing the weight in kg by the square of height in meters. Weight loss was calculated as the difference between the

current weight and the weight in the last three-six months as reported by the patient. Patients were considered undernourished when they presented an unintentional (*i.e.*, without voluntary dietary restriction) weight loss $> 10\%$ in the last 3-6 mo. Obesity was defined as a BMI ≥ 30 , and overweight a BMI between 25 and 29.9. Obese patients were considered undernourished when they lost more than 10% of their weight while receiving their usual diet. The risk of malnutrition was calculated using three different specific tools, as shown in Table 1.

Specifically, the calculation of the three methods are described in detail in the following text: (1) the Malnutrition Universal Screening Tool (MUST) was used for outpatients. This method was based on the BMI, the unintentional weight loss and the presence of acute disease that was able to significantly reduce nutrient intake in the following five days. The total score ranged from 0-6; a score of 0 indicated null or low risk of malnutrition, a score of 1 suggested a moderate risk of malnutrition, and a score ≥ 2 was indicative of a severe risk of malnutrition^[44]. We considered a score ≥ 2 to identify patients at nutritional risk.

The Nutritional Risk Screening Score 2002 (NRS-2002) has been recommended by ESPEN to screen inpatients. This test evaluates the nutritional risk (score: 0-3) and the severity of disease (score: 0-3) with an additional point for patients ≥ 70 years old. The final score ranges from 1 to 7. The patient is considered at nutritional risk for scores higher than 3^[45].

The Mini Nutritional Assessment (MNA) is a tool for elderly patients (≥ 65 years). This tool has two parts. The first part consists of six items and results in a score between 0 and 14; a score lower than 12 is considered indicative of risk of undernutrition and leads to the patient answering the second part of the tool, which is composed of 12 items with a possible maximal score of 16. A total score < 17 is indicative of malnutrition, a score between 17 and 25 indicates risk of undernutrition, while scores > 25 are indicative of well-nourished patients^[46-48].

We used the MUST and NRS-2002 to evaluate the risk of malnutrition in < 65 -year-old patients and the MNA for those ≥ 65 years old.

Ethical considerations

This study was designed with the aim of obtaining epidemiological data and anthropometric measurements that did not compromise patient's safety. All data were anonymous. Patients were referred using the first two letters of their name and surname and with a consecutive number.

A written informed consent statement was obtained from each patient prior to study inclusion. The study was conducted with the consensus of the local ethical committees of each center and of all the patients.

Statistical analysis

The results were presented as the mean \pm SD. Categorical data were described as frequencies. The nonparametric Mann-Whitney *U* test was used to compare continuous

Table 1 Subscores of the three nutritional risk screening tests used in the study

Test	Subscore			Nutritional risk score
MUST	BMI (score: 0-2)	Unintentional weight loss (score: 0-2)	Acute disease able to significantly reduce nutrient intake in the following 5 d (score: 2)	≥ 2
NRS-2002	Pre-test: BMI < 20.5; weight loss, reduced caloric intake, acute disease	Nutritional risk: Weight loss, BMI, caloric intake (score: 0-3)	Severity of disease (score: 0-3)	Age ≥ 70 -yr-old (score: 1)
MNA	First part (six items: Caloric food intake, weight loss, motility, psychological stress, neuropsychological disease, BMI (score: 0-14)	If subscore ≤ 11 : Complete second part	Second part (12 items: Home and nutritional autonomy, drugs, bedsores, daily meals, brachial and calf circumference; (maximal score of 16)	17-25

MUST: Malnutrition Universal Screening Tool; NRS: Nutritional Risk Screening; MNA: Mini Nutritional Assessment.

variables, and χ^2 test was used to compare categorical data. Two-tailed *P* values less than 0.05 were considered statistically significant.

Univariate and multivariate analyses were used to identify potential predictors of malnutrition. A linear trend test was used to assess associations with severity of disease. A stepwise backward logistical regression analysis, adjusted for age and gender and considering acute, chronic and neoplastic disease independent of each other, was performed to identify significant independent predictors of malnutrition. Statistical analyses were performed using SPSS software version 12.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Five hundred and ninety-seven patients were enrolled. We excluded from the statistical analysis five patients for incomplete data and 79 cirrhotic patients because of the negative effects of ascites and peripheral edema on nutritional parameters.

In Table 2 we report the anthropometric and nutritional data of the 513 patients enrolled in the 19 gastroenterology units participating in the study: 51.4% were males and 48.6% females, and the average age was 59.8 ± 17.8 years without a significant difference between the centers.

In total, 39.8% of the patients required hospitalization, 12.1% were DH patients and 48.1% were ambulatory patients. Approximately 30.8% of the patients were urgently hospitalized, 21.2% of the cases had a planned admission, 22.2% needed a follow-up evaluation and 25.8% were at their first medical visit.

In Table 3 we report the age, gender, medical evaluation setting and disease category of patients according to their age category.

Gastrointestinal diseases were acute in 72.1% of the cases, chronic in 16.7% and neoplastic in 11.1%. In particular, chronic diseases were more frequent in younger participants (22.6% vs 9.0% in older patients, $P < 0.001$), while neoplastic diseases were more represented in the elderly patients (5.6% in younger patients vs 18.8%, $P < 0.001$).

Table 4 shows the prevalence of each pathology included in the three categories: Acute disease, chronic diseases and cancers according to age.

Undernutrition

The mean prevalence of undernutrition in our population was 12.1%:4.6% in the ambulatory and DH settings and 19.6% in patients requiring hospitalization.

The undernourished patients were affected by chronic, acute and neoplastic disease at rates of 8%, 74% and 18%, respectively.

In Table 5 we report the distribution of undernutrition, risk of malnutrition, obesity and overweight among inpatients and outpatients in both categories of age. In both categories of age, the rate of undernourished inpatients was significantly higher compared to that of outpatients.

As shown in Figure 1, the prevalence of undernutrition in chronic, acute and neoplastic gastrointestinal diseases was 4.3%, 11.0% and 17.6%, respectively, with a prevalence significantly higher in neoplastic patients than in those with chronic disease ($P = 0.03$). The linear trend test showed that the prevalence of undernutrition was significantly higher in hospital admitted patients ($P = 0.01$).

The logistical regression analysis corrected for age, gender and acute, chronic and neoplastic disease showed that gastrointestinal cancer was a risk factor for undernutrition with an odds ratio of 2.7 (95%CI: 1.2-6.4, $P = 0.02$).

Risk of malnutrition

The mean prevalence of risk of malnutrition in our population was 23.8%. In Table 5 we show the prevalence of risk of malnutrition among inpatients and outpatients, and in Table 6 we report the prevalence of risk of malnutrition according to the three screening tests and age group. Of the < 65-year-old patients, the 24.7% of inpatients were at risk of malnutrition; in the elderly participants, the MNA screening tool revealed a risk of malnutrition in inpatients that was higher than that of elderly outpatients (69.2% vs 40.6%, respectively, $P < 0.001$).

Table 2 Characteristics of the patients in the 19 gastroenterological units participating in the study

P value: ¹*P* < 0.05. ²Wilcoxon rank-sum (Mann-Whitney) test; ³χ² test. Significant standardized adjusted residual.

Of the outpatients at risk of malnutrition, acute and chronic gastrointestinal diseases had the same prevalence (50%); ten outpatients were affected by cancer, but none were at risk of malnutrition. In this population, only the 17.7% of patients with chronic gastrointestinal disease and 8.8% of those with acute gastrointestinal disease were at risk of malnutrition.

The inpatients at risk of malnutrition were affected by acute disease in 61.5% and by gastrointestinal cancer in 38.5% of the cases.

The elderly patients at risk of malnutrition presented chronic, acute and neoplastic disease in 5.2%, 67.0%, and 27.8% of the cases, respectively.

Figure 2 shows that the frequency of risk of malnutrition increased progressively with hospitalization, reaching statistical significance (*P* < 0.007) in the presence

of neoplasm.

Overweight and obesity

The prevalence of overweight and obesity in our population was, respectively, 28.6% and 15.6%. In Table 5, we report the rate of overweight and obesity in outpatients (31.7% and 18.3%, respectively) and in inpatients (25.5% and 13.0%, respectively) according to age group. Moreover, the rate of overweight and obesity did not show a difference in age. The prevalence of overweight and obesity was, respectively, 28.7% and 19.1% in chronic, 29.1% and 15.7% in acute, and 26.4% and 11.3% in neoplastic disease.

In our population, we found that no obese outpatients presented a weight loss > 10% in the last 3-6 mo, while the prevalence of risk of malnutrition was 15% higher

in elderly subjects (36.8%). The rate of undernutrition was 12% in the hospitalized obese patients, and the prevalence of risk of malnutrition was 13.3% in young obese inpatients and increased up to 80% in those > 65

years old.

Of the overweight outpatients, the rate of undernutrition was 2%, while it was 8.9% in overweight inpatients. The rate of overweight outpatients at risk of malnutrition was

Figure 1 Prevalence of undernutrition in presentations of acute, chronic and neoplastic gastrointestinal diseases. ^a $P = 0.03$, neoplastic vs chronic. Linear trend test: $P = 0.01$.

Figure 2 Prevalence of risk of malnutrition in presentations of acute, chronic and neoplastic gastrointestinal diseases. ^a $P < 0.007$, neoplastic vs chronic and acute.

28.3%, but this rate reached 33.3% in those hospitalized.

DISCUSSION

This study was designed to define the nutritional state of patients with gastroenterological disease. Regarding the diseases included in this study, we want to specify that cirrhotic patients were excluded because of the obscuring effect of compartmentalized ascites on body weight^[31,36,49]. However, diseases causing reduced albumin levels, which decreases oncotic pressure and allows for diffuse fluid leakage into the interstitial space, were not excluded, as fluid retention has to be considered a direct consequence of malnutrition.

Our data found that undernutrition affected approximately 12% of all patients; in particular, we documented that the rate of prevalence of undernutrition was significantly higher in inpatients (20%) than in outpatients. This is a consequence of the fact that acute diseases requiring hospitalization reduce caloric intake because of the presence of abdominal pain, diarrhea and vomiting. The use of tools to evaluate the risk of malnutrition should allow us to focus our attention on patients who have not yet begun to lose weight.

It was also interesting to note that younger and neoplastic inpatients were more frequently malnourished than the other groups, and this was due to the high rate of chronic inflammatory gastrointestinal diseases in our younger population (IBD: 11.4% vs 1.4% and celiac disease: 3.5% vs 0% in < 65-year-old and > 65-year-old patients, respectively) and the metabolic abnormalities characterizing cancer cachexia. Indeed, logistic regression confirmed that (1) the rate of undernutrition increased with the severity of disease; and (2) gastrointestinal cancer was a risk factor for undernutrition.

Very little data can be found in the literature concerning the prevalence rates of undernutrition in gastroenterology units. In our population, the prevalence of undernutrition was similar to those reported in other European^[8] and Italian studies^[28] but differed from other studies^[9,29,30,50] because of both (1) the different

tools used to evaluate malnutrition; and (2) the diverse stages of disease. In this study, we reported for the first time (1) the rate of undernutrition in gastroenterology outpatients; and (2) the correlation of undernutrition with hospital admission.

Regarding the risk of malnutrition, we want to emphasize that all of the screening tools we used were well-validated in identifying the patients who would develop undernutrition in the absence of an adequate nutritional care plan and that the NRS-2002 has shown a good predictive value for mortality, length of stay and complications. Few data have been published about the risk of malnutrition in the gastroenterology population^[9,10,50]. In this study, we demonstrated that, in the gastroenterology department, inpatient and elderly patients had a greater frequency of risk of malnutrition than outpatients and younger patients, especially if affected by cancer; additionally, this risk was lower for those with chronic gastrointestinal disease. We must also highlight the fact that the NRS-2002 in inpatients was more frequently influenced by a reduction in caloric intake than by weight loss.

In our population, the NRS-2002 disclosed a risk of malnutrition in 36.7% of the inpatients. This value was lower than that reported in a Danish study evaluating gastro-surgery patients^[9] but higher than data from Romanian gastroenterology departments^[50].

Moreover, while young inpatients were undernourished or at risk of malnutrition at a similar prevalence, elderly inpatients were at a greater risk of malnutrition. These data indicate that the management of malnutrition in gastrointestinal departments should have different targets according to patients' age: We should probably treat undernutrition with artificial nutrition in younger patients, while oral supplementation should be recommended to prevent malnutrition in elderly patients. Very limited data are available on the evaluation of the risk of malnutrition in outpatients. In this setting, our data indicated that patients with nutritional risk were more often affected by chronic disease, in which the catabolic

effects of inflammatory cytokines influence nutritional status^[4,51,52].

Overweight and obesity represent another aspect of malnutrition that entails excessive fat mass in body composition. In recent years, a number of works have reported an increasing incidence of obesity in the general population, but data on the prevalence of obesity and overweight in the gastroenterological population have been limited. The average prevalence of overweight-obesity in our study was 22.7%; this rate of obesity was lower than those reported in a hospital setting in previous Italian^[28-30] reports but was higher than the Italian general population rate, especially in outpatients.

We also found that approximately 10% of the obese and overweight hospitalized patients were undernourished and that the risk of malnutrition was present in more than one-third of the obese and overweight gastroenterological patients, with rates that reached 80% in > 65-year-old obese inpatients.

The prevalence of obesity and overweight in outpatients was higher than in inpatients but was not statistically significant.

It is not surprising that in obese patients, undernutrition and risk of malnutrition could be present at the same time. An involuntary weight loss > 10% and/or reduction in caloric intake allowed us to identify patients who, despite having excess weight, met the criteria for malnutrition or risk of malnutrition. These data indicate that we must keep in mind that even obese patients can be malnourished and that we must investigate the risk of malnutrition especially among elderly gastroenterological patients, regardless of their weight at admission.

A possible bias of this study was the voluntary participation of the gastrointestinal units including centers that paid major attention to nutritional aspects. Another limitation of this work was the difference in the population size and in the frequency of disease, which was often determined by each center's particular experience; it was thus difficult to study undernutrition and the risk of malnutrition for each single disease.

Overall, our data noted that 55% of inpatients and 22% of outpatients were undernourished and at risk of malnutrition and that half of the outpatients and nearly one-third of inpatients were obese or overweight. In our population, only 19.7% and 36.6% of inpatients and outpatients, respectively, did not present nutritional abnormalities (weight loss, risk of malnutrition, overweight or obesity). These data indicate that 80.3% of inpatients and 63.4% of outpatients would require nutritional competence in gastrointestinal units to assess the degree of malnutrition, to correctly design appropriate therapeutic programs to improve protein-caloric alterations and to prevent complications.

COMMENTS

Background

Malnutrition has adverse effects on clinical outcomes, but many health care workers do not adequately consider it as a relevant aspect of the clinical management of patients. In the literature, few data are available regarding the prevalence of malnutrition (undernutrition, obesity,) and risk of malnutrition in European and Italian gastroenterology departments, with rates that depend on the criteria adopted for their identification, the medical or surgical setting and the age of the patients.

Research frontiers

A better understanding of the prevalence of malnutrition and nutritional risk according to the severity of disease (chronic, acute and cancer) in outpatients and inpatients would facilitate the identification of patients with impairment of nutritional status and with adequate nutritional management.

Innovations and breakthroughs

For the first time, they studied undernutrition, risk of malnutrition (using three different nutritional screening tools) and obesity according to the severity of gastroenterological disease (chronic, acute and cancer) in both admitted patients and outpatients.

Applications

The authors' data showed that there was a different distribution of undernutrition, risk of malnutrition and obesity according to the severity of disease and age group among inpatients and outpatients, which indicates that an appropriate nutritional care plan in gastrointestinal departments to achieve different nutritional targets may be needed.

Terminology

Undernutrition: When patients presented an unintentional (*i.e.*, without voluntary dietary restriction) weight loss > 10% in the last 3-6 mo; The MUST (Malnutrition Universal Screening Tool), NRS-2002 (Nutritional Risk Screening Score 2002) and MNA (Mini Nutritional Assessment) are three screening nutritional tests that identify patients at risk of malnutrition; BMI: Body mass index (calculated by dividing the weight in kg by the square of height in meters). Obesity: BMI \geq 30; overweight: BMI between 25 and 29.9.

Peer-review

The authors have excluded cirrhotics because of the obscuring effect of ascitis and or edema. Inflammatory diseases may cause a drop in serum albumin

levels that decrease oncotic pressure and favors fluid leakage to the interstitial space, that may reach up to 5 l before edema is clinically evident.

Abstract

AIM: To verify the safety and validity of laparoscopic surgery for the treatment of colorectal cancer in elderly patients.

METHODS: A meta-analysis was performed of a systematic search of studies on an electronic database. Studies that compared laparoscopic colectomy (LAC) in elderly colorectal cancer patients with open colectomy (OC) were retrieved, and their short and long-term outcomes compared. Elderly people were defined as 65 years old or more. Inclusion criteria were set at: Resection of colorectal cancer, comparison between laparoscopic and OC and no significant difference in backgrounds between groups.

RESULTS: Fifteen studies were identified for analysis. LAC was performed on 1436 patients, and OC performed on 1810 patients. In analyses of short-term outcomes, operation time for LAC was longer than for OC (mean difference = 34.4162, 95%CI: 17.8473-50.9851, $P < 0.0001$). The following clinical parameters were lower in LAC than in OC: Amount of estimated blood loss (mean difference = -93.3738, 95%CI: -132.3437 to -54.4039, $P < 0.0001$), overall morbidity (OR = 0.5427, 95%CI: 0.4425-0.6655, $P < 0.0001$), incisional surgical site infection (OR = 0.6262, 95%CI: 0.4310-0.9097, $P = 0.0140$), bowel obstruction and ileus (OR = 0.6248, 95%CI: 0.4519-0.8638, $P = 0.0044$) and cardiovascular complications (OR = 0.4767, 95%CI: 0.2805-0.8101, $P = 0.0062$). In analyses of long-term outcomes (median follow-up period: 36.4 mo in LAC, 34.3 mo in OC), there was no significant difference in overall survival (mean difference = 0.8321, 95%CI: 0.5331-1.2990, $P = 0.4187$) and disease specific survival (mean difference = 1.0254, 95%CI: 0.6707-1.5675, $P = 0.9209$). There was also no significant difference in the number of dissected lymph nodes (mean difference = -0.1360, 95%CI: -4.0553-3.7833, $P = 0.9458$).

CONCLUSION: LAC in elderly colorectal cancer patients had benefits in short-term outcomes compared with OC except operation time. The long-term outcomes and oncological clearance of LAC were similar to that of OC. These results support the assertion that LAC is an effective procedure for elderly patients with colorectal cancer.

Core tip: Safety and effectiveness of laparoscopic surgery (LAC) in elderly has been unknown. A meta-analysis was performed of a systematic search of studies on an electronic database. Studies that compared LAC in elderly colorectal cancer patients with open colectomy (OC) were retrieved, and their short and long-term outcomes compared. Fifteen studies which had 1436 LAC and 1810 OC were identified. In short-term outcomes, blood loss, morbidity, incisional surgical site infection, bowel obstruction and cardiovascular complications were superior in LAC except operation time. There was no significant difference in long-term outcomes. LAC is an effective procedure for elderly with colorectal cancer.

INTRODUCTION

People are living longer across the globe. According to the World Health Organization, 6.9% of the world was over the age of 65 in 2000 with an estimated increase to 10.4% in 2025 and a further rise to 16.4% in 2050^[1]. This estimation is valid in all regions of the world. Average life expectancies in 2025 are estimated to be 77 years old in the Americas and Europe and 72 years old in Asia. Colorectal cancer is the third most common malignant neoplasm in the world and aging is assumed to be one of the risk factors for colorectal carcinogenesis^[2]. Elderly patients have a higher American Society of Anesthesiologists score, higher cardiac and pulmonary comorbidity rate and lower preoperative nutritional conditioning than younger patients^[3-5]. Therefore, there is a high risk associated with even minimally invasive surgery in elderly patients. Several studies have reported the benefits of laparoscopic colorectal surgery in elderly patients^[6-10]. Most studies concluded that laparoscopic surgery had a lower postoperative morbidity rate and shorter length of hospital stay when compared to open surgery. Several large-scale systematic reviews that

compare laparoscopic colorectal surgery with open surgery have been published in recent years^[11,12]. They report that laparoscopic surgery has lower mortality, lower overall morbidity, lower cardiac and respiratory complications, lower wound infection and shorter length of hospital stay. However, they analyzed both colorectal cancer and benign diseases together. The surgical procedure for colorectal cancer differs from that for benign disease because optimal lymph node dissection and resection, with a securing safety margin, are vital in malignant neoplasm surgery. Therefore, a study analyzing laparoscopic surgery that targeted only colorectal cancer was required.

Moreover, the results of previous reviews reported only short-term outcomes. The evaluation of long-term outcomes is very important in the analysis of treatment efficacy for malignant neoplasia. The purpose of the present review is to clarify the benefits of laparoscopic surgery in elderly patients with colorectal cancer. We analyzed not only short-term but also long-term outcomes.

MATERIALS AND METHODS

Eligibility criteria

Elderly people were defined as 65 years old or more, as outlined by the World Health Organization^[1]. All studies were limited to randomized controlled or comparative studies. The subject of each study was limited to colorectal cancer and studies that included any benign disease were excluded. Backgrounds were similar between both groups, and had at least 15 patients in one group. The results had to include a comparison between laparoscopic and open surgery.

Outcomes

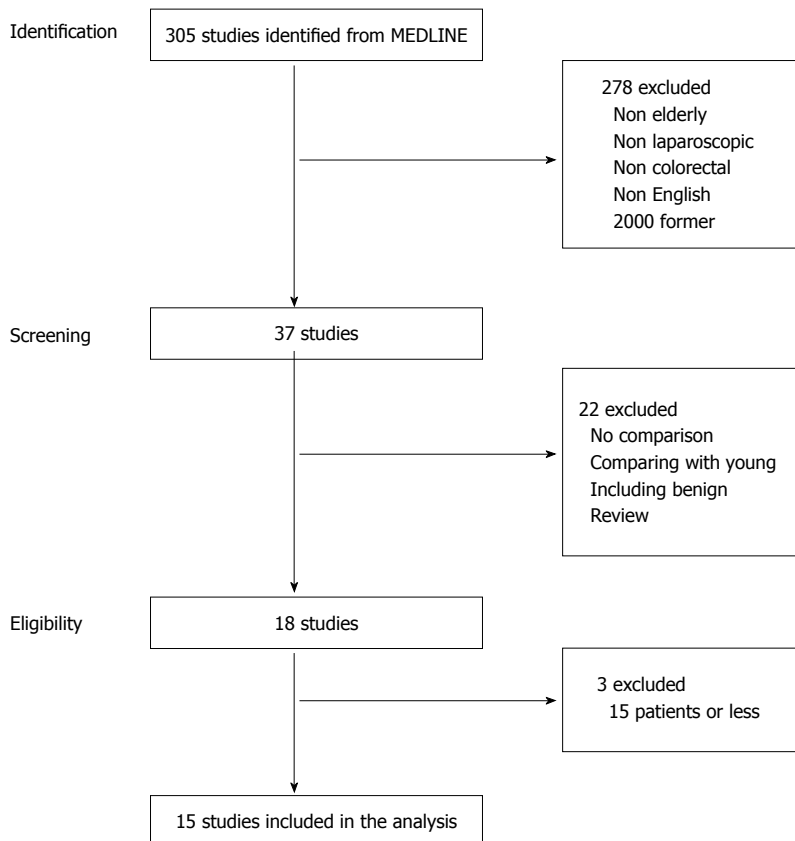

Short-term outcomes analyzed in the present study were as follows: Operative time, amount of estimated blood loss, mortality, overall morbidity, incisional surgical site infection, deep surgical site infection, anastomotic leakage, bowel obstruction and ileus, pneumonia, cardiovascular complication, time of normal bowel function and length of postoperative hospital stay. Duration of short-term was defined after the operation within 30 d.

The overall and disease specific survival rates were measured as long-term outcomes.

The number of dissected lymph nodes was used as an indicator of oncological clearance.

Study selection

The literature search was performed electronically using PubMed (MEDLINE). The search terms were as follows: Elderly or old, colorectal cancer or colon cancer, and laparoscopic surgery or laparoscopic colectomy (LAC) in combination with Boolean operators AND or OR. The language was limited to English. Studies were selected from those published after 2000 because they included the long-term results of several randomized

controlled studies that compared laparoscopic and open surgery^[13-18]. Moreover, developments in laparoscopic surgery instrumentation might influence short-term results in studies conducted in more recent years.

Assessment of study quality

The number of randomized controlled study was only one in this meta-analysis^[19]. The randomized controlled study was assessed for methodological quality using the Cochrane Handbook^[20]. Five of six items were at low risk of bias. Blinding of the study was not possible.

The comparative studies were assessed by the Newcastle-Ottawa Quality Assessment Scale (NOS)^[21]. Twelve of 14 studies had 6 or more star points on the NOS scale.

Statistical analysis

The odds ratios (ORs) for each study and 95% CIs were calculated from event numbers of categorical variables of short-term results. Pooled ORs were calculated using a random effect model. The mean value difference between continuous variables of short-term results and the number of dissected lymph nodes was also calculated using a random effect model. In the analysis of long-term results, 95% CIs of survival comparison and the number of patients in each study were synthesized using a random effect model. Synthesis of data was performed using the DerSimonian-Laird method^[22]. Study heterogeneity was checked by means of Cochran's Q statistic. If the P value of the heterogeneity test was

less than 0.05 in significance level, a null hypothesis of homogeneity was dismissed and study heterogeneity was proved. Publication bias among the studies was checked using the Egger test or Begg test accordingly. If the P value for publication bias was less than 0.10 a null hypothesis of no bias was dismissed and publication bias was confirmed.

RESULTS

Study profile

Thirty seven studies were identified by the first screening of MEDLINE. The reviews and studies that included benign disease cases or no data comparison between laparoscopic and open surgery were excluded. Finally, 15 studies were selected for analysis (Figure 1)^[19,23-36]. The types of studies were as follows: 1 randomized controlled, 2 case-matched, 1 prospective comparative and 11 retrospective comparative studies. In total, 1436 laparoscopic surgeries and 1810 open surgeries were analyzed. Conversion to open surgery was described in 9 studies. The range of conversion rate was between 0% and 13.9%, and the incidence of total patients was 4.5%. A summary of study characteristics is shown in Table 1.

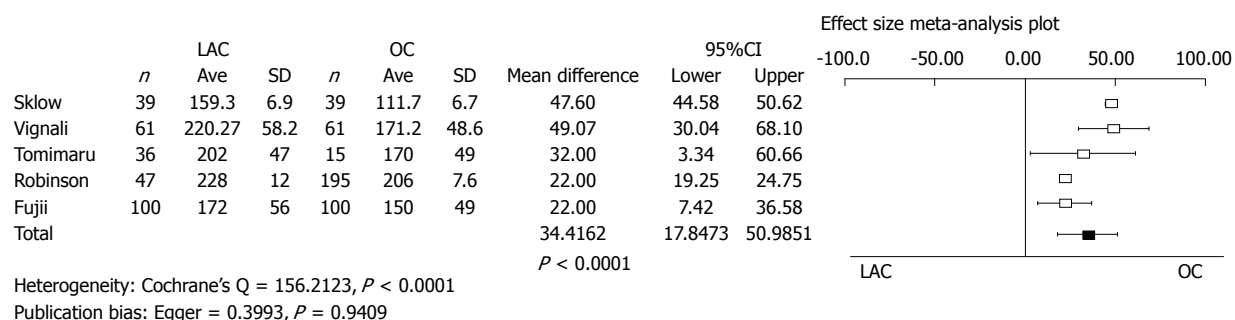

Short-term outcomes

Operation time: Five studies reported operative time as the mean value with standard deviation. The operation time of LAC was significantly longer than OC (mean difference = 34.4162, 95%CI: 17.8473-50.9851, $P <$

0.0001). The heterogeneity was statistically significant (Cochrane's $Q = 156.2123$, $P < 0.0001$). Publication bias was not evident (Egger = 0.3993, $P = 0.9409$) (Figure 2).

Amount of estimated blood loss: Six studies reported the amount of estimated blood loss as a mean value with standard deviation. The operation time of LAC was significantly less than OC (mean difference = -93.3738, 95%CI: -132.3437 to -54.4039, $P < 0.0001$). Heterogeneity was statistically evident (Cochrane's $Q = 74.1364$, $P < 0.0001$). Publication bias was not evident (Egger = 0.9129, $P = 0.7776$) (Figure 3).

Mortality: Four studies reported mortality. There was no significant difference between LAC and OC in mortality (OR = 0.5052, 95%CI: 0.2438-1.0467, $P = 0.0662$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 2.0911$, $P = 0.5537$, Egger = -0.6646, $P = 0.5883$).

Overall morbidity: Thirteen studies reported incidence of overall morbidity. The overall morbidity of LAC was significantly less than for OC (OR = 0.5427, 95%CI: 0.4425-0.6655, $P < 0.0001$). Heterogeneity was not evident (Cochrane's $Q = 14.7867$, $P = 0.2533$). Publication

bias was statistically evident (Egger = -1.3526, $P = 0.0310$) (Figure 4).

Incisional surgical site infection: Twenty studies reported the incidence of incisional surgical site infection. The incisional surgical site infection of LAC was significantly less than for OC (OR = 0.6262, 95%CI: 0.4310-0.9097, $P = 0.0140$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 15.2636$, $P = 0.1707$, Egger = -0.3638, $P = 0.6557$) (Figure 5).

Deep surgical site infection: Four studies reported the incidence of deep surgical site infection. There was no significant difference between LAC and OC in deep surgical site infection (OR = 0.8234, 95%CI: 0.3298-2.0556, $P = 0.6771$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 6.3512$, $P = 0.0957$, Egger = -3.0524, $P = 0.1922$).

Anastomotic leakage: Twenty studies reported the incidence of anastomotic leakage. There was no significant difference between LAC and OC in anastomotic leakage (OR = 0.9138, 95%CI: 0.5667-1.4735, $P =$

0.7115). Heterogeneity and publication bias were not evident (Cochrane's $Q = 8.0075$, $P = 0.7126$, Egger = 0.0396, $P = 0.9632$) (Figure 6).

Bowel obstruction and ileus: Ten studies reported the incidence of bowel obstruction and ileus. Bowel obstruction and ileus of LAC was significantly less than for OC (OR = 0.6248, 95%CI: 0.4519-0.8638, $P = 0.0044$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 8.7612$, $P = 0.4596$, Egger = -1.1383, $P = 0.1602$) (Figure 7).

Pneumonia: Three studies reported the incidence of pneumonia. There was no significant difference between LAC and OC in the incidence of pneumonia (OR = 0.4526, 95%CI: 0.1976-1.0365, $P = 0.0608$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 2.3251$, $P = 0.3127$, Egger = 0.1846, $P = 0.9743$).

Cardiovascular complication: Eight studies reported the incidence of cardiovascular complication. Cardiovascular complications of LAC was significantly less than for OC (OR = 0.4767, 95%CI: 0.2805-0.8101, $P = 0.0062$). Heterogeneity was not evident (Cochrane's Q

Recovery time of normal bowel function: Five studies reported the recovery time of normal bowel function as the mean value with standard deviation. There was no significant difference in the recovery time to normal bowel function between LAC and OC (mean difference = -0.8573, 95%CI: -1.8778 to 0.1632, $P = 0.0997$). Heterogeneity was statistically evident (Cochrane's $Q = 379.9427$, $P < 0.0001$). Publication bias was not evident (Egger = 5.4503, $P = 0.5226$).

Length of postoperative hospital stay: Three studies reported the length of postoperative hospital stay as mean value with standard deviation. There was no significant difference in the length of postoperative hospital stay between LAC and OC (mean difference = -1.3336, 95%CI: -3.3995 to 0.7322, $P = 0.2058$).

Heterogeneity was not evident (Cochrane's $Q = 3.9019$, $P = 0.1421$). Publication bias was statistically evident (Egger = -1.4308, $P = 0.0689$).

Long-term outcomes

Overall survival: Hinoi *et al.*^[32] reported overall survival in colon and rectal cancer separately. Three analyses of two studies reported the overall survival with 95%CI. There was no significant difference in the overall survival between LAC and OC (mean difference = 0.8321, 95%CI: 0.5331 to 1.2990, $P = 0.4187$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 3.3977$, $P = 0.1829$, Egger = -1.9819, $P = 0.3846$) (Figure 9).

Disease specific survival: Hinoi *et al.*^[32] reported disease specific survival in colon and rectal cancer separately. Three analyses of two studies reported the disease specific survival with 95%CI. There was no

significant difference in the disease specific survival between LAC and OC (mean difference = 1.0254, 95%CI: 0.6707 to 1.5675, $P = 0.9209$). Heterogeneity and publication bias were not evident (Cochrane's $Q = 0.1648$, $P = 0.9209$, Egger = -0.4921, $P = 0.1559$) (Figure 10).

Oncological clearance

The number of dissected lymph nodes: Two studies reported the number of dissected lymph nodes as the mean value with standard deviation. There was no significant difference in the number of dissected lymph nodes between LAC and OC (mean difference = -0.1360, 95%CI: -4.0553 to 3.7833, $P = 0.9458$). Heterogeneity

and publication bias were not evident (Cochrane's $Q = 3.2471$, $P = 0.0716$, Kendall tau rank correlation coefficient by Begg test = 1.0000, $P = 0.3173$).

Study quality

There was only one randomized controlled study^[19] which contained the following; random sequence generation, allocation concealment, blinding of participants, personnel and outcome assessors, incomplete outcome data, selective reporting and other potential threats to validity.

The study which had 5 or less star points on the NOS scale related to 5 short-term outcomes; amount of estimated blood loss, overall morbidity, incisional surgical site infection, anastomotic leakage and time of normal

bowel function. These outcomes were synthesized with studies which had 6 or more star points. Results were similar to the primary analyzed results and there was no conversion of interpretation.

DISCUSSION

Two systematic reviews that compare LAC with OC report benefits in short-term outcome. Grailey *et al.*^[11] report that LAC reduces the length of hospital stay, intraoperative blood loss, pneumonia, time to normal bowel function, cardiac complication and wound infection. Antoniou *et al.*^[12] report that LAC had a decreased risk for mortality, overall morbidity, plus cardiac and respiratory complications. Their results are similar to those reported in this review. However, they included analyses for both colorectal cancer and benign disease. Large scale, randomized studies and reviews that compare long-term results between LAC and OC in all generations report no difference in colon cancer patients^[37]. However, long-term results of randomized studies and reviews with elderly patient have not yet been reported. This meta-analysis, which compared LAC and OC in elderly colorectal cancer patients, demonstrates advantages in short-term and equivalency with respect to long-term outcomes and oncological clearance. These results will be useful in informing the selection of operative approach in elderly patients.

In analyses of the amount of estimated blood loss, overall morbidity, incisional surgical site infection and cardiovascular complication were all reduced in LAC. These results are similar to previous reports^[11,12]. It has been suggested that decreases in blood loss and postoperative pain reduce the stress of surgery, and therefore reduce overall morbidity. The reduction in cardiovascular complications might also be due to decrease in blood loss. Bowel obstruction and ileus was also reduced in LAC. Bowel obstruction and ileus were not distinguished in this analysis, because the definition was not clear in some studies and data was assigned to both conditions. This was not shown in previous reviews and it is supposed that the incidence of ileus increase is due to the extent of lymph node dissection in colorectal cancer. The exposure of intestines and major trauma to the abdominal wall might explain the increase in incidence of bowel paralysis and adhesion in OC.

The operative time of LAC was longer than OC. This

result was consistent with past reports, too. However, pneumonia was not increased and overall morbidity was decreased in LAC. Mean difference in operative time was about 34 min. The increase in operative time and pneumoperitoneum may not cause adverse effects on postoperative morbidity.

In this meta-analysis, there were no significant differences in mortality, incidence of pneumonia and recovery time of normal bowel function, which is not consistent with past reports. However, all LAC results tended to be lower than OC and p-values were close to being significantly different (mortality; OR = 0.5052, 95%CI: 0.2438- 1.0467, $P = 0.0662$, pneumonia; OR = 0.4526, 95%CI: 0.1976-1.0365, $P = 0.0608$, recovery time of normal bowel function; mean difference = -0.8573 , 95%CI: -1.8778 to 0.1632 , $P = 0.0997$). These inconsistent results may be due to the fact that patients who underwent elective colorectal surgery could be considered to be at relatively low risk. The reason for there being no significant difference in recovery time of normal bowel function is unknown. There might have been a significant difference if the time period of the data collection was a number of days not hours.

The incidences of deep surgical site infection and anastomotic leakage were similar between LAC and OC (deep surgical site infection; OR = 0.8234, 95%CI: 0.3298-2.0556, $P = 0.6771$, anastomotic leakage; OR = 0.9138, 95%CI: 0.5667-1.4735, $P = 0.7115$). It has been suggested that surgical invasiveness of the retroperitoneal dissection and anastomotic procedure are similar between LAC and OC in colorectal cancer surgery.

There was no significant difference in length of postoperative hospital stay.

This may be due to differences in the standard for hospital discharge in each study and may also be related to differences in the insurance systems in each country. Thus there might be a large bias in social factors between studies.

In analyses of long-term outcomes, both overall and disease specific survival rates were similar. There was also no significant difference in the number of dissected lymph nodes. This reveals the fact that LAC had similar treatment success to OC. The results of randomized studies and Cochrane review were also supported by this meta-analysis in elderly colorectal cancer surgery

patients^[13-18,37].

The limitation of this review is that it consists of only one randomized controlled study. Thus there were publication biases in analyses of overall morbidity, cardiovascular complication and length of postoperative hospital stay. Analysis of high risk elderly patients with impaired cardiac and pulmonary function might be required in the future. A secondary limitation of this study is that long-term outcomes were limited to three data sets from two studies. The analysis of more long-term results, that include details on the specific form of relapse, may thus be required.

LAC in elderly colorectal cancer patients had benefits in short-term outcomes such as amount of estimated blood loss, overall morbidity, incidences of incisional surgical site infection, bowel obstruction and ileus and cardiovascular complications. The only area where LAC did not show a benefit over OC was for operative time. The long-term outcomes and oncological clearance of LAC were similar to that of OC. These results support the view that LAC is an effective and safe procedure for elderly patients with colorectal cancer.

COMMENTS

Background

Laparoscopic surgery for colorectal cancer is increasing rapidly, particularly among elderly patients. However, neither the safety nor the effectiveness of laparoscopic surgery in this demographic has yet been determined.

Research frontiers

Some systematic reviews that compare laparoscopic colectomy (LAC) with open colectomy for elderly had reported benefits in short-term outcome.

Innovations and breakthroughs

However, past reports included benign diseases, and no report about long-term results. The authors analyzed for elderly colorectal cancer only and long-term outcomes.

Applications

Some short-term outcomes were superior in LAC except operation time. There was no significant difference in long-term outcomes. LAC is an effective procedure for elderly with colorectal cancer.

Terminology

LAC: Laparoscopic colectomy.

Peer-review

Good review article, scientific and rigorous analysis.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, William Small, MD, Professor, Department of Radiation Oncology, Northwestern Memorial Hospital, Robert H. Lurie Comprehensive Cancer Center, Chicago, IL 60611, United States

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Colorectal cancer is the second leading cause of death from cancer among adults. The disease begins as a benign adenomatous polyp, which develops into an advanced adenoma with high-grade dysplasia and then progresses

to an invasive cancer. Appropriate apoptotic signaling is fundamentally important to preserve a healthy balance between cell death and cell survival and in maintaining genome integrity. Evasion of apoptotic pathway has been established as a prominent hallmark of several cancers. During colorectal cancer development, the balance between the rates of cell growth and apoptosis that maintains intestinal epithelial cell homeostasis gets progressively disturbed. Evidences are increasingly available to support the hypothesis that failure of apoptosis may be an important factor in the evolution of colorectal cancer and its poor response to chemotherapy and radiation. The other reason for targeting apoptotic pathway in the treatment of cancer is based on the observation that this process is deregulated in cancer cells but not in normal cells. As a result, colorectal cancer therapies designed to stimulate apoptosis in target cells would play a critical role in controlling its development and progression. A better understanding of the apoptotic signaling pathways, and the mechanisms by which cancer cells evade apoptotic death might lead to effective therapeutic strategies to inhibit cancer cell proliferation with minimal toxicity and high responses to chemotherapy. In this review, we analyzed the current understanding and future promises of apoptotic pathways as a therapeutic target in colorectal cancer treatment.

Key words: Colorectal cancer; Apoptotic pathways; Drug resistance; Colorectal cancer therapies; Apoptosis

Core tip: Evasion of apoptosis has been established as a prominent hallmark of several human cancers, contributing to both tumor progression and chemo-resistance. In colorectal cancer development, the balance between the rates of cell growth and apoptosis that maintains intestinal epithelial cell homeostasis is impaired progressively. Recent studies indicated that failure of apoptosis may be an important factor in the evolution of colorectal cancer and its poor response to chemotherapy

and radiation. We herein discussed the mechanisms of apoptosis, abnormal expression of apoptosis-related genes and future promises of apoptotic pathways as a therapeutic target for colorectal cancer chemoprevention and treatment.

Abraha AM, Ketema EB. Apoptotic pathways as a therapeutic target for colorectal cancer treatment. *World J Gastrointest Oncol* 2016; 8(8): 583-591 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i8/583.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i8.583>

INTRODUCTION

Colorectal is the second driving reason for death from malignancy among adults^[1]. The diseases starts as a benign adenomatous polyp, which changes into a propelled adenoma with high-rate dysplasia that advances to aggressive tumor^[2]. The development of colorectal cancer (CRC) shows that tumor is a multistep procedure. The continuous process of cell division and differentiation of intestinal epithelium can be subverted by genetic alteration that switch the progenitor cells into tumor cells. This change is not prompt but occurs progressively through various stages as the cells get increasingly mutated, depending on the activation of oncogenes and the inactivation of tumor suppressors^[3]. The aim of this review was to summarize evidences on the role of apoptotic pathways in the initiation and progression of CRC and their potentials as a therapeutic target.

APOPTOSIS AND ITS ROLE IN CANCER

Apoptosis is an implicit cell suicide pathway that helps to remove cells that are no more required or have extreme injury to their DNA and cytoskeleton^[4]. Since defined by Kerr *et al.*^[5] in the 1970's, apoptosis remains amongst the most explored topics in biologic investigation. Being a very selective process, apoptosis is vital both in normal and pathological processes.

Mainly three fundamental sorts of biochemical changes are seen in apoptosis: (1) stimulation of caspases; (2) DNA and protein degradation; and (3) membrane alterations and detection by phagocytic cells. Specific morphological changes of apoptotic cells comprises nuclear compression and disintegration, cell contraction, active membrane blebbing, and loss of linkage to extracellular lattices or to neighboring cells. These alterations involve chromosomal DNA cleavage into internucleosomal rubbles, translocation of phosphatidylserine, and stimulation of proteases distinguished as the caspases^[6,7].

The unique characteristics of apoptosis is the activation various enzymes that are cysteine protease families called caspases^[7]. Activated caspases slice several key cellular proteins and degraded the nuclear

scaffold and the cytoskeleton. They additionally stimulate DNAase, which advances nuclear DNA degradation processes^[8].

MECHANISMS OF APOPTOSIS

Since they are both the initiators and destroyers, caspases play a key role in apoptotic processes. Caspases are initiated by three separate pathways: The intrinsic (or mitochondrial), the extrinsic (or death receptor) and the intrinsic endoplasmic reticulum pathways^[9]. The extrinsic pathway is initiated by triggering cell death receptors on the cell surface which leads to activation of the intracellular apoptotic machinery. The signals are originated from the activation of specific proapoptotic membrane receptors, a subclass of tumour necrosis factor (TNF) receptor family, through ligands, for example, FasL23/CD95L (receptor Fas/CD95) and Apo2 ligand TNF-linked apoptosis-initiating binding groups (Apo2L/TRAIL) (receptors DR4 and DR5)^[10]. These receptors have an internal components that mobilize core proteins including TNF receptor-associated death domain (TRADD) and fas-associated death domain (FADD)^[11]. Upon binding of the ligand to its receptor, the death-inducing signaling complex (DISC) that causes stimulation of caspase 8 formed^[9]. Thusly, caspase 8 activate the remaining downstream caspase enzymes. In some group of cells, the stimulation of caspase 8 could be the only prerequisite conditions to accomplish death, but in other cell types; caspase 8 cooperates with the intrinsic apoptotic processes by splitting Bid (a proapoptotic member of the Bcl-2 protein), causing the successive release of cytochrome-c^[12,13].

As the name suggests, the intrinsic pathway starts inside the cell. Intracellular stimuli such as irreversible genetic impairment, hypoxia, high calcium (Ca^{2+}) concentrations and elevated oxidative stress are amongst the triggers of intrinsic mitochondrial pathway. Irrespective of the inducers, this pathway caused an increase in mitochondrial porousness and the discharge of cytochrome-c and other proapoptotic proteins into the cytosol^[14]. This process is strictly controlled by Bcl-2 family proteins, termed after the *Bcl-2* gene originally detected at the chromosomal breakpoint of the translocation of chromosome 18 to 14 in follicular non-Hodgkin lymphoma^[15]. There are two classes of the Bcl-2 proteins: The pro-apoptotic proteins (such as Bax, Bakand, Bad, Bcl-Xs, Bid, Bik, Bimand Hrk) and the anti-apoptotic proteins (such as Bcl-2, Bcl-XL, Bcl-W, Bfl-1 Mcl-1). While anti-apoptotic proteins control apoptosis by delaying the mitochondrial release of cytochrome-c, the pro-apoptotic proteins accomplish by stimulating such releases. It is not the total amount, but rather the equilibrium between the pro- and anti-apoptotic proteins that regulate whether apoptosis should be started or not^[16]. Additional apoptotic factors that are released from the mitochondria into the cytosol contains apoptosis-inducing factor (AIF), second mitochondria-derived activator of caspase (SMAC), inhibitor of apoptosis

proteins (IAP), binding protein with low pI (DIABLO) and Omi/high-temperature requirement protein A (HtrA2). The cytoplasmic release of cytochrome c stimulates caspase 3 through the formation of a complex called apoptosome made up of cytochrome c, apoptotic protease activating factor 1 (APAF-1) and caspase 9. Active caspase-9 then activates caspase-3, which continually triggers the remaining of the caspase cascade and resulted in apoptosis^[17]. On the other hand, SMAC/DIABLO or Omi/HtrA2 stimulates caspase activation by binding to inhibitor of apoptosis proteins (IAPs) which then leads to disturbance in the interaction of IAPs with caspase 3 or 9^[16]. The intrinsic and extrinsic apoptotic pathways come together at caspase-3, which splits the inhibitor of the caspase-activated deoxyribonuclease, and the caspase-activated deoxyribonuclease causes nuclear apoptosis. The triggered enzymes cleave regulatory and structural molecules, ending in the death of the cell^[9]. Caspases also disturb the cytoskeletal structure, cell cycle and signaling process, eventually leading to the morphological indicators of apoptosis, for instance, DNA condensation and disintegration, and membrane blebbing^[4]. In early stage of apoptosis, there is expression of phosphatidylserine (PS) in cell membrane, which is overturned from the inside. This lets prompt detection of deceased cells by macrophages, causing phagocytosis without the release of pro-inflammatory mediators^[18].

The equilibrium between pro- and anti-apoptotic pathways comprises a vital role in the control of cell death, and disturbances in the balance between proteins have been associated in increased carcinogenesis by reducing apoptosis in tumor cells^[19,20].

ABNORMAL EXPRESSIONS OF GENES CONTROLLING APOPTOSIS IN CRC

CRC development is defined by the consecutive accumulation of mutations in genes controlling epithelial cell growth and differentiation^[21]. Genomic instability (gene mutations) and epigenetic alterations are the major mechanisms for CRC development^[22]. Approximately 60%-80% of CRC display genomic instability^[23]. In CRC, genomic instability takes several forms each with a different cause including mutations in specific genes that control mitosis, sequential inactivation of tumor-suppressor genes, such as adenomatous polyposis coli (APC) (chromosome 5q), P53 (chromosome 17p), and deleted in CRC (DCC), mothers against decapentaplegic homolog 2 (SMAD2), and SMAD4 (chromosome 18q) through numerous changes in chromosomal copy number and structure^[21]. The loss of genomic stability can initiate the evolution of CRC by enabling the acquisition of different cancer-related mutations^[24]. The building up of genomic modifications may bring changes in the level of apoptotic cell death, and many of these genes have been found to control apoptosis. Tumor-suppressor genes and oncogenes genes commonly associated with apoptosis

and CRC development are the tumor suppressor genes: Adenomatous polyposis coli (APC), P53 and the proto-oncogene Bcl-2.

ADENOMATOUS POLYPOSIS COLI

Changes in the adenomatous polyposis coli (APC) gene have been linked to about 60% of colorectal neoplasia signifying that APC mutations may be a central event in the development of colorectal carcinogenesis^[25-27]. APC protein is synthesized in normal epithelial cells as they moved towards the uppermost part of the crypt. Interruption of normal APC function distracts the equilibrium between new cell development at the bottom of the crypts and cell death at the top of the crypts, promoting the expansion of the descendants of APC-mutant cells^[28,29].

The absence of functional APC leads to an inappropriately and constitutively activation of the Wnt signaling pathway, thereby promoting colorectal tumor initiation^[30,31]. Stimulation of the Wnt pathway overwhelms the phosphorylation of the onco-protein β -catenin, causing its stabilization and nuclear translocation. β -catenin then cooperates with T-cell factor/lymphocyte enhancer factor (TCF/LEF) to induce expression of Wnt target pro-proliferative and anti-apoptotic genes. In normal cells, where Wnt signaling is controlled, cytoplasmic β -catenin is phosphorylated by the glycogen synthase kinase 3 β (GSK-3 β) within a complex comprising APC and Axin, leading to the degradation of β -catenin via the ubiquitin proteasome pathway. The complex also activates transcription of TCF target genes such as c-myc, cyclin-D1, and peroxisome proliferator-activated receptor delta which are known to influence cell proliferation and apoptosis^[32-34]. APC, as constituent of this multifaceted complex, not only contributes to the β -catenin degradation but also hinders its nuclear positions, thereby abrogating transcription of Wnt target genes^[35].

P53 GENE

The tumor suppressor gene, P53 functions to assimilate a diversity of cellular strains into an array of reactions that include apoptosis. Its product attaches to particular sequences in DNA and control transcription of various pro-apoptotic genes such as Bax and the BH3 only proteins puma and noxa^[36]. These genes and proteins inactivate anti apoptotic proteins Bcl-2 and Bcl-xL and cause the release of cytochrome c from mitochondria. P53 also promotes the synthesis of apoptosis effector proteins such as APAF-1 and caspase 6^[37]. Moreover, P53 has main components of the extrinsic apoptosis pathway such as the death receptor Fas and DR5 as well as the BH3 only protein Bid that couples the extrinsic pathway to the intrinsic pathway^[38]. Although not adequately investigated, P53 repress the key inhibitor of apoptosis proteins (IAP) gene, which may stop caspase activity. P53 also blocks survival pathways including the PI3 kinase/AKT survival pathway that neutralize

apoptosis by promoting transcription of the PI_3 kinase inhibitor, phosphatase and tensin homolog (PTEN) and in doing so prevents inhibition of P53 by mouse double minute 2 homolog (MDM2)^[39]. Furthermore, P53 can pledge cell cycle detention, DNA healing, and senescence, besides apoptosis. The P53 protein may possibly also react to DNA injury by activating either growth seizure at G1 or G2 phase of the cell cycle, or automated cell decease. By similar fashion, P53 defend the cells from scheduled to duplicate injured DNA^[37]. Thus, deletion of P53 gene through the CIN pathway is undutiful to cause the transition of adenoma to carcinoma in CRC^[24]. It has also been documented that P53 efficiently affects reactions to chemotherapeutic medications utilized as a part of CRC treatment^[40].

Reports showed that P53 of gene deletions and mutations has been noticed in up to 85% of colorectal tumors and typically occurs throughout the transition from adenoma to adenocarcinoma^[41]. Cells with mal-functional P53 are tolerant to chromosomal instability coming from telomere restriction and have an influential selection benefit. The adenoma/carcinoma shift of CRC is amongst occasions where failure of apoptosis is pivotal in the progression of malignant clones. In contrast, few immune-histochemical studies did not back the main role of mutant P53 protein as an inhibitor of apoptosis in CRC progression^[42].

BCL-2 PROTEINS

As mentioned above, the intrinsic pathway is tightly controlled by Bcl-2 family proteins^[43]. Bcl-2 protein is regularly expressed only in the bottom half of the crypts of the colon, consistent to the stem cell compartment, where Bcl-2 is supposed to defend stem cells from apoptosis^[44]. Most colonic adenomas express Bcl-2 protein at abnormal states all through the neoplastic epithelium while non-neoplastic polyps have regular Bcl-2 expression. In this manner, overexpression of Bcl-2 may contribute to the switch between hyperplastic epithelium and adenomas. Bcl-2 protein expression in colorectal carcinomas is greater than in ordinary mucosa but lesser than in adenomas^[45-47]. On the other hand, tumor necrosis factor (TNF)- α could promote the expression of nuclear factor (NF)- κ B and triggers anti-apoptotic Bcl-2 proteins^[4]. High expression of Bcl-2 leads to resistance to chemotherapeutic drugs and radiation therapy, whereas diminished Bcl-2 expression promotes apoptotic reactions to chemotherapeutic drugs. Furthermore, overexpression of Bcl-2 could lead to gathering of cells in the G0 phase of cell cycle and subsidizing to chemoresistance^[48]. Additionally, overproduction of Bcl-2 in the intrinsic pathway may perhaps inhibit extrinsic mediated apoptosis. Subsequently, the *Bcl-2* gene could be one of the genes that regulate the occurrence of apoptotic cell death in colorectal neoplasms. Certainly, alterations in the expression of other members of the Bcl-2 proteins has been revealed during evolution of colorectal tumors, such as the anti-apoptotic proteins Bcl-XL, mcl-1 and the

pro-apoptotic protein Bak, that may be more important than Bcl-2^[49].

TARGETING APOPTOSIS PATHWAYS IN CRC TREATMENT

Proper apoptotic signaling is basically central to conserve a healthy balance between cell death and survival and in keeping genome stability^[50]. As a rule, it is thought that the equilibrium between the rates of cell growth and apoptosis sustains intestinal epithelial cell homeostasis, and this stability gets disturbed during cancer expansion^[51,52]. In accordance with this, there is an expanding proof to support the speculation that failure of apoptosis might be an essential component in the expansion of colorectal tumor and its poor response to chemotherapy and radiation.

Interruption of apoptosis causes an irregularity in typical tissue homeostasis by promoting cell development. It additionally permits the survival of hereditarily modified cells, adding to both tumor growth and progression^[53]. Thus, apoptotic pathways can be modified by tumor cells transcriptionally, translationally, and post-translationally. Altogether, these mechanisms are not limited and tumor cells can utilization various strategies to escape apoptosis^[54]. The other explanation behind focusing on apoptosis in the treatment of malignancy depends on the perception that this procedure is dysregulated in tumor cells yet not in ordinary cells^[4]. Tumor cells have acquired blocks to apoptosis but are continually driven to recruit it by genomic and other aberrations. Accordingly, if proapoptotic pathways could be invigorated, these cells would be more helpless to death than ordinary cells^[55].

Researchers are actively searching on a targets in every single defect in the apoptotic pathways to re-establish the apoptotic signaling pathways and eradicate tumor cells^[56]. Study of apoptosis has hinted the basis for novel targeted therapies that can bring death in malignant cells or prepare them to proven cytotoxic agents and radiation therapy^[55]. Consequently, the activation of apoptosis is emerging as a key approach to treat colorectal tumor^[57] and substantial effort has been devoted in isolating pro-apoptotic and apoptotic targets comprising the extrinsic and/or intrinsic pathways with therapeutic potential^[58]. Directed stimulation of the extrinsic pathway by pro-apoptotic receptors, inactivation of Bcl-2 proteins, caspase modulation, and IAP inhibition are amongst these methods.

EXTRINSIC PATHWAY AS A THERAPEUTIC TARGET

Several members of the extrinsic apoptotic pathway hold potential biomarkers and therapeutic targets in colorectal malignancy. The death receptor Fas (CD95), tumor necrosis family receptor (TNFR), and its ligand are assumed to be participated in colorectal tumor progression. Aberrations in these death-signaling

pathways are described in the circumvention of the extrinsic apoptotic pathway. This could be as a result of FasL overexpression in colon cancer cells, that enables these cells to escape cell death by the immune reactions^[59]. The pro-apoptotic Fas ligand possesses strong cytotoxic activity towards various types of tumors cells; despite, hepatotoxic side effects limit its usage. In contrast, activation of the pro-apoptotic receptors DR4 and DR5 by enhanced soluble recombinant human Apo2L/TRAIL (rhApo2L/TRAIL) signifies a better approach, providing effective antitumor activity but marginal cytotoxicity in healthy cells^[55]. Besides, tumor cells that are not amenable to apoptosis induced through FasL are sensitive to Apo2L/TRAIL^[60]. These directed therapies play a key role in cancer therapy by increasing the extent of apoptotic cell death through stimulation of TRAIL receptor. From the candidates, recombinant TRAIL and monoclonal agonist antibodies directed against the TRAIL receptors are highly promising targets^[61]. There are limited studies investigating the role of TRAIL and its receptors DR4 and DR5 as colon cancer biomarkers. In contrast to colorectal tumors and matched normal mucosa, reports indicated that tumor expression of TRAIL is often lesser in normal mucosa^[62,63]. The results of preliminary studies verified the ability of Apo2L/TRAIL to act synergistically with common chemotherapies in a wide variety of malignancies and are especially convincing^[64]. This interaction may be ascribed to the additional activation of the caspase cascade by the extrinsic and intrinsic pathways^[65]. Besides, Apo2L/TRAIL has been found to overcome tumor cell confrontation to chemotherapy in some experimental models^[66] and to work together with chemotherapy even in cells lacking P53. Based on these facts, numerous pro-apoptotic receptor agonists (PARAs) are in clinical trial^[67]. Since the extrinsic pathway activates apoptosis independently, treatments that initiate this mechanism have also the potential to induce cell death in cancers with a variety of responses to common drugs^[57].

INTRINSIC MITOCHONDRIAL PATHWAY AND BCL-2 FAMILY PROTEINS AS A THERAPEUTIC TARGETS

Common cancer treatments seem to trigger apoptosis mainly by the intrinsic pathway, and failure of this pathway could contribute to the development of drug resistance^[68]. So far, approaches targeting the intrinsic apoptosis pathway were focusing on Bcl-2 family proteins^[69]. Bcl-2 was initially qualified as a compelling anticancer target in studies that revealed its capacity to cooperate with the *myc* oncogene in driving B cell lymphomas in mice^[55]. The disequilibrium between pro- and anti-apoptotic Bcl-2 proteins can promote cancer cell survival^[20]. This can be due to an under-expression or over-expression of the pro-apoptotic proteins and anti-apoptotic proteins, respectively, or a combination of both^[70,71]. About 30%-94% of human CRC has been

found to over-express Bcl-2^[72]. Overexpression of anti-apoptotic Bcl-2 family proteins is often correlated with aggressive cancer, recurrence, poor prognosis, and chemo-resistance to cancer therapeutics^[73]. In addition, Bcl-2 and Bax are inversely correlated in colon cancer and over-expression of Bcl-2 in primary CRC specimens is a negative prognostic factor^[72]. Accordingly, these proteins are labeled as exceedingly promising therapeutic targets to design pharmacological manipulation of cell death by inactivating anti-apoptotic Bcl-2 family proteins^[20]. Recent studies found that inactivation of Bcl-2 proteins through small interfering RNAs (siRNAs) caused induction of cell apoptosis and then a decrease in tumor growth. Consequently, several microRNAs such as miR-195, miR-24-2, and miR-365-2 have been identified. These miRNAs regulate Bcl-2 expression, act as negative regulators of Bcl-2 *via* direct binding to the 3'-UTR of the *Bcl-2* gene, showing their therapeutic potentials^[20,74].

An additional approach to improve the response of apoptotic stimuli could be stimulation of pro-apoptotic protein expression. Drugs that simulate the action of the BH3 domain by binding to Bcl-2 like proteins and triggering apoptosis are under investigation^[75]. Both genetic and epigenetic alterations of several pro-apoptotic members of the Bcl-2 family have been described^[20]. Under the physiological condition, the pro-apoptotic and anti-apoptotic members of the Bcl-2 family can cooperate to maintain a dynamic balance. Small molecule inhibitors of Bcl-2 such as HA14-1 or Bcl-2 antisense Oblimersen have been tested in experimental therapy for CRC. Preliminary data suggest that Oblimersen alone only had limited therapeutic efficacy, but this agent can significantly sensitize cancer cells to other therapeutic agents induced apoptosis^[72].

TARGETING P53

Inhibition of P53 is one of common mutations, arising in more than half of tumors, and gives a key resistance machinery that supports these tumor cells to escape apoptosis initiation in response to various injuries caused by common therapies^[68]. P53 serves as a transcription factor controlling downstream genes that have role in stopping cell cycle, DNA reparation, and apoptosis. The main role that P53 plays is shown by the numerous tumors that have mutation in this gene. Impairment of *P53* gene in several tumors resulted in genomic instability, impaired cell cycle control, and inhibition of apoptosis. When DNA damages, P53 keeps the cell at a checkpoint until the damage is reversed. If the damage is permanent, apoptosis is activated^[76]. One of the most crucial roles of P53 is its capacity to activate apoptosis by both transcription-dependent and transcription-independent means. The disturbance of this process can cause tumor progression and chemo-resistance^[20,77].

There are various methods that target P53 to activate apoptosis, such as targeting P53 family proteins, inactivation of P53-MDM2 contact, returning mutated

P53 back to their normal function, removing mutant P53, producing P53-based vaccines, and gene therapy to repair P53 mutation^[20,78]. The role of P53 is adversely controlled by onco-proteins such as MDM2 (known as HDM2 in humans) and MDMX by an interaction with the P53 transactivation domain (P53TAD)^[20,79]. Hence, one of the key targets for cancer therapy is inactivation of the P53TAD-MDM2/MDMX contact by the small molecule MDM2 antagonist that maintain P53 by avoiding its interaction with MDM2 and selectively brings senescence in tumor cells. Some of these small-molecule MDM2 inhibitors, for example R7112 (Nutlin-3, analogs of cis-imidazoline) and JNJ-26854165 (a tryptamine derivative) are now under clinical investigations^[20,80,81].

TARGETING INTRACELLULAR CASPASE INHIBITORS

Since caspases are important initiator and executor of apoptosis, it seems reasonable to consider that impairment in caspase activity could reduce apoptosis and lead to carcinogenesis. Down-regulation of different caspases has been observed in different cancers^[20,82]. Strategies targeting caspase includes modification of intracellular caspase inhibitors, for example, the IAPs and FLICE (FADD-like ICE) inhibitory protein or c-FLIP which are intracellular inhibitors of extrinsic apoptosis signaling. In recent times, compounds that reduce the expression of c-FLIP and sensitize cells to Apo2L/TRAIL-induced apoptosis have been identified^[83].

Overexpression of IAPs has been associated with resistance of cancers to apoptosis^[84]. One of the encouraging anticancer approach comprises the use of small molecules that bind IAPs and stop their inhibitory effect on caspases. On the other hand, small molecule caspase activators that possessed arginine-glycine-aspartate motif decrease the activation threshold of caspase. This initiates auto-activation of procaspase-3, and finally, sensitizes cancer cells to chemotherapeutic agents^[20,85]. Several drugs have been designed to activate caspases. For example, apoptin is a caspase activator agent which employs a tumor-preferential apoptotic action and specifically initiate apoptosis in cancer but not healthy cells^[86]. Polyphenylurea XIAP chelators have been found to overcome the inhibitory effects of XIAP on caspase 3 and 7, promoting apoptosis in wide variety of malignant cells with minimal toxicity to ordinary cells^[11]. In addition, they sensitized tumor cells to apoptosis initiated through cancer drugs or *via* Apo2L/TRAIL. Alternatively, small molecule drugs simulate the effect of Smac by attaching to IAPs and stop their action. Particularly, Smac mimetics can synergize with Apo2L/TRAIL to initiate increased levels of caspase activation and apoptosis^[87].

An additional possibility to deplete IAP expression is through RNA interference (RNAi), which consists of producing and transferring small interfering RNA (siRNA) into tumor cells to avoid the overexpression of IAPs or similar other molecules. Treatment with XIAP siRNA

along with conventional chemotherapy can powerfully reduce XIAP synthesis and initiate cellular apoptosis^[38]. On the other hand, healthy cells are less dependent on IAPs, thus providing an significant advantage for these novel agents^[88].

CONCLUSION

Although non-steroidal anti-inflammatory drugs (NSAIDs) are currently the most widely used agents for chemo-prevention in CRC, the significant toxicity associated with long-term NSAID use, such as gastrointestinal bleeding, limits the complete advantage of NSAID-treatment in high-risk patients^[89]. This obliges the design of nontoxic agents that could initiate apoptosis with minimal toxicity and reduce the opportunity for acquired drug resistance. CRC treatments developed to stimulate apoptosis might play a critical effect in limiting the development and progression of CRC^[90]. As a result, a better understanding of the apoptotic signaling pathways and the instruments by which colorectal tumor cells escape apoptotic death could lead to potent treatment tactics to limit cancer cell growth. Currently, direct activation of the extrinsic pathway by pro-apoptotic receptors, inactivation of Bcl-2 proteins, caspase modification, and IAP inhibition are amongst the promising candidates. Identification of further chemotherapeutic targets that explicitly initiate apoptosis could provide new approaches to prevent colonic tumors. In the future, strategies that use apoptotic pathways will create new effective remedies with minimal toxicity.

Abstract

Recent research has shown that the alteration of combinations in gene expression contributes to cellular phenotypic changes. Previously, it has been demonstrated that the combination of cadherin 1 and cadherin 2 expression can identify the diffuse-type and intestinal-type gastric cancers. Although the diffuse-type gastric cancer has been resistant to treatment, the precise mechanism and phenotypic involvement has not been revealed. It may be possible that stem cells transform into gastric cancer cells, possibly through the involvement of a molecule alteration and signaling mechanism. In this review article, we focus on the role of catenin beta 1 (CTNNB1 or β -catenin) and describe the regulation of CTNNB1 signaling in gastric cancer and stem cells.

Key words: CTNNB1 signaling; β -catenin; Epithelial-mesenchymal transition; Gastric cancer; Stem cell

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: CTNNB1 signaling is essential for revealing cancer mechanisms. The molecular dynamism in stem cells and cancer is illustrated with a pathway cascade. The CTNNB1 protein interacts with signaling molecules upon stimulation, leading to the transcription of genes related to cell proliferation. Mutations of signaling molecules are also important factors for cancer development. CTNNB1 signaling in stem cells and cancer are mainly described in the article.

INTRODUCTION

Transformed cells have dynamic molecular alterations, which can be identified *via* gene profiling^[1]. Essential genes can be identified using advancing human genomic techniques, such as the clustered regularly interspaced short palindromic repeats (CRISPR) gene editing system^[2]. In gastrointestinal cancers, various molecules, including catenin beta 1 (CTNNB1 or β -catenin), have important roles in phenotypic transitions^[3-6]. Mutations in β -catenin or adenomatous polyposis coli (APC) induce β -catenin/T cell transcription factor (TCF) signaling in colon cancer^[7,8]. Meanwhile, Wnt/ β -catenin signaling has a role in stem cell signaling^[3,9]. The inhibition of glycogen synthase kinase 3 beta (GSK3 β) promotes v-myc avian myelocytomatosis viral oncogene homolog (c-Myc or MYC) and β -catenin activity toward endoderm identification *via* forkhead box A2 (FoxA2) expression^[9]. In cancer stem cells (CSCs), β -catenin signaling, which is downstream of the CSC marker prominin 1 (CD133 or PROM1), is required for CSC maintenance^[10]. Although CD133-induced β -catenin signaling activation is cancer cell-type specific, β -catenin binds to the proximal promoter regions of integrin subunit beta 6 (*ITGB6*) and *ITGB8* in gastric cancer cell lines^[10]. This β -catenin signaling may be regulated by specific target genes^[10].

Genomic rearrangements in the telomerase reverse transcriptase gene (*TERT*) and the up-regulation of *TERT* are important factors in high-risk neuroblastoma^[11]. The detection of causative mutations in cancers has been facilitated since the completion of the Human Genome Project^[12,13]. Because several individual mutations in gastrointestinal cancers have been identified as being targeted by tumor infiltrating lymphocytes, the mutations in cancer signaling cascades should be analyzed in the context of possible cancer immunotherapy^[14]. Signaling molecules, including β -catenin and signal direction switch caused by misregulation of expression, are the main focus of this article.

CTNNB1 AND WNT SIGNALING

The canonical Wnt signaling pathway includes Wnt-Frizzled, dishevelled (DVL), Axin, GSK3 inactivation, and β -catenin dephosphorylation, stabilization and translocation into the nucleus^[3]. The translocated β -catenin together with TCF transcriptionally regulates Wnt target genes, whereas the disruption of Wnt signaling caused by mutations in pathway genes can cause cancer^[3]. The interaction of β -catenin and E-cadherin may be involved in cell-cell communication and signal transduction^[15]. The disruption of VE-cadherin localization is involved in β -catenin phosphorylation and signaling *via* microparticles that are important for cell-cell communication in endothelial cells. However, this β -catenin activation is independent of Wnt/Frizzled^[16]. Tubeimoside-1, which has anti-tumor properties, has been shown to inhibit the growth and invasion of colorectal cancer cells through inhibiting the Wnt/ β -catenin signaling pathway^[17]. The Wnt/ β -catenin

pathway is essential to the epithelial-mesenchymal transition (EMT) in breast cancer cells over-expressing C-X-C motif chemokine ligand 12 (CXCL12, or stromal cell-derived factor-1; SDF-1)^[18]. The E6 region of high-risk human papillomavirus (HPV)-16, one of the possible causes of esophageal cancer, induces cell growth of esophageal cancer through activation of the Wnt/ β -catenin signaling pathway and downregulation of miR-125b^[19]. GSK3-mediated β -catenin phosphorylation is a key event in Wnt/ β -catenin signaling^[20]. GSK3 associates with AXIN to phosphorylate and regulate β -catenin^[20]. These studies indicate the importance of Wnt/ β -catenin signaling in tumorigenesis and EMT.

CTNNB1 SIGNALING IN GASTRIC CANCER

TERT activates Wnt/ β -catenin signaling and promotes MYC expression^[21]. The expression of TERT in gastric cancer is correlated with advanced TNM stages and lymphatic metastasis, which suggests TERT may be a therapeutic target for GC patients^[21]. GC invasion and metastasis are associated with molecular mechanisms for TERT^[21]. MYC expression is regulated by TERT *via* the Wnt/ β -catenin pathway^[21]. Dishevelled-Axin domain containing 1 (DIXDC1), a positive regulator of the Wnt pathway, is a significant prognostic indicator of intestinal-type gastric carcinoma^[22]. DIXDC1 contains a DIX domain that is involved in the formation of a complex along with Axin, Dvl, APC, GSK3 β , and β -catenin^[22,23]. It has been shown that GSK3 β -dependent phosphorylation of β -catenin is inhibited in the presence of Axin^[23]. Axin regulates Wnt signaling as scaffold for the APC-glycogen synthase kinase-3 β - β -catenin complex to down-regulate β -catenin, and Axin mutations in the DIX domain abolish JNK activity, whereas β -catenin signaling is not affected by Axin mutations^[24]. MicroRNA-1225-5p (miR-1225-5p) has been reported to function as a tumor suppressor for gastric carcinoma, acting through inhibition of the insulin receptor substrate-1 (IRS1) and β -catenin signaling pathways to suppress gastric carcinoma proliferation and metastasis^[25].

CTNNB1 SIGNALING IN STEM CELLS

Wnt/ β -catenin signaling plays an important role in stem cell maintenance. The self-renewing mesenchymal cells with stem cell characteristics inhabit a niche for maintaining their stemness^[26]. By modifying β -catenin in mouse osteoblasts, acute myeloid leukemias with common chromosomal alterations occur, and Notch signaling increases in hematopoietic cells^[26,27]. The stem cell niche may be regulated by Wnt signaling and the nuclear accumulation of β -catenin^[27]. Upon activation of β -catenin, the Notch ligand jagged 1 is up-regulated in osteoblasts, which leads to the activation of Notch signaling in hematopoietic stem cell progenitors, moving them towards malignant transformation^[27].

In glioma stem cells, interleukin 17 receptor (IL-17R)

expression is involved in self-renewal^[28]. IL-17 up-regulates the expression of stemness/mesenchymal markers, such as fibronectin, CD44 and SOX2, in glioma stem cells^[28]. IL-17 regulates signal transducer and activator of transcription 3 (STAT3), nuclear factor κ -light-chain-enhancer of activated B cells (NF- κ B), GSK3 β and β -catenin in glioma stem cells^[28].

In CXCL12 (or SDF-1)-overexpressed breast cancer cells, the Wnt/ β -catenin pathway is required for the EMT, which induces cancer stem cell-like phenotype formation toward proliferation and metastasis in breast cancer cells^[18,29]. Breast tumorigenesis can be suppressed by inhibition of β -catenin/LEF-1 signaling^[30]. A synthesized peptide (TAT-NLS-BLBD-6) inhibits the nuclear interaction of β -catenin and LEF-1 in human breast cancer cells, suppressing Wnt/ β -catenin signaling and resulting in inhibition of tumorigenesis^[30]. Considering that TAT-NLS-BLBD-6 inhibits β -catenin/LEF-1 downstream target genes, including *CDKN2A*, *CLDN1*, *ID6* and *SOX2*, Wnt/ β -catenin signaling is likely to promote oncogenesis *via* LEF-1-targeted gene expression^[30].

The Notch and Wnt/ β -catenin signaling pathways play important roles in maintaining and promoting liver cancer stem cells^[31]. Liver cancer stem cells expressing stemness markers, such as CD90, CD24, CD13 and CD133, with poor prognosis in patients are maintained by Notch and Wnt/ β -catenin signaling^[31]. Upon niche formation, WNT-SHH signaling modulates stem cell fates^[32]. While canonical Wnt signaling mediated by β -catenin and LEF-1 is essential for placode formation, the combination of SHH and Wnt signals may be crucial for stem cell niche formation^[32].

Interleukin-22 (IL-22) induces epithelial regeneration through intestinal stem cells (ISCs), whose niche provides Wnt, Notch and epidermal growth factor signals for normal epithelial maintenance^[33]. Wnt/ β -catenin signaling maintains these ISCs, whereas the IL-22 pathway may be involved in STAT3 signaling and cross-linked^[33].

CTNNB1 AND THE EPITHELIAL-MESENCHYMAL TRANSITION

SNAI1 and CTNNB1 pathway in EMT

The loss of E-cadherin and the transformation of cells to the mesenchymal phenotype are involved in Smad signaling and the formation of β -catenin/LEF-1 complexes^[34]. Transforming growth factor β 1 (TGF β 1) promotes the EMT *via* the Smad-independent Ras-Raf-MEK-ERK-AP-1 signaling pathway, which up-regulates the expression of the snail family zinc finger 1 (*SNAI1*) gene^[34]. IL-8 plays a role in the maintenance of the tumor EMT through both autocrine and paracrine pathways^[35]. The IL-8 pathway transduces the Ras-ERK and PI3K-AKT signals to induce IL-8 transcription through Snail and Twist, which activate the autocrine IL-8 pathway^[35]. Moreover, IL-8 promotes E-cadherin transcription through Brachyury^[35]. The paracrine IL-8 pathway consists of the recruitment of tumor-associated macrophages and neutrophils into tumor sites to promote EMT using

cytokines^[35].

The expression of EMT regulator SNAI1 is correlated with an increased risk of tumor relapse in breast cancer patients and the progression of colorectal cancer^[36]. E-cadherin loss promotes the expression of EMT regulators, including β -catenin and NF- κ B, which suggests that the pathway for SNAI1 and β -catenin may be crosslinked^[36-39]. The expression of cadherin 1 (CDH1 or E-cadherin) is a marker of tumor aggressiveness in routinely processed radical prostatectomy specimens^[40]. The disease progression in patients with high-stage category cancers can be predicted with the expression of CDH1^[40]. Decreased CDH1 may release β -catenin from the β -catenin complex, allowing it to translocate into the nucleus and activate transcription of target genes, such as MYC^[40,41]. The cancer metastatic process is mediated *via* circulating tumor cells expressing EMT markers such as *ETV5*, *NOTCH1*, *SNAI1*, *TGFB1*, *ZEB1* and *ZEB2*^[42]. Considering that the expression of CTNNB1 is up-regulated in endometrial circulating tumor cells in endometrial cancer, CTNNB1 is a potential therapeutic target for endometrial cancer^[42]. SNAI1, SNAI2, and SNAI3 expression in the ductal epithelium is up-regulated during development, and SNAI1 and SNAI2 are co-expressed with insulin^[43]. CDH1 expression decreases during the EMT process in β -cell differentiation into islets. The expression of β -catenin is altered in process of β -cell clustering formation in islets^[43].

TGF β and CTNNB1 signaling in EMT

The TGF β -induced EMT is regulated by phosphatase and tensin homologue deleted from chromosome 10 (PTEN), a tumor suppressor gene in lung cancer cells^[44]. Upon stimulation with TGF β , β -catenin translocates into nucleus. This activity is inhibited by the deletion of the phosphatase and C2 domains of unphosphorylated PTEN^[44]. The expression of E-cadherin is down-regulated with TGF β , which is inhibited by the phosphatase and C2 domains of unphosphorylated PTEN^[44]. The isoflavone calycosin-7-O- β -D-glucopyranoside induces osteogenic differentiation through the BMP and WNT/ β -catenin-signaling pathways^[45]. Osteogenic differentiation is regulated by TGF β signaling, which suggests some coordination of the β -catenin and TGF β signaling pathways^[45]. Jumoni domain-containing protein 2B (JMJD2B) may also be involved in TGF β 1-mediated β -catenin nuclear accumulation^[46]. Nuclear translocation of β -catenin may be regulated by JMJD2B in the EMT process^[46]. TGF β 1 down-regulates the canonical WNT signaling pathway and inhibits photoreceptor differentiation of adult human Müller stem cells^[47]. In human Müller stem cells, TGF β 1 down-regulates WNT2B, dickkopf WNT signaling pathway inhibitor 1 (DKK1) and active β -catenin and up-regulates WNT5B to inhibit canonical Wnt signaling^[47].

CTNNB1 IN CANCER STEM CELLS

Extrinsic factors are important when assessing cancer risk^[48]. Stem cell division is related to cancer development, emphasizing the importance of understanding the mole-

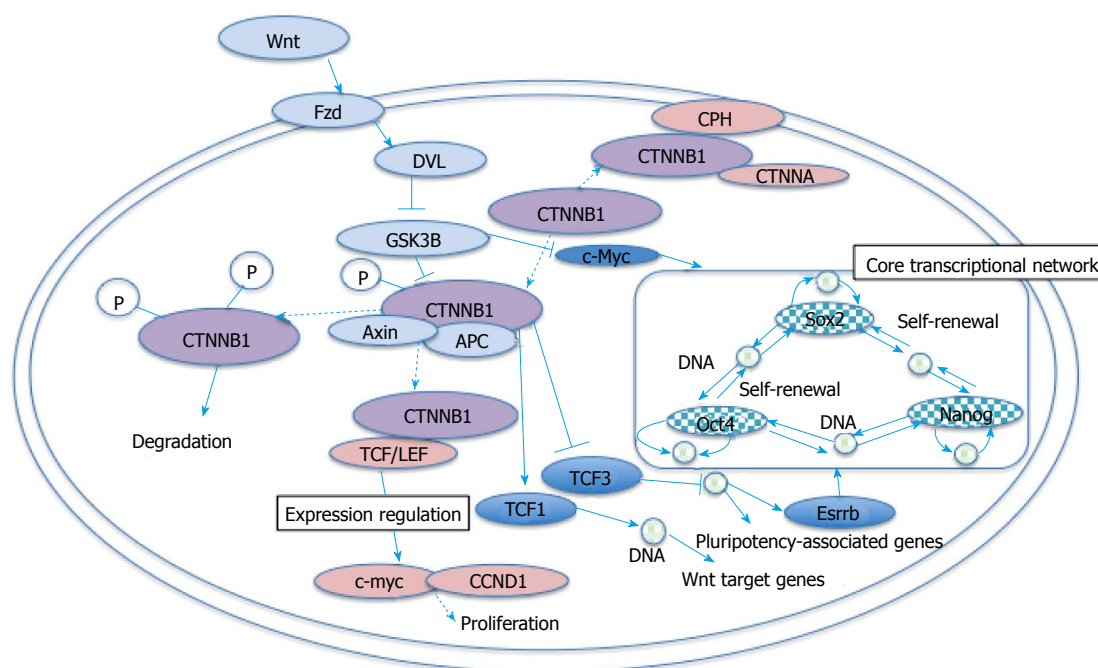

Figure 1 Main WNT/β-catenin pathway involved in cancer and stem cells. Wnt inhibits CTNNB1 phosphorylation by GSK3B, which leads to the transcription of pro-proliferation related genes via binding of CTNNB1 to TCF or LEF. P indicates phosphate. Red color shows molecules in pathways in cancer, whereas blue color shows molecules in signaling pathways regulating pluripotency of stem cells (KEGG). DVL: Dishevelled; TCF: T cell transcription factor; APC: Adenomatous polyposis coli.

cular pathways involved in stem cell maintenance, gastric cancer and cell proliferation^[48]. Ginsenoside Rh2, which inhibits growth of some types of cancer, decreases the number of CSC-like cells in hepatocellular carcinoma, possibly through β-catenin signaling^[49]. Furthermore, the CSC markers CD133 and Epithelial cell adhesion molecule (EpCAM) are decreased by ginsenoside Rh2^[49]. It is suggested that high levels of β-catenin are a signature of CSC-like cells^[49]. Wnt/β-catenin signaling leads to the translocation of β-catenin into nucleus and the transcription of *c-Myc*, *Axin2* and *Brachyury*^[50]. Axin is stabilized with GSK3β and inhibits β-catenin signaling^[50]. The proliferation of CSCs may also be regulated by Wnt/β-catenin signaling^[50]. The periprostatic adipose tissue-derived adipocytes regulate migration of prostate cancer cells^[51]. The chemokine CCL7 secretion of adipocytes stimulates the migration of CCR3-expressing prostate tumor cells^[51]. This signaling that is mediated by chemokines in CSCs could be a future target for investigation.

MUTATIONS IN CTNNB1-RELATED SIGNALING AND CANCER

Mutations of SMAD family member 4 (*Dpc4* or *Smad4*) and *Apc* in mice cause malignant intestinal tumors and stromal cell proliferation^[52]. The *DPC4* (*SMAD4*) gene is important for the TGFβ signaling pathway, which inhibits normal cell growth and promotes malignant cell growth^[52]. *APC* mutations in papillary thyroid carcinoma are associated with familial adenomatous polyposis^[53]. Through binding to 20-amino acid repeats, the APC/β-catenin signaling pathway is related to the development

of thyroid cancer in patients with familial adenomatous polyposis^[53]. Mutations in *AXIN2* cause colorectal cancer, in which the mutations stabilize β-catenin and activate β-catenin/TCF signaling^[54]. The *AXIN2* mutations result in accumulated nuclear β-catenin^[54]. *CTNNB1* and *APC* mutations also occur in colorectal cancer with defective DNA mismatch repair^[54]. For the treatment of cancer, identifying novel genome-wide therapeutic targets is essential, which suggests the importance of mutational studies in the cancer genome^[55]. Main WNT/β-catenin pathway involved in cancer and stem cells is shown in cartoon (Figure 1). The network information source is mainly from Kyoto Encyclopedia of Genes and Genomes (KEGG) (<http://www.genome.jp/kegg/>).

CONCLUSION

Our knowledge is increasing due to recent advances in bioinformatics and computational capacity. How to efficiently utilize this new data and knowledge is an important issue for future development of the big data era. The WNT/β-catenin pathway is involved in cancer and pluripotent stem cell signaling, which may suggest the mechanism underlying cancer stem cells. As cancer therapeutics has different effects in different genomic condition, individual medicine may be predicted with genetic variants. One useful direction for the use of genomic information may be the identification of targets for the treatment of diseases with appropriate predictions.

Abstract

Beside its poor prognosis and its late diagnosis, pancreatic cancer remains one of the most painful malignancies. Optimal management of pain in this cancer represents a real challenge for the oncologist whose objective is to ensure a better quality of life to his patients. We aimed in this paper to review all the treatment modalities incriminated in the management of pain in pancreatic cancer going from painkillers, chemotherapy, radiation therapy and interventional techniques to agents under investigation and alternative medicine. Although specific guidelines and recommendations for pain management in pancreatic cancer are still absent, we present all the possible pain treatments, with a progression from medical multimodal treatment to radiotherapy and chemotherapy then interventional techniques in case of resistance. In addition, alternative methods such as acupuncture and hypnosis can be added at any stage and seems to contribute to pain relief.

Key words: Pain management; Interventional; Medical; Treatment; Pancreatic cancer

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This paper presents a road map for the pain management of pancreatic cancer. All treatment modalities incriminated in the management of pain in pancreatic cancer going from painkillers, chemotherapy, radiation therapy and interventional techniques to agents under investigation and alternative medicine are reviewed and their indications are discussed.

INTRODUCTION

Pancreatic cancer (PC) is one of the most aggressive tumors with less than 5% survival at 5 years^[1]. More than 80% of these tumors are detected at an advanced stage because of the difficulty of diagnosis^[2]. At early stages, PC remains an asymptomatic disease. Many signs and symptoms appear gradually with advancing disease as jaundice, abdominal and back pain, weight loss and poor appetite, digestive problems, diabetes and blood clots. Abdominal and back pain has always been one of the major symptoms in patients with PC with more than 50% of patients with PC suffering from pain^[3]. There is no pathognomonic pain description, but often, over time, the pain of PC may radiate more through the abdomen to the back area. Due to the preponderance and the relevance of this symptom, in some clinical trials^[4,5], pain control was considered as one of the criteria of response to the treatment.

Many physiopathology mechanisms are incriminated in generating pain in this disease. Understanding the mechanism of pain will help the oncologists adapt the treatment panel to ensure a good quality of life for their patients.

We aimed in this review to describe first the different hypotheses of pain physiopathology in pancreatic cancer, to discuss medical and interventional options and finally to present a road map for oncologists leading to the optimum pain management in pancreatic cancer.

RESEARCH

Search strategy for the identification of studies

Electronic searches of the literature, published till September 2015, were conducted using PubMed database to identify articles reporting the pain management of pancreatic cancer.

Only trials describing pancreatic cancer pain management modalities were included. The year of publication of the article was not among the exclusion criteria. Search strategies employed included key words and Boolean operators described as follows: "Pancreatic cancer" and "pain management". This search was augmented by a hand search of the reference lists of relevant articles included in the literature review. Two different investigators performed the search ML and HK and the abstracts were independently reviewed for possible inclusion.

Types of studies: Review articles, peer review articles and some ongoing trials evaluating pancreatic cancer pain management modalities were included in the review. The language of publication of eligible studies was restricted to English.

Selection criteria

The articles to be included were first selected individually on the basis of their titles by 2 of the authors. Then, the abstracts of the available articles were examined. Our searches yielded 24 study reports from the PubMed database. These selected articles were then evaluated by 2 authors (ML and HK). Finally, 18 reports published till September 2015 were considered eligible by both authors and were retrieved for data extraction. Some of the remaining studies were used in the introduction and the discussion sections.

PHYSIOPATHOLOGY OF PAIN IN PC

Pain in PC may be the result of three components: Visceral, somatic, and neuropathic pain. Visceral nociceptive influxes are produced by ductal obstruction, damage and inflammation in the upper abdominal viscera. Somatic pain is caused by cancer extension into the peritoneum and bones. The signals reach the celiac plexus nerves, at T12-L1 vertebral levels, *via* the sympathetic system. Primary sensory neurons involved in pain sensation release predominantly substance P and glutamate in the dorsal horn of the spinal cord. From there, they synapse through the splanchnic nerves with T5-T12 dorsal root ganglia, then to the central nervous system^[6]. The most characteristic aspect of pancreatic neoplasia is an extrapancreatic nerve plexus invasion, which consists of the first route of metastasis. This may explain the neuropathic pain sensation. Pour *et al*^[7] highlighted the histogenetic similarity between neuronal cells and the pancreatic cancer cells. The two types of cells may share identical growth factor receptors and surface adhesion molecules and have an affinity to neural tissues. Although PC cells damage nerves^[8], several studies showed a harmony with cell-to-cell adhesion and migration of pancreatic cancer cells along the dorsal root ganglia neuritis inducing a mutual trophic nerve-cancer cell interaction^[9-11]. Nerve cells neurotrophic factors and chemokines are capable of boosting PC cell invasiveness, multiplication, and locomotion. On the other hand, PC cells secrete neuromodulatory agents, which cause neuroplasticity and neuropathic pain. An increase of density of calcitonin gene-related peptide (CGRP) and tyrosine hydroxylase was noted, connoting a proliferation of nerve growth factors^[12]. Studies have shown that growing sensory fibers are associated with necrotic damage of the nerve fiber endings and increased pain sensation^[13].

Another described mechanism of pain is the neo-vascularization and increased density of sensory and sympathetic nerve fibers within these newly formed vessels^[12]. Molecules secreted by tumor cells such as vascular endothelial growth factor, artemin, interleukin-1 and prostaglandins play a role in the interaction between the vascular system and the sensory neurons^[14,15].

In addition to the local nerve invasion, a high density of macrophages is noted within the tumor, which in-

duces excessive expression and secretion of nerve growth factors^[16]. The pancreas is innervated by sensory neurons that express CGRP and tyrosine kinase receptor A, which are the receptors of nerve growth factors. The high density of macrophage-secreted nerve growth factors activates the sensory nerves and generates pain afferents. Thus inflammation *via* macrophages and other inflammatory cells contributes to the pain sensation.

The NGF also activates the transient receptor potential vanilloid receptor subtype 1 (TRPV1)^[17]. The TRPV1 is a nonselective cation channel, which increases the permeability for sodium and calcium ions when activated and causes neuronal depolarization with burning sensation and release of substance P. In fact, an upregulation of substance P receptors, neurokinin receptors-1 (NK1-R), was described in pancreatic cancer. NK-1 antagonist MEN 11467 inhibited pancreatic cancer cell growth^[18].

Of interest, the presence of pain is a predictor of survival in pancreatic adenocarcinoma^[5,15,19]. This is not the case in other pancreatic malignancies where tumoral invasion mechanisms are different and do not imply neural invasion. In addition, the localization of the tumor plays a role in the pain pattern, pancreatic body presenting the highest incidence cancer localization in pancreas^[20]. This is probably due to its proximity to the celiac plexus.

In conclusion, pain in pancreatic cancer has a complex physiopathology. It eminently implies a neuronal invasion and a neurogenic inflammation.

PAIN MANAGEMENT MODALITIES IN PC

Medical approach

Opioids and derivatives: Most cancer related pain is controlled by pharmacological oral treatments. The optimal management is based on the World Health Organization (WHO)'s analgesic ladder, with a progressive administration of nonopioids (aspirin and paracetamol); then, as necessary, mild opioids (codeine); then strong opioids, until reaching pain relief. Morphine, the standard "step 3" opioid, has been widely used for the control of chronic cancer pain, especially in moderate to severe pain^[21], and is the first-line medical therapy for pancreatic cancer^[22]. Oral route is the gold standard with two types of molecules: Normal release with rapid onset for breakthrough pain and modified release marked by a long acting effect, used for maintenance treatment^[21]. The second route of administration, if patient is unable of oral intake is subcutaneous. The oral, sublingual and nebulized routes of administration of morphine are not common because there is no evident superiority over the oral route^[21].

Fentanyl is an alternative to morphine for cancer pain management in its different administration routes. Transdermal patches are suitable for patients whose opioids requirements are stable^[23,24]. Sublingual fentanyl tablets and nasal spray may be an option for breakthrough pain^[25,26].

Oxycodone showed a superior analgesic effect on visceral pain in a tissue-differentiated experimental pain model^[27]. This hypothesis was not clinically confirmed. Similar analgesia is provided with oral morphine and oxycodone^[28] and particularly in PC^[29].

Buprenorphine is another strong opioid available as a prescription choice. A systemic review by Schmidt-Hansen *et al.*^[30] ranked Buprenorphine as a "fourth-line option" after morphine, oxycodone and fentanyl in cancer pain management.

At the end-of-life stage in advanced PC, thoracic epidural opioid in combination with local anesthetics could be considered^[31].

Opioids must be employed with regards to their considerable potential for side effects including sedation and respiratory depression, pruritus, nausea and constipation. The prescription of a stool softener and laxatives for constipation, diphenhydramine for pruritus, and antiemetics for nausea are recommended.

Apart from the classically known opioids side effects, several experimental studies performed on mouse models showed that morphine can interfere with regulation of cancer cell growth by inhibiting apoptosis and by stimulating angiogenesis and metastasis^[32,33]. So far, the results of both *in vitro* and *in vivo* studies are contradictory and not conclusive. The effect appears to vary depending on the cancer cell type. Prospective randomized controlled trials are currently conducted to find an answer to this dilemma^[34]. In the meanwhile, opioids are still a central cornerstone in the management of pancreatic cancer pain.

Antiepileptics: Considering the multidimensional PC pain mechanisms, adjuvant medications and multimodal approach are recommended. Gabapentin and Pregabalin are anti-epileptic agents used as first line treatment in neuropathic pain, including diabetic neuropathy^[35], post herpetic pain^[36], and neuropathic pain of central origin^[37]. Their effectiveness is also demonstrated in cancer-related neuropathic pain^[38]. Their target is voltage dependent calcium channel. They block calcium influx into presynaptic nerve terminals, thus reducing the release of excitatory neurotransmitters on spinal neurons. Upstream transmission of neuropathic pain in the central nervous system and neuronal excitability are consecutively inhibited^[39]. These molecules may have beneficial effects as adjuvants and opioids - sparing for coeliac plexus pain^[40,41].

Corticosteroids: Steroids have been proved particularly useful as adjuvant therapy for visceral pain^[42]. Glucocorticoids inhibit prostaglandin synthesis, a precursor of inflammation cascade, and reduce vascular permeability decreasing tissue edema. Steroid receptors are also localized in the central and peripheral nervous systems and are responsible for neuron plasticity, decreasing discharge in an injured nerve and in neuropathic pain^[43]. Moreover, perioperative dexamethasone administration has been associated with improved survival after

Table 1 Potential molecules that were under investigation

Molecule	Mechanisms	Ref.
Capsaicin/resiniferatoxin	Activation of vanilloid receptors on cancer cells, inducing apoptosis	Hartel <i>et al</i> ^[17]
MEN 11467	NK-1R antagonists, inhibiting cell growth and neuronal invasion	Friess <i>et al</i> ^[18]
HSV-Enk viral vector	Increased met-enkephalin production in the peripheral nerve terminal endings and in dorsal root ganglion, reducing pain	Lu <i>et al</i> ^[45] Yang <i>et al</i> ^[46]
Phentolamine	Alpha-adrenergic blockade of sympathetic induced pain	Yasukawa ^[47]

NK-1R: Neurokinin-1 receptors; HSV-Enk: Herpes simplex virus carrying the human preproenkephalin.

pancreatic adenocarcinoma resection^[44].

Approaches under investigation

As mentioned before, neurokinin receptors-1 receptor and its ligand substance P are activated in PC, which contribute to cancer cell growth and neuronal invasion^[18]. A promising treatment approach is to target this pathway by NK-1R antagonists MEN 11467, inhibiting nerves alteration and neuropathic pain. Table 1 summarizes the molecules under investigation^[17,18,45-47].

Chemotherapy and radiation therapy

Pain control is largely implemented as secondary end point in the trials evaluating chemotherapeutic regimen in PC. In 1997, the approval of gemcitabine as the standard of care in the treatment of advanced PC was not only based on the small benefit in survival (less than 2 mo) but also on the better pain control. Twenty-three point eight percent of patients receiving Gemcitabine in advanced PC were classified as positive in pain category (pain intensity or/and analgesic use was reduced), while only 4.8% of patients receiving 5-FU were considered in the same category. FOLFIRINOX also showed a better quality of life and pain control in the management of metastatic PC^[4,5].

Radiation therapy is frequently used in PC for many purposes going from local control of the disease when associated to chemotherapy in adjuvant or locally advanced setting, to pain management and control in palliative and metastatic disease. Radiotherapy is particularly effective in controlling and relieving pain caused by large tumors compressing other organs or structures, such as nerves or the spine. The effect of radiation therapy is usually late, and it occurring many weeks after the initiation of treatment. The radiation therapy can shrink the tumor, which may help in relieving the pain. The radiation therapy can also be effective in targeting some metastatic lesions.

Interventional therapies

Celiac plexus block and neurolysis: Despite all the available analgesics and the possibility of combination of different molecules, treatment is often suboptimal, and many side effects are observed^[48,49]. Thus, more efficient forms of pain management are essential for such patients. An alternative approach is the use of celiac plexus block (CPB) or neurolysis (CPN).

The major component of pancreatic carcinoma pain is mediated by sympathetic fibers from the pancreas and is relayed through the celiac plexus to the splanchnic nerves. A local anesthetic, mainly bupivacaine, can be used in combination with steroids to temporary inhibit the celiac plexus^[50]. Celiac plexus neurolysis (CPN) represents the prolonged interruption of the plexus by the injection of alcohol or phenol^[51]. Formerly, it was managed by anesthesiologists and radiologists *via* a posterior approach. However, complications occurred in 1% of cases, secondary to displacement of the needle, causing paraplegia or pneumothorax when entering the spinal artery or diaphragm respectively^[52-54]. Anterior approach evolved lately *via* the guidance of transcutaneous ultrasound, X-ray fluoroscopy, computed tomography, or recently endoscopic ultrasonography^[55-57]. Endoscopic ultrasonography which permits direct access to the celiac plexus, is an attractive technique compared to percutaneous CPN, because complications can be avoided. Furthermore, it allows ultrasound guided fine needle aspiration sampling and tumor staging^[58-60].

Sympathetic inhibition can be as well done at the level of the splanchnic nerves. Splanchnicectomy consists in sectioning the roots of the splanchnic nerves from T5 to T10. The approach by thoracotomy was first described in 1942 by Mallet-Guy^[61]. Thoracoscopic splanchnicectomy, less invasive, was introduced in 1993^[62]. Good results were noted with thoracoscopic unilateral left splanchnicectomy^[63,64]. It can be repeated for right side in case of pain recurrence or done bilaterally from the beginning^[63]. With splanchnicectomy, analgesic effects last for approximately 2 mo, even for 3 mo of partial to complete relief^[52].

Intrathecal therapy

Intrathecal therapy can be proposed for end-of-life stages or in refractory pain^[30]. The implantable intrathecal drug delivery systems are an alternative with reduced drug toxicities and improvement of pain scores^[65]. Various molecules can be used including morphine, fentanyl, local anesthetics, baclofen and/or clonidine^[66,67].

Alternative medicine

Acupuncture: The developments of effective and safe therapeutic strategies that complement pharmaceutical treatment are interesting in the management of PC pain. Acupuncture analgesia has been widely used to

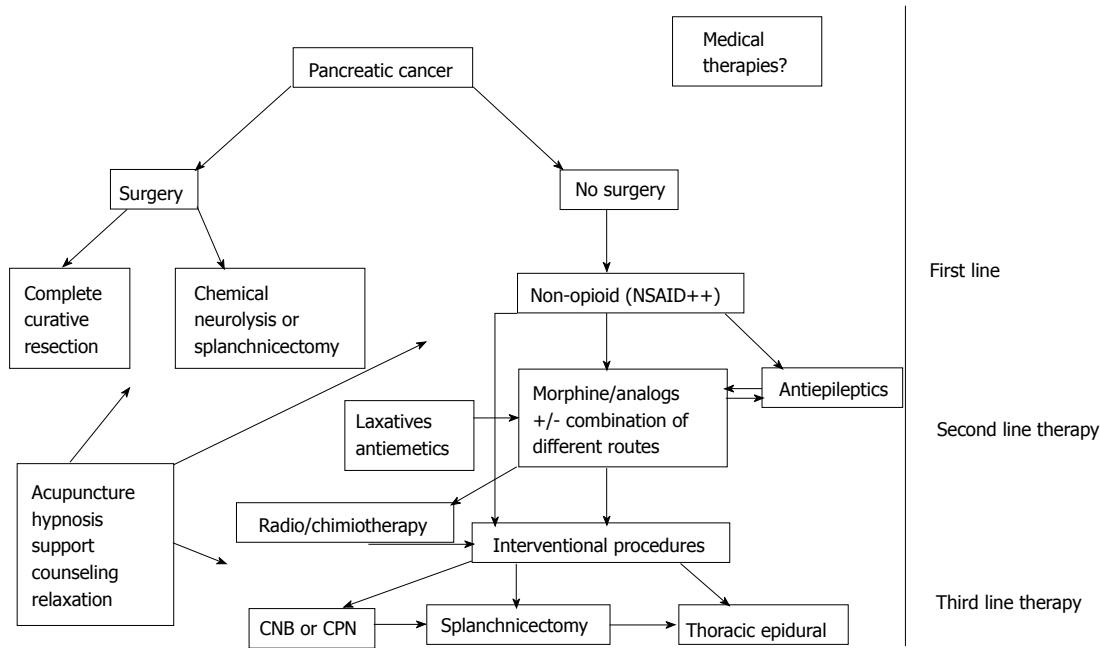

Figure 1 Algorithm of pancreatic cancer pain management. CPN: Celiac plexus neurolysis; NSAID: Non-steroidal anti-inflammatory drug.

treat cancer pain^[68]. A systemic review published in 2012 including a total of 15 randomized controlled trials, showed that acupuncture is an effective adjunctive method in cancer pain management and pain relief was superior compared to drug therapy alone^[69]. Chen *et al.*^[70] showed the effect of acupuncture on PC pain. Acupuncture's effects can be explained as viscerocutaneous, cutaneo-visceral, cutaneo-muscular, and visceromuscular reflexes^[71]. Jiaji points, which correlate to segmental dispersion of the sympathetic and parasympathetic systems, were chosen on the nerve segments of the pancreas.

Hypnosis

Hypnosis is an increasingly used approach to pain control in patients with cancer. There is significant evidence that hypnosis is useful at reducing cancer-related pain^[72,73]. Hypnosis modulates the pain sensation by a functional disconnection between the prefrontal cortex, center of decision-making and the anterior cingulate, zone playing a role in attention and motivation. This will make therapeutic suggestions easily integrated^[74].

DISCUSSION

With the presence of a large panel of strategies and modalities in the pain management of PC and the absence of clear recommendations and guidelines, every oncologist is treating pain in PC according to their own experience. The choice of pain management modality depends of the pain characteristics and physiopathology, the stage and the prognosis of the disease, the performance status of the patient, his comorbidities, his past medical history and his future therapeutic options (Figure 1).

Owing to the fact that PC pain involves visceral, somatic and neuropathic components, the main therapeutic approach is a multimodal analgesia. A combination of drugs and/or techniques with distinct mechanisms of action leads to a synergistic effect and allows a better analgesia with decreased consumption of opioids, and hence lesser opioid-related adverse events. A standardized multimodal analgesia protocol based on available evidence is hard to be proposed in PC patients. The essential points remain the addition of antiepileptics for neuropathic pain, the frequent use of corticosteroids and the referral to an interventional procedure after a pluridisciplinary case study. The patients with metastatic disease will benefit more from systemic therapies if the pain is multi-localized and generalized. However, local treatments such as radiation therapy can play a role in controlling pain by targeting some well-defined metastasis generating pain. Patient with a poor prognosis (survival less than three months) will not benefit from an interventional therapeutic approach as patients with better prognosis, because of the risk of the intervention, especially in patients with bad performance status, compared to the time of benefice.

The presence of comorbidities or the past medical history can guide the pain management in PC. Chronic use of corticoids should be careful because of the increased risk of gastric bleeding, especially when combined to non-steroidal anti-inflammatory drugs, which amplify the risk by 15-folds^[75]. Gastric protection should be considered. Patients presenting long-term constipation or ileus paralytic should receive morphine associated to laxatives with close surveillance. Patients with PC have a higher risk of developing thrombosis, and are usually under prophylactic or therapeutic anti-coagulants. Special considerations should be taken to discontinue anticoagulant therapy in

Table 2 Summarizing all treatment approaches, administration route or techniques and indications

Treatment approaches	Medications and modalities	Administration route/techniques	Indications
Medical treatment	Opioids and derivatives	Per os S/C Patch (fentanyl)	Moderate to severe pain Impossible oral intake (occlusion) Breakthrough pain
	Antiepileptics corticosteroids	Nasal Per os Per os or IV	Breakthrough pain Neuropathic pain Adjuvant, especially in metastatic bone pain
Interventional treatment	Celiac plexus block (LA) or neurolysis	Transcutaneous guidance ¹ or endoscopic ultrasonography	Refractory pain
Alternative medicine	Splanchnicectomy	Thoracotomy, thoracoscopy	Intractable pain in non resectable tumor
	Intrathecal therapy	Implantable intrathecal drug delivery systems	End-of-life stage
Chemotherapy and radiation therapy	Acupuncture	Jiaji points	adjuvant to drug therapy and/or interventional techniques
	Hypnosis	Sessions with an expertise	Any stage of pain
	FOLFIRINOX	IV	Locally advanced tumor
	Gemcitabine		

¹Ultrasound, X-ray fluoroscopy or computed tomography. S/C: Subcutaneous; IV: Intravenous; LA: Local anesthetics.

interventional therapeutic approach (celiac plexus block, intra-theal treatment), if the patient is under chronic thromboprophylactic prevention for primary or secondary risk. The discontinuation of anticoagulation is sometimes a reasonable cause to choose less invasive analgesic strategies in high-risk patients.

In PC patients who have not received chemotherapeutic agents, transitory painkillers and not a definitive pain management approach will be a logical option, while waiting for the response to the treatment.

Finally, the choice of pain management modality can be influenced by the team expertise and abilities. Celiac plexus neurolysis under endoscopic ultrasonography requires specialized equipment and expert specialists, which are not always available. CT scan or X-ray fluoroscopy guided posterior approach remains an equivalent technique with good results. Thoracotomic bilateral splanchnicectomy is mainly reserved for patients who require abdominal surgery (occlusion, biliary and/or intestinal bypass), making it a two-in-one procedure with no additional surgical risk for the patient^[76].

CONCLUSION

Developing pain management recommendations in pancreatic cancer seems to be an interesting and practical target for oncologists and palliative care physicians, since more than the half of these patients will develop severe pain without any detailed and structured road map. We exposed all the pain treatments that are available and proven efficient and safe, medical multimodal treatment, radiotherapy, chemotherapy and finally interventional techniques as a last resort (Table 2). Team expertise and competence remain the major factors in the treatment choice.

Abstract

AIM: To assess blood chitinase 3-like 1 (CHI3L1) levels for 2 mo after minimally invasive colorectal resection (MOCR) for colorectal cancer (CRC).

METHODS: CRC patients in an Institutional Review Board approved data/plasma bank who underwent elective MOCR for whom preoperative (PreOp), early post-operative (PostOp), and 1 or more late PostOp samples [postoperative day (POD) 7-27] available were included. Plasma CHI3L1 levels (ng/mL) were determined in

duplicate by enzyme linked immunosorbent assay.

RESULTS: PreOp and PostOp plasma sample were available for 80 MICR cancer patients for the study. The median PreOp CHI3L1 level was 56.8 CI: 41.9-78.6 ng/mL ($n = 80$). Significantly elevated ($P < 0.001$) median plasma levels (ng/mL) over PreOp levels were detected on POD1 (667.7 CI: 495.7, 771.7; $n = 79$), POD 3 (132.6 CI: 95.5, 173.7; $n = 76$), POD7-13 (96.4 CI: 67.7, 136.9; $n = 62$), POD14-20 (101.4 CI: 80.7, 287.4; $n = 22$), and POD 21-27 (98.1 CI: 66.8, 137.4; $n = 20$, $P = 0.001$). No significant difference in plasma levels were noted on POD27-41.

CONCLUSION: Plasma CHI3L1 levels were significantly elevated for one month after MICR. Persistently elevated plasma CHI3L1 may support the growth of residual tumor and metastasis.

Key words: Colorectal cancer; Recurrence; Minimally invasive colorectal resection; Chitinase 3-like 1; Metastasis

Core tip: Colorectal cancer (CRC) resection surgery is well known to be associated with short lived immunosuppression and transient plasma protein changes. We have documented that a second set of blood protein alterations that last for 3 to 5 wk after CRC; interestingly, all of these proteins play a role in angiogenesis. This group of pro-angiogenic proteins includes vascular endothelial growth factor, placental growth factor, angiopoietin-2, monocyte chemo-attractant protein-1 and matrix metalloproteinase 2. Our published data further confirms that pro-angiogenic postoperative plasma from cancer patients stimulates *in vitro* endothelial cell proliferation, migration, and invasion. In this manuscript we are presenting data to demonstrate that a pro-angiogenic protein, chitinase 3-like 1, in CRC patients remain elevated for month after minimally invasive colorectal resection.

INTRODUCTION

Colorectal cancer (CRC) is the second most diagnosed cancer in the United States, with an expected 142820 cases and 50830 deaths in 2013^[1]. Surgical resection is the primary treatment for the 80% of CRC patients who present without metastatic disease. While this procedure is considered curative for these patients,

more than 40% who present with stage II or III disease will develop a recurrence^[1,2].

It has been hypothesized that surgical resection of tumors may paradoxically contribute to the development of cancer recurrences. Murine studies have shown those laparotomy and bowel resections are associated with increased tumor growth and establishment vs results in anesthesia control mice^[3-5]. In humans, numerous case reports have noted increased tumor growth soon after surgery in patients with residual cancer^[6-9]. A number of mechanisms, including surgery-related immunosuppression and the removal of primary tumor generated anti-angiogenic factors, have been proposed to account for accelerated tumor growth after surgery^[10,11]. Of interest, the last decade has seen the emergence of another possible mechanism, namely surgery-related proangiogenic plasma compositional changes that may support the establishment of metastases and the growth of already present tumor deposits during the early post-surgical period.

Angiogenesis or neo-vascularization is necessary for tumor growth greater than 1-2 mm^[3,12,13]. During a nascent tumor's initial avascular dormant stage, cells obtain nutrients by passive diffusion only. The activation of what has been called the "angiogenic switch" leads to the development of new vessels that infiltrate and extend beyond the tumor mass which permits growth and, later, metastasis. Similarly, further growth of established metastases requires new vessel formation.

It has been shown that colorectal resection is associated with continual elevations (2-5 wk) in the blood levels of a number of angiogenesis promoting proteins including vascular endothelial growth factor (VEGF), angiopoietin-2 (Ang-2), placental growth factor (PIGF), soluble vascular cell adhesion molecule-1 (sVCAM-1), monocyte chemotactic protein-1 (MCP-1), and matrix metalloproteinase-3 (MMP-3)^[14-18]. Furthermore, human plasma from the second and third weeks after surgery has been shown to promote endothelial cell (EC) proliferation, invasion, and migration, which are key steps in angiogenesis^[14,19]. It is possible, therefore, that the postoperative (PostOp) plasma composition may encourage the growth of residual tumor metastases after "curative" colorectal resection of a primary tumor. In an effort to better understand the impact of surgery the search goes on for other proteins with proangiogenic effects whose blood levels may be increased after surgery.

Chitinase 3-like 1 (CHI3L1), also named as YKL-40 and human cartilage glycoprotein-39 (HCgp-39), is a member of the glycosyl hydrolase 18 protein family^[20]. The substrate for this family of proteins is chitin, a polymer of N-acetyl-glucosamine. Importantly, chitins are not found in mammals yet these proteins are produced by a number of mammalian cell types including EC's neutrophils, macrophages, and vascular smooth muscle cells. CHI3L1 does not have any known enzymatic activity in mammals, however, it is believed that this protein binds to endogenous carbohydrates such as hyaluronic

Figure 1 Enzyme linked immunosorbent assay determined preoperative and postoperative chitinase 3-like 1 levels of colorectal cancer patients. CHI3 L1 levels are expressed median and 75% quartile range: [PreOp vs POD1 ($n = 79$), PreOp vs POD3 ($n = 76$), PreOp vs POD7-13 ($n = 62$), PreOp vs POD14-20 ($n = 22$)] $^bP \leq 0.001$; PreOp vs POD 21-27 ($n = 20$), $^dP = 0.001$. PreOp: Preoperative; CHI3L1: Chitinase 3-like 1; POD: Postoperative day.

acid and heparin as well as specific receptors such as the interleukin (IL)-13 receptor $\alpha 2$ in macrophages^[21]. CHI3L1 and other members of the glycosyl hydrolase 18 protein families are thought to play a role in innate and specific immune function, tissue remodeling, and the proliferation of fibroblasts, epithelial, synovial, and other cell types. CHI3L1 has also been shown to limit inflammation related organ injury and apoptosis in some settings^[21].

There is also experimental evidence that CHI3L1 promotes tumor angiogenesis. Several investigators have demonstrated that CHI3L1, *in vitro*, increased EC (HUVEC) migration and tube formation which are essential initial steps in the process of angiogenesis^[22,23]. Macrophages in tumor stroma have also been shown to express CHI3L1 which likely also promotes tumor angiogenesis^[24].

Blood levels of CHI3L1 are negligible under normal physiologic conditions, however, elevated blood levels of CHI3L1 have been found in patients with chronic inflammatory conditions^[25] and a wide variety of cancers including colorectal^[22,26], breast^[27], prostate^[28], lung^[29,30], thyroid^[31], endometrial^[32], pancreatic^[33], hepatocellular^[34], ovarian^[35], gastric cancer^[36], and malignant melanoma^[37]. Additionally, for the majority of these malignancies, a correlation has been demonstrated between blood levels of CHI3L1 and a poor prognosis^[26,29-44]. Also, increased expression of CHI3L1 in CRC has been shown to be strongly associated with increased microvascular density^[22]. Although it has been shown that serum levels of CHI3L1 are elevated prior to surgery in CRC patients, the impact of surgical resection on blood levels after surgery are unknown. Because CHI3L1 involved in tissue remodeling and angiogenesis we hypothesized that following minimally invasive colorectal resection (MICR) for CRC blood levels of CHI3L1 might be increased. This

study was carried out to investigate plasma levels of CHI3L1 during the first 4 to 6 wk following MICR for CRC.

MATERIALS AND METHODS

Patient selection for study

Patient populations who underwent elective MICR were selected for this study from an Institutional Review Board (IRB) approved multi center plasma and data bank that was organized by Columbia University and that included the following institutions: New York Presbyterian Hospital, Columbia University; the Ferguson Clinic, Grand Rapids, Michigan and Mount Sinai West Hospital Center, New York. The broadly stated purpose of this effort is to study the physiologic, immunologic, and oncologic ramifications of open and minimally invasive surgical methods. Prospective data including demographic, operative, and short term recovery statistics were collected for all patients. Patients who were immunosuppressed or transfused perioperatively were excluded. Patients undergoing urgent or emergent surgery were, likewise, excluded.

Blood sampling and processing

To be eligible for entry into this study preoperative (PreOp) and, at least, several PostOp plasma samples had to be available for CRC patients who underwent MICR. Of note, blood samples after postoperative day (POD) 7 were obtained at follow up office appointments but were not scheduled on a specific POD. Late post-operative samples were not available on the same day from all patients so the late samples were bundled into 7 d (or longer) time periods (POD 7-13, POD 14-20, POD 21-27, and POD 28-41). Samples were collected in tubes containing heparin. The samples were processed within 6 h of collection, and the plasma fraction stored in aliquots at -80°C until the assay was performed.

Plasma CHI3L1 analysis

Plasma CHI3L1 levels were determined in duplicate using commercially available enzyme linked immunosorbent assay (ELISA) (R and D Systems, Minneapolis). CHI3L1 concentrations are reported as nanograms per milliliter (ng/mL).

Statistical analysis

For continuous variables, data are expressed as mean \pm SD. Frequencies and percentages were determined for categorical variables. In regards to the CRC Pre vs PostOp CHI3L1 comparisons, the results are reported as the median and 95% CIs and the Wilcoxon signed rank test was used to analyze the data. Correlation between PostOp CHI3L1 plasma levels and incision size and length of surgery was evaluated by the Spearman's rank correlation coefficient (r_s). All data analysis was performed utilizing SPSS version 15.0 (SPSS, Inc., Chicago, IL). Because the sample size varies for the POD 7-13, POD 14-20, POD 21-27 and POD 28-41 time points a separate Pre-Op bar is included for each time point in the Figure 1.

Table 1 Demographic and clinical characteristics of the study population

Age, years (mean \pm SD)	65.66 \pm 12.83
Sex, n (%)	
Male	42 (52.5)
Female	38 (47.5)
Incision length, cm (mean \pm SD)	7.78 \pm 3.61
Operative time, min (mean \pm SD)	308.3 \pm 124.2
Length of stay, d (mean \pm SD)	6.68 \pm 4.30
Type of resection, n (%)	
Right	24 (30.0)
Transverse	5 (6.2)
Left	6 (7.5)
Sigmoid/rectosigmoid	13 (16.3)
LAR/AR	26 (32.5)
APR	2 (2.5)
Subtotal/total	4 (5.0)
Surgical method, n (%)	
Laparoscopic-assisted	47 (59.0)
Hand-assisted/hybrid laparoscopic	33(41.0)

RESULTS

A total of 80 MICR patients with CRC (42 male/38 female, age 65.66 \pm 12.83 years) were included in the study. The majority of patients underwent right colectomy, lower anterior resection/anterior resection, or sigmoidectomy (Table 1). Laparoscopic-assisted methods were used in 59% while hand-assisted minimally invasive methods were utilized in 41% of the patients. There were 12 conversions (15%) to open methods (defined as final incision > 7 cm in laparoscopic-assisted cases and incision > 11 cm in hand-assisted cases). The mean surgical incision length was 7.8 \pm 3.6 cm for the entire population, the mean operative time was 308.3 \pm 124.2 min. The mean length of stay was 6.6 \pm 4.3 d. Seven complications (8.8%) were noted including small bowel obstruction (3), wound infection (1), hernia (1), hyperkalemia (1), and hematoma (1). There were no perioperative deaths. The cancer pathological stage breakdown of the study population was as follows: Stage I, 20 (25.0%); stage II, 25 (31.3%); stage III, 32 (40%); stage IV, 3 (3.7%).

The median PreOp CHI3L1 level was 56.8 CI: 41.9, 78.6 ng/mL (n = 80). Significantly elevated median plasma levels were noted on POD 1 (667.7 CI: 495.7, 771.7 ng/mL, n = 79, P < 0.001), POD 3 (132.6 CI: 95.5, 173.7 ng/mL, n = 76, P < 0.001), POD 7-13 (96.4 CI: 67.7, 136.9 ng/mL, n = 62, P < 0.001), POD 14-20 (101.4 CI: 80.7, 287.4 ng/mL, n = 22, P < 0.001), and POD 21-27 (98.1 CI: 66.8, 137.4 ng/mL, n = 20, P = 0.001) when compared to PreOp levels. The percent increase from median baseline at each time point was 1068% at POD 1, 157% at POD 3, 88% at POD 7-13, 50% at POD 14-20, and 64.0% at POD 21-27. No significant difference found at the POD 28-41 time point.

To determine whether there was a statistical correlation between incision length and post surgery plasma

CHI3L1 levels, the laparoscopic-assisted group (mean incision size 5.8 cm) and the hand-assisted group (mean incision, 10.7 \pm 3.5 cm) were compared. While the mean incision size for the hand assisted group was higher, there was no statistically significant difference in PostOp plasma CHI3L1 levels between the groups. Furthermore, at 5 of the 6 PostOp time points there was no correlation between CHI3L1 levels and incision length. There was a statistically significant correlation between incision length and CHI3L1 levels at the POD 14-20 time point. There was no significant correlation between cancer stage and PreOp CHI3L1 plasma level.

DISCUSSION

We have demonstrated in several studies that elective surgery for CRC is associated with persistent plasma protein changes that render the blood proangiogenic for 2-3 wk as judged by *in vitro* invasion, migration and EC proliferation analysis^[14-18]. This is in contradistinction to the vast majority of serum proteins that have been studied perioperatively whose levels are transiently elevated after major surgery (alterations resolving in < 1 wk such as IL-2, IL-6, CRP, etc). CHI3L1, which has been shown to promote EC proliferation and tube formation among its other effects, can now be added to the list of persistently elevated proangiogenic proteins.

In this study, mean plasma CHI3L1 levels of 80 CRC patients rose to a peak of 1068% over the PreOp baseline value on POD1, and remained significantly elevated at 50%-157% over baseline for four weeks after MICR until returning to baseline at the POD 28-34 time point. Of note, the percent changes in CHI3L1 levels over baseline were amongst the highest observed when compared to the results of the 9 other proteins previously shown to have long duration plasma increases post MICR.

Because CHI3L1 levels have been shown to be increased preoperatively in cancer patients when compared to tumor free patients, a fall in blood levels would be anticipated after the primary tumor is resected. Why then do plasma levels of CHI3L1 rise during the first month after surgery? Most likely there are several mechanisms. As regards the initial elevation during the first 3-4 d after MICR, although unproven, it is possible that macrophages and polymorphonuclear leukocytes (PMN's), which play a vital role in the acute inflammatory response that follows surgery, generate the added CHI3L1. This hypothesis is based on the following observations. Both PMN's and macrophages have been shown to generate CHI3L1 in the setting of chronic inflammation (e.g., IBD and rheumatoid arthritis) and blood levels of CHI3L1, known to be increased in these patients, have been shown to directly correlate with disease severity.

As regards the persistent plasma elevation noted during weeks 2 to 4, the authors believe, also admittedly without direct evidence, that the healing surgical wounds are the source of the added CHI3L1. Since CHI3L1 has

been shown to play key role in tissue remodeling as well as angiogenesis it is certainly possible that it is involved with the wound healing process^[9,26]. The hypothesis is that wound levels are very high such that the CHI3L1 spills over into the blood stream raising plasma levels. Support for this concept can be found in several human studies that measured VEGF levels in wound fluid and the blood of surgery patients.

In a Dutch study of MICR patients, on POD 4, wound VEGF fluid levels were found to be 7 times higher than serum concentrations which were elevated over PreOp baseline levels^[45]. The same research team, in a study of mastectomy patients noted that on POD 4 wound VEGF levels were between 23 and 32 times greater than serum levels^[46]. There is also strong preliminary unpublished data of the authors suggesting that wound levels of ANG2, and MMP2 are elevated and many times higher than plasma concentrations after MICR (plasma levels also elevated 3-4 wk). Further, the fact that the proteins shown to have markedly elevated wound levels play roles in neovascularization (like CHI3L1) indirectly suggests that the origin of the CHI3L1 during most of the first PostOp month is the wound. As mentioned above, the authors are currently conducting a study that is simultaneously assessing wound and plasma protein levels which will soon shed more light on this topic.

What are the potential clinical ramifications, if any, of the month long elevation in CHI3L1 levels? There is some research evidence that CHI3L1 may play a direct role in chronic inflammation related epithelial cancer development *via* up-regulation of β catenin^[25]. As mentioned earlier, in addition to promoting angiogenesis in general there is strong *in vivo* evidence that CHI3L1 promotes tumor angiogenesis in particular. Macrophages are known to promote cancer progression by producing a number of growth and proangiogenic factors^[47]. Tumor associated macrophages lack antigen presenting abilities and have been found to cluster in avascular areas of breast carcinomas^[47-49]. Kawda *et al.*^[22] revealed that the CHI3L1 increased the secretion of inflammatory chemokines, IL-8 and monocyte chemo-attractant protein-1 (MCP-1), from SW480 cells *via* mitogen-activated protein kinase (MAPK) pathway *in vitro*. Furthermore, CHI3L1 expressing colon cancer cells significantly increased macrophage recruitment in xenograft mice, as well as tumor growth and angiogenesis^[22]. Persistently elevated levels of plasma CHI3L1 levels together with IL8 and MCP-1^[17] may collectively enhance the blood angiogenic property after MICR.

The proangiogenic effects of CHI3L1 should be considered in the context of the other 9 proteins (all with proangiogenic effects) whose levels have also been shown to be persistently elevated after MICR. There is a concern that these plasma changes might promote tumor angiogenesis early after resection of the primary cancer in patients with established distant micro-metastases. Further, these compositional changes may encourage the establishment of new metastases

by circulating viable tumor cells present in the blood stream after surgery. Is there any evidence of increased tumor growth after surgery in humans?

The medical literature contains numerous case reports of rapid growth of residual metastases after major surgery^[7-9]. In particular, rapid growth of pre-existing metastatic cancer in the liver after resection of the primary colorectal tumor has been noted by several investigators^[6,50-52]. Of note, in one investigation the vascular density of metastases has been noted to be significantly increased over the pre-resection baseline several months after primary resection; this suggests that tumor angiogenesis is stimulated after surgery^[53]. Finally, there is strong experimental data showing that surgical trauma is associated with accelerated tumor growth^[3-5].

The data from this study and others mentioned above suggest that the first month after surgery may be a precarious time for cancer patients who harbor residual tumor since the plasma composition is proangiogenic for up to a month. The fear is that these conditions will foster blood vessel formation in the tumor and, in so doing, will promote tumor growth. Because conventional adjuvant or palliative PostOp chemotherapy is usually started 4 to 8 wk post operatively the patient is left to their own during this time period. It is logical to administer some type of anti-cancer treatment in this unused time window. The challenge is to find effective anti-cancer agents that do not interfere with the process of wound healing. Presently, a phase I clinical trial is underway that is assessing perioperative treatment with polyphenon E (a green tea extract) and a milk thistle plant component called siliphos. Both agents have been shown to inhibit tumor growth while not inhibiting wound healing which makes them safe for the early PostOp period^[54].

A weakness of this study was the relatively small number of late plasma samples collected. Most of the late samples were obtained during follow-up visits scheduled by the patients; unfortunately, many patients refused late PostOp blood draws. Thus, there were fewer late samples than at the PreOp, POD 1, and POD 3 time points. This made it necessary to bundle the late samples into 7 to 13 d blocks. Also, the timing of the late samples varied considerably. A larger study will allow a more meaningful correlation of PreOp CHI3L1 levels and cancer stage. Similarly, a follow up study with more uniform and comprehensive PostOp blood sampling should allow a better assessment of PostOp levels, in general, as well as the impact of surgical method, if any, on post surgery plasma levels.

The results of this study demonstrate that surgical stress, in particular MICR, is associated with notably increased plasma levels of CHI3L1 that persist for 1 mo after surgery. The source of this elevation is unclear. The clinical implications of these findings, if any, are uncertain. In theory, among other possible effects, this transient plasma alteration may promote tumor angiogenesis in patients with residual cancer after surgical resection of the primary tumor. The fact that plasma levels of 9 other

proteins with proven proangiogenic effects have been shown to be elevated for 2 to 4 wk after MICR lends support to this hypothesis. Further study of perioperative plasma CHI3L1 levels and of the clinical ramifications of the surgery-related long duration proangiogenic plasma compositional changes appear to be warranted.

COMMENTS

Backgrounds

Major abdominal surgery is well known to be associated with a brief period of immunosuppression and short lived plasma protein changes. Recently, another group of blood protein alterations that lasts at least 3 to 5 wk after colorectal cancer (CRC) resection have been noted. All of these proteins play a role in angiogenesis. This set of proangiogenic proteins includes vascular endothelial growth factor (VEGF), placental growth factor (PIGF), angiopoietin-2, soluble vascular adhesion molecule-1 (sVCAM-1), monocyte chemo-attractant protein-1 (MCP-1) and matrix metalloproteinase-3. Proangiogenic chitinase 3-like 1 (CHI3L) protein promotes *in vitro* human endothelial cell (EC) migration and tube formation, however, the impact of minimally invasive colorectal resection (MICR) for CRC on plasma levels of CHI3L1 is unknown.

Research frontiers

CHI3L1, is a member of the Chitinase family of proteins and has chemotactic and proangiogenic properties similar to those of MCP-1 and IL8 that are mediated, in part, by MCP-1. Colon, breast, and hepatocellular carcinomas have been shown to express higher levels of CHI3L1. It has been shown that CHI3L1 may utilize its chitin binding ability to communicate with other signal transduction pathways to modulate inflammation, apoptosis, tissue remodeling, cell growth and angiogenesis. CHI3L1 has been shown to promote *in vitro* cancer cell proliferation, macrophage recruitment, human EC migration and tube formation, and contributes to wound healing. The authors analyzed preoperative (PreOp) and post-MICR CHI3L1 levels in CRC patients. Significantly elevated blood levels of CHI3L1 may promote tumor angiogenesis and therefore, the growth of residual tumor during the first month after MICR.

Innovations and breakthroughs

Persistently elevated plasma levels of the proangiogenic proteins including VEGF, Ang-2, PIGF, sVCAM-1 and MMP3 have been noted for 3-5 wk after CRC resection. Plasma from the 2nd and 3rd weeks after CRC resection has been shown to stimulate EC proliferation and migration *in vitro* when compared to EC culture results with PreOp plasma. This study reports that plasma CHI3L1 levels are significantly elevated over PreOp levels for a month after MICR for CRC. These persistent plasma compositional changes may promote tumor angiogenesis and growth in patients with residual cancer deposits in the 1st postoperative (PostOp) month.

Applications

This study results further support that persistent plasma compositional changes may promote tumor angiogenesis and growth in patients with residual cancer deposits in the first PostOp month. Thus, it is logical to give anti-cancer therapy perioperatively, for safe use in this period, in addition to having anti-cancer effects, candidate agents must not impair wound healing.

Terminology

The significantly increased blood proangiogenic protein levels during the early PostOp period after MICR and open colorectal resection may be associated with the short lived acute inflammatory response that occurs after surgery and resolves in the first week. In contrast, the later and persistent elevation noted during weeks 2-4 after surgery may be related to wound healing. Persistently elevated plasma CHI3L1 levels shown in this study, together with the similarly increased levels of the other proangiogenic proteins such as VEGF, ANG2, PIGF, sVCAM-1 and MMP3 may collectively promote tumor angiogenesis and therefore, the growth of residual tumor during the first month after MICR.

Peer-review

The paper is written in a good language, the logic is clear and the subject and results are discussed graphically and meaningfully.

Abstract

AIM: To investigate the role of the Wnt/ β -catenin pathway in pancreatic neuroendocrine neoplasms (PanNENs).

METHODS: Tissue microarrays containing 88 PanNENs were immunohistochemically labeled with antibodies to β -catenin, E-cadherin, adenomatous polyposis coli (APC), chromogranin and synaptophysin. One case had only metastatic tumors resected, whereas others ($n = 87$) received pancreatectomy with or without partial hepatectomy. Pathology slides, demographic, clinicopathologic, and follow up data were reviewed. Patients' demographics, clinicopathologic features, and immunohistochemical results from 87 primary tumors were compared between patients with low stage (stage I / II) and high stage (stage III/IV) tumors. In addition, correlation of immunohistochemical results from primary tumors with disease-specific survival (DSS) was evaluated.

RESULTS: Strong membranous β -catenin staining in the primary tumor was observed in all 13 stage III/IV PanNENs as compared to 47% (35/74) of stage I / II

tumors ($P < 0.01$). However, the strong membranous β -catenin staining was unassociated with tumor grade or DSS. Decreased membranous β -catenin staining was associated with decreased membranous E-cadherin labeling. Nuclear β -catenin staining was seen in 15% (2/13) of stage III/IV PanNENs as compared to 0% (0/74) of stage I/II tumors ($P = 0.02$). The case with metastasectomy only also showed nuclear β -catenin staining. Two of the three cases with nuclear β -catenin staining were familial adenomatous polyposis (FAP) patients. Lack of APC expression was seen in 70% (57/81) of the cases, including the 3 cases with nuclear β -catenin staining. Expression of E-cadherin and APC in primary tumor was not correlated with tumor grade, tumor stage, or disease specific survival.

CONCLUSION: The Wnt/ β -catenin pathway was altered in some PanNENs, but did not impact DSS. PanNENs in FAP patients demonstrated nuclear β -catenin accumulation and loss of APC.

Key words: β -catenin; Familial adenomatous polyposis; Pancreatic neuroendocrine neoplasm; Adenomatous polyposis coli; E-cadherin

Core tip: Dysregulation of the Wnt/ β -catenin pathway is present in some pancreatic neuroendocrine neoplasms (PanNENs). However, compared to other malignancies, this signaling pathway may have different functions in PanNENs as strong membranous β -catenin expression is more frequently present in stage III/IV tumors and membranous expression of β -catenin and E-cadherin does not have a prognostic importance in this setting. Additionally, PanNENs arising in patients with familial adenomatous polyposis (FAP) demonstrate abnormal nuclear β -catenin accumulation, and PanNENs may be one of the extraintestinal manifestations of FAP.

Immunohistochemical analysis of the Wnt/ β -catenin signaling pathway in pancreatic neuroendocrine neoplasms. *World J Gastrointest Oncol* 2016; 8(8): 615-622 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i8/615.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i8.615>

INTRODUCTION

Although rare, pancreatic neuroendocrine neoplasms (PanNENs) are the second most common malignancy in the pancreas, accounting for 1%-2% of pancreatic tumors^[1,2]. Most PanNENs are well-differentiated, with a 10 year survival rate of approximately 40%. Based on mitotic count and Ki67 labeling index, the World Health Organization (WHO) 2010 has classified PanNENs into three grades: Grade 1 with Ki67 $\leq 2.0\%$ and mitotic

rate < 2 mitoses/10 high power fields (HPFs), grade 2 with Ki67 3%-20% or mitotic rate 2-20 mitoses/HPFs, and grade 3 with Ki67 $> 20\%$ or mitotic rate > 20 mitoses/HPFs^[3]. Grade 1 and 2 tumors are considered as well-differentiated neuroendocrine tumors, while grade 3 PanNENs include well-differentiated tumors with Ki67 $> 20\%$ and poorly differentiated neuroendocrine carcinomas^[4].

PanNENs, like many other tumors, are thought to evolve following cellular dysregulation and proliferation. One of the pathways known to be involved in normal cell growth, proliferation, differentiation, and apoptosis is the Wnt/ β -catenin signaling pathway. It is then conceivable that dysregulation of this critical homeostatic pathway may lead to tumor growth and proliferation. In fact, most colonic adenocarcinomas arise from tubular adenomas through dysregulation of the Wnt/ β -catenin pathway^[5]. Gastrointestinal well-differentiated neuroendocrine tumors, colonic glandular-neuroendocrine mixed tumors, and pancreatic acinar cell tumors have all been reported to have mutations and/or altered expression in the Wnt/ β -catenin pathway^[6-10]. A subset of ileal neuroendocrine neoplasms have been shown to have adenomatous polyposis coli (APC) mutations or loss of heterozygosity^[11]. However, it is unclear whether this pathway plays a significant role in pancreatic endocrine tumorigenesis. In this study, we assessed the expression of β -catenin, E-cadherin and APC in PanNENs.

MATERIALS AND METHODS

Patient selection

This study was approved by the Vanderbilt Institutional Review Board. Tissue microarrays (TMAs) were constructed from the resection specimens of 88 PanNEN patients who underwent pancreatectomy only ($n = 84$), pancreatectomy with partial hepatectomy ($n = 3$), and metastasectomy (partial hepatectomy) only ($n = 1$) at Vanderbilt University Medical Center from 01/1998 to 08/2012. The TMAs included 2-6 tumor and 1-2 normal pancreatic tissue cores from each patient studied. Demographic and clinicopathologic information was abstracted from the electronic medical record. Pathologic data were also recorded upon reviewing of original hematoxylin and eosin-stained slides. The American Joint Committee on Cancer TNM staging system 7th edition was used to divide PanNENs into four stages: Stage I (T1-2N0M0), stage II (T3N0M0 or T1-3N1M0), stage III (T4N0-1M0), and stage IV (T1-4N0-1M1). Stage I and II PanNENs were grouped into low stage disease, whereas stage III and IV high stage disease. Patient outcomes were confirmed using the social security death index.

Immunohistochemistry

Immunohistochemical labeling for β -catenin, E-cadherin, APC, chromogranin and synaptophysin was performed. Details of the antibodies used in this study are provided in Table 1.

Table 1 List of antibodies used

Antibody	Source	Dilution
β-catenin	BD Bioscience CAT# 610154 Mouse monoclonal (San Jose, CA)	1:1000
E-cadherin	BD Bioscience CAT# 610182 Mouse Monoclonal (San Jose, CA)	1:800
APC	Abcam (ab15270) Rabbit Polyclonal (Cambridge, MA)	1:200
Chromogranin	Abcam (ab15160) Rabbit polyclonal (Cambridge, MA)	1:500
Synaptophysin	Abcam (ab32127) Rabbit monoclonal (Cambridge, MA)	1:500

APC: Adenomatous polyposis coli.

Unstained slides were first deparaffinized by routine methods. Antigen retrieval was performed as follows: Slides were heated in citrate buffer (pH 6.0) at 100 °C for 20 min or in EDTA (pH 9.0) at 98 °C for 20 min, followed by a 10-min cool down to room temperature. All slides were then quenched with 0.03% (v/v) H₂O₂ with NaN₃ for 5 min. Slides were blocked for 20 min with serum-free protein block (Dako, Carpinteria, CA), followed by application of primary antibodies. Slides were then incubated with Evison + HRP-labeled polymer (Dako) for 30 min, followed by 5 min incubation with DAB (Dako).

Immunohistochemical stains were reviewed by two pathologists (VW and CS). Membranous β-catenin and E-cadherin staining was scored as negative (0), weak (1), moderate (2) or strong (3). Scores from replicate cores were averaged. Those with an average score > 2 were considered strong labeling, and those with ≤ 2 as decreased. Nuclear β-catenin and cytoplasmic APC staining was scored as positive and negative (in at least 10% of the tumor cells). Immunohistochemical results from primary tumor were used for statistical analysis.

Statistical analysis

Immunohistochemical labeling for β-catenin, E-cadherin and APC was compared between PanNENs and normal pancreas using the Fisher's exact test. Immunohistochemical results were also correlated with clinicopathologic parameters using standard bivariate methods. Kaplan-Meier disease-specific survival (DSS) curves were plotted and compared by Cox proportional hazards regression using the Stata® software package (v13, StataCorp, College Station, TX). All reported *P* values were derived from two-tailed hypothesis tests.

RESULTS

The 88 patients included 46 females and 42 males. The demographics and clinicopathological features of the 87 cases with primary tumor resected are listed in Table 2. While 85% (74/87) of the tumors were WHO grade 1 or 2 well-differentiated tumors, 15% (13/87) were WHO grade 3 well-differentiated tumors with Ki67 > 20%. Poorly differentiated neuroendocrine carcinomas including

small cell carcinomas and large cell neuroendocrine carcinomas were excluded from this study as they are known to have very different molecular and biologic features from well-differentiated tumors^[3,4]. Most patients (74/87, 85%) had low stage tumors (stage I / II). High stage tumors were associated with large tumor size, high tumor grade, infiltrative growth pattern and lymphovascular invasion, but did not show associations with age, gender, syndrome, tumor functionality, perineural invasion and tumor necrosis (Table 2).

To explore whether the Wnt/β-catenin pathway was altered in PanNENs, TMAs were labeled with antibodies to β-catenin, E-cadherin and APC. Membranous β-catenin labeling was strong in the exocrine pancreas, but was weak in normal pancreatic islets (Figure 1A). Over half of the PanNENs studied (48/87, 55%) displayed strong membranous staining for β-catenin in the primary tumor (Figure 1B and C, Table 2). Interestingly, all 13 stage III /IV PanNENs strongly expressed membranous β-catenin in primary tumor, compared to only 47% (35/74) of stage I / II tumors (Table 2, *P* < 0.01). There was no correlation between membranous β-catenin staining and tumor grade.

As expected, most primary tumors (85/87, 98%) were negative for nuclear β-catenin labeling (Table 2). However, when stratified by tumor stage, nuclear β-catenin staining was more often present in tumors of high stage (2/13, 15% vs 0/74, 0% of stage I / II tumors; *P* = 0.02). In addition, the case with metastasectomy only (stage IV) also showed nuclear β-catenin staining. Histologically, each of the 3 tumors with nuclear β-catenin labeling showed the typical morphologic

Figure 1 β -catenin expression in the pancreas and pancreatic neuroendocrine neoplasms (original magnification 200 \times). A: Strong membranous β -catenin staining in the exocrine pancreas and weak membranous staining in pancreatic islets (black arrows); B: Weak membranous β -catenin staining in one pancreatic neuroendocrine neoplasm; C: Strong membranous β -catenin staining in another pancreatic neuroendocrine neoplasm.

features of well-differentiated neuroendocrine tumors (Figure 2A and D). Additional immunohistochemical labeling was subsequently performed to rule out solid-pseudopapillary neoplasms (SPNs), a pancreatic tumor characterized by nuclear accumulation of β -catenin and loss of membranous E-cadherin. Each expressed both neuroendocrine markers (synaptophysin and chromogranin, Figure 2B and C) and E-cadherin (membranous, Figure 2E), consistent with neuroendocrine neoplasms.

Careful review of the clinical history disclosed that two of the three cases with nuclear β -catenin expression were from FAP patients. One was a fifty-year-old male who presented with a stage IV PanNEN and multiple colonic adenocarcinomas arising in the setting of polyposis at the initial diagnosis. Sequencing the *APC* gene demonstrated a germline 853delT mutation. The other was a forty-year-old female who presented with a stage IV PanNEN. She had undergone total colectomy for FAP at 22 years of age. *APC* gene sequencing demonstrated a germline R564X (1690C < T) mutation. Immunohistochemical staining of the PanNENs from both patients showed loss of APC expression (Figure 2F).

Similar to β -catenin, membranous E-cadherin labeling was frequently strong in pancreatic acinar cells, but weak in pancreatic islets (Figure 3A). Strong membranous E-cadherin expression in the primary tumor was observed in 44% (38/87) of PanNENs (Figure 2E), whereas decreased membranous E-cadherin expression

was present in more than half of the cases (Figure 3B). Complete loss of membranous E-cadherin expression was only observed in one case (1/87, 11%), which also showed decreased membranous β -catenin labeling and complete loss of APC expression. However, nuclear β -catenin accumulation was not seen in the tumor. No associations between membranous E-cadherin expression and tumor grade or stage were observed in this series. Noteworthy is that tumors with decreased membranous β -catenin also showed decreased membranous E-cadherin staining compared to cases with strong membranous β -catenin staining ($P < 0.01$).

Cytoplasmic APC labeling was not seen in the exocrine pancreas, but was detected in most of the pancreatic islets (Figure 3C). While 86% (30/35) of normal pancreatic islets in this study clearly expressed APC, only 30% (24/80) of the primary tumors retained APC expression (Figure 3D, $P < 0.01$). Of note, all 3 cases with nuclear β -catenin staining demonstrated loss of cytoplasmic APC expression (Figure 2F). There was no correlation between APC and β -catenin expression ($P > 0.05$). APC expression was not correlated with tumor stage or grade ($P > 0.05$).

Median follow-up for the cases with resected primary tumor was 47 mo (range, 0.3-163 mo) during which 13 patients (15%) died of progressive disease (Table 2). Univariate analysis showed that high tumor stage, tumor functionality, large tumor size, high tumor grade, infiltrative growth pattern, and lymphovascular and

Figure 2 A pancreatic neuroendocrine neoplasm from a familial adenomatous polyposis patient (original magnification 200 ×). perineural invasion were all associated with decreased DSS. In multivariate survival analysis, stage III/IV disease demonstrated a significantly worse DSS (hazard ratio = 10.4, $P < 0.05$) compared to stage I / II disease. When controlling for tumor stage and WHO grade, none of the immunohistochemical markers showed prognostic significance.

DISCUSSION

In the current study we investigated expression of select Wnt/ β -catenin pathway components in PanNENs. Approximately half of PanNENs displayed strong expression of β -catenin at the plasma membrane. As expected, strong membranous expression of β -catenin correlated with strong membranous E-cadherin. In many

other malignancies, decreased membranous β -catenin and E-cadherin expression predicts poor prognosis. We observed that in PanNENs, strong membranous β -catenin expression was frequently present in stage III / IV tumors and that membranous expression of β -catenin and E-cadherin did not have a prognostic importance in this setting. These data suggest that the role of the Wnt/ β -catenin signaling pathway in PanNENs is different than in other neoplasms such as gastric and colon adenocarcinomas^[5,12-15].

APC mutations have been implicated in the development of enterochromaffin cell neuroendocrine neoplasms, and are seen in 23% of these types of tumors arising in the midgut^[11]. However, alterations in APC have not been well characterized in neuroendocrine neoplasms of the foregut. We report that most PanNENs show loss of

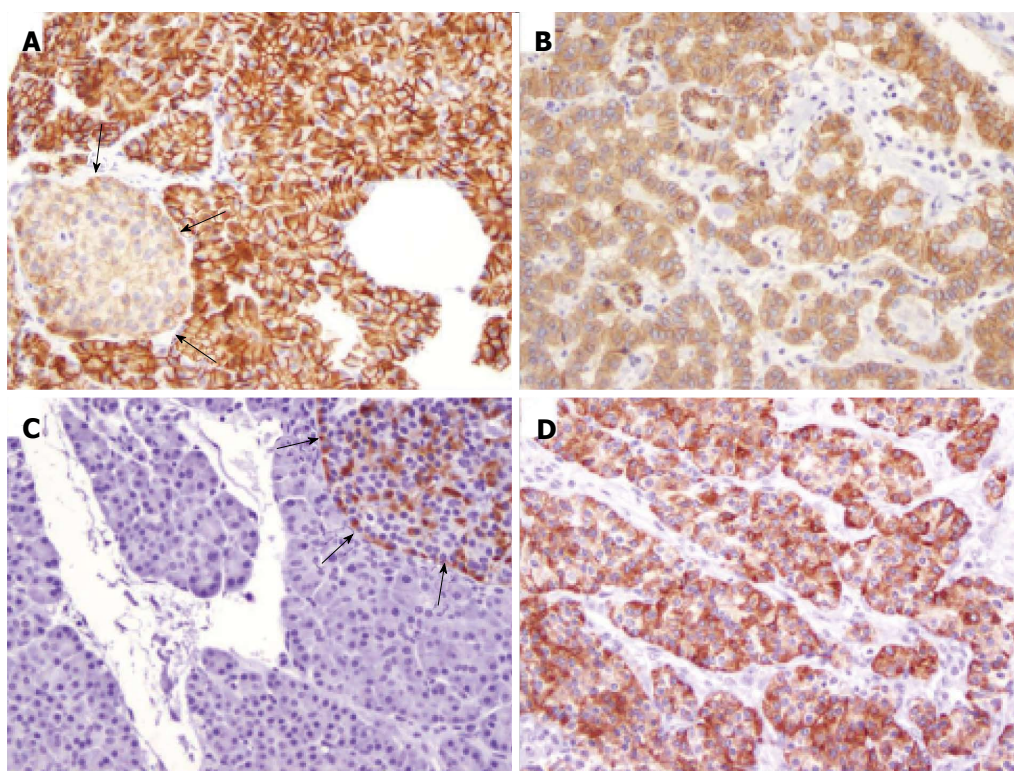

Figure 3 Expression of E-cadherin and adenomatous polyposis coli in the pancreas and pancreatic neuroendocrine neoplasms (original magnification 200 ×). A: Strong membranous E-cadherin labeling in the exocrine pancreas and weak membranous E-cadherin labeling in pancreatic islets (black arrows); B: Weak membranous E-cadherin in one pancreatic neuroendocrine neoplasm; C: Expression of cytoplasmic APC by pancreatic islets (black arrows) but not by the exocrine pancreas; D: Cytoplasmic APC labeling in one pancreatic neuroendocrine neoplasm. APC: Adenomatous polyposis coli.

APC expression, which may increase β -catenin signaling capacity for processes such as cell-cycle, apoptosis, and differentiation. Other described mutations in PanNENs may also lead to increased β -catenin signaling. For example, studies of MEN-1 deficient PanNENs (sporadic and familial) and pulmonary neuroendocrine tumors suggest that *MEN-1* mutations lead to increased β -catenin signaling^[16,17]. Canonical β -catenin signaling is characterized by β -catenin accumulation within nuclei, where it regulates gene expression. However, we detected nuclear β -catenin in only 3 of 88 tumors and did not observe differences in β -catenin expression between non-syndromic and MEN-1-associated PanNENs (data not shown). Nevertheless, strong membranous β -catenin expression was observed in 55% of PanNENs, which was not present in normal pancreatic islets. In a mouse model, knockout of β -catenin expression has been shown to suppress tumorigenesis and growth of *Men1*-deficient PNENs^[17]. Therefore, β -catenin may represent a potential therapeutic target in these tumors.

The three tumors in our study with strong nuclear β -catenin expression also showed loss of APC expression (two of these tumors were from FAP patients). FAP is defined by mutations in the *APC* gene on chromosome 5q21^[18]. APC binds β -catenin, targeting it for degradation. Therefore, when APC is mutated, β -catenin accumulates in the nucleus and activates gene transcription. Loss of APC expression, as well as nuclear accumulation of β -catenin, suggest that the *APC* gene is biallelically

inactivated in these two FAP-associated tumors, and that PanNENs may be another extra-intestinal manifestation in patients with FAP. Prior to this investigation, an association between PanNENs and FAP had not been described.

Abnormal nuclear β -catenin accumulation has been demonstrated in other FAP-associated tumors, such as desmoid-type fibromatosis. Nuclear β -catenin expression was also recently described in intestinal neuroendocrine tumors from FAP patients^[19]. Abnormal nuclear β -catenin accumulation has also been demonstrated in Sertoli cell tumors of the testis^[20] and hepatoblastomas^[21] arising in FAP patients. Pancreatoblastoma^[22] and adrenocortical carcinoma^[23] also show nuclear and cytoplasmic staining for β -catenin, while papillary thyroid carcinoma^[24] has been found to have cytoplasmic labeling in FAP patients.

Abnormal immunolabeling for β -catenin in PanNENs in patients with FAP also has important implications in the pathological diagnosis of these neoplasms. In the pancreas, SPNs almost always harbor β -catenin gene mutations, and these neoplasms characteristically show nuclear β -catenin expression. SPN is one of the primary differential diagnoses for PanNENs, since these tumors can have a solid growth pattern; conversely, PanNENs can occasionally show pseudopapillary areas. Additionally, the cells of both can be round-to-oval, with uniform nuclei^[25]. PanNENs and SPNs of the pancreas both express CD56 and synaptophysin. Differentiating these tumors is often based on the presence of nuclear β -catenin in

SPN. Our results suggest that, at least for patients with FAP, nuclear β -catenin labeling should not be used as a primary diagnostic criterion for differentiating these lesions, as both neoplasms will have nuclear staining. Instead, other immunostains should be performed. For example, SPNs, but not PanNENs, will express CD10, show loss of membranous E-cadherin, and be negative for chromogranin^[26].

In summary, dysregulation of the Wnt/ β -catenin pathway is present in some PanNENs. However, this signaling pathway may have different functions in PanNENs as compared to other malignancies. Additionally, PanNENs arising in patients with FAP demonstrate abnormal nuclear β -catenin accumulation, and PanNENs may be one of extraintestinal manifestations of FAP.

COMMENTS

Background

Alterations in the Wnt/ β -catenin signaling pathway may lead to tumor growth and proliferation. For example, most colonic adenocarcinomas arise from tubular adenomas through dysregulation of the Wnt/ β -catenin pathway. In addition, reduced membranous expression of β -catenin and E-cadherin is associated with a poor prognosis in most malignancies.

Research frontiers

Dysregulation of the Wnt/ β -catenin signaling pathway is seen in some neuroendocrine tumors of the gut.

Innovations and breakthroughs

Dysregulation of the Wnt/ β -catenin pathway is present in some pancreatic neuroendocrine neoplasms (PanNENs). However, compared to other malignancies, this signaling pathway may have different functions in PanNENs as membranous expression of β -catenin and E-cadherin does not have a prognostic importance in this setting. Additionally, PanNENs arising in patients with familial adenomatous polyposis (FAP) demonstrate abnormal nuclear β -catenin accumulation, and PanNENs may be one of the extraintestinal manifestations of FAP.

Applications

β -catenin may represent a potential therapeutic target in PanNENs as strong membranous β -catenin expression was observed in 55% of PanNENs and knockout of β -catenin expression has been shown to suppress tumorigenesis and growth in a mouse model. Nuclear β -catenin accumulation is seen in some PanNENs, especially those from FAP patients, which should be differentiated from solid pseudopapillary neoplasm, a low-malignant pancreatic tumor with similar morphology and expressing nuclear β -catenin. In addition, screening for PanNEN may be needed in patients with FAP.

Peer-review

This is a nice study.

Abstract

AIM: To investigate a link between lymph node yield and systemic inflammatory response in colon cancer.

METHODS: A prospectively maintained database was interrogated. All patients undergoing curative colonic resection were included. Neutrophil lymphocyte ratio (NLR) and albumin were used as markers of SIR. In keeping with previously studies, $NLR \geq 4$, albumin < 35 was used as cut off points for SIR. Statistical analysis was performed using 2 sample *t*-test and χ^2 tests where appropriate.

RESULTS: Three hundred and two patients were included for analysis. One hundred and ninety-five patients had $NLR < 4$ and 107 had $NLR \geq 4$. There was no difference in age or sex between groups. Patients with $NLR \geq 4$ had lower mean lymph node yields than patients with $NLR < 4$ [17.6 ± 7.1 vs 19.2 ± 7.9 ($P = 0.036$)]. More patients with an elevated NLR had node positive disease and an increased lymph node ratio (≥ 0.25 , $P = 0.044$).

CONCLUSION: Prognosis in colon cancer is intimately linked to the patient's immune response. Assuming standardised surgical technique and sub specialty pathology, lymph node count is reduced when systemic inflammatory response is activated.

Core tip: A fascinating field of research is the relationship between systemic inflammatory response and loco-regional inflammatory response in colorectal cancer. This manuscript examines this relationship in a large cohort of patients from a tertiary referral centre. We measured systemic response by assessing serum markers at diagnosis and we measured local response by looking at pathological lymph node counts in the post operative surgical specimen. This is the first report to show that patients with evidence of an activated systemic inflammatory response at diagnosis have a reduced nodal harvest at time of surgery. This finding sheds light on the complex interaction between cancer and the patient. This host-tumour response forms the basis for the most advanced cancer research today.

Activated systemic inflammatory response at diagnosis reduces lymph node count in colonic carcinoma. *World J Gastrointest Oncol* 2016; 8(8): 623-628 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i8/623.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i8.623>

INTRODUCTION

Prognosis in colon cancer is largely predicted by clinico-pathological criteria, namely the TNM system which divides patients into groups based on tumour invasion, local nodal involvement and distant metastatic spread. Since its inception over 50 years ago^[1], TNM has been used to predict patient prognosis following surgery. While easy to apply and reproducible, recent research has highlighted deficiencies in the TNM system. Higher absolute lymph node counts improve patient prognosis regardless of stage^[2] and an increased lymph node ratio in node positive disease reduces prognosis^[3], two variables not measured by TNM.

Tumour-host immunological response is an important factor in prognosis at both a local and systemic level^[4,5], another feature not measured by TNM. Local response has been assessed by looking at lymphocytic infiltration of colonic tumour and an improved survival is seen in patients who have mounted a local lymphocytic response^[6]. Readily available markers of systemic inflammatory response (SIR) have prognostic value in patients undergoing surgery for colon cancer^[7]. A combination of C-reactive protein and albumin (the modified Glasgow prognostic score) and the neutrophil-lymphocyte ratio (NLR) have been proposed as surrogate markers of patient systemic immune response to cancer. A high modified Glasgow Prognostic Score (mGPS) and/or an elevated NLR (≥ 4) infer a poorer prognosis. A combination of an activated local response and the lack of an activated SIR imparts an improved prognosis^[7], strengthening the link between cancer survival and immune response at both a local and systemic level.

To date, the information gleaned from lymph node

harvest has revolved around absolute number and the presence or absence of cancer spread. Improved prognosis from higher lymph node counts has been explained as essentially a sampling error in patients with sub optimal surgical resection^[8]. This explanation cannot account for the wide variance in yields experienced even in centres where radical excisions are performed as a matter of routine^[9].

Lymph nodes are the first line of defence in the loco-regional immune response to cancer. It is possible that an increased local response to cancer results in lymph node hypertrophy resulting in an increased lymph node yield. Failure of a local response may result in less lymph node activation and allow for systemic "escape" resulting in activation of the systemic immune response. If this is the case, assuming standardised surgical and pathology techniques, a lower lymph node yield could be expected in patients with signs of an activated SIR in the preoperative period.

The aim of this study was to investigate a link between lymph node yields and systemic inflammatory response in patients undergoing surgery for colonic carcinoma.

MATERIALS AND METHODS

Patients who had undergone elective surgery for colon cancer between January 2007 and July 2013 were identified from a prospectively maintained database. Due to the known effect of radiotherapy on lymph node counts^[10], rectal cancer patients were excluded. All surgeries were performed by the same subspecialty trained consultant surgeons and all samples analyzed by the same pathology department. Laparoscopic and open procedures were included.

Using a hospital-wide electronic patient record computer system, the results of pre-operative bloods drawn either on the day prior to or morning of surgery were recorded.

Neutrophil-lymphocyte ratio was derived from a standard white cell differential and in keeping with previous studies, an NLR of ≥ 4 and albumin < 35 were used as cut off levels indicating an activated SIR.

Statistical analysis was performed using Minitab v16 (Minitab Ltd. Coventry, United Kingdom). Continuous and categorical variables were analysed with 2 sample student's *t*-test and χ^2 tests where appropriate. Statistical analysis was performed by author RPK who has training in statistical methodology.

RESULTS

Three hundred and sixteen patients were identified for inclusion in the study. Fourteen patients were excluded due to incomplete data and analysis of CRP was ultimately abandoned as it was not routinely measured pre-operatively. The majority of the patients were male (168 vs 124) and the median age was 71. One hundred and seventy-eight patients had a laparoscopic

or lap-assisted operation. One hundred and twenty-four patients had either a planned open operation or a lap to open conversion. Most patients were either stage II (45%) or stage III (37%) (Table 1). Lymph node count did not vary significantly based on operative approach, age or gender (Table 2).

Of the 302 patients included for analysis. One hundred and ninety-five patients had NLR < 4 and 107 had NLR ≥ 4. Patients with an NLR ≥ 4, (*i.e.*, activated systemic inflammatory response) had a reduced total nodal count (17.6) compared to patients with an NLR of < 4 (19.2). Hypoalbuminaemia did not impact on lymph node count. Patients with low albumin and an elevated NLR were not more likely to have a reduced lymph node count than patients with elevated NLR alone (Table 3). NLR ≥ 4 correlated with an elevated lymph node ratio. A higher proportion of patients with NLR ≥ 4 had lymph node positive disease (Table 4).

DISCUSSION

The host-tumour response is at the forefront of cancer research and exploration of the relationship between the patient and their cancer has yielded success in areas previously resistant to traditional chemotherapy^[11]. Higher lymph node counts correspond with improved prognosis in colon cancer^[8]. The relationship is preserved within cancer stages^[2]. An activated systemic inflammatory response, in the preoperative period,

correlates with poor prognosis in colon cancer^[12]. While the reason for this finding is not clearly defined it is possible that an activated SIR represents a loss of local control and is an early marker of systemic awareness of a heretofore localised cancer process. The data presented here propose a unifying explanation for these separately defined phenomena.

Previous work has shown that neutrophil lymphocyte ratios can predict survival in many cancer types^[13]. Different ratios have been tested to find a reliable measure of activated systemic inflammatory response^[14,15]. The ratio that carries the greatest level of evidence is NLR ≥ 4^[16,17]. In our patient cohort, a preoperative elevated NLR correlated with a reduced lymph node yield (19 vs 17).

The clinical significance of a two-node difference may be questioned. While the finding is statistically significant it is worth asking whether there is any useful information to be gained. Cserni *et al*^[18] examined a large cohort of colon patients in the SEER database looking at the impact of nodal yield on survival. An improvement in prognosis was observed with increasing lymph node harvest. This finding was maintained in node negative and node positive patients. Indeed it was shown that with each additional node resected there is an associated increase in survival. Given this information, the findings in the current study may well provide important prognostic information.

Many studies have examined lymph node number and oncological outcome^[19]. Lymph node counts below 12 correlate with poor outcome, a finding largely explained by variances in surgical quality^[20]. However, even in good surgical specimens, low yields are sometimes encountered and many centres have questioned the validity of a binary marker of surgical quality in colon cancer^[21,22]. Regardless of this on-running controversy,

Table 5 Description of modified glasgow prognostic score

mGPS	Score
Crp \leq 10, albumin \geq 35	0
Crp \leq 10, albumin $<$ 35	0
Crp $>$ 10	1
Crp $>$ 10 and albumin $<$ 35	2

mGPS: Modified glasgow prognostic score.

the lymph node count in both categories in the present study was well above 12 therefore surgical quality is not in question.

Other factors can impact on lymph node yield. Age, gender and laparoscopic surgery can affect lymph node count however these factors were not found to influence yields in the present study. Lymph node counts are highly dependent on quality of pathological examination and this may represent the single greatest factor that influences inter-institutional variability in nodal yields^[23]. A single sub-specialty pathology department analysed all specimens in the present study limiting the impact of the pathologist on lymph node harvest.

NLR \geq 4 was compared to established measures of patient prognosis. Positive to negative lymph node ratios are a strong prognostic indicator in colonic carcinoma^[3]. Prognosis falls as ratios increase and a cut off of 0.25 (1 in 4 nodes positive) has particular prognostic significance^[24]. In the current patient cohort, a significant link is apparent between NLR and LNR of 0.25 and above. Lymph node ratios are dependent on absolute lymph node count and it is possible that previous findings regarding lymph node ratios are in fact a surrogate for the relationship between local and systemic inflammatory responses to cancer.

How systemic inflammatory response and cancer interact is a matter of debate. One theory suggests suppression of anti-tumour immunity by recruiting regulatory T cells and activating chemokines^[25] resulting in tumour growth and spread. It has been proposed that SIR acts as a marker of pre-existing comorbid disease and high risk pathological tumour characteristics (*i.e.*, lymphovascular invasion, peritoneal involvement.) Interestingly, studies designed to explore this question have not shown a link^[7].

A significant relationship was not shown for albumin and lymph node yield in our study. This was not an unexpected finding given previous work by the Glasgow group. The original Glasgow Prognostic Score assigned a score of 1 for hypoalbuminaemia. Further work showed no prognostic significance for hypoalbuminaemia alone^[26] (Table 5). The modified score only attributes a score for a low albumin if there is a concomitant elevated C reactive protein. As CRP was not measured in the present study, albumin levels did not provide any added benefit.

Our study has limitations. Due to the nature of the institutional database, patient information is not available regarding co-morbid conditions. However, all

included patients represent elective surgical candidates, deemed fit for surgery with no acute illness precluding an operation. The exclusion of emergency procedures lends some security regarding confounding causes of elevated markers of systemic inflammatory response. We were unable to complete our analysis of CRP due to levels not being available on the majority of our patients. While a pre-operative CRP is desirable, it does not form part of the standard pre-operative work up for our patients and is unlikely to be a routine test performed in most institutions. All patients undergo a full blood count prior to surgery therefore neutrophil lymphocyte ratio should be a readily available measure in all hospitals.

The primary focus of our study is on the peri-operative period but there is much scope for further research in this field. We have not reported long term outcomes and survival data in our patient cohort as the median follow-up time period in the study group was not of sufficient length. These patients will be followed prospectively and outcome will be reported in future planned analyses.

This study, albeit preliminary, may yield important prognostic value for our patients. Pre-operative identification of SIR could potentially alter treatment decisions, *i.e.*, serve as an indication for adjuvant chemotherapy, determine frequency of clinical and radiological surveillance as well as confer additional prognostic information.

Although the mechanism remains poorly understood, it is evident that there is an intrinsic link between the host immune response and patient outcome in colon cancer. The results of this study indicate that lymph node count is reduced where systemic inflammatory response is activated in colon cancer. We propose that neutrophil-lymphocyte ratio can therefore be used to predict nodal yield and provide additional valuable information regarding prognosis.

COMMENTS

Background

A host systemic inflammatory response to a tumour has been shown to negatively affect prognosis in patients undergoing surgery for colonic carcinoma. Surrogate markers of systemic inflammatory response researched to date have included routine laboratory investigations such as serum albumin, C-reactive protein and the neutrophil-lymphocyte ratio which together comprise the modified glasgow prognostic score. A more pronounced systemic inflammatory response as shown by a high glasgow prognostic score infers a poor prognosis in colon cancer. Lymph node count in colon cancer has long been established as a surgical quality indicator. Research has shown that a higher lymph node yield confers improved prognosis, a phenomenon which appears to be independent of nodal disease burden. This has previously been attributed to selection bias with lower nodal yield thought to be associated with the quality of the operating surgeon and examining histopathologist. However, this does not explain the large variation in nodal yields that sub-specialist centres encounter, where departments of highly specialised surgeons and histopathologists are routinely involved in multi-disciplinary cancer care.

Research frontiers

The host-tumour immune response is a fascinating field of cancer research

that promises success in offering new treatment modalities in areas previously resistant to more conventional therapies. Current research supports that neutrophil lymphocyte ratios and similar markers of systemic inflammatory response can predict survival in many cancer types, likewise with local inflammatory response as characterised by tumour-infiltrating lymphocytes. These phenomena are at present not incorporated into any staging or classification system for colon cancer, despite the overwhelming evidence that they provide invaluable prognostic information. Considering this wealth of information, current research is exploring the exciting realm of immunotherapy, for which many clinical trials are underway.

Innovations and breakthroughs

The relationship of prognosis in colon cancer with systemic inflammatory response has been researched to date, as has that with lymph node yield. To the authors' knowledge however, this is the first study to examine a link between these two phenomena. The study supports that poor prognosis in colon cancer is due in part to failed or impeded local immune response to a tumour and subsequent systemic loss of control. The findings may also explain why lymph node counts are often highly variable, even in sub-speciality tertiary referral centres where variance in surgical and histopathological quality is unlikely to be a major confounding factor. This research suggests that the current focus on an absolute number of nodes as an indicator of quality is perhaps flawed, and a change in perspective with regards to lower-than-expected nodal yields should be employed.

Applications

The results of this study may offer important prognostic value for the patients. In identifying SIR pre-operatively, the authors can identify patients in whom lower nodal yield and a poorer prognosis is anticipated. This may potentially alter post-operative course of treatment, *i.e.*, serve as an indication for adjuvant chemotherapy, determine frequency of clinical and radiological surveillance, as well as pave the way for the development of novel pre-operative immunotherapeutic interventions.

Terminology

Systemic inflammatory response (SIR): Reaction to an infectious or non-infectious stimulant by activation of whole body inflammatory cascade following failure of local immunological homeostasis; lymph node yield: Number of lymph nodes identified in pathological specimen following oncological resection; neutrophil-lymphocyte ratio (NLR): Ratio of circulating neutrophils to lymphocytes. A circulating neutrophilia relative to a lymphopaenia is a surrogate marker of systemic inflammatory response. In keeping with previous studies, we chose a NLR of $\geq 4:1$ as the cut-off for SIR; lymph node ratio: Ratio of positive to negative nodes in a specimen.

Peer-review

The manuscript describes findings of statistical-analysis to assess a link between lymph node yields and systemic inflammatory response in patients undergoing for colon carcinoma. Authors suggest an intrinsic link between the host immune-response and patient outcome in colon cancer, and propose that neutrophil-lymphocyte ration can be used to predict nodal yield and provide additional valuable information regarding prognosis. This article is concisely written, and contains interesting findings.

Abstract

AIM: To measure the compliance of an Academic Hospital staff with a colorectal cancer (CRC) screening program using fecal immunochemical test (FIT).

METHODS: All employees of "Attikon" University General Hospital aged over 50 years were thoroughly informed by a team of physicians and medical students about the study aims and they were invited to undergo CRC screening using two rounds of FIT (DyoniFOB® Combo H, DyonMed SA, Athens, Greece). The tests were provided for free and subjects tested positive were subsequently

referred for colonoscopy. One year after completing the two rounds, participants were asked to be re-screened by means of the same test.

RESULTS: Among our target population consisted of 211 employees, 59 (27.9%) consented to participate, but only 41 (19.4%) and 24 (11.4%) completed the first and the second FIT round, respectively. Female gender was significantly associated with higher initial participation ($P = 0.005$) and test completion - first and second round - ($P = 0.004$ and $P = 0.05$) rates, respectively. Physician's (13.5% *vs* 70.2%, $P < 0.0001$) participation and test completion rates (7.5% *vs* 57.6%, $P < 0.0001$ for the first and 2.3% *vs* 34%, $P < 0.0001$ for the second round) were significantly lower compared to those of the administrative/technical staff. Similarly, nurses participated (25.8% *vs* 70.2%, $P = 0.0002$) and completed the first test round (19.3% *vs* 57.6%, $P = 0.004$) in a significant lower rate than the administrative/technical staff. One test proved false positive. No participant repeated the test one year later.

CONCLUSION: Despite the well-organized, guided and supervised provision of the service, the compliance of the Academic Hospital personnel with a FIT-based CRC screening program was suboptimal, especially among physicians.

Core tip: The fecal immunochemical test (FIT) for hemoglobin represents an attractive alternative to colonoscopy for population colorectal cancer (CRC) screening programs, since it combines high diagnostic effectiveness and wide acceptance, probably in relation to its non-invasive nature. Accordingly, we assessed the compliance of the staff of an Academic Hospital with a CRC screening program by means of FIT. Despite the well-organized, guided and supervised provision of the service, our results indicated very low overall uptake rate of the test and, interestingly, significantly less compliance of physicians and nurses as compared to the rest Hospital personnel.

Academic hospital staff compliance with a fecal immunochemical test-based colorectal cancer screening program. *World J Gastrointest Oncol* 2016; 8(8): 629-634 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i8/629.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i8.629>

INTRODUCTION

Colorectal cancer (CRC) screening using colonoscopy

in average-risk adults aged more than 50 years (or in younger subjects with a family history of CRC) decreases the incidence and mortality rates for CRC through detection and removal of premalignant lesions^[1]. Given that the compliance of the general population in colonoscopy screening programs is low, other screening modalities have been implemented as well^[2]. The high diagnostic performance of the fecal immunochemical test (FIT) as compared to other CRC screening tests combined with its superior acceptability as a non-invasive screening measure^[3,4] result in being widely recommended for CRC screening. In addition, a positive FIT-test could represent a stronger motivation for patients to participate in colonoscopy-based CRC screening programs. However, there are no studies to confirm or reject the latter assumption, especially among health care providers.

The aim of this study was to evaluate the compliance of the staff of an Academic Hospital with a CRC screening program using FIT.

MATERIALS AND METHODS

During an initiation event at the Conference Auditorium of our Hospital, expert Gastroenterologists of the Hepatogastroenterology Unit of the Second Department of Internal Medicine and Research Institute, Medical School, Athens University presented the study aims and outlines to "Attikon" University General Hospital employees. Employees aged 50 years or older were identified through the Human Resources Department of the Hospital. They were thoroughly informed by a team of physicians and medical students and they were invited to be screened for CRC by means of two rounds of FIT (DyoniFOB® Combo H, DyoniMed SA, Athens, Greece).

Candidates received directly as well as by mail a letter explaining the rationale of the program, an informed consent form to sign before the procedure and a questionnaire that covered demographic data of the participants and family history for CRC or colonic polyps. In addition, a FIT kit was provided for free with instructions for collecting the stool sample and returning the kit for processing at the Hepatogastroenterology Unit of our Hospital. Upon the return of the first kit, participants were requested to repeat the procedure with a second kit. Participants were informed on their results and those who tested positive were offered colonoscopy. One year after completing the two rounds, all participants were contacted by telephone in order to be reminded of the need to repeat screening.

The study outcome was to evaluate the compliance of the Hospital personnel with a FIT-based screening program by measuring the personnel participation rates.

The study protocol and the participants' informed consent form had been approved by the Attikon University General Hospital Ethics Committee.

Statistical analysis

Categorical variables presented as value (%) were

Table 1 Baseline characteristics of study participants and non-participants

Characteristics	Participants <i>n</i> (%)	Non-participants <i>n</i> (%)
Gender		
Male	23 (39)	93 (61)
Female	36 (61)	59 (39)

analyzed using a χ^2 test or Fisher's exact test with the Yates correction, as needed. *P* value < 0.05 indicated statistical significance.

The statistical methods used in the present study were reviewed by Professor Konstantinos Triantafyllou, Medical School, National and Kapodistrian University, Athens, Greece who has been trained in biostatistics.

RESULTS

The study was carried out from September 2013 to March 2015.

Target population - initial willingness to participate

The target population - 116 males and 95 females - consisted of 133 physicians, 31 nurses and 47 administrative and technical staff members.

Fifty-nine (27.9%) employees agreed to participate and signed the informed consent form; 23 (19.8%) males vs 36 (37.9%) females (*P* = 0.005). All of them were asymptomatic, none had family history of CRC but 14 had a family history of colonic polyps. Participants as well as non-participants baseline characteristics are presented in Table 1.

Physicians showed significantly lower willingness to participate (18 of 133 or 13.5%) in comparison to the administrative and technical staff group (33 of 47 or 70.2%, *P* < 0.0001) and the nurses group (8 of 31 or 25.8%, *P* = 0.03).

1st FIT round completion

Among the participants, only 41 returned the first kit for evaluation indicating an overall completion rate of 19.4%; 15% and 54% of the participants with and without a family history of colonic polyps, respectively (*P* = 0.74). The first FIT round was completed by significantly more female in comparison to male participants (27 of 95 or 28.4% vs 14 of 116 or 12.1%, *P* = 0.004).

As shown in Figure 1, there was higher test com-

pletion rate in the administrative and technical staff group (57.6%) in comparison to the physicians' and nurses groups (7.5% and 19.3%; *P* < 0.0001 and *P* = 0.004, respectively).

2nd FIT round completion

The overall completion rate for the second FIT test was 11.4% (Figure 1). Only 24 of the 40 employees who received the second test kit returned it for evaluation; 5% with family history of colonic polyps and 34% without (*P* = 0.06).

Similarly to the first round, significantly more female participants completed both first and second FIT rounds in comparison to male participants (16 of 95 or 16.8% vs 8 of 116 or 6.8%, *P* = 0.05).

Figure 1 shows that the physicians' group second FIT round completion rate (2.3%) was the lowest in comparison to the nurses and the administrative/technical staff groups (16.1% and 34%; *P* = 0.007 and *P* < 0.0001, respectively). No difference (*P* = 0.11) was detected between nurses and administrative/technical staff groups in second FIT round completion rates.

Out of the 65 performed FIT examinations, a single test was proved false positive based on the colonoscopy that followed. One year later, we informed by telephone the 41 study participants who completed at least the first FIT round for the need to repeat screening. Twenty-two of them denied further screening since they believed that the negative results of their past tests would last forever, while 18 were willing to undergo screening annually. Only one of the participants accepted to be screened, but even this subject did not finally proceed to being tested.

DISCUSSION

A fundamental aspect of all screening programs and a prerequisite for their success is participation and compliance of the target population. Even though several tests for CRC screening exist, their participation rates remain suboptimal^[5,6]. Population screening programs include endoscopic procedures (*i.e.*, colonoscopy, flexible sigmoidoscopy or colon video capsule endoscopy), radiologic tests, including barium enema and computed tomography-colonography and fecal tests, such as the fecal occult blood test (FOBT) and FIT. FIT, being a non-invasive screening test could serve as an attractive alternative to colonoscopy for CRC screening, since it combines effectiveness and wide acceptance, probably due to its non-invasive nature. This has resulted in its widespread adoption in countries with organized CRC screening programs^[3,7]. Recently, a CRC screening program using biannual FIT that was conducted in Italy revealed not only a reduction by 30% in CRC mortality of the general population but also a 10% decrease in CRC incidence after 8 years of study^[8].

In the present study we evaluated for the first time, the compliance of the staff of an Academic Hospital to a non-invasive CRC screening program, using FIT.

Figure 1 Significantly less physicians and nurses completed the two rounds of the fecal immunohistochemical test compared to the hospital administrative and technical personnel.

We proceeded with two rounds of FIT testing in order to obtain better test sensitivity without compromising overall test uptake, based on the results of a study that showed that the participation rate was similar when completing one or two samples of the FIT test^[9].

Three randomized trials have indicated a participation rate for FIT approximately 60%, higher than that of the gFOBT^[9-11], while the reported overall participation rate in the FIT studies ranges widely from 17%-77%^[8-12].

Our results showed that: (1) the overall uptake of the FIT was within the lower reported rates worldwide, even in subjects with positive family history for colonic polyps; (2) significantly less physicians and nurses completed the FIT screening program compared to the hospital administrative and technical personnel; (3) female individuals showed both a higher willingness to participate and a higher participation rate after the two FIT rounds; and (4) participants were reluctant to continue screening annually.

The screening completion rate of our population was deemed lower - 19.4% for the first and 11.4% for the second round, respectively - than expected for a well organized, controlled and supervised in the participants' occupational environment program. As shown in Figure 1 the low overall screening completion rate is a consequence of physicians - mainly - and nurses' low completion rates. These disappointing rates, reaching the lowest 2.25% among physicians for the second test round, may indicate a major study limitation. Issues like embarrassment and discomfort may have eventually influenced the compliance of the medical and nursing staff, since there was an interaction between the providers of the screening test and the participants in the same practice. Low participation rates among hospital employees were shown during a CRC screening program that consisted of a questionnaire, followed by an endoscopic procedure among the personnel of an Academic Medical Center in Israel. The program yielded

similar results to ours, as merely 24.7% of the staff that was invited to participate completed the questionnaire; 16.2% of them agreed to be further tested^[13].

Providing the tests by dedicated unrelated to the participants services, *e.g.*, committees organized by the Ministry of Health, although more complex, time consuming and expensive, could eventually, overcome this obstacle.

On the other hand, in a cancer screening program for cervical, breast, colorectal and prostate cancers in health care workers in Italy, the participation rate was higher than that of the general population with an overall compliance of 83.8%^[14]. Moreover, it has been suggested that compliance to other cancer screening programs, such as screening for prostate cancer in men and breast cancer in women has been positively associated with compliance to CRC screening^[15]. Therefore, regional and site specific issues may also be important for CRC screening program successful implementation.

Several additional factors influence CRC-screening uptake; awareness for CRC, different screening modalities - invasive and non-invasive - as well as the way in which the latter are offered to the population. Interestingly, almost half of our screening subjects who completed at least the first test round denied further screening due to ignorance for repeating CRC screening annually. Similarly, in a recent study among Greek medical students it was shown that there is lack of information about CRC screening^[16]. Awareness of the risk factors for CRC, signs and symptoms as well as the prognosis of the disease are all factors that can increase screening uptake^[17,18]. European studies have reported low awareness about CRC compared to other cancers such as lung cancer and prostate in men and breast cancer in women^[19].

Low educational level has been associated with low participation rates in CRC screening programs^[17], whereas it has also been demonstrated that there is a positive association between low socio-economic status with low screening compliance rates^[20]. Interestingly, the majority (55%) of employees who initially consent to be screened were at the intermediate of basic educational level (four nurses and 28 administrative/technical staff members) compared to those with high educational level (18 physicians, 4 nurses and 5 administrative/technical staff members). This discordance with the existing literature could, at least partially, be explained by the small number of participants and the aforementioned issues of embarrassment and discomfort.

In a recent investigation regarding screening programs for breast and cervical cancers at a University Hospital in Turkey among female health care personnel, it was concluded that female physicians and nurses don't pay the adequate attention to these screening programs^[21]. Nevertheless, in our study the completion rate of both FIT rounds was higher among the female compared to that of the male hospital staff (16.8% vs 6.8%).

Our study is limited by the small, very selected (emplo-

yeas of an academic health care provision) sample, which is not representative of the general population, and our results might not be directly extrapolated to other medical facilities worldwide. Another study caveat is the limited test candidate's baseline information provided by the Human Resources Department of the Hospital that precluded the identification of predictors of participation in the program beyond that of female gender. Finally, we acknowledge as limitations of our study the fact that no data was captured regarding possible participants' CRC screening in the past or current bowel symptoms. Identification of the reasons for non-compliance would have also been of great interest, although not available in the present study.

In conclusion, the compliance of the Attikon University General Hospital personnel with a FIT-based CRC screening program was suboptimal, especially among physicians, despite the well-organized, guided and supervised provision of the service.

ACKNOWLEDGMENTS

DyonMed SA, Athens, Greece kindly provided the fecal immunochemical test (DyoniFOB® ComboH) for the study purposes.

COMMENTS

Background

Colorectal cancer (CRC) screening by means of colonoscopy decreases the incidence and mortality rates for CRC through early detection and removal of premalignant lesions. Fecal immunochemical test (FIT) is also implemented as a CRC screening modality and has the advantage of being a non-invasive tool. The authors aimed to assess the compliance of an Academic Hospital staff with a CRC screening program using FIT.

Research frontiers

According to the results, the compliance of the Academic Hospital personnel with a FIT-based CRC screening program was suboptimal, especially among physicians.

Innovations and breakthroughs

Although it is established that low educational level is associated with low participation rates in CRC screening programs, the results of this study indicate that those with high educational level exhibited less compliance as compared to those of low-intermediate one.

Applications

The results of the present study may enhance the efforts for better population awareness regarding CRC screening.

Terminology

The FIT is a non-invasive test that detects human hemoglobin in stool and represents an efficacious means of CRC screening. Compliance refers to the individual's adherence to a recommended diagnostic or therapeutic procedure.

Peer-review

It is an interesting manuscript on important topic. The paper is well-written.

Abstract

AIM: To estimate the levels of serum cytokines in chronic pancreatitis (CP) and pancreatic ductal adenocarcinoma (PDAC) patients in order to evaluate their usefulness as possible biomarkers.

METHODS: The study included 167 Caucasian patients: 74 with PDAC (28 men and 42 women, aged 30-88 years), 78 with CP (50 men and 21 women, aged 20-79 years) and 15 age-matched healthy controls hospitalized in the Department of Digestive Tract Diseases, Medical University of Lodz, Poland between 2006 and 2013. Serum MCP-1, transforming growth factor (TGF)- β 1, HA and s-Fr were measured in patients with CP ($n = 78$), PDAC ($n = 74$) and healthy controls ($n = 15$) using ELISA (Corgenix United Kingdom Ltd R and D Systems). The severity of CP was assessed according to the Cambridge classification.

RESULTS: Both patients with CP and PDAC had a significantly higher mean TGF- β 1 serum level (1066 ± 582

and 888 ± 356 vs 264 ± 93 , $P < 0.0001$), mean s-Fr (2.42 ± 1.385 and 2.41 ± 1.275 vs 0.6 ± 0.370 , $P < 0.0001$) and mean HA (199 ± 254 and 270 ± 358 vs 40 ± 26 , $P < 0.0001$) compared to controls. There was no difference in mean MCP-1 between all the groups. There were no significant differences in any cytokine levels between the PC and PDAC groups. No significant differences between serum cytokines depending on age, gender or smoking status were found in CP patients. Mean s-Fr concentration was significantly higher in CP, lasting longer than 5 years compared to those with a shorter disease clinical course (2.639 ± 1.125 vs 1.870 ± 0.970 , $P < 0.03$). There was no correlation between tumor size, localization or TNM classification and serum TGF- β 1, MCP-1, s-Fr and HA levels in patients with PDAC. No significant differences between cytokines depending on diabetes presence in CP were found. Nevertheless, mean serum TGF- β 1 concentration in PDAC patients was higher in those with diabetes compared to the remaining group (986 vs 839 , $P = 0.043$).

CONCLUSION: Serum TGF- β 1, s-Fr and HA may be considered additional diagnostic markers of CP and PDAC. TGF- β 1 may be useful to predict endocrine insufficiency in PDAC.

Core tip: Fibrosis begins in an early stage of the disease in chronic pancreatitis and in pancreatic ductal adenocarcinoma. Cytokines such as transforming growth factor beta-1, hyaluronic acid, soluble fractalkine and monocyte chemoattractant protein-1 take part in connective tissue proliferation. It is essential to diagnose pancreatic diseases in the early stage in order to start an appropriate therapy. Cytokines can be useful clinical biomarkers.

INTRODUCTION

Pancreatic fibrosis is the characteristic feature of chronic pancreatitis (CP) and pancreatic ductal adenocarcinoma (PDAC)^[1]. The inflammation in CP leads to irreversible destruction of pancreatic parenchyma, interstitial fibr-

osis and the following loss of exocrine and endocrine tissue^[2]. Consequently, CP significantly impairs quality of life^[3]. The mechanisms which induce fibrosis in PDAC and CP are not completely elucidated but involve persistent activation of pancreatic stellate cells (PSC). The fibrosis process starts in the early stage of CP and progresses with the duration of the disease^[4]. Accurate biological and functional markers of early stage CP are strongly needed for early treatment and prevention of complications. Furthermore, as patients with longstanding CP are at a markedly increased risk of developing pancreatic cancer, diagnosing CP at an early stage may result in cancer prevention^[5]. According to Whitcomb *et al*^[6], pancreatic fibrosis itself in chronic CP is a major risk factor for pancreatic cancer. Interstitial fibrosis markers could play a potential role as early stage CP diagnostic markers.

PDAC coexists with CP in 20%-35% of cases. In these circumstances, diagnostic tools such as US, EUS and CT are insufficient because their sensitivity and specificity is unsatisfactory^[7]. Several early stage markers have been proposed in CP and PDAC^[8]. Transforming growth factor beta-1 (TGF- β 1) and extracellular matrix proteins, especially hyaluronic acid (HA) and pro-collagen III peptide (P-III-P), are suggested to play a pivotal role in early stage pancreatitis^[7,9]. TGF- β 1 expression was found in adjacent areas to pancreatic fibrosis in PSC and acinar cells. TGF- β 1 is thought to regulate the synthesis of collagen in PSC^[10,11]. TGF- β 1 contributes to healing, acts as monocyte and fibroblast chemoattractant factors and increases synthesis and secretion of extracellular matrix^[12]. In addition, TGF- β 1 plays a role in wound healing, stimulating growth of connective tissue and scar formation^[13,14]. Basically, the same process takes place in pancreatic tissue when areas of focal necrosis are replaced by fibrosis. High expression of TGF- β 1 is observed in the fibrosis area in models of chronic pancreatitis in rats^[15]. TGF- β 1 up-regulates collagens at the same time as down-regulating collagenases and stromelysins in fibroblasts^[16]. Inhibition of the TGF- β 1 signaling pathway significantly reduced fibrosis in experimental pancreatitis models^[17,18].

Soluble fractalkine (s-Fr) was also proposed as a marker of early stage pancreatic fibrosis. S-Fr activates multiple signaling cascades in PSCs. This cytokine directly induces PSC proliferation without increasing the release of inflammatory mediators^[19]. S-Fr is secreted from PSC in response to various stimuli and contributes to the CP progression, also enhancing the migration of inflammatory cells, inducing vascular smooth muscle and endothelial cell proliferation^[20].

Monocyte chemoattractant protein-1 (MCP-1) acts like a strong chemoattractant factor for monocytes, macrophages and lymphocytes. Recent studies show that blocking MCP-1 activity suppresses the progression of experimental CP induced with dibutyltin dichloride in rats^[21]. Decreasing MCP-1 and TGF- β levels with anti-inflammatory drugs resulted in a reduced severity of CP, including the extent of inflammatory cell infiltration

and stromal fibrosis in a caerulein-induced CP mouse model^[22].

In addition to CP, pancreatic fibrosis also plays a crucial role in PDAC. Progressive fibrosis associated with PDAC may have diagnostic and prognostic relevance. Fibrotic degeneration is considered one of the major causes of chemotherapy resistance. New diagnostic markers are strongly needed in order to diagnose PDAC at an early stage.

Diabetes develops in more than half of patients with chronic pancreatitis^[23]. Most patients with pancreatic tumors have impaired glucose tolerance^[24]. Endocrine and exocrine insufficiency are both consequences of advanced fibrosis.

The aim of this study was to determine the potential diagnostic value of early stage fibrosis markers such as chemokines (s-Fr and MCP-1), cytokines (TGF- β 1) and markers of extracellular matrix (HA) in patients with CP and PDAC. Moreover, the usefulness of these cytokines as possible biomarkers of endocrine pancreatic function in CP and PDAC was considered.

MATERIALS AND METHODS

Patient selection

The study included 167 Caucasian patients: 74 with PDAC (28 men and 42 women, aged 30-88 years), 78 with CP (50 men and 21 women, aged 20-79 years) and 15 age-matched healthy controls hospitalized in the Department of Digestive Tract Diseases, Medical University of Lodz, Poland between 2006 and 2013. Written informed consent was obtained from all patients. The study protocol was approved by the ethics committee of Lodz Medical University.

Study design

The diagnosis of pancreatic tumors was established by ultrasound, computed tomography or endoscopic methods (EUS, ECPW). Histological samples were obtained by different methods: Endoscopic ultrasound-guided fine needle aspiration, brushing at ECPW or surgical sampling. The size of the tumor ranged from 1.5 to 6.0 cm in PDAC patients. At the time of diagnosis most tumors were over 3 cm in size (55.5%) and localized in the head of pancreas (86%). PDAC patients were classified according to the TNM classification: T1 = 21 patients (28%); T2 = 31 patients (42%); T3 = 10 patients (13%); T4 = 12 patients (16%); N0 = 55 patients (74%); N1 = 19 patients (26%); M0 = 47 patients (64%); and M1 = 27 patients (36%). Twenty-eight (38%) of PDAC patients had coexisting CP. Twenty-four PDAC patients (56%) had an average weight (BMI 18.5-24.99; mean 23.1 kg/m²), 11 patients were obese, 2 were overweight and 6 had a BMI under 18.5. Diabetes mellitus, if not diagnosed earlier, was detected with an abnormal glucose tolerance test (OGTT) in 24 PDAC patients.

The diagnosis of CP was determined by standard imaging criteria and clinical course. The diagnosis of

CP was based on the following findings: Calcifications, pancreatic stones, dilatation, stenosis or cyst formation of the main pancreatic duct and its branches shown by ultrasound, computed tomography or endoscopic retrograde pancreatography. Most CP patients had a history of alcohol abuse (42 patients, 59.2%). CP patients were classified into two groups according to Cambridge classification^[25]: 23 patients with mild CP (normal + equivocal + mild) and 43 with severe CP (moderate + marked). Among the studied CP patients, most (31 patients, 77%) had an average weight (BMI 18.5-24.99, mean 21.1 kg/m²), 4 were obese, none were overweight and 5 had a BMI under 18.5. Mean CP duration was 5.9 years (range 1-19). Diabetes mellitus coexisted in 30 patients (42.5%). All cases were DM type 2. We also evaluated the potential prognostic value of tested substances in PDAC, correlating survival with TGF- β 1, MCP-1, s-Fr and HA serum levels.

Peripheral venous blood samples were obtained from all analyzed patients at the time of hospital admission. Serum TGF- β 1, MCP-1, s-Fr and HA concentrations were determined with ELISA (Corgenix United Kingdom Ltd R and D Systems). Correlation of chemokines, cytokines and clinical data at the time of diagnosis in CP and PDAC patients was evaluated.

Statistical analysis

Statistical analysis and graphical data presentation were performed using PANDAS (Python Data Analysis Library) and Matplotlib in the IPython Notebook environment. The significance of differences between the groups was assessed using non-parametric methods (Mann-Whitney test). Two-sided *P* values were computed and a difference was considered statistically significant at *P* \leq 0.05.

RESULTS

Patients with CP and PDAC had a significantly higher plasma HA level (199 ± 254 and 270 ± 358 vs 40 ± 26 ng/mL, *P* < 0.0001) (Figure 1) compared to the controls. In CP patients, the TGF- β 1 level was 1066 ± 582 pg/mL and in PDAC patients, 888 ± 356 pg/mL, which was significantly higher than in healthy controls, 264 ± 93 pg/mL, *P* < 0.0001 (Figure 2). Our study showed a significant difference between s-Fr level in CP and PDAC patients compared to controls (2.42 ± 1.385 and 2.41 ± 1.275 vs 0.6 ± 0.370 ng/mL, *P* < 0.0001) (Figure 3).

MCP-1 level did not significantly differ between CP (313 ± 453 pg/mL) and PDAC (318 ± 481 pg/mL) patients or controls (252 ± 288 pg/mL), (*P* = NS) (Figure 4).

There was no significant differences between s-Fr, HA, TGF- β 1 and MCP-1 levels in CP and PDAC patients.

In CP patients, only the s-Fr level depended on the duration of the disease (Figure 5). In patients with a CP duration of more than 5 years, serum level of s-Fr

Figure 2 Serum transforming growth factor-β1 in pancreatic adenocarcinoma and chronic pancreatitis patients compared to healthy controls. PDAC: Pancreatic adenocarcinoma; TGF-β1: Transforming growth factor-β1; CP: Chronic pancreatitis.

Figure 4 Serum monocyte chemoattractant protein-1 in pancreatic adenocarcinoma and chronic pancreatitis patients compared to healthy controls. MCP-1: Monocyte chemoattractant protein - 1; PDAC: Pancreatic adenocarcinoma; CP: Chronic pancreatitis.

was significantly higher compared to CP patients with a shorter disease clinical course (2.639 ± 1.125 vs 1.87 ± 0.970 , $P < 0.03$).

In patients with PDAC and diabetes, serum level of TGF-β1 was significantly higher than in PDAC without endocrine insufficiency (986 ± 341 vs 844 ± 364 , $P < 0.05$) (Figure 6).

No significant differences between serum level of TGF-β1, s-Fr, HA or MCP-1 depending on etiology, age, gender, endocrine insufficiency or Cambridge score in CP patients were found.

There was no correlation between tumor size, localization, TNM classification or coexisting CP and serum TGF-β1, MCP-1, s-Fr and HA levels in patients with PDAC. No tested substances in PDAC patients was related to survival.

The levels of tested substances also did not correlate with each other in both pancreatic diseases. The relationship of the levels of fibrosis markers and desmoplasia in PDAC should be examined in patients who undergo resection. However, in our study only 9 PDAC patients had surgery and statistical analysis

requires a larger study group.

DISCUSSION

In this study, we showed that CP patients had elevated serum levels of HA, TGF-β1, s-Fr but not MCP-1 compared to the healthy controls. Similarly, Yasuda *et al.*^[26] showed elevation of TGF-β1 and s-Fr but not MCP-1 levels in patients with CP. In the Pedersen *et al.*^[27] study, serum MCP-1 levels were also not different in patients with CP and controls. However, in experimental rat CP models, serum and pancreatic MCP-1 concentration significantly increased with the progression of fibrosis^[28]. It is known that migration of monocytes is one of the earliest events in the formation of pancreatic fibrosis. Thus, MCP-1 is considered to be a profibrogenic factor in the progression of chronic pancreatitis and is thought to be a marker of early stage pancreatitis^[29]. It may be assumed that the level of MCP-1 is normalized in patients with a longer disease clinical course.

Our results showed a significantly higher serum level of s-Fr in CP with a duration over 5 years compared

Figure 5 Serum soluble fractalkine level depends on the duration of chronic pancreatitis. s-Fr: Serum soluble fractalkine; CP: Chronic pancreatitis.

to those with a shorter clinical course. Other studies confirmed that the s-Fr serum level increases with the progression of CP^[30]. Ceyhan *et al.*^[30] assessed the s-Fr and its receptor (CX3CR1) levels in CP and normal pancreas by QRT-PCR, Western Blot and immunohistochemistry analyses. Their expression correlated with the severity of fibrosis and CP duration.

The observations of D'Heese *et al.*^[31] also suggest that s-Fr level correlates noticeably with severe fibrosis and the presence of pain in CP. Ceyhan *et al.*^[30] showed that fractalkine mRNA expression was associated with the severity of fibrosis in CP and CP duration.

Evaluation of serum in CP patients revealed significantly higher TGF- β 1 levels compared to healthy controls. This corresponds with the findings of Detlefsen *et al.*^[32] who studied material obtained after surgical resection. They found TGF- β receptors expressed on most myofibroblasts in the pancreatic tissue from CP patients. Moreover, receptors were mainly expressed in the early to moderate stages of pancreatic fibrosis.

In cases with more advanced tissue damage, the expression of TGF- β receptor appeared to be less intense than during the early stages^[32]. This finding may suggest that TGF- β 1 should be taken into consideration as an early stage fibrosis marker.

Other authors suggested that the expression of TGF- β 1 in CP tissue (detected by PCR assay and confirmed by Western blot assay) rises with the severity of CP assessed by the presence of exocrine and endocrine insufficiency, pain (scored 0-4) and complications associated with CP^[26]. However, no correlation between CP advancement and TGF- β 1 levels was found in our study.

We found that serum levels of HA, TGF- β 1, s-Fr were elevated in PDAC patients compared to healthy controls. Similar results were obtained by Erkan *et al.*^[33] who described elevated levels of extracellular matrix proteins, laminin, procollagen III peptide (P-III-P) and HA in patients with PDAC. The levels of tested substances increased with the fibrosis advancement. In our study,

Figure 6 In pancreatic adenocarcinoma patients with coexisting diabetes mellitus, transforming growth factor- β 1 serum level was significantly higher than in pancreatic adenocarcinoma patients without endocrine insufficiency. TGF- β 1: Transforming growth factor- β 1.

we found that plasma TGF- β 1 levels were elevated in PDAC patients with coexisting diabetes compared to patients without endocrine insufficiency. This finding corresponds with the findings that TGF- β signaling stimulation inhibits proliferation of the pancreatic β -cells *in vitro*^[34]. Furthermore, overexpression of TGF- β 1 in the pancreatic β -cells of transgenic mice (which express TGF- β -inducible early response gene on acinar cells) induces islet cell development from ductular-like structures^[35]. We did not find any studies analyzing the correlation between TGF- β 1 levels in pancreatic disorders and co-existing diabetes in humans in the current literature.

In our study, there was no significant difference between the concentration of MCP-1 in PDAC patients and healthy controls. Some authors have hypothesized that serum MCP-1 levels are elevated in obese PDAC patients. In our study, MCP-1 level was not significantly higher in PDAC patients with a BMI above 25 compared to those with a normal weight. Other findings show a correlation of high circulating MCP-1 levels in obese individuals in general^[36]. This may be the reason why mostly cachectic or average weight PDAC and CP patients do not show elevated MCP-1 levels.

Other investigators have suggested that MCP-1 may be the differentiation marker for benign and malignant lesions (comparing PDAC and IPMN)^[37]. However, our results showed no differences between MCP-1 levels in PDAC and CP patients. We were also looking for a correlation between various clinical features and levels of tested markers in CP patients. No significant differences between serum level of TGF- β 1, s-Fr, HA and MCP-1 depending on etiology, age, gender, endocrine insufficiency or Cambridge score in CP patients were found. In our study, the level of s-Fr was not significantly higher in those with alcohol-related CP compared to CP of other etiologies. In the CP rats study, Uchida *et al.*^[38] proved a positive correlation of fractalkine level and alcohol intake. They used Wistar/Bonn Kobori (WBN/Kob) rats, widely accepted as a rodent model of CP.

We also looked for the correlation between various clinical features and levels of tested markers in CP patients. No correlation was found between tumor size, localization and serum TGF- β 1, MCP-1, s-Fr and HA levels.

Our results reveal that the levels of the markers did not correlate with each other. Similar results were published by Ito^[29] who showed that serum s-Fr did not correlate with MCP-1 or TGF- β 1 in CP patients. Our results were confirmed in the Adrych *et al.*^[39] study in which no association between serum TGF- β 1 and serum hyaluronic acid in CP patients was found. Our study confirmed that levels of fibrosis markers are elevated in CP and PDAC patients compared to healthy controls. However, tested substances do not distinguish CP from PDAC so they are not useful in a differential diagnosis. We did not find a correlation between marker levels and coexisting CP in PDAC patients.

Despite the considerable progress that has been made recently, the PDAC and CP prognosis is still poor and there are no specific treatments that can alter the course of these diseases.

The present study reveals that serum TGF- β 1, s-Fr and HA may be considered additional diagnostic markers of CP and PDAC. This study showed a relationship between the duration of CP and serum concentration of s-Fr. Elevated s-Fr levels in CP patients with a longer disease clinical course suggest a correlation of the severity of CP and the advancement of fibrosis. Thus, s-Fr may be considered a biological marker of CP and may be useful to assess the progression of CP.

Our results confirm results from other studies, suggesting that s-Fr could be used as an early stage PDAC marker before the invasive stage begins^[40]. Moreover, TGF- β 1 level was elevated in patients with concomitant diabetes. Therefore, assessing TGF- β 1 level may be useful to predict endocrine insufficiency in PDAC patients.

COMMENTS

Background

Late diagnosis of chronic pancreatitis or pancreatic adenocarcinoma limits treatment and results in a worse prognosis. Despite worldwide investigation, suitable diagnostic markers have not been proposed yet.

Research frontiers

Different serum fibrosis markers are taken into consideration as diagnostic and prognostic markers.

Innovations and breakthroughs

This is the first study to evaluate different fibrosis markers in the serum of chronic pancreatitis (CP) and pancreatic ductal adenocarcinoma (PDAC) patients compared to healthy controls. Significantly higher s-Fr, HA and transforming growth factor- β 1 serum levels compared to healthy controls suggest the potential utility of tested substances as diagnostic markers.

Applications

The presented results require further investigations in a larger study group.

Terminology

Pancreatic fibrosis is the characteristic feature of chronic pancreatitis and

pancreatic ductal adenocarcinoma. Revealing desmoplasia at an early stage can be a useful diagnostic tool.

Peer-review

This study presents a topic of interest in a diagnostic field. The methods and study population are adequate and the conclusions are reasonable and of possible practical use. This article presents an important issue and is the first study to evaluate different fibrosis markers in the serum of CP and PDAC patients compared to healthy controls.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Deliang Cao, MD, PhD, Associate Professor, Department of Medical Microbiology, Immunology and Cell Biology, Simmons Cooper Cancer Institute, Springfield, IL 62794, United States

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Colorectal cancer (CRC) is a significant cause of cancer-related morbidity and mortality all over the world. Improvements of cytotoxic and biologic agents have

prolonged the survival in metastatic CRC (mCRC), with a median overall survival of approximately 2 years and more in the past two decades. The biologic agents that have proven clinical benefits in mCRC mainly target vascular endothelial growth factor (VEGF) and epidermal growth factor receptor (EGFR). In particular, bevacizumab targeting VEGF and cetuximab and panitumumab targeting EGFR have demonstrated significant survival benefits in combination with cytotoxic chemotherapy in the first-line, second-line, or salvage setting. Aflibercept, ramucirumab, and regorafenib are also used in second-line or salvage therapy. Recent retrospective analyses have shown that *KRAS* or *NRAS* mutations were negative predictive markers for anti-EGFR therapy. Based on the evidence from large randomized clinical trials, personalized therapy is necessary for patients with mCRC according to their tumor biology and characteristics. The aim of this paper was to summarize the results of the major randomized clinical trials and highlight the benefits of the molecular targeted agents in patients with mCRC.

Key words: Metastatic colorectal cancer; Aflibercept; Ramucirumab; Regorafenib; Cetuximab; Panitumumab; Targeted therapy; Bevacizumab

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The development of molecular targeted agents contributes to prolonging survival of patients with metastatic colorectal cancer (mCRC). One anti-vascular endothelial growth factor agent, bevacizumab, and two anti-epidermal growth factor receptor (EGFR) agents, cetuximab and panitumumab, have demonstrated clinical benefits in first-line, second-line, or salvage therapy in combination with cytotoxic chemotherapy. Moreover, *RAS* mutation has been proven to be a negative biomarker for anti-EGFR therapy in recent retrospective analyses. This article summarizes the evidence from large clinical trials and highlights the benefit of the molecular targeted agents in patients with mCRC.

Ohhara Y, Fukuda N, Takeuchi S, Honma R, Shimizu Y, Kinoshita I, Dosaka-Akita H. Role of targeted therapy in metastatic colorectal cancer. *World J Gastrointest Oncol* 2016; 8(9): 642-655 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i9/642.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i9.642>

INTRODUCTION

Colorectal cancer (CRC) is one of the most common causes of cancer-related mortality^[1]. Earlier diagnosis through screening colonoscopy and improvements of treatment techniques have contributed to prolonged survival in the curable stage of CRC^[2]. Nevertheless, metastases are present in about 25% of patients with CRC at the time of diagnosis, and almost 50% of patients with CRC in total will develop metastases. Unfortunately, although the prognosis is usually limited in metastatic CRC (mCRC), systemic chemotherapy can control the disease, alleviate the symptoms related to cancer, and prolong survival^[3]. Systemic chemotherapy for mCRC consists mainly of fluoropyrimidines [intravenous 5-fluorouracil (5-FU) and oral capecitabine], irinotecan, and oxaliplatin. The most common treatment regimens for mCRC are FOLFIRI [bolus and infusional 5-FU/leucovorin (LV) plus irinotecan], FOLFOX (bolus and infusional 5-FU/LV plus oxaliplatin), and CapeOX (oral capecitabine plus oxaliplatin). These combination therapies have contributed to improving the response rate (RR) and prolonging survival in patients with mCRC^[4-6].

Since the Mid 2000s, biologic agents have been developed and demonstrated further clinical benefit in combination with cytotoxic chemotherapy. The biologic agents used for mCRC target angiogenesis (bevacizumab, aflibercept, ramucirumab, and regorafenib) and the epidermal growth factor receptor (EGFR) (cetuximab and panitumumab)^[7]. Bevacizumab has shown clinical benefit with both irinotecan-based and oxaliplatin-based regimens^[8-11]. Moreover, the continuation of bevacizumab after failure of first-line bevacizumab-containing chemotherapy was found to contribute to prolonging the survival of patients with mCRC^[12]. Anti-EGFR antibody agents, cetuximab and panitumumab, demonstrated a survival benefit in mCRC patients^[13,14]. At first, these agents were used in all mCRC patients, and then, no benefit of anti-EGFR agents was observed in mCRC tumors with activating mutation of *KRAS* exon 2^[15-17]. In addition, several recent studies have shown that all-*RAS* mutations in exon 2, 3, or 4 of *KRAS* or *NRAS* were negative predictive factors for anti-EGFR treatment^[18-20]. From these results, cetuximab and panitumumab have been used only in mCRC patients with *RAS* wild type.

The results of the major randomized clinical trials are summarized, and the benefits of the molecular targeted agents in patients with mCRC are highlighted.

ANTI-ANGIOGENIC AGENTS

Angiogenesis is a constitutional process to form a new

vascular network, through budding from host vascular endothelial cells and inserting into the pre-existing blood vessels. Especially in malignant tumors, angiogenesis plays important roles in tumor progression, invasion, and metastasis to distant organs^[21]. Vascular endothelial growth factor (VEGF) is one of the important factors that regulate tumor angiogenesis. VEGF is a family of secreted polypeptides that consists of five members [VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF)]^[22,23]. The members of the VEGF family bind to three variants of receptors, VEGFR-1 (FLT-1), VEGFR-2 (FLK-1/KDR), and VEGFR-3 (FLT-4)^[24,25]. VEGFR-2 is mainly responsible for the angiogenic pathway, whereas VEGFR-1 can act as a soluble circulating form that regulates VEGF binding to cell surface receptor^[26].

Anti-angiogenic agents exert their anti-neoplastic activities not only by inhibiting tumor angiogenesis but also by normalizing the tumor blood vessels. Vessel normalization ensures drug delivery to the tumor, which can increase the efficacy of cytotoxic agents^[27]. Thus, inhibition of angiogenesis has become a key strategy in cancer treatment^[28,29].

Bevacizumab

Bevacizumab is a recombinant humanized monoclonal IgG antibody that selectively binds to VEGF-A, and it demonstrates anti-tumor activity by blocking VEGFR2^[30,31]. It was first approved in 2004 by the United States Food and Drug Administration (FDA) for CRC in combination with other cytotoxic agents. Because of its functional activity, adverse events are mainly related to blood vessels. In several large trials, vascular-related adverse events such as hypertension, arterial/venous thromboembolic events, bleeding, gastrointestinal perforation, wound healing complications, fistula/intra-abdominal abscess, and proteinuria were reported^[32,33]. Rarely, reversible posterior leukoencephalopathy, which can cause various neurological symptoms, has been reported^[34]. Most of these adverse events are manageable by appropriate medication and withdrawal of bevacizumab.

First-line treatment: The benefit of bevacizumab added to chemotherapy was first reported in the AVF2107g trial^[8], in which 813 previously untreated mCRC patients were randomly assigned to either IFL (irinotecan, fluorouracil, and leucovorin) plus bevacizumab or IFL plus placebo. The addition of bevacizumab showed significant improvements in overall survival [OS, 20.3 mo vs 15.6 mo, hazard ratio (HR) = 0.66, $P < 0.001$], progression-free survival (PFS, 10.6 mo vs 6.2 mo, HR = 0.54, $P < 0.001$), and RR (44.8% vs 34.8%, $P = 0.004$). From this result, the FDA first approved bevacizumab in combination with 5-FU-based first-line chemotherapy in mCRC. Later, FOLFIRI plus bevacizumab showed a further survival benefit compared with modified IFL (mIFL) plus bevacizumab in the phase III BICC-C trial^[35]. The FOLFIRI arm had

a trend to longer PFS (11.2 mo vs 8.3 mo, $P = 0.037$) and OS (28.0 mo vs 19.2 mo, $P = 0.28$) compared with the mIFL arm. The RR was not significantly different between the two arms (57.9% vs 53.3%). Based on these results, FOLFIRI plus bevacizumab also became one of the standard regimens in the first-line treatment of mCRC.

Oxaliplatin-based chemotherapy combined with bevacizumab was evaluated in the NO16966 trial^[9,36]. In this pivotal 2x2 factorial randomized phase III trial, 1400 mCRC patients were assigned to oxaliplatin-based first-line chemotherapy (FOLFOX4/CapeOX) with or without bevacizumab. Although the median OS (21.3 mo vs 19.9 mo, HR = 0.89, $P = 0.0769$) and RR [38% vs 38%, odds ratio (OR) = 1.00, $P = 0.99$] were not significantly different between the two arms, the median PFS was significantly improved in the bevacizumab-containing arm compared with the placebo arm (9.4 mo vs 8.0 mo, HR = 0.83, $P = 0.0023$). Similar results were shown in the randomized phase II TREE-1/2 trial, which evaluated the safety and efficacy of bevacizumab added to chemotherapy (mFOLFOX6/bFOL/CapeOX)^[37]. Moreover, the benefit of cetuximab added to chemotherapy plus bevacizumab was evaluated in the CAIRO2 trial^[38]. However, in this phase III trial, the combination of CapeOX plus cetuximab and bevacizumab resulted in a significant decrease in PFS and no difference in OS and RR compared to CapeOX plus bevacizumab alone. In the *KRAS* wild type population, there were no significant differences in PFS (10.5 mo vs 10.4 mo, $P = 0.30$) and OS (21.8 mo vs 22.4 mo, $P = 0.64$), while RR was higher in chemotherapy with cetuximab than in chemotherapy without cetuximab. In the CAIRO2 trial, although patients with *KRAS* mutant type might have had a worse outcome for PFS and OS, no survival benefit of adding cetuximab onto bevacizumab plus chemotherapy was observed even in the *KRAS* wild population. Moreover, a meta-analysis also showed the poor prognosis of the combination of anti-EGFR agents and bevacizumab^[39].

Tegafur/gimeracil/oteracil (S-1) plus oxaliplatin (SOX regimen) for mCRC patients showed efficacy and safety in several trials from Asia^[40]. The phase III SOFT trial investigated the non-inferiority of SOX plus bevacizumab in comparison with mFOLFOX6 plus bevacizumab^[41]. The median PFS was 11.7 mo in the SOX plus bevacizumab arm compared with 11.5 mo in the mFOLFOX6 plus bevacizumab arm [HR = 1.04, $P = 0.015$ (non-inferiority)], and OS was 29.6 mo vs 29.7 mo [HR = 1.018, $P = 0.0133$ (non-inferiority)].

Recently, a combination of all cytotoxic agents (5-FU, oxaliplatin, and irinotecan) was developed to maximize tumor response as the FOLFOXIRI regimen in the treatment of mCRC^[42]. Based on this strategy, the efficacy and safety of FOLFOXIRI plus bevacizumab were evaluated in the TRIBE trial^[43]. In this trial, 508 mCRC patients were randomly assigned to receive FOLFOXIRI plus bevacizumab or FOLFIRI plus bevacizumab. Although FOLFOXIRI plus bevacizumab did not improve

OS (31.0 mo vs 25.8 mo, HR = 0.83, $P = 0.125$), a prolonged PFS (12.1 mo vs 9.7 mo, HR = 0.77, $P = 0.006$) and a higher RR (65% vs 53%, OR = 1.64, $P = 0.006$) were observed in the FOLFOXIRI plus bevacizumab arm compared with the FOLFIRI plus bevacizumab arm. The incidence of grade 3/4 adverse events, especially neutropenia, diarrhea, and stomatitis, was significantly higher in the FOLFOXIRI plus bevacizumab arm than in the FOLFIRI plus bevacizumab arm.

In elderly patients, there is no clear evidence of safety with the combination of bevacizumab with oxaliplatin or irinotecan-based chemotherapy. The AVEX trial was designed to evaluate the efficacy and safety of bevacizumab plus capecitabine in mCRC patients aged 70 years and older^[44]. In this trial, 280 elderly patients with a median age of 76 years (range 70-87 years) were randomized to bevacizumab plus capecitabine or capecitabine alone. PFS was improved with the addition of bevacizumab compared to capecitabine alone (9.1 mo vs 5.1 mo, HR = 0.53, $P < 0.0001$). Improved RR was also observed with bevacizumab plus capecitabine (19.3% vs 10.0%, $P = 0.042$), though OS was not significantly different (20.7 mo vs 16.8 mo, HR = 0.79, $P = 0.182$). Although the incidence of grade 3 or worse adverse events related to chemotherapy was slightly higher in the combination group (40% vs 22%), the combination of bevacizumab and capecitabine was a well-tolerated regimen (Table 1).

Second-line and salvage treatment or beyond progression:

In the E3200 trial, FOLFOX plus bevacizumab as second-line therapy in patients with mCRC after first-line irinotecan-based therapy without bevacizumab demonstrated significantly longer PFS and OS compared with the control arm of FOLFOX alone (PFS 7.3 mo vs 4.7 mo, HR = 0.61, $P < 0.0001$; OS 12.9 mo vs 10.8 mo, HR = 0.75, $P = 0.0011$)^[45]. It should be noted that bevacizumab was not administered in first-line therapy, and the dose of bevacizumab was higher (10 mg/kg) in this trial.

Furthermore, continuation of bevacizumab after disease progression in patients previously treated with bevacizumab seemed to have benefit in the large observational BRIT study^[46]. Based on this result, an open-label, phase III, ML18147 trial was conducted to evaluate the survival benefit of continuing bevacizumab as second-line chemotherapy^[12]. The use of bevacizumab beyond progression showed better OS (11.2 mo vs 9.8 mo, HR = 0.81, $P = 0.0062$) and PFS (5.7 mo vs 4.1 mo, HR = 0.68, $P < 0.0001$) compared with chemotherapy alone.

TAS-102 is a novel oral cytotoxic agent that contains the thymidine-based nucleic acid analogue, trifluridine, and a thymidine phosphorylase inhibitor, tipiracil hydrochloride. In salvage line treatment of mCRC, it was reported that TAS-102 could significantly improve OS compared with placebo in the RECURSE trial^[47]. Recently, the phase I/II C-TASK FORCE trial was conducted to investigate the efficacy and safety of

Table 1 Clinical trials of anti-angiogenic therapies in metastatic colorectal cancer

Trial name	Regimens	<i>n</i>	ORR	PFS (mo)	OS (mo)
First-line chemotherapy					
AVF2017g	IFL + Bevacizumab	402	44.8%	10.6	20.3
BICC-C	FOLFIRI + Bevacizumab	57	57.9%	11.2	28.0
NO16966	FOLFOX/CapeOX + Bevacizumab	699	38%	9.4	21.3
TREE-1/2	FOLFOX + Bevacizumab	71	52%	9.9	26.1
CAIRO2	CapeOX + Bevacizumab	378	50%	10.7	20.3
SOFT	SOX + Bevacizumab	256	61.5%	11.7	29.6
TRIBE	FOLFOXIRI + Bevacizumab	252	65.1%	12.1	31.0
AVEX ¹	Capecitabine + Bevacizumab	140	19.3%	9.1	20.7
Second-line, salvage-line chemotherapy, or beyond progression					
E3200	FOLFOX + Bevacizumab	286	22.7%	7.3	12.9
ML18147	Chemotherapy + Bevacizumab	410	5.4%	5.7	11.2
C-TASK FORCE	TAS-102 + Bevacizumab	25	4.0%	5.6	11.2
VELOUR	FOLFIRI + Afibercept	612	19.8%	6.9	13.5
RAISE	FOLFIRI + Ramucirumab	536	13.4%	5.7	13.3
CORRECT	Regorafenib	505	1.0%	1.9	6.4

¹AVEX trial enrolled mCRC patients aged 70 years and older. ORR: Objective response rate; PFS: Progression-free survival; IFL: Bolus 5-fluorouracil/leucovorin/irinotecan; FOLFIRI: Bolus and infusional 5-fluorouracil/leucovorin/irinotecan; FOLFOX: Bolus and infusional 5-fluorouracil/leucovorin/oxaliplatin; CapeOX: Capecitabine/oxaliplatin; SOX: S-1 (tegafur/gimeracil/oteracil)/oxaliplatin; FOLFOXIRI: Infusional 5-fluorouracil/leucovorin/irinotecan/oxaliplatin; OS: Overall survival; mCRC: Metastatic colorectal cancer.

TAS-102 plus bevacizumab in the salvage line setting. Median OS was 11.2 mo and PFS was 5.6 mo. In addition, although the RR was only 4.0%, the disease control rate was 72% with tolerable toxicity. However, the sample size was quite small ($n = 25$)^[48] (Table 1).

Aflibercept

Aflibercept is a recombinant fusion protein that can bind to VEGF-A, VEGF-B, and PlGF. It can act as a soluble decoy receptor, preventing these ligands from binding to their receptors and inhibiting the VEGF pathway. In the VELOUR study, aflibercept plus FOLFIRI demonstrated significant improvements in OS (13.5 mo vs 12.1 mo, HR = 0.82, $P = 0.032$) and PFS (6.9 mo vs 4.7 mo, HR = 0.76, $P < 0.0001$) compared with placebo plus FOLFIRI in previously treated mCRC patients^[49]. The RR was 19.8% in the aflibercept plus FOLFIRI arm and 11.1% in the FOLFIRI alone arm ($P = 0.0001$). The profile of adverse events was similar to that previously reported with bevacizumab, but some adverse events associated with cytotoxic agents were reported at a higher incidence in the aflibercept arm (Table 1).

Ramucirumab

Ramucirumab is a human IgG-1 monoclonal antibody targeting the extracellular domain of VEGFR-2, which is the primary mediator of the VEGF pathway. By binding to VEGFR-2, ramucirumab prevents all VEGF ligands from binding to VEGFR-2 and inhibits the VEGF pathway. In the phase III RAISE study, 1072 patients with disease progression on bevacizumab, oxaliplatin, and fluoropyrimidine were randomized to ramucirumab plus FOLFIRI or FOLFIRI alone as second-line treatment^[50]. Ramucirumab plus FOLFIRI demonstrated better OS (13.3 mo vs 11.7 mo, HR = 0.84, $P = 0.0219$) and PFS (5.7 mo vs 4.5 mo, HR = 0.79, $P < 0.0005$)

than FOLFIRI alone. The RR was similar in the two arms (13.4% in ramucirumab plus FOLFIRI vs 12.5% in FOLFIRI alone), as was the frequency of serious adverse events (36% in ramucirumab plus FOLFIRI vs 31% in FOLFIRI alone). From this result of RAISE, ramucirumab was approved in 2015 by FDA for mCRC in combination with FOLFIRI (Table 1).

Regorafenib

Regorafenib is an oral multi-kinase blocker that inhibits the activity of several protein kinases related to the angiogenic pathway (VEGFR-1, VEGFR-2, VEGFR-3, TIE-2), the oncogenic pathway (KIT, RET, RAF1, BRAF), and the tumor microenvironment (PDGFR and FGFR)^[51]. The CORRECT trial was conducted to evaluate the efficacy and safety of regorafenib in patients with mCRC who had progressed after all approved standard therapies^[52]. Patients treated with regorafenib had slightly prolonged OS (6.4 mo vs 5.0 mo, HR = 0.77, $P = 0.0052$) and PFS (1.9 mo vs 1.7 mo, HR = 0.49, $P < 0.0001$) compared with placebo. The most frequent adverse events of grade 3 or higher were hand-foot skin reaction, fatigue, diarrhea, hypertension, and rash or desquamation. Of note, fatal drug-induced liver injury was observed (Table 1).

ANTI-EGFR AGENTS

EGFR is a transmembrane glycoprotein that belongs to the human epidermal growth factor receptor (HER)-erbB family of tyrosine kinase receptors^[53]. Ligand binding to EGFR leads to the autophosphorylation of the intracellular domain and activates the downstream signaling pathway, including RAS/RAF/MAPK, STAT, and PI3K/AKT. The activation of the signaling pathway modulates cell proliferation, adhesion, angiogenesis,

migration, and metastasis^[54,55].

Cetuximab and panitumumab are anti-EGFR monoclonal antibodies used for mCRC in daily practice. The mechanisms of cetuximab and panitumumab are described below. At present, the use of cetuximab or panitumumab is restricted only to mCRC patients with *KRAS* and *NRAS* wild type because it was found that cetuximab or panitumumab had no effect in mCRC patients with the activating mutation of *KRAS* and *NRAS* oncogene^[20,56].

Cetuximab

Cetuximab is a chimeric, anti-EGFR monoclonal antibody of the IgG1 class targeted against the extracellular domain of the EGFR. By binding to the EGFR, cetuximab blocks intracellular EGFR signaling and modulates tumor cell growth by inhibiting proliferation, angiogenesis, and differentiation, stimulating apoptosis, and preventing metastasis^[57,58]. Cetuximab was first approved in 2004 in combination with irinotecan for mCRC patients with irinotecan-refractory disease. After that, several experimental analyses showed that the activating mutation of *KRAS* exon 2 was associated with intrinsic resistance to cetuximab. Given these findings, cetuximab was used only in mCRC patients with *KRAS* wild type^[15,56]. Moreover, recently, some reports revealed that use of anti-EGFR drugs for mCRC contributed to acquisition of a *KRAS* mutation^[59,60]. Misale *et al.*^[59] offered two possible explanations for the discordant results of *KRAS*: Heterogeneity of *KRAS* status within the primary tumor; and clonal selection during the process of metastasis. In this report, among 10 patients with *KRAS* wild type who acquired resistance to anti-EGFR therapy, 6 patients had the *KRAS* mutation after progression on anti-EGFR therapy. In the six patients for whom sufficient pre-treatment tumor samples were available for *KRAS* testing, *KRAS* mutations were found to be absent at pre-treatment. Similarly, Diaz *et al.*^[60] showed that emergence of mutant *KRAS* from wild type *KRAS* was a mediator of acquired resistance to anti-EGFR antibodies. These results indicate that treatment with anti-EGFR antibodies is associated with the acquisition of secondary *KRAS* mutations.

The most common toxicities are skin rash and hypomagnesemia^[61,62]. To prevent severe skin toxicity, preventive skin treatments are often performed for patients treated with cetuximab.

First-line treatment in *KRAS*-WT mCRC: The efficacy of cetuximab combined with chemotherapy in the first-line setting for mCRC was evaluated in two pivotal clinical trials: The phase III CRYSTAL study and the phase II OPUS study^[63-66].

In the CRYSTAL study, 1198 mCRC patients were randomly assigned to two treatment groups: FOLFIRI plus cetuximab or FOLFIRI alone. Tumor samples from 1063 patients were used for *KRAS* mutation analysis, and 397 patients (37%) had *KRAS* codon 12 and 13 mutations. Of 666 patients (63%) with *KRAS* wild type,

the benefit of addition of cetuximab to FOLFIRI was demonstrated as significantly improved RR (57.3% vs 39.7%, OR = 2.07, $P < 0.001$), PFS (9.9 mo vs 8.4 mo; HR = 0.70, $P = 0.0012$), and OS (23.5 mo vs 20.0 mo; HR = 0.80, $P = 0.0093$) compared with FOLFIRI alone. In the OPUS study, 337 mCRC patients received either FOLFOX-4 alone or FOLFOX-4 plus cetuximab. *KRAS* analysis was performed in 315 of the 337 cases. Among these patients, 179 (57%) were *KRAS* wild type. In the *KRAS* wild type population, patients treated with cetuximab in combination with FOLFOX-4 demonstrated a higher RR (57% vs 34%; OR = 2.551, $P = 0.0027$) and a better PFS (8.3 mo vs 7.2 mo; HR = 0.567, $P = 0.0064$) compared with those treated with FOLFOX-4 alone. No benefit in terms of OS was observed (22.8 mo vs 18.5 mo; HR = 0.855, $P = 0.39$).

In contrast, the phase III COIN trial including 1630 patients with mCRC who were randomized to an oxaliplatin-based regimen (FOLFOX or CapeOX) with or without cetuximab did not show any benefit with the addition of cetuximab to chemotherapy in terms of PFS (8.6 mo vs 8.6 mo; HR = 0.96, $P = 0.60$) and OS (17.0 mo vs 17.9 mo; HR = 1.04, $P = 0.67$) compared with chemotherapy alone, even in the *KRAS* wild type population^[67,68]. However, exploratory subgroup analyses demonstrated that the cohort of patients treated with FOLFOX plus cetuximab showed improved PFS (HR = 0.72, $P = 0.037$), while the cohort of CapeOX plus cetuximab had no significant difference in PFS compared with chemotherapy alone (HR = 1.02, $P = 0.88$). The RR improved from 57% to 64% with the addition of cetuximab to the oxaliplatin-based regimen. In the COIN trial, exploratory analyses were conducted in order to identify somatic molecular profile of the EGFR pathway, and its relationship to the site of the primary and metastases^[69]. *KRAS* mutations were more common in the right colon as compared to those from the left colon, and *BRAF* mutations were more common from the transverse and right colon as compared to those from the left colon. *KRAS* mutations were associated with lung-only metastases, *BRAF* mutations with peritoneal and nodal-only metastases, and microsatellite instability was associated with nodal-only metastases. At the point of differences between primary sites, other study reported that hepatic and pulmonary metastases were more frequently found in left-sided carcinomas, and peritoneal metastasis in right-sided carcinomas in the analyses based on 17641 patients with mCRC^[70]. Moreover, NORDIC VII was conducted to investigate the efficacy of cetuximab combined with the FLOX regimen^[71]. Patients were randomized to the following three arms: FLOX alone, cetuximab and FLOX, or cetuximab combined with intermittent FLOX. Even in patients with *KRAS* wild type, there was no evidence that cetuximab adds a significant benefit to NORDIC FLOX in first-line treatment of mCRC. From these negative results of the COIN and NORDIC VII studies, it seems that neither CapeOX nor FLOX is suitable for combination therapy with cetuximab.

Table 2 Clinical trials of anti-epidermal growth factor receptor therapies in metastatic colorectal cancer with *KRAS* wild type

Trial name	Regimens	n	ORR	PFS (mo)	OS (mo)
First-line chemotherapy					
CRYSTAL	FOLFIRI + Cetuximab	316	57.3%	9.9	23.5
OPUS	FOLFOX + Cetuximab	159	57%	8.3	22.8
COIN	FOLFOX/CapeOX + Cetuximab	362	64%	8.6	17.0
NORDIC-VII	FLOX + Cetuximab	97	46%	7.9	20.1
PRIME	FOLFOX + Panitumumab	325	55%	9.6	23.9
Second-line, salvage-line chemotherapy, or beyond progression					
20050181 trial	FOLFIRI + Panitumumab	303	36%	6.7	14.5
PICCOLO	Irinotecan + Panitumumab	230	34%	5.5	10.4
CO.17	Cetuximab	117	13%	3.7	9.5
20020408 trial	Panitumumab	124	17%	12.3 wk	8.1

ORR: Objective response rate; PFS: Progression-free survival; OS: Overall survival; FOLFIRI: Bolus and infusional 5-fluorouracil/leucovorin/irinotecan; FOLFOX: Bolus and infusional 5-fluorouracil/leucovorin/oxaliplatin; CapeOX: Capecitabine/oxaliplatin; FLOX: Bolus 5-fluorouracil/leucovorin/oxaliplatin.

In adding cetuximab to cytotoxic chemotherapy, the FOLFOX or FOLFIRI regimen is considered the best partner in mCRC patients with *KRAS* wild type. Thus, based on the positive results of the CRYSTAL and OPUS studies, the addition of cetuximab to FOLFOX or FOLFIRI was established as a gold standard in mCRC patients with *KRAS* wild type (Table 2).

Second-line and salvage treatment in *KRAS*-WT mCRC: Cetuximab monotherapy was compared with best supportive care (BSC) in heavily pretreated patients with mCRC after failure of fluoropyrimidines, irinotecan, and oxaliplatin (NCIC CO.17 trial)^[72]. A total of 572 mCRC patients were randomized to cetuximab plus BSC or BSC alone. Cetuximab improved OS and PFS and preserved quality of life measures. After the CO.17 trial, a retrospective analysis was performed to determine whether *KRAS* mutation status was associated with survival in the cetuximab and BSC groups^[16]. A total of 69% (394/572) of the cases were examined for *KRAS* mutation status. A *KRAS* mutation was detected in 40.9% of the cetuximab group and in 42.3% of the BSC group. For patients with *KRAS* wild tumors, treatment with cetuximab compared with supportive care alone significantly improved OS (9.5 mo vs 4.8 mo; HR = 0.55; $P < 0.001$) and PFS (3.7 mo vs 1.9 mo; HR = 0.40; $P < 0.001$).

The efficacy of cetuximab in combination with chemotherapy in the salvage setting was evaluated in two randomized clinical trials: The BOND-1 trial and the EPIC trial^[13,14]. The BOND-1 trial was a randomized phase III study that enrolled 329 patients with irinotecan-resistant mCRC. The superiority of cetuximab plus irinotecan in terms of RR and PFS was demonstrated compared with cetuximab alone. In the phase III EPIC trial, 1298 mCRC patients who experienced first-line fluoropyrimidine and oxaliplatin treatment failure were randomly assigned to either irinotecan plus cetuximab or irinotecan alone. The addition of cetuximab to irinotecan improved RR and PFS compared with irinotecan alone. However, both trials did not show the

benefit of cetuximab in combination with chemotherapy with respect to OS compared with monotherapy. So far, the detailed results of *KRAS* status in the BOND and EPIC trials have not been published (Table 2).

Panitumumab

Panitumumab is a fully human, monoclonal antibody targeting the EGFR with high affinity. The mechanism of inhibiting EGFR signaling pathway is similar to that of cetuximab, as described above^[73]. Panitumumab was first approved in 2006 by the United States FDA for the treatment of EGFR-expressing mCRC with disease progression despite prior treatment. The most common toxicities are skin rash and hypomagnesemia, like cetuximab. The utility of preventive skin treatment in panitumumab therapy has been reported in prospective studies^[74,75].

First-line treatment in *KRAS*-WT mCRC: The phase III PRIME study was conducted in chemo-naïve mCRC patients to evaluate the efficacy of panitumumab in combination with the FOLFOX-4 regimen in the first-line setting^[76]. In the PRIME study, 1183 mCRC patients were randomly assigned to receive FOLFOX-4 with or without panitumumab. The *KRAS* status of the tumors was available in 1096 of these patients (93%), and 440 patients (40%) had a mutation of *KRAS* status. In the *KRAS* wild type population, the FOLFOX-4 plus panitumumab arm had significantly improved PFS compared with the FOLFOX-4 arm (9.6 mo vs 8.0 mo; HR = 0.80, $P = 0.002$). There was no significant difference between FOLFOX-4 plus panitumumab and FOLFOX-4 alone in terms of OS and RR (OS 23.9 mo vs 19.7 mo, HR = 0.83, $P = 0.072$; RR 55% vs 48%, OR = 1.35, $P = 0.068$). This result of the PRIME study was similar to that of the OPUS trial. From the results of these two studies (phase II OPUS and phase III PRIME), the efficacy of the addition of anti-EGFR agents to oxaliplatin-based chemotherapy was demonstrated (Table 2).

Second-line and salvage treatment in KRAS-WT mCRC:

The role of panitumumab in combination with chemotherapy in the second-line or salvage setting for mCRC was evaluated in the following two trials. First, in the phase III 20050181 trial, 1186 patients were enrolled and randomized to two treatment arms: FOLFIRI plus panitumumab and FOLFIRI alone^[77,78]. The *KRAS* status of the tumors was investigated in 1083 cases (91%), and *KRAS* mutation was found in 45% (486/1083). In the wild type *KRAS* population, addition of panitumumab to the FOLFIRI regimen led to a significant improvement in PFS compared with FOLFIRI alone (6.7 mo vs 4.9 mo; HR = 0.82, *P* = 0.023). However, addition of panitumumab to chemotherapy did not show a significant difference in OS; and the FOLFIRI plus panitumumab arm had a trend to better OS than the FOLFIRI arm (14.5 mo vs 12.5 mo; HR = 0.92, *P* = 0.37). The RR was significantly higher in the panitumumab-containing regimen (36% vs 10%; OR = 5.50, *P* < 0.0001). Second, in the PICCOLO trial, irinotecan plus panitumumab was compared with irinotecan alone as a salvage treatment in patients with fluorouracil-resistant mCRC^[79]. Whereas no significant difference was observed in OS between the groups (10.4 mo vs 10.9 mo; HR = 1.01, *P* = 0.91), the irinotecan plus panitumumab group had a longer PFS (5.5 mo vs 4.7 mo; HR = 0.78, *P* = 0.015) and a higher RR (34% vs 12%; OR = 4.12, *P* < 0.0001) than the irinotecan monotherapy group.

The efficacy of panitumumab monotherapy for *KRAS* wild type mCRC was evaluated in the phase III 20020408 study^[17,80]. Patients with mCRC were randomly assigned to either panitumumab monotherapy or BSC alone. Patients treated with panitumumab had better RR and PFS compared with those with BSC (RR 17% vs 0%; PFS 12.3 wk vs 7.3 wk, HR = 0.45, *P* < 0.0001). Although no significant difference in OS was observed between the panitumumab arm and the BSC arm (8.1 mo vs 7.6 mo; HR = 0.99), this was because 76% (90/119) of patients with BSC received panitumumab treatment after progression under the cross-over protocol (Table 2).

The benefit of panitumumab treatment for mCRC patients with cetuximab-refractory disease was evaluated in several clinical trials. In the PANERB trial, 106 mCRC patients with *KRAS* wild type who experienced progression on cetuximab-based chemotherapy were enrolled^[81]. Of the 106 patients, 48 (45%) had an objective response with the cetuximab-containing treatment. Among these 48 patients, 15 (31%) had an objective response, and 23 (47%) in total had a clinical benefit with panitumumab therapy. On the other hand, 28 of 106 patients had disease progression on cetuximab-based treatment. Of these 28 patients, only 4 patients (14%) had clinical benefit with panitumumab therapy. Moreover, some clinical trials showed that panitumumab was not active (RR, 0%) as a salvage therapy in patients with cetuximab-resistant *KRAS* wild type mCRC^[82,83].

TREATMENT STRATEGY ACCORDING TO *KRAS* OR ALL *RAS* WILD TYPE mCRC

Anti-VEGFR and anti-EGFR treatments for patients with KRAS wild type mCRC

Recently, three large randomized clinical trials (PEAK, FIRE-3, and CALGB/SWOG 80405) were conducted to compare anti-EGFR agent-containing chemotherapy with bevacizumab-containing chemotherapy in *KRAS* wild type mCRC patients in the first-line setting (Table 3).

First, the phase II PEAK study was conducted in 285 mCRC patients with wild-type *KRAS* to compare FOLFOX plus panitumumab with FOLFOX plus bevacizumab as first-line treatment^[18]. Although median PFS was similar between the panitumumab arm and the bevacizumab arm (10.9 mo vs 10.1 mo; HR = 0.87, *P* = 0.353), median OS was significantly prolonged in the panitumumab arm compared with the bevacizumab arm (34.2 mo vs 24.3 mo; HR = 0.62, *P* = 0.009). The RR was 57.8% in the panitumumab arm and 53.5% in the bevacizumab arm. Second, the phase III FIRE-3 study was conducted to evaluate the superiority of FOLFIRI plus cetuximab to FOLFIRI plus bevacizumab in mCRC patients with *KRAS* wild type as first-line treatment^[19]. A total of 592 patients with *KRAS* wild type tumors were randomly assigned and received treatment, with 297 in the FOLFIRI plus cetuximab group and 295 in the FOLFIRI plus bevacizumab group. The FIRE-3 study did not show differences in terms of RR (62% in the cetuximab group vs 58% in the bevacizumab group; OR = 1.18, *P* = 0.18) and PFS (10.0 mo in the cetuximab group vs 10.3 mo in the bevacizumab group; HR = 1.06, *P* = 0.55), while OS was prolonged in the cetuximab-containing regimen (28.7 mo in the cetuximab group vs 25.0 mo in the bevacizumab group; HR = 0.77, *P* = 0.017). Finally, in the CALGB/SWOG 80405 study, 1137 patients with *KRAS* wild type were randomized to two arms: Cytotoxic chemotherapy (FOLFOX or FOLFIRI) plus cetuximab or bevacizumab^[84]. No benefit of the cetuximab-containing regimen was observed for PFS (10.4 mo vs 10.8 mo; HR = 1.04, *P* = 0.55) or OS (29.9 mo vs 29.0 mo; HR = 0.925, *P* = 0.34) compared with the bevacizumab-containing regimen. The RR was significantly higher in the cetuximab arm than in the bevacizumab arm (65.6% vs 57.2%, *P* = 0.02).

The efficacy of panitumumab combined with FOLFIRI in the second-line setting was evaluated in the phase II SPIRITT study^[85]. The SPIRITT study compared FOLFIRI in combination with panitumumab or bevacizumab for *KRAS* wild type mCRC patients with progression on a bevacizumab-containing oxaliplatin-based regimen. A total of 182 patients were randomly assigned to FOLFIRI combined with panitumumab or bevacizumab. Median PFS and OS were similar between the FOLFIRI with panitumumab arm and the FOLFIRI with bevacizumab arm (PFS 7.7 mo vs 9.4 mo, HR = 1.01, *P* = 0.97; OS 18.0 mo vs 21.4 mo; HR = 1.06, *P* = 0.75). The RR

Table 3 Clinical trials comparing anti-epidermal growth factor receptor therapy *vs* anti-vascular endothelial growth factor therapy in metastatic colorectal cancer with *KRAS* wild type

Trial name	Regimens	n	ORR	PFS (mo)	OS (mo)
First-line chemotherapy PEAK	FOLFOX + Panitumumab	142	57.8%	10.9	34.2
	FOLFOX + Bevacizumab	143	53.5%	10.1	24.3
	(HR, <i>P</i> -value)		-	HR = 0.87	HR = 0.62
				<i>P</i> = 0.353	<i>P</i> = 0.009
FIRE-3	FOLFIRI + Cetuximab	297	62%	10.0	28.7
	FOLFIRI + Bevacizumab	295	58%	10.3	25.0
	(HR, <i>P</i> -value)		OR = 1.18	HR = 1.06	HR = 0.77
			<i>P</i> = 0.18	<i>P</i> = 0.55	<i>P</i> = 0.017
CALGB/SWOG 80405	Chemotherapy ¹ + Cetuximab	578	65.6%	10.4	29.9
	Chemotherapy ¹ + Bevacizumab	559	57.2%	10.8	29.0
	(HR, <i>P</i> -value)		<i>P</i> = 0.02	HR = 1.04	HR = 0.925
				<i>P</i> = 0.55	<i>P</i> = 0.34
Second-line chemotherapy SPIRITT	FOLFIRI + Panitumumab	91	32%	7.7	18.0
	FOLFIRI + Bevacizumab	91	19%	9.2	21.4
	(HR, <i>P</i> -value)		-	HR = 1.01	HR = 1.06
				<i>P</i> = 0.97	<i>P</i> = 0.75

¹Chemotherapy regimens were FOLFOX or FOLFIRI. ORR: Objective response rate; PFS: Progression-free survival; OS: Overall survival; HR: Hazard ratio; OR: Odds ratio; FOLFIRI: Bolus and infusional 5-fluorouracil/leucovorin/irinotecan; FOLFOX: Bolus and infusional 5-fluorouracil/leucovorin/oxaliplatin.

was 32% in the panitumumab arm and 19% in the bevacizumab arm.

Treatment outcome of anti-EGFR therapy for patients with *RAS* wild type mCRC

An activating mutation of *KRAS* exon 2 has been found to be a negative predictive marker in mCRC, as described above. *KRAS* status was used for patient selection for anti-EGFR treatment. *NRAS* is one of the *RAS* oncogene family members, and somatic mutations like *KRAS* gene have been detected within the *NRAS* gene. A retrospective analysis of the PRIME study showed that 17% of patients with *KRAS* exon 2 wild type had mutations in *RAS* exons (*KRAS* exon 3, 4 and *NRAS* exon 2, 3). An activating mutation of *NRAS* exon 4 was not detected in this analysis^[19]. Patients with all-*RAS* wild type who received panitumumab plus FOLFOX had a prolonged OS compared with those with *KRAS* exon 2 wild type (25.8 mo in *RAS* wild type and 23.9 mo in *KRAS* wild type). A similar outcome was demonstrated in the CRYSTAL study^[86]. From these results, the negative predictive factors were any mutations in either *KRAS* or *NRAS* codons 12, 13, 59, 61, 117, and 146 hotspots. Now, all-*RAS* wild type patients can be defined as those without the above mutations.

All-*RAS* subset analyses were performed in three randomized clinical trials that compared anti-EGFR agent-containing chemotherapy with bevacizumab-containing chemotherapy: PEAK, FIRE-3, and CALGB/SWOG 80405. In PEAK and FIRE-3, a further survival benefit was observed in the anti-EGFR arm compared with the bevacizumab arm in mCRC patients with *RAS* wild type (OS in PEAK, 41.3 mo vs 28.9 mo, HR = 0.63, *P* = 0.058; OS in FIRE-3, 33.1 mo vs 25.6 mo, HR = 0.70, *P* = 0.011)^[18,19]. In contrast, CALGB/SWOG 80405

demonstrated no significant difference in OS between cetuximab plus chemotherapy and bevacizumab plus chemotherapy even in the *RAS* wild type population (32.0 mo vs 31.2 mo, HR = 0.90, *P* = 0.40)^[84]. The outcomes of these trials were discussed in several groups^[87-90]. Meta-analyses of the three studies were performed for the *RAS* wild type subset in order to compare anti-EGFR therapy with anti-VEGF therapy^[87]. Although no significant difference in PFS was observed between anti-EGFR and anti-VEGF agents combined with chemotherapy (HR = 0.92, 95%CI: 0.71-1.18, *P* = 0.50), the anti-EGFR arm had better OS (HR = 0.77, 95%CI: 0.63-0.95, *P* = 0.016) and RR (OR = 1.46, 95%CI: 1.13-1.90, *P* = 0.004) compared with the anti-VEGF arm. On the other hand, these three clinical trials aimed to reveal the superiority of anti-EGFR therapy compared with anti-VEGF therapy in *KRAS* wild type mCRC, but they did not meet the primary endpoints of their studies; the primary endpoint was PFS in PEAK, RR in FIRE-3, and OS in CALGB/SWOG 80405. Although anti-EGFR therapy in the first-line setting has a favorable trend compared with anti-VEGF therapy, the treatment strategy in *RAS* wild type mCRC has been controversial. In the future, one ongoing clinical trial may resolve this problem. The phase III STRATEGIC-1 by GERCORE is now ongoing to investigate the appropriate sequential strategy for *RAS* wild type mCRC^[91]. In the STRATEGIC-1 trial, patients are randomized to receive either FOLFIRI plus cetuximab as first-line followed by oxaliplatin-based regimen combined with bevacizumab as second-line, or an oxaliplatin-based regimen by OPTIMOX plus bevacizumab as first-line followed by an irinotecan-based regimen combined with bevacizumab as second-line and by anti-EGFR therapy with or without irinotecan as third-line. We eagerly await the results of this trial (Table 4).

Table 4 Treatment outcome by anti-epidermal growth factor receptor therapy as first-line treatment in metastatic colorectal cancer with *RAS* wild type

Trial name	Regimens	<i>n</i>	ORR	PFS (mo)	OS (mo)
CRYSTAL	FOLFIRI + Cetuximab	178	66.3%	11.4	28.4
	FOLFIRI	189	38.6%	8.4	20.2
	(HR, <i>P</i> -value)		OR = 3.31 <i>P</i> < 0.001	HR = 0.56 <i>P</i> = 0.0002	HR = 0.69 <i>P</i> = 0.0024
PRIME	FOLFOX + Panitumumab	259	-	10.1	25.8
	FOLFOX	253	-	7.9	20.2
	(HR, <i>P</i> -value)		-	HR = 0.72 <i>P</i> = 0.004	HR = 0.77 <i>P</i> = 0.009
PEAK	FOLFOX + Panitumumab	88	63.6%	13.0	41.3
	FOLFOX + Bevacizumab	82	60.5%	9.5	28.9
	(HR, <i>P</i> -value)		-	HR = 0.65 <i>P</i> = 0.029	HR = 0.63 <i>P</i> = 0.058
FIRE-3	FOLFIRI + Cetuximab	171	65%	10.4	33.1
	FOLFIRI + Bevacizumab	171	60%	10.2	25.6
	(HR, <i>P</i> -value)		OR = 1.28 <i>P</i> = 0.32	HR = 0.93 <i>P</i> = 0.54	HR = 0.70 <i>P</i> = 0.011
CALGB/SWOG 80405	Chemotherapy ¹ + Cetuximab	270	68.6%	11.4	32.0
	Chemotherapy ¹ + Bevacizumab	256	53.8%	11.3	31.2
	(HR, <i>P</i> -value)		<i>P</i> < 0.01	HR = 1.1 <i>P</i> = 0.31	HR = 0.9 <i>P</i> = 0.4

¹Chemotherapy regimens were FOLFOX or FOLFIRI. ORR: Objective response rate; PFS: Progression-free survival; OS: Overall survival; HR: Hazard ratio; OR: Odds ratio; FOLFIRI: Bolus and infusional 5-fluorouracil/leucovorin/irinotecan; FOLFOX: Bolus and infusional 5-fluorouracil/leucovorin/oxaliplatin.

OTHER TARGETED AGENTS

The efficacy of chemotherapy combined with tyrosine kinase inhibitor of the EGFR (gefitinib or erlotinib) was evaluated in several phase II studies. First, a total of 27 patients with pretreated mCRC received FOLFOX plus gefitinib in the single-arm phase II study^[92]. The RR was 33% and median PFS was 5.4 mo. Most common grade 3/4 toxicities were neutropenia (48%) and diarrhea (48%). Second, the phase II study was conducted in 100 mCRC patients to compare FOLFIRI plus gefitinib with FOLFIRI alone as first-line setting^[93]. The adding gefitinib to FOLFIRI demonstrate no improvement of RR (47.9% vs 45.1%) or PFS (8.3 mo vs 8.3 mo) compared with FOLFIRI alone, but had more toxicities with grade 3/4 (67.3% vs 52.1%). Finally, the efficacy of capecitabine plus erlotinib in chemo-naïve mCRC patients was evaluated in a small sample size phase II study^[94]. A total of thirteen patients with mCRC were enrolled in this phase II study. The RR was 20% (2/10), but 4 of 13 patients discontinued therapy because of adverse events. From these results, the adding the EGFR tyrosine kinase inhibitor with chemotherapy showed high toxicities and no improvement of ORR.

Two targeted agents, ganitumab and conatumumab, were evaluated in the randomized phase II study in mCRC patients with mutant *KRAS* as second-line setting^[95]. Ganitumab is a human IgG monoclonal antibody targeting the type I insulin-like growth factor receptor and conatumumab is a fully human monoclonal IgG1 antibody targeting the proapoptotic death receptors 5. A total of 155 patients were randomized 1:1:1 to receive FOLFIRI plus conatumumab, ganitumab, or placebo. The median PFS was 6.5 mo (HR = 0.69; *P* = 0.147), 4.5 mo

(HR = 1.01; *P* = 0.998), and 4.6 mo. The median OS was similar between three arms (12.3 mo vs 12.4 mo vs 12.0 mo).

Recently, the clinical benefit of dual-targeted therapy with trastuzumab and lapatinib in patients with *KRAS* wild type, HER2-positive mCRC in the phase II HERACLES study^[96]. In the HERACLES study, 914 patients with *KRAS* exon 2 wild type were screened, and 48 (5%) patients were identified as HER2-positive status. A total of 27 patients with HER2-positive received trastuzumab plus lapatinib treatment as salvage setting. The ORR was 30% and the toxicity was tolerable. The combination of trastuzumab plus lapatinib might be a novel therapeutic option for patients with HER2-positive mCRC.

CONCLUSION

The development of biological and cytotoxic agents has contributed to prolonged survival in mCRC patients, with a median OS of approximately two years and more. In the past two decades, many beneficial therapeutic options and regimens have appeared in daily practice for mCRC, based on the results from randomized clinical trials. Personalized therapy should be performed for mCRC patients according to their clinical and biological factors, such as performance status, organ function, metastasis sites, and tumor biology including *RAS* status. Especially in *RAS* wild type mCRC, anti-EGFR agents, such as cetuximab and panitumumab, have been shown to improve objective response and survival in several clinical trials. Anti-EGFR agents are absolutely key drugs for the *RAS* wild type population. Based on the evidence for anti-EGFR therapy as first-line, second-

line, and salvage therapy, we should plan personalized treatment strategies for patients with RAS wild type mCRC. On the other hand, bevacizumab in combination with chemotherapy has demonstrated clinical benefits in any treatment line. Bevacizumab has been shown to fit any cytotoxic regimens, such as FOLFOX, CapeOX, FOLFIRI, FOLFOXIRI, SOX, or TAS-102. Moreover, continuing bevacizumab beyond progression prolonged survival in mCRC patients who experienced clinical benefit in prior bevacizumab-containing chemotherapy. In addition, we have many biological agents for the second-line or salvage therapy, such as aflibercept, ramucirumab, and regorafenib. Based on the evidence and patients' characteristics, it will be necessary to construct personalized therapy for mCRC patients.

Abstract

Pancreatic cancer is the fifth leading cause of cancer death and has the lowest survival rate of any solid cancer. Endoscopic ultrasound-guided fine-needle aspiration biopsy (EUS-FNA) is currently capable of providing a cytopathological diagnosis of pancreatic malignancies with a higher diagnostic power, with a sensitivity and specificity of 85%-89% and 98%-99%, compared to pancreatic juice cytology (PJC), whose sensitivity and specificity are only 33.3%-93% and 83.3%-100%. However, EUS-FNA is not effective in the cases of carcinoma *in situ* and minimally invasive carcinoma because both are undetectable by endoscopic ultrasonography, although PJC is able to detect them. As for the frequency of complications such as post endoscopic retrograde cholangiopancreatography pancreatitis, EUS-FNA is safer than PJC. To diagnose pancreatic cancer appropriately, it is necessary for us to master both procedures so that we can select the best methods of sampling tissues while considering the patient's safety and condition.

Key words: Endoscopic ultrasound-guided fine-needle aspiration biopsy; Cytology; Pathology; Pancreatic juice cytology; Pancreatic cancer

Core tip: In the era of cyto-pathological diagnosis of pancreatic cancer, endoscopic ultrasound-guided fine-needle aspiration biopsy (EUS-FNA) and pancreatic juice cytology (PJC) represent the most promising procedures for diagnosing pancreatic malignancies. However, there haven't been any reports that compared the utilities and faults of these procedures. In this review we have

highlighted the current role of EUS-FNA and PJC in the diagnosis process for pancreatic malignancies.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) currently ranks fifth when it comes to death involving cancer. It also, when it comes to solid cancers, has the lowest survival rate^[1,2]. The current survival rate for patients with PDAC after 5 years with the condition is less than 3.5%^[3,4]. An early diagnosis is crucial to improve the prognosis. However, for a number of reasons, including the inaccessibility of the pancreas and the highly malignant property of the disease, an early diagnosis is still difficult to obtain, despite the constant improvements in diagnostic imaging. Furthermore, it is especially difficult to distinguish between a PDAC and a pancreatic inflammatory lesion, which includes chronic pancreatitis (CP), or a benign stricture of the main pancreatic duct (MPD), and between intra-ductal papillary mucinous carcinoma IPMC and intra-ductal papillary mucinous neoplasm (IPMN). Being able to differentiate PDAC from other conditions is important, because not only are the treatments for each of these conditions different, but the prognosis for CP and other rare tumors is better than that for PDAC. A cyto-pathological diagnosis is desirable before beginning therapy in cases in which a qualitative diagnosis for the pancreatic mass by various imaging studies is not possible. In fact, 5%-10% underwent pancreatoduodenectomy based on a diagnosis that was made before surgery. However, after performing surgery of the primary pancreatic or periampullary malignancy, it is later proven histopathologically to be CP, a benign fibrous common bile duct stricture or so on^[5-7]. After performing endoscopic ultrasound-guided fine-needle aspiration biopsy (EUS-FNA) for a pancreatic mass, the frequency of a PDAC does not reach 80%^[8,9], which is very important because the treatment strategy for a resection case and an unresectable case are different between PDAC and pancreatic neuroendocrine tumor cases^[10-14].

There are many diagnostic procedures in cytopathological treatment including, abdominal ultrasound guided fine-needle aspiration biopsy, computed tomography guided fine-needle aspiration biopsy, EUS-FNA, pancreatic juice cytology (PJC), and Endoscopic pancreatography guided biopsy. I will give an outline mainly on EUS-FNA and PJC in this review.

PROCEDURE OF AN EUS-FNA

Vilmann *et al.*^[15] was the first person to describe the EUS-FNA of a pancreatic mass in 1992. These days, EUS-FNA is the preferred method to sample pancreatic mass lesions, replacing for the most part other methods because EUS-FNA is considered the best diagnostic modality for pancreatic masses with a higher accuracy than that of biopsies under CT or US guidance.

There is a door knocking method and a fanning method in EUS-FNA. The door knocking method is a nice procedure that is useful in obtaining a specimen from a mass, especially one with fibrotic tissue, and, as for the fanning method, the utility is proved by RCT^[16].

FNA needles, which are available in sizes from 19 to 25 gauge (G), are available commercially. A recent meta-analysis suggests that a 22-G and a 25-G needle have a similar specificity rate after being used with 1292 patients being diagnosed with pancreatic malignancies^[17]. The same study showed that the 25-G needle did appear to have a higher sensitivity when compared to the 22-G needle. Another study found that 25-G needles seemed to be more advantageous over the 22-G needles when it comes to the adequacy of passes. No difference in accuracy, number of passes or complications was found^[18]. However, 25-G needles should be considered first in cases in which one must sample from the pancreatic head or uncinate process lesions, as in some studies it has appeared that the 25-G needle has a reduced chance of experiencing technical failures over 22-G needles in such situations^[19,20]. 19-G needles, on the other hand, are not often used in the duodenum because of their natural rigidity. However, recently, a more flexible needle has been made of nitinol to improve its ability to function well (Flex 19, Boston Scientific, Natick, MA). An initial study using these new and improved needles included 38 patients. Thirty-two of the 38 patients had pancreatic head/uncinate lesions. The use of the needles provided adequate samples for cytological analysis in all 32 patients. There were no reported technical failures or procedure related complications^[21]. Ramesh *et al.*^[22] reported that there is no significant difference in the performance of flexible 19-G and 25-G needles although the procurement of histological core tissue with the flexible 19-G needles was significantly higher (88% vs 44%, $P < 0.001$).

As for aspiration, there is a report that compared non-aspiration, aspiration of 10 mL, the aspiration of the slow pull method, and 10-20 mL, but a constant opinion was not obtained from the sampling rate about accuracy^[23-27].

EUS-FNA accuracy is also impacted by the skill level and whether or not a cytopathologist is available^[28-30]. It has recently been shown, in a meta-analysis that covered 34 studies, that rapid on-site evaluation had a significant determinant on the accuracy of EUS-FNA when it comes to the diagnosis of pancreatic masses^[28]. Two studies have evaluated the optimal number of EUS-

FNA passes^[29,31] to be 5-7 passes for pancreatic masses in order to get the best diagnostic yield. For situations in which rapid pathology interpretation is not possible, this information may prove to be useful.

It is considered that the white specimens in EUS-FNA samples include histological evidence, and, as for the red specimen, it is thought to be the blood component. When inspected by a 19-G needle, a histologic core was found to be present in white specimens 78.9% of the time, and in red specimens 9.3% of the time^[32]. It is reported in multiple meta-analysis that ROSE is useful in solving the problem mentioned above^[28,33].

Whereas, a meta-analysis suggests 25-G needles have a higher sensitivity rate than 22-G needles when it comes to diagnosing pancreatic malignancy^[17], it is expected in the future that EUS-FNA by using a 25-G needle will become more mainstream because of the ease of its puncture. At that time, reexamination re-examination may be required if it is necessary to perform immunohistochemical staining after performing ROSE, due to the smaller sample size meaning a decreased chance of there being a histologic core in the sample. Furthermore, there is a fundamental problem in that globally, there are not enough pathologists capable of performing ROSE.

We developed the target sample check illuminator (TSCI) to be a device that would solve the above problem^[34]. The mean number of needle punctures was 2.4 (range, 1-5), and the agreement rate between TSCI and histopathology in 142 samples was 93.7% (133/142). No differences in detection capacity were observed in cancerous or non-cancerous lesions. When presence of the target specimen was confirmed by TSCI, 91.4% (53/58) of the patients were able to finish the tests, and the mean number of needle punctures was 1.2 (67/58).

DIAGNOSTIC POWER OF EUS-FNA

Two recent studies reported a sensitivity of 85% and 89% based on cytology for the diagnosis of malignancy. The specificity for the same was found to be 98% and 99% respectively^[28,35].

It is useful in the improvement of the diagnostic ability of EUS-FNA to use a genetic analysis from EUS-FNA samples. Recent meta-analysis reported that combining K-ras mutation analysis with routine cytology moderately improves the ability of EUS-FNA to differentially diagnose between PDAC and pancreatic inflammatory masses. In a total of eight studies, with 696 cases of PDAC and 138 cases of pancreatic inflammatory masses, the pooled sensitivity, specificity, positive likely ratio and negative likely ratio of K-ras mutation analysis combined with cytopathology for diagnosis of PDAC vs pancreatic inflammatory masses were 90%, 95%, 13.45, and 0.13, respectively. Especially, among total 123 patients whose EUS-FNA results were inconclusive or negative, fifty-nine

had K-ras mutations and were finally diagnosed with PDAC (48%, 59/123)^[36]. In addition, there are several possible means of processing aspirated samples obtained by EUS-FNA for molecular and other ancillary tests^[37].

COMPLICATION WITH EUS-FNA

Complications from EUS-FNA include pain, bleeding, fever, and infection. Rare complications such as, acute portal vein thrombosis^[38], peritoneal seeding of tumor cells^[39], and ruptured pseudoaneurysm of the splenic artery^[40] have also been reported. A recent systematic review by Wang *et al.*^[41], who identified 51 articles with a total of 10941 patients, reported that the mortality rate attributable to EUS-FNA-specific morbidity was 0.02% (2/10941) and that out of 8246 patients with pancreatic lesions only 60 (0.82%) patients reported any complications. About 36/8246 patients had pancreatitis. Of those patients, 75% of the cases were mild. Out of the total number of patients, one of them with severe pancreatitis died. The total rates of pain, bleeding, fever and infection were 0.38%, 0.10%, 0.08% and 0.02% respectively. Two point two percent of patients were reported to have peritoneal seeding of tumor cells after receiving EUS-FNA. However, it seems to be lower than that caused by CT-guided FNA (16.3%)^[42]. There was no increase in the risk of peritoneal carcinomatosis in pancreatic masses to be found^[43]. Beane *et al.*^[44] found there to be no difference in the survival rate of patients with PDAC who underwent EUS-FNA than with those who did not. Not only was there no difference, but a recent study that looked at the risk of gastric/peritoneal recurrence in cases where EUS-FNA was performed found EUS-FNA was not associated with increased needle track seeding^[45]. Furthermore, preoperative EUS-FNA was evaluated in 498 patients, and it was found that it had no negative effect on the survival rate of patients with resected pancreatic cancer^[46].

LIMITATION FOR EUS-FNA

Even though EUS-FNA has an excellent accuracy and a low incidence of major complications, it does have several limitations. We cannot perform EUS-FNA when we cannot detect a tumor in EUS. Actually, we cannot identify the carcinoma *in situ* (CIS) in EUS^[47]. Secondly, even though EUS-FNA has a very high sensitivity rate, when it comes to pancreatic tumors, its negative predictive value is only 55%-65%^[35,48]. As such, EUS-FNA does not allow us to rule out the possibility of a malignancy. Third, if the patient has CP the diagnostic accuracy of EUS-FNA decreases^[49,50]. It might also hinder cytological interpretation of pancreatic FNA, thus giving EUS-FNA a decreased sensitivity^[51]. Fourth, EUS-FNA for pancreatic cancer has a false-positive rate of 1.1%, usually in patients with CP^[52]. Fifth, we may not be able to perform EUS-FNA when we cannot

discontinue the use of an antithrombotic drug.

PROCEDURE, DIAGNOSTIC POWER, AND COMPLICATION OF PJC

McCune *et al.*^[53] developed the ERCP process in 1968. As for the sampling of the pancreas lesion, Endo was the first person to perform a collection of pancreatic juice under the ERP^[54]. The process of PJC is used in all of the following procedures: Brushing cytology, cytodiagnosis with pancreatic duct lavage fluid (PDLF), cytodiagnosis by using endoscopic nasopancreatic drainage (ENPD), and cytodiagnosis by using secretin. Now I will present the methods, diagnosis results, and complications of each procedure.

Brushing cytology

A cytopathological diagnosis by using brushing cytology is easier than conventional aspiration cytology because it can collect fresh cells.

However, the sensitivity (33.3%-65.8%) and the accuracy (46.7%-76.4%) are not so good because it is difficult to perform and collect enough cells^[55,56]. Recently, scraping cytology with a guide-wire yielded 71.4%-93% sensitivity, 100% specificity, 100% positive predictive value, 75%-84.4% negative predictive value, and 88.8%-94% accuracy^[8,57].

However, this diagnosis rate is shown to improve by mastering the procedure^[56].

When we diagnose a CIS by PJC for a pancreatic duct stenosis case, when we are unable to see the pancreatic mass in imaging studies, and resected it, it is usually the case that there is no cancer at the site of stenosis in the MPD. The stenosis is caused by inflammation due to a CIS, which was derived from a branch duct. For this reason, the diagnostic power of brushing cytology is uncertain. As for the complications rate of brush cytology, it has been reported that acute pancreatitis is a possible complication with a rate of 4.2%-33.3%^[8,55-57].

ENPD method

The ENPD method places 5 or 6-French ENPD tubes in the patient for up to 2-3 d^[58,59]. Iiboshi *et al.*^[58] diagnosed 15 CIS using this method. Sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy of the ENPD method for pancreatic cancer were 80%-100%, 83.3%-100%, 93.3%-100%, 71%-100%, and 87%-95%, respectively, revealing significantly higher sensitivity than the conventional method ($P = 0.0001$)^[58]. As for the complications of the ENPD method, post endoscopic pancreatitis (PEP) has a rate of 7.5%. In particular, the incidence rate of PEP of ENPD method for BD-IPMN is higher than the conventional method^[60].

Cytodiagnosis by using secretin

Due to the fact that secretin stimulates pancreatic exocrine function, we are able to obtain more pancreatic

juice when secretin is present than without it. Finally, we can obtain pancreatic epithelial cells by using secretin. Administration of secretin was performed conventionally before collecting pancreatic juice for cytodiagnosis^[54,60]. Secretin may be required in cases in which a sufficient amount of material was not able to be obtained by conventional methods or it may be needed to aspirate mucous fluid in intraductal papillary mucinous neoplasm^[57]. Nakaizumi reported that the sensitivity for PDAC was 76% in PJC by using secretin^[61]. As for the complications of secretin, at the top of the attached document, it shows a rate of 1.9% for nausea, 0.7% for flushing, and 0.5% for stomachache and vomiting^[62]. We have not experienced any adverse events with the secretin administration. Also, we confirmed that the quantity of pancreatic juice significantly increases even though the secretin load in diluted form is 1/32.

Cytodiagnosis with pancreatic duct lavage fluid

Imamura's process requires us to inject a saline from injection lumen, before aspirating it by the negative pressure from a guide-wire lumen with a different syringe at the same time by using double or triple-lumen cannule after brushing cytology in ERP. The sensitivity of pancreatic cancer diagnosis by this procedure is 83%, and pancreatitis was not a side-effect due to PDLF^[63]. We choose to do PJC by using secretin if a catheter is able to pass through the narrow segment of the MPD, and PDLF if the catheter cannot pass.

If secretin is used in cases where a catheter is unable to pass the stenosis of the MPD, the pancreatic ductal pressure in the caudad area past the stenosis increases, and this causes pancreatitis.

GENETIC ANALYSIS WITH PANCREATIC JUICE

It is useful in the improvement of the diagnostic ability of PJC to use a genetic and molecular analysis from PJC samples in cases in which a small quantity of specimen was obtained from PJC and the adjuvant diagnosis of the cytodiagnosis is negative. In a diagnosis for pancreatic cancer, sensitivity improves by adding the *K-ras* mutation analysis with routine cytology^[64]. There are some reports about the utilities of telomerase activity^[65], DNA methylation^[66], Smad4^[67], and KL-6^[68,69] measurement in pancreatic juice.

LIMITATION OF PJC

First, the accuracy of PJC is generally only around 40%-70%^[55,56] except in some institutions^[8,57,58]. Second, we cannot diagnose pancreatic neuroendocrine tumor, solid pseudopapillary neoplasm, or pancreatic acinar cell carcinoma, because they are not connected to the MPD. Third, it is hard to perform immunostaining because it is difficult to obtain a specimen as compared with EUS-FNA. Fourth, around 4.2%-33.3% of complications such as PEP

can occur after PJC^[8,55-57,60], but it is reported that the risk decreases for PEP with diclofenac administration. Elmunzer *et al.*^[70] reported that post-ERCP pancreatitis developed in 27 of 295 patients (9.2%) in the indomethacin group and in 52 of 307 patients (16.9%) in the placebo group ($P = 0.005$). Moderate-to-severe pancreatitis developed in 13 patients (4.4%) in the indomethacin group and in 27 patients (8.8%) in the placebo group ($P = 0.03$).

USE OF EUS-FNA AND PJC

Generally, EUS-FNA is better in diagnostic ability and adverse events than PJC. Therefore, if we can perform EUS-FNA, we should choose EUS-FNA, and it is desirable to only choose PJC in the following cases: (1) we can not detect a mass in EUS; (2) it is difficult to perform EUS-FNA when avoiding blood vessels and the MPD; (3) it is difficult to stop use of antithrombotic medicine; and (4) there aren't any institutions capable of performing EUS-FNA in the neighborhood.

Furthermore, there are some reports that the diagnostic accuracy of EUS-FNA and/or PJC was significantly higher than that of EUS-FNA or PJC alone^[8,71].

In conclusion, although there are some complications such as acute pancreatitis and dissemination, if the frequency of complications and the physical burden of surgery for patients are taken into consideration, it is perhaps better to obtain tissue before treatment begins. Since there are various methods of sampling tissue, it is important to choose the procedure while considering the patient's condition and safety.

Abstract

Helicobacter pylori (*H. pylori*) infection was thought to be the main cause of gastric cancer, and its eradication showed improvement in gastric inflammation and dec-

reased the risk of gastric cancer. Recently, a number of studies reported the occurrence of gastric cancer after successful eradication. Patients infected with *H. pylori*, even after eradication, have a higher risk for the occurrence of gastric cancer when compared with uninfected patients. Metachronous gastric cancer occurs frequently following the endoscopic removal of early gastric cancer. These data indicate that metachronous cancer leads to the occurrence of gastric cancer even after successful eradication of *H. pylori*. The pathogenesis of this metachronous cancer remains unclear. Further research is needed to identify biomarkers to predict the development of metachronous gastric cancer and methods for gastric cancer screening. In this article, we review the role of the *H. pylori* in carcinogenesis and the histological and endoscopic characteristics and risk factors for metachronous gastric cancer after eradication. Additionally, we discuss recent risk predictions and possible approaches for reducing the risk of metachronous gastric cancer after eradication.

Key words: *Helicobacter pylori*; Eradication; Atrophic gastritis; Intestinal metaplasia; Metachronous gastric cancer

Core tip: *Helicobacter pylori* (*H. pylori*) eradication and endoscopic resection appeared to reduce the risk of gastric cancer. However, recent studies show that the risk of metachronous gastric cancer increases in the background of gastric mucosal atrophy even after successful eradication. Thus, curing *H. pylori* infections may not prevent metachronous gastric cancer in background mucosa with intestinal metaplasia. We review the risk factors and possible approaches for reducing the risk of metachronous gastric cancer.

cancer after *Helicobacter pylori* eradication. *World J Gastrointest Oncol* 2016; 8(9): 663-672 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i9/663.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i9.663>

INTRODUCTION

Gastric cancer is the fourth most common cancer in the world and the second leading cause of cancer deaths worldwide with more than 700000 deaths annually^[1]. After the discovery of *Helicobacter pylori* (*H. pylori*) in 1983, the casual relationship between this bacterium and gastritis or gastric cancer has been steadily elucidated. In 1994, *H. pylori* was classified as a carcinogen by the International Agency for Research on Cancer of the World Health Organization (WHO). A 2009 meta-analysis showed that *H. pylori* eradication appeared to reduce the risk of gastric cancer^[2]. In Japan, approximately 99% of gastric cancers are caused by *H. pylori*; thus, *H. pylori*-negative gastric cancer constitutes less than 1% of all cases^[3].

H. pylori eradication has been one of the major therapeutic strategies to reduce gastric cancer incidence in healthy individuals and gastric cancer patients who have undergone endoscopic mucosal resection. The number of gastric cancers diagnosed and treated at an early stage increased after the development of endoscopic treatments. Ten years ago, more than 50% of early-stage gastric cancers were endoscopically treated, and the 5-year survival rate of early-stage gastric cancer patients after endoscopic treatment was 90%^[4]. Large lesions can be resected *en block*, including both the mucosa and submucosa, by endoscopic submucosal resection (ESD), which has improved histopathological diagnoses and decreased tumor recurrence. The endoscopic removal of early-stage gastric tumors does not affect the overall cancer risk. Research on gastric cancers after *H. pylori* eradication has been conducted for more than a decade. In 2008, an open-label, randomized controlled trial indicated that the occurrence of metachronous gastric cancer is reduced by approximately 1/3 after eradication^[5]. This study led to the recommendation of *H. pylori* eradication in patients with endoscopically treated gastric cancer. In Japan in 2013, health insurance covered *H. pylori* eradication as a treatment for gastritis, and this treatment was expected to reduce the incidence of gastric cancer^[6]. However, a subsequent Japanese study indicated that even after *H. pylori* infection is cured and gastric inflammation is eliminated, the risk for developing gastric cancer remains; furthermore, this risk was dependent on the level of gastric mucosal atrophy present before eradication therapy^[7]. Thus, the gastric mucosa endures continuous *H. pylori*-induced inflammation that increases the risk of metachronous gastric cancer even after treatment. Previous studies revealed that *H. pylori* eradication does not reduce the incidence of metachronous gastric cancer in patients who underwent endoscopic resection and recommended that

eradication should be performed before the progression of gastric mucosal atrophy. Extensive atrophy in the stomach and intestinal metaplasia of multiple areas causes gastric cancer and may increase the risk for metachronous gastric cancer when compared with cases of chronic gastritis mucosa^[8-11].

Currently, the success of a gastric cancer prevention strategy depends on timing because the treatment must be introduced before the progression of gastric carcinogenesis. However, recent studies on gastric cancer suppression suggested that critical features of gastric carcinogenesis can be reversed *via* molecular mechanisms.

Thus, monitoring patients for signs of gastric cancer after eradication is important. Here, we review the observed macroscopic and histological gastric mucosal changes, risks for metachronous gastric cancer, and possible approaches for reducing gastric cancer. We also discuss some of the potential molecular mechanisms for gastric cancer development after eradication.

H. PYLORI-INDUCED GASTRIC CANCER

A mechanism for carcinogenesis from *H. pylori*-triggered inflammation was first proposed by Correa^[12,13]. Correa proposed that chronic inflammation causes superficial gastritis that progresses to multifocal atrophic gastritis, followed by intestinal metaplasia, wherein gastric epithelium undergoes an "epithelial-mesenchymal transition" and begins to exhibit an intestinal phenotype. The subsequent stage consists of dysplasia culminating in invasive carcinoma, thus completing the "pre-cancerous cascade". This mechanism can be influenced by interactions between host and pathogen genotypes and environmental factors, such as socioeconomic indicators, a high-salt diet, low fruit/vegetable intake and smoking^[14]. In particular, *H. pylori* is the sole bacterium to be classified by the WHO as a class I carcinogen^[15].

Gastric cancer is an inflammation-associated cancer that occurs as a result of the infection which causes chronic, life-long, gastric mucosal inflammation. The pathogenesis of gastric cancer depends on the presence of genetic instability, that is, a consequence of *H. pylori*-induced acute and chronic inflammation, direct bacterial host interactions, and interactions with exogenous factors to produce carcinogens locally in the stomach^[16]. However it should be added that *H. pylori* is recognized as the primary cause of gastric cancer, it is a necessary but insufficient cause of gastric cancer which is typical of infectious cause of cancer such as relation between hepatitis C virus and liver cancer or human papilloma virus and cervical cancer.

Recent studies have shown that *H. pylori* infection causes gastric cancer by inducing gene mutations, aberrant DNA methylation, and disturbance of intracellular signaling pathways. Point mutations and aberrant DNA methylation accumulated even in normal mucosa, leading to field cancerization^[17,18]. We describe below a

molecular mechanism of the gastric cancer.

Field cancerization

Field cancerization was first proposed by Slaughter *et al.*^[19] based on a study of oral stratified squamous epithelium in 1953. This phenomenon, also known as widespread carcinogenesis, can be caused by long-term exposure to common cancer inducers in several body areas. During field cancerization, abnormalities caused by exposure to cancer inducers can accumulate while the organism continues to appear normal. *H. pylori* infections contribute to carcinogenesis and field cancerization by causing point mutations and DNA methylation abnormalities in the gastric mucosa.

Gene mutations caused by activation-induced deaminase

Activation-induced deaminase (AID) is a member of the cytidine deaminase family, which includes DNA- and RNA-editing enzymes. AID expression is highly regulated, restricted to germinal center B cells and essential for somatic hypermutation and class-switch recombination in B cells^[20]. Infection with cag pathogenicity island (cag PAI)-positive *H. pylori* ectopically induced the high expression of AID in human gastric epithelial cells, leading to multiple mutations in the *TP53* tumor suppressor gene.

AID expression is induced by the activation of NF- κ B caused by the *H. pylori*-induced inflammation in gastric epithelium cells. Additionally, *TP53* mutations are induced by AID-producing gastric epithelium cells, which play an important role in stomach carcinogenesis.

AID upregulation in *H. pylori*-infected stomachs occurs *via* the introduction of bacterial macromolecules through the type IV secretion system encoded by cag PAI and inflammatory cytokines, such as tumor necrosis factor (TNF), that are produced by *H. pylori*-related gastric inflammation. Infection with cag PAI-positive *H. pylori* resulted in aberrant AID expression in gastric epithelial cells, leading to the generation of somatic mutations in the host genome, such as the *TP53* gene. Cag PAI-positive *H. pylori* is more commonly associated with AID upregulation than cag PAI-negative *H. pylori*, and NF- κ B activation provides evidence linking the pathogenic strain of *H. pylori* to the accumulation of nucleotide alterations and the subsequent development of gastric cancer^[21].

DNA methylation abnormalities caused by chronic inflammation

H. pylori infection potently and temporarily induces methylation of multiple CpG islands (CGIs) in specific promoter regions, including tumor suppressor genes. Aberrant DNA methylation in gastric mucosa is associated with an increased risk of gastric cancer. Methylation levels in *H. pylori*-positive individuals were higher when compared with cases of *H. pylori*-negative gastric cancer^[22]. The persistence of DNA methylation in the

gastric mucosa decreases after *H. pylori* eradication^[17]. Chronic inflammation causes *H. pylori*-induced DNA methylation and thus may be more important than the infection itself. The expression of certain inflammatory genes, such as *TNF*, *IL-1 β* , and *Nos2*, increases DNA methylation^[23]. These data suggest a relationship between inflammatory signals and DNA methylation.

Disruption of intracellular signaling by the direct action of the virulence factor CagA

CagA is a protein produced by *H. pylori* that is directly injected into gastric epithelium cells through a type IV secretion system. Next, CagA activates Ras-Erk signaling by binding to Src homology 2-containing protein tyrosine phosphatase^[24,25]. Cell death in the gastric mucosa is inhibited by activating extracellular signal-regulated kinase and promoting myeloid cell leukemia-1 protein expression, which subsequently inhibits apoptotic cell death and delays the turnover of epithelial cells^[26].

Influence of *H. pylori* on carcinogenesis

Accumulation of point mutations: Frequent *TP53* mutations were discovered in the *H. pylori*-infected gastric mucosa of non-cancer patients using new sequencing technologies. Increased cytidine deaminase activity in these tissues appeared to increase these mutations and thus may promote gastric carcinogenesis in patients with *H. pylori* infection because most of the mutations were C: G to T: A^[27].

Accumulation of DNA methylation: The DNA methylation induced by helicobacter infection remains at the stem cell level in non-infected mucosa after eradication, and the residual methylation level correlates with carcinogenic risk^[17].

PREVENTION OF GASTRIC CANCER BY *H. PYLORI* ERADICATION

For one approach to inhibit gastric cancer, early prevention is important. *H. pylori* eradication stops the progression cancer risk and reverse some of mucosal damage. Multicenter clinical study results that the incidence of new gastric cancers who have a history of such disease and are thus at high risk for developing further gastric cancers was reduced by one-third among those with *H. pylori* eradication compared to no eradication therapy^[5]. This study also added that eradication did not prevent development on gastric cancer completely, the risk for gastric cancer is directly related to the degree of atrophy. A large-scale cohort study from Taiwan followed 80000 patients with peptic ulcer for 10 years after *H. pylori* eradication therapy^[28]. They reached the conclusions that the earlier eradication obviously reduce the incidence of gastric cancer. A meta-analysis of randomized controlled trials in 2014 showed that *H. pylori* eradication decreased the risk for gastric cancer in healthy asymptomatic infected individuals by

34%^[29]. However it remains unclear whether *H. pylori* eradication among those at lower risk. On the other hand, when there is not *H. pylori* infection, and there is not inflammation of the stomach, it may be said that you do not need to worry about gastric cancer immediately.

GASTRIC CANCER DEVELOPMENT AFTER ERADICATION

Endoscopic resection is widely applied as a curative treatment for gastric cancer. However, metachronous gastric cancer following endoscopic resection is becoming a major problem due to gastric mucosa atrophy and chronic inflammation of the intestinal epithelium caused by *H. pylori*.

Metachronous gastric cancer means here that a new cancer is found separately from an initial cancer with or without *H. pylori*. The metachronous gastric cancer contains gastric cancer after *H. pylori* eradication.

Uemura *et al*^[30] were the first to report that *H. pylori* eradication after endoscopic resection decreased the occurrence of metachronous cancer. A prospective randomized trial in Japan showed that *H. pylori* eradication reduced the risk of metachronous gastric cancer during a 3-year follow-up period. In contrast, a prospective randomized trial in South Korea showed that eradication after endoscopic resection did not reduce the incidence of metachronous gastric cancer^[31]. The percentage of metachronous gastric cancers after endoscopic treatment was 8.5% during a follow-up period of up to 11.1 years, which did not significantly differ from the 14.3% cancer rate in the eradicated group^[8]. And other studies conducted in Japan did not support eradication after endoscopic resection^[6,9].

The efficacy of *H. pylori* eradication at preventing metachronous gastric cancer after endoscopic resection remains controversial. One of the causes which has no significant difference between eradicated group and not eradicated group, there exists nearly 30% overlooked cancers and those are often found by whole follow-up for 1 or 2 years. There is the report that cumulative incidence rate of metachronous gastric cancer was lower in the eradication group and the high risk of metachronous gastric cancer probably does not continue after 10 years^[32]. Yoon *et al*^[33] reviewed 13 studies and 6237 patients in a meta-analysis of the beneficial effects of *H. pylori* eradication and recommended that patients who received endoscopic treatment should also receive eradication therapy. Similarly, Yuhara *et al*^[34] assessed 2 randomized control trials and 5 retrospective cohorts. There was variability in the observation period, atrophic degree of the background gastric mucosa, sanitization period and definition of the eradication group; however, the risk of metachronous gastric cancer in the non-eradication group was higher when compared with eradication group. Thus, eradication after endoscopic treatment may reduce the risk of metachronous gastric cancer.

There is one more thing to be added. That is, re-current infection after successful *H. pylori* eradication. The causes to become positive again after *H. pylori* eradication was classified in "relapse" and "re-infection" by various kinds of judging methods. "Relapse" is the phenomenon that increases again after quantity of bacteria decreased in sensitivity or less of the testing concerned temporarily, and becomes positive by reexamination. "Re-infection" means *H. pylori* completely disappeared after eradication, they were infected with different *helicobacter* newly. The reinfection rate of *H. pylori* is reported 0.22%-11.5% and the variations date may reflect differences in the prevalence of *H. pylori*, hygienic environment, and false-negative eradication judgment^[35,36]. Generally, it is not necessary to mind gastric cancer risk of re-infection because there are few re-infection.

Gastric mucosal changes after successful *H. pylori* eradication

Atrophic mucosa with intestinal metaplasia in differentiated gastric cancer and undifferentiated cancer of the gastric fundic gland mucosa are well-known examples of the relationship between gastric cancer and the background mucosa^[37].

The continued study of *H. pylori* and gastric cancer has revealed a link between nodular gastritis in young women and undifferentiated gastric cancer^[38]. Yagi *et al*^[39] reported the regular arrangement of collecting venules (RAC) using a magnifying endoscope, and Nakajima^[40,41] reported the RAC based on radiography. Both studies noted the importance of assessing background gastric mucosa with diagnostic imaging. *H. pylori* infected gastric mucosa presents with strong active gastritis that is immediately improved after eradication.

Kato *et al*^[42] reported that spotty redness is significantly improved and related to eradication success in a multicenter study comparing unsuccessful and successful groups.

Using NBI magnifying observation, Okubo *et al*^[43] showed that enlarged or elongated pits improved to small oval or pinhole-like round pits and the density of fine irregular vessels decreased after successful eradication without severe gastric atrophy or intestinal metaplasia. Kong *et al*^[44] reported histological changes after successful eradication using a meta-analysis. This study illustrates a very strong correlation between the eradication of *H. pylori* infection and improvement in intestinal metaplasia in the gastric antrum but not in the corpus and between gastric atrophy in both the antrum and the corpus. After eradication, the neutrophilic infiltration of the lamina propria of the gastric mucosa and the lymphocytic infiltration of plasma cells were immediately improved^[45,46].

Endoscopic detection of gastric cancer after successful eradication

Gastric cancer after successful *H. pylori* eradication is often difficult to diagnose by endoscope because

of the indistinct borderline or disappearance of the characteristic surface structures of tumors.

In 2005, Ito *et al.*^[47] discovered that metachronous gastric cancers were difficult to identify endoscopically due to flattened and obscured tumor cells with an outer layer that lacked atypical columnar epithelium. Saka *et al.*^[48] described many characteristic changes in gastric cancer detection after successful *H. pylori* eradication: (1) a gastritis-like mucosal pattern that is often ill-delineated; (2) a portion of the gastritis-like gastric mucosa that contains a pattern distinct from the background mucosa; and (3) a mucosal pattern of a white zone that exhibits “morphological heterogeneity” and “direction diversity” using NBI magnifying endoscopy. These changes can impair the detection of gastric cancer after eradication; however, an area exhibiting “morphological heterogeneity” and “direction diversity” when compared with the background mucosa is relatively easy to diagnose as cancer^[49].

With regard to the gastritis-like gastric mucosa, Kitamura *et al.*^[50] reported that “epithelium with low-grade atypia (ELA)” is frequently observed on the surface of gastric tumors after successful eradication therapy. Caudal-related homeobox 2 (CDX2) was not expressed, and neither p53- nor Ki67-positive cells were found in ELA, regardless of their expression in tumors. The presence of ELA positively correlated with the clinical interval between eradication and gastric cancer detection. Moreover, Yamamoto *et al.*^[51] reported that the average diameter of gastric tumors was smaller and the Ki-67 index was lower in patients who underwent *H. pylori* eradication. An analysis of macroscopic morphology revealed mainly depressed-type tumors and a high ratio of gastric differentiated-predominant mixed type lesions after a long eradication interval. *H. pylori* eradication may suppress growth, intestinalization, and acid hyposecretion during the development of gastric cancer.

These studies show a long-term risk for gastric cancer after successful eradication. Thus, endoscopic follow-ups must consider the distinct characteristics of gastric cancer after eradication.

Development and risk of metachronous gastric cancer

Various risks have been associated with the development of atrophic mucosa. Patients with precancerous changes in the gastric mucosa show an increased risk of gastric cancer. *H. pylori* eradication does not prevent the development of gastric cancer in all patients; furthermore the risk of cancer is higher in patients with precancerous changes prior to eradication^[52-55].

There is continued speculation on gastric cancer diagnoses after eradication. Some researchers question the discovery of gastric cancer after eradication. Asaka *et al.*^[56] suggested a cancer diagnosis could be due to a preexisting tumor that was not detected endoscopically prior to eradication and the potential inhibitory effect of *H. pylori* eradication on tumor growth. That is, there are two kinds of the gastric cancer that discovery after

eradication even if it occurs before eradication and the new cancer occurred after eradication truly. Take *et al.*^[55] found that the incidence of developing gastric cancer after amelioration of an *H. pylori* infection was 0.30% per year; furthermore, the cancer could develop as long as 10 years after *H. pylori* eradication even without gastric inflammation. It was also reported that doubling time of the intramucosal carcinoma is approximately 16.6 mo^[57] and it takes more than 10 years from occurrence of gastric cancer cell until we can recognize visually endoscopically^[48]. Thus, gastric cancer cannot be completely prevented by eradication of *H. pylori*.

Well-known risk factors of gastric cancer after successful eradication include another active *H. pylori* infection, increased age, and atrophic gastritis severity at the time of eradication therapy^[11,58,59]. The independent risk factors of metachronous gastric cancer are male sex, severe gastric mucosal atrophy, and multiple gastric cancers prior to a successful *H. pylori* eradication^[8,58,60,61].

Shiotani *et al.*^[62] showed that atrophy in biopsy specimens from the lesser curvature of the corpus was strongly associated with gastric cancer risk. A serum pepsinogen I level less than 25 ng/mL prior to eradication was significantly associated with subsequent tumor development.

Other reported risk factors include aberrant DNA methylation, microsatellite instability, aberrant expression of miRNAs, CD44v9 expression by tumor cells, and microscopic foci of intramucosal neoplasia elsewhere in the stomach.

The next chapter describes the prevention of metachronous gastric cancer through the use of predictive markers.

POSSIBLE APPROACHES FOR REDUCING CANCER RISK

Arginine adenosine-5'-diphosphate ribosylation inhibitors and prostaglandin E2

Patients presenting with atrophic gastritis, metaplasia, or dysplasia are routinely subjected to eradication therapy targeting the underlying infection; however, eradication is only partly effective at reversing atrophy and often fails to treat metaplasia and dysplasia^[63].

Patients with any of these conditions have at least a 10-fold increased risk of developing gastric cancer; thus, a “watch-and-wait” strategy is not appropriate. For high-risk patients, improved treatments for metaplasia have been reported.

Recently, patients and animals taking tamoxifen have been shown to have regression in intestinal metaplasia^[64]. Olaparib (Lynparza™), an Arginine adenosine-5'-diphosphate ribosylation (ADP-ribosylation) inhibitor used for ovarian cancer, has been shown to reverse intestinal metaplasia. ADP-ribosylation inhibitors may successfully prevent and cure helicobacter-induced gastric preneoplasia^[65]. Prostaglandin E2 showed efficacy as a

treatment during the early stages of *Helicobacter*-induced gastric carcinogenesis^[66].

Interactions between *H. pylori* and CD44v9-positive cancer stem cells

Researchers have sought to understand why all *H. pylori* infected people do not develop gastric cancer.

CD44v9, one of the main surface marker proteins of cancer stem cells, prevents the accumulation of reactive oxygen species and contributes to the increased resistance of tumors to anticancer drugs^[67]. CD44 overexpression, especially variant 9 (CD44v9), has been implicated in the local inflammatory response and metaplasia-carcinoma sequence in the human stomach^[68].

As a long-term survival strategy for the stomach, the CagA released by *H. pylori* is degraded via VacA-mediated autophagy^[69]. In contrast, CD44v9-expressing cancer stem cells accumulate intracellular CagA by suppressing autophagy. Therefore, the presence of CD44v9-expressing cancer stem cells is strongly associated with an increased risk of gastric carcinogenesis in the presence of *H. pylori*. CD44v9-positive cancer stem cells can appear after long-term inflammation. Chemopreventive treatments targeting this cancer protein may restore autophagy^[69,70]. It would be important index to examine CD44v9-expressing when we evaluate a recurrence risk of the gastric cancer that occur after eradication of *H. pylori*.

Treating DNA methylation abnormalities with demethylating agents

Reversal of DNA methylation abnormalities may be effective for gastric cancer prevention. *H. pylori* infection induces DNA methylation abnormalities, which create the groundwork for cancerogenesis in the gastric mucosa. The carcinogenic risk can be assessed by measuring the extent of DNA methylation abnormalities that result in a "point of no return". Nanjo *et al.*^[71] identified seven specific CGIs that show increased methylation levels after *H. pylori* infection. EMX1, NKX6-1, and NEFM were particularly influential, and the carcinogenic gastric cancer risk was 23.8 times higher in cases of increased EMX1 methylation. These cancer risks also apply to individuals with past infections.

A multicenter prospective cohort study by Asada *et al.*^[72] showed that the methylation level in the non-cancerous gastric mucosa of patients with gastric cancer was significantly ($P = 0.042$) associated with an increased risk of developing metachronous gastric cancers. Specifically, the methylation level of miR-124a-3 results in an elevated risk of metachronous gastric cancer; furthermore, similar trends were observed for EMX1 and NKX6-1. In conclusion, miR-124a-3 is an informative biomarker for predicting the risk of metachronous gastric cancer^[73].

CDX2 is a transcriptional control factor that is indispensable for intestinal epithelium differentiation, and it functions as a tumor suppressing factor for tumors derived from intestinal epithelium. DNA methylation is frequently found in the *CDX2* gene promoter region

due to the development of intestinal gastric tumors that inactivate the gene. In addition, CDX2 is not expressed in stomachs uninfected by *H. pylori*. Early eradication prevents gastric cancer by inhibiting aberrant CDX2 expression. *H. pylori* eradication can reverse the gastric phenotype and diminish aberrant CDX2 expression in the early stages of intestinalization^[11,74].

The technique used to determine the presence or absence of gastric cancer consists of harvesting DNA with an endoscope. The genetic DNA methylation rate of SRY-box containing gene 17 (*SOX17*) was assessed before and after endoscopic submucosal dissection. The pathological examination revealed that the DNA methylation rate of *SOX17* was significantly decreased in all of the patients after endoscopic submucosal dissection. A decreased DNA methylation rate of *SOX17* can be used to infer the extent of the resection. A decreased DNA methylation ratio after ESD should be observed during routine follow-ups. In contrast, an increased ratio indicates an incomplete resection and may suggest the need for additional surgery^[75].

DNA demethylating agents are used for myelodysplastic syndrome patients. Demethylation of the gastric mucosa has been considered as a potential treatment. Additional research on treatment adaptation and side effects are needed to determine the applicability of preventing gastric cancer by inhibiting aberrant DNA methylation.

Chromosomal aberration of carcinoma tissue is not found in precancerous lesions; however, DNA methylation abnormalities can be used to identify both carcinomas and precancerous lesions. Examination of aberrant DNA methylation after eradication can be used to differentiate a high risk group from the sample population (Figure 1). Additional studies are needed to determine the relationships between aberrant DNA methylation and the invasion degree and cancer prognosis.

Utilization of pepsinogen serum levels and an *H. pylori* antibody titer

A novel and rapid diagnostic method has been introduced in Japan. This simple method, which consists of a pepsinogen serum level assay and helicobacter antibody titer, can be easily applied to large populations.

Yoshida *et al.*^[76] reported that altered DNA methylation levels in the stomach mucosa closely correlated with *H. pylori*-associated gastritis as assessed by serum pepsinogen II levels and a helicobacter antibody titer. Moreover, 4655 healthy asymptomatic subjects with no eradication treatment and who were followed-up for 16 years were divided into four groups based on the pepsinogen and antibody levels. This study showed a graded and significant rise in the hazard ratio for gastric cancer as chronic gastritis worsened. The mild atrophic gastritis group showed high gastric mucosa inflammation, which is a risk factor for diffuse-type cancer^[77]. These results indicate that gastric cancer mainly develops from the gastritis-atrophy-metaplasia-cancer sequence and

Figure 1 Relationship between gastric mucosae methylation levels and *Helicobacter pylori* infection/gastric cancer (modified from Maekita *et al*^[22]). Residual aberrant methylation even after eradication is thought to reflect methylation in gastric gland stem cells. From endoscopically biopsied tissue, predicting GC risk based on the accumulation of aberrant DNA methylation in the gastric mucosae. ESD: Endoscopic submucosal resection; GC: Gastric cancer; *H. pylori*: *Helicobacter pylori*.

partly from active inflammation-based carcinogenesis. Notably, at-risk individuals require follow-up because this serum method should be used as a risk examination and not as a cancer screening. We previously reported that Congo-red chromoendoscopy methods can be used to identify high-risk areas after eradication. Biopsies of high-risk areas (non-acid-secreting area) revealed sustained hyperproliferation, accumulation of p53 protein and immunoreactivity for Ki-67^[78]. Moreover, we demonstrated that a slow-releasing L-cysteine capsule effectively eliminated acetaldehyde from the gastric juice of PPI-treated aldehyde dehydrogenase 2 (ALDH2)-active and ALDH2-deficient subjects. These novel methods may aid in the prevention of gastric cancer, especially in established high-risk groups^[79].

Eventually, we have got one method to make *H. pylori* may become extinct before the future children infect. However, we should take measures to cope with the gastric cancer which may occur after *H. pylori* eradication. Surveillance and follow-up based on the feature or the gastric cancer including remnant stomach after *H. pylori* eradication is important, and it can be said there is little invasive method more than a stomach is removed. Additional studies are needed to clarify these surveillance methods under multiple conditions and determine their reliability as biomarkers for metachronous gastric cancers.

Abstract

Gastric cancer is the fourth most common cancer and

the second leading cause of cancer deaths worldwide. Chemotherapy is one of the major treatments for gastric cancer, but drug resistance limits the effectiveness of chemotherapy, which results in treatment failure. Resistance to chemotherapy can be present intrinsically before the administration of chemotherapy or it can develop during chemotherapy. The mechanisms of chemotherapy resistance in gastric cancer are complex and multifactorial. A variety of factors have been demonstrated to be involved in chemoresistance, including the reduced intracellular concentrations of drugs, alterations in drug targets, the dysregulation of cell survival and death signaling pathways, and interactions between cancer cells and the tumor microenvironment. This review focuses on the molecular mechanisms of chemoresistance in gastric cancer and on recent studies that have sought to overcome the underlying mechanisms of chemoresistance.

Key words: Drug resistance; Gastric cancer; Chemotherapy

Core tip: Although chemotherapy remains one of the primary therapeutic modalities used in the treatment of gastric cancer, chemoresistance limits the effectiveness of chemotherapy and results in treatment failure. The elucidation of the mechanisms of drug resistance will be very helpful for the prediction of sensitivity to chemotherapy and the reversal of drug resistance to improve therapeutic efficacy. The mechanisms of drug resistance have been broadly investigated in recent years. In this review, we summarize the molecular mechanisms of chemoresistance in gastric cancer and discuss the progress in the reversal of drug resistance.

INTRODUCTION

Gastric cancer is one of most common malignant tumors. It currently ranks as the fourth most common cancer and is the second leading cause of cancer deaths worldwide. The incidence of gastric cancer varies greatly in different regions, and over 70% of new cases and deaths occur in developing countries. The highest incidence rates are observed in Eastern Asia, Eastern Europe, and South America, whereas the lowest rates are observed in North America and most parts of Africa^[1].

Although the incidence of gastric cancer has declined due to improved living standards, a reduction in chronic *H. pylori* infection and increased screening activities, the overall outcome has not significantly improved over the last few decades. The treatment outcomes for gastric cancer are determined by the stage of the tumor at presentation and the condition of the patients. Surgery is the only potentially curative treatment for gastric cancer. The five-year overall survival rate after surgery varies from 70%-95% in early stage patients to 20%-30% in advanced-stage patients. Moreover, more than two-thirds of patients have unresectable disease when they are diagnosed^[2]. Therefore, chemotherapy is used to relieve symptoms in patients with unresectable tumors and to reduce the risk of recurrence and metastasis in patients with localized disease after surgery. Perioperative chemotherapy can improve the 5-year survival rate from 23% to 36.3% among patients with resectable adenocarcinoma of the stomach compared with surgery alone^[3]. In addition, chemotherapy has shown only a modest benefit in patients with metastatic disease with an average survival of approximately ten months^[4,5].

Although chemotherapy plays an important role in the treatment of both local and metastatic gastric cancer, the efficacy of chemotherapy is limited by chemoresistance. Chemotherapeutic resistance, whether intrinsic or acquired, is a complex and multifactorial phenomenon that is associated with tumor cells as well as with the tumor microenvironment^[6]. With the development of modern biological techniques, the mechanisms of chemoresistance have been broadly investigated in recent years. This review focuses on the molecular mechanisms of chemoresistance in gastric cancer and on recent studies that have sought to overcome the underlying mechanisms of chemoresistance.

REDUCED INTRACELLULAR CONCENTRATION OF DRUGS

Drug efflux

The ATP-binding cassette (ABC) transporter family has been shown to be associated with chemoresistance. These transmembrane proteins can reduce the intracellular concentrations of drugs *via* an increase in the efflux of drugs and the redistribution of drugs away from the site of action. This family of proteins is composed of 49 members that are divided into 7 subclasses (ABCA-

ABCG). ABCB1, also known as P-glycoprotein and MDR1, was the first ABC transporter to be identified and has been studied extensively. The overexpression of ABCB1 has been found in human gastric cancer cell lines and in clinical gastric cancer tissues^[7-9]. The association between ABCB1 expression and the clinicopathological characteristics of patients with gastric cancer is not fully understood. According to one study, ABCB1 expression was less frequent in locally advanced tumors and was absent in primary tumors where distant metastases were also present^[8]. In another study, ABCB1 expression was also associated with well and moderately differentiated tumors and intestinal-type tumors, but it did not indicate poor prognosis of gastric cancer patients treated with 5-fluorouracil (5-FU) and doxorubicin-based adjuvant chemotherapy^[10]. Recent reports have suggested that the expression of ABCB1 is related to poor prognosis in gastric cancer patients^[9,11]. Further studies have indicated that the expression of ABCB1 is associated with chemoresistance in patients with gastric cancer, as its presence in tumor cells may be an indicator of a lack of sensitivity to chemotherapy^[12-15]. The expression of ABCB1, which results in acquired chemoresistance, can be induced by chemotherapy. The expression rate of ABCB1 increased from 27.8% to 37.5% after the administration of adriamycin-based chemotherapy. ABCB1 expression after chemotherapy has been correlated with a higher rate of systemic recurrence^[16]. ABCB1 has been demonstrated to affect intrinsic and acquired resistance of gastric cancer cells to chemotherapeutic agents. Blocking the expression of ABCB1 can reverse multidrug resistance in human gastric carcinoma cells^[17,18]. Other ABC transmembrane proteins, such as ABCC1, which is also known as multidrug resistance-associated protein, are also associated with multidrug resistance in gastric cancer^[9,19,20].

The expression of ABCB1 is regulated by a variety of factors. NF-kappa B is a transcriptional factor that can bind to gene promoters or enhancer sites to promote the transcription of those genes. Bentires-Alj *et al.*^[21] identified a consensus NF-kappa B binding site in the first intron of the human *ABCB1* gene and demonstrated that NF-kappa B can bind to this intronic site and activate reporter gene transcription. Gu *et al.*^[22] demonstrated that upon paclitaxel stimulation, cyclooxygenase-2 induced the expression of ABCB1 in gastric cancer cells *via* the NF-kappa B pathway. Another study found a positive association between phosphorylated AKT (p-AKT) and ABCB1 expression in both gastric cancer tissues and gastric cancer cell lines. Moreover, it was shown that the expression of ABCB1 was reduced by the inhibition of the phosphatidylinositol-3 kinase (PI3K)/AKT pathway in SGC7901/ADR cells. Ubiquitin ligase Cbl-b can also down-regulate the expression of ABCB1 through the suppression of the PI3K/AKT signaling pathway. These findings indicated that the PI3K/AKT pathway might regulate the expression of ABCB1 and may be correlated with chemoresistance^[23]. Recently, some studies have demonstrated that microRNAs play an important role

in chemoresistance *via* the regulation of the expression of ABCB1. miR-508-5p can repress the expression of ABCB1 by targeting the 3'UTR of ABCB1^[24]. miR-106a and miR-27a, through the up-regulation of ABCB1 expression, are also involved in chemoresistance in gastric cancer^[25,26]. In addition, the long non-coding RNA PVT1 has been shown to increase the expression of multidrug resistance-related genes [*ABCB1*, *ABCC1*, *mTOR* and Hypoxia-inducible factor-1 α (HIF-1 α)], which in turn results in the development of chemoresistance in gastric cancer^[27].

Drug inactivation

Glutathione *S*-transferases (GSTs) are a family of phase II detoxification enzymes that catalyze the conjugation of glutathione (GSH) to a broad variety of hydrophobic and electrophilic compounds. GSTs are involved in chemoresistance because they inactivate drugs. The expression of glutathione *S*-transferase-pi (GST-pi) has been found in both gastric cancers and in normal gastric mucosa, but the total GST enzyme activity and the absolute amounts of GST-pi protein were significantly higher in tumors compared with those of matched normal mucosa^[28]. Differences were found in the GSH and GST parameters between responsive and progressive patients with gastric cancer who were treated with chemotherapy, which suggests a role for the GSH/GST system in the susceptibility of gastric tumor cells to chemotherapy^[29]. The overexpression of GST-pi has been found to be significantly related to the sensitivity of gastric cancer to cisplatin^[30]. It was reported that GST- α is correlated with cisplatin resistance in gastric cancer, and the quantification of GST- α can be used to predict the clinical effects of cisplatin in patients with gastric cancer^[31]. Lastly, 3 β -acetyl tormentic acid has been shown to sensitize multidrug-resistant cells to antineoplastic drugs through the modulation of intracellular levels of GSH and GST activity^[32].

Reduced prodrug activation

The reduced activation of prodrugs may decrease the intracellular concentrations of the corresponding active drugs, which results in the reduction of chemotherapeutic efficacy. 5-FU is a common chemotherapy drug whose activation involves thymidine phosphorylase, uridine phosphorylase and orotate phosphoribosyl transferase. Lower expression or impaired activity of these enzymes has been associated with chemoresistance to 5-FU in gastric cancer^[33-35].

ALTERATIONS IN DRUG TARGETS

DNA topoisomerases are a class of nuclear enzymes that modulate DNA topology during chromosomal transactions, such as gene transcription and DNA replication, recombination and repair. Topoisomerases are targets of various chemotherapeutic agents such as doxorubicin, etoposide, mitoxantrone and irinotecan. Alterations

in topoisomerases could affect a patient's response to chemotherapy as well as resistance. A series of studies revealed higher Topo-II expression in gastric carcinomas compared with normal gastric mucosa, and this increased expression was correlated with clinicopathological parameters such as tumor location, histological type, infiltration depth, distant metastases and tumor stage^[36-39]. A reduction in Topo-II expression was also found to contribute to the resistance of human gastric cancer cells to adriamycin and other topo II-targeted drugs *in vitro*^[40]. Furthermore, Topo-II expression has been negatively correlated with hydroxycamptothecin, adriamycin and mitomycin C resistance in gastric cancer tissues^[41].

Paclitaxel is an anti-microtubule drug that interferes with tubulin and that stabilizes microtubule composition, normal spindle assembly and cell division, which all result in cancer cell death. The clinical effectiveness of paclitaxel and the expression of the microtubule-associated protein tau have therefore been investigated^[42]. Among 20 cases of inoperable or noncurative, resected gastric cancer, 14 demonstrated positive tau expression while 6 were negative for tau expression. All six tau-negative cases showed a favorable response to paclitaxel, whereas 12 of the 14 tau-positive cases showed progressive disease or no change after paclitaxel administration. These results indicated that tau-negativity may be used to select gastric cancer patients who will respond favorably to paclitaxel treatment. Another study demonstrated that the sensitivity of gastric cancer patients to paclitaxel treatment was inversely correlated with the expression of class III β -tubulin and the microtubule-associated protein tau^[43]. Additionally, low miR-34c-5p expression and high microtubule-associated protein tau protein expression were found in paclitaxel-resistant gastric cancer samples. The overexpression of miR-34c-5p causes a significant down-regulation of tau protein expression, which leads to an increase in the chemosensitivity of paclitaxel-resistant gastric cancer cells. Therefore, the modulation of microtubule-associated proteins might play an important role in the chemoresistance of gastric cancer cells to paclitaxel^[44].

DYSREGULATION OF CELL SURVIVAL AND DEATH

Chemotherapeutic drugs cause DNA damage and induce cell death, and escape from cell death is one of the mechanisms of chemoresistance. The promotion of cell survival and resistance to apoptosis are both hallmarks of cancer cells. Accumulating evidence has shown that the dysregulation of cell survival and death is involved in the resistance of cancer cells to chemotherapeutic drugs.

BCL-2 family members

The BCL-2 protein family comprises a group of apoptosis regulators. These proteins can be divided into the following three subfamilies: The anti-apoptotic subfamily,

which contains the BCL-2, BCL-xL, BCL-w, MCL-1, BFL1/A-1, and BCL-B proteins; the pro-apoptotic subfamily, which contains the BAK, BAX, and BOK proteins; and the BH3-only protein subfamily, which contains the pro-apoptotic BIM, BID, BIK, BAD, BMF, HRK, PUMA, and NOXA proteins^[45]. Interactions among the BCL-2 protein family members within the mitochondrial outer membrane control cellular commitment to apoptosis^[46]. The role of the BCL-2 family of proteins in chemoresistance has been studied extensively.

Studies have demonstrated that the overexpression of BCL-2 is associated with chemoresistance to cytotoxic chemotherapeutic agents in patients with gastric cancer^[47,48]. The silencing of BCL-2 increased cell apoptosis and decreased resistance to 5-FU in gastric adenocarcinoma cells^[49]. This suggested that the modulation of BCL-2 expression could affect chemosensitivity in gastric cancer. A recent study showed that Rho GDP dissociation inhibitor 2 rendered gastric cancer cells resistant to cisplatin *via* the up-regulation of BCL-2 expression^[50]. In addition, microRNAs are small, endogenous noncoding RNAs that negatively regulate gene expression at the posttranscriptional level. Several microRNAs, such as miR-204, miR-181b, miR-15b and miR-16, were found to up-regulate the expression of BCL-2, which resulted in multidrug resistance in human gastric cancer cells^[51-53].

The pro-apoptotic protein BAX has been demonstrated to predict clinical responsiveness to chemotherapy in patients with gastric cancer^[54]. Increased BAX expression has also been shown to sensitize KATO III cells to chemotherapeutic agent-induced apoptosis through the enhancement of the release of cytochrome c from mitochondria^[55]. Our studies showed that interferon regulatory factor 1 enhanced the chemosensitivity of gastric cancer cells to 5-FU through the induction of PUMA-mediated apoptosis^[56,57]. Other BCL-2 family members (BCL-xL, BAK, MCL-1) have also been demonstrated to function in the regulation of chemotherapy-induced apoptosis^[58,59]. This indicated that proteins in the BCL-2 family, through interactions among its members, play a pivotal role in the determination of cell fate following chemotherapy.

p53

The p53 tumor suppressor gene plays an important role in various processes, including cell cycle regulation, DNA repair and apoptosis. In one study, mutations in the p53 gene were found in 0%–77% of gastric carcinomas^[60]. Moreover, p53 alterations including a high frequency of p53 mutations, loss of heterozygosity, overexpression of the p53 protein, and consequently, the loss of p53 function, are early events in gastric cancers; they are also important biomarkers that are used to determine prognosis and treatment response^[61]. Although the relationship between p53 and chemoresistance in gastric cancer has been studied for many years, the results are not consistent. Recently, a meta-analysis was performed

to expound the relationship between p53 status and the response to chemotherapy^[62]. Thirteen published studies were eligible, including 564 cases, which were identified and analyzed. The results showed that p53 positive status (*i.e.*, high expression of p53 protein and/or a mutant p53 gene) was associated with an improved response in patients with gastric cancer who received chemotherapy. This indicated that p53 status might be a useful predictive biomarker for response to chemotherapy in gastric cancer. A later study showed that rAd-p53 enhanced the sensitivity of gastric cancer cells to chemotherapy *via* the promotion of apoptosis^[63]. The restoration of p53 was able to overcome cisplatin resistance in gastric cancer through the inhibition of AKT as well as through the induction of BAX^[64].

PI3K/AKT pathway

The PI3K/AKT pathway is a vital regulator of cell growth, proliferation and survival. The stimulation of receptor tyrosine kinases or G-coupled proteins activates PI3K, which in turn activates AKT; the phosphorylation of AKT is required for the complete activation of AKT. Activated AKT then phosphorylates various substrates so that it can exert its functions in cell proliferation, growth, anti-apoptosis and cell cycle progression. Aberrant activation of the PI3K/AKT pathway, which is believed to play an important role in resistance to chemotherapy, has been reported in human malignancies including gastric cancer.

Mutations in PIK3CA, which lead to increased PI3K activity, have been reported in gastric cancer^[65,66]. The expression of AKT and p-AKT was found in 74% and 78% of gastric carcinomas, respectively^[67]. It has been reported that the expression of p-AKT is correlated with depth of infiltration of the tumor, number of infiltrated lymph nodes, and overall survival^[68]. Moreover, several studies have shown that activated AKT is associated with increased resistance to multiple chemotherapeutic agents including 5-FU, adriamycin, mitomycin C and cis-platinum^[69,70]. Further studies demonstrated that chemotherapeutic reagents can induce activation of the PI3K/AKT signaling pathway, which results in acquired chemoresistance in gastric cancer cells^[71,72]. In addition, in one study, the overexpression of AKT decreased the chemosensitivity of gastric cancer cells to cisplatin, whereas the down-regulation of AKT reversed the resistant phenotype of gastric cancer cells *in vitro* and *in vivo*^[73,74].

Studies have reported that the aberrant activation of the PI3K/AKT pathway can be induced by various factors, including mutations in PIK3CA^[65], loss of PTEN function^[69], mutations in AKT isoforms^[75], and upstream activation of other growth pathways (*e.g.*, EGFR signaling pathway)^[76]. Although the PI3K/AKT pathway plays an important role in chemoresistance, the mechanism of PI3K/AKT activation that results in chemoresistance is not fully understood. It has been reported that NF-kappa B is a downstream target of AKT and that chemothera-

peutics induce AKT activation, I κ B α phosphorylation and degradation, and finally, NF-kappa B activation. Inducible AKT and NF-kappa B activities are involved in the chemoresistance of gastric cancer cells. The activation of NF-kappa B is one part of the mechanism of chemoresistance induced by AKT^[77]. Survivin is another downstream target of AKT. In cisplatin-resistant gastric cancer cells, higher levels of survivin and p-AKT have been observed. According to one study, specific inhibition of AKT reduced the expression of survivin and enhanced the sensitivity of cisplatin-resistant cells to cisplatin^[78]. Another study showed that the up-regulation of p-AKT expression could confer multidrug resistance in gastric cancer cells through the up-regulation of BCL-2 expression and the down-regulation of BAX expression^[79].

Because the PI3K/AKT pathway plays a vital role in chemoresistance in gastric cancer, the targeting of PI3K/AKT has emerged as a promising approach to reverse chemotherapy resistance. A recent study reported that LY294002, a selective inhibitor of PI3K, might overcome intrinsic and acquired resistance to 5-FU *via* the down-regulation of activated p-AKT and mitochondria-dependent apoptosis in gastric cancer cells^[80]. An AKT inhibitor (MK-2206) has also been demonstrated to augment the efficacy of chemotherapeutics in gastric cancer, but the magnitude of synergy depends on the treatment sequence. Furthermore, in one study, MK-2206 administered before chemotherapy resulted in the highest synergistic effect compared to the effects when it was administered after or concurrently with chemotherapy^[81].

Mitogen-activated protein kinase pathway

The mitogen-activated protein kinase (MAPK) signaling pathway is widely expressed in multicellular organisms, where it plays a critical role in multiple biological processes, such as cell proliferation, differentiation, and cell death. Dysregulation of the MAPK signaling pathway is associated with the occurrence and progression of various cancers including gastric carcinoma^[82]. Moreover, numerous studies have demonstrated that the MAPK pathway is also involved in chemotherapy resistance in gastric cancer. According to one study, phosphorylated mitogen-activated protein kinase (p-MAPK) was positive in 59.6% of patients with metastatic gastric cancer. Moreover, the expression of p-MAPK in primary tumors and metastatic lesions was similar. The overall survival was found to be significantly shorter in p-MAPK-positive patients. This indicated that p-MAPK expression might be a potential negative prognostic parameter in patients with metastatic gastric cancer who are treated with chemotherapy^[83]. The activation of the p38-MAPK pathway was found in vincristine-resistant gastric cancer SGC7901/VCR cells and was determined to be responsible for the modulation of multidrug resistance^[84]. In addition, the inhibition of p38 MAPK significantly increased gastric cancer cell sensitivity to doxorubicin through the induced expression of the pro-apoptotic protein BAX and a concomitant decrease in BCL-2 expression^[85].

TUMOR MICROENVIRONMENT

The tumor microenvironment consists of the extracellular matrix (ECM), various cells including cancer-associated fibroblasts, immune and inflammatory cells, and blood or lymph vessels. Increasing evidence has shown that the tumor microenvironment has multiple functions in tumorigenesis, invasion, and metastasis, as well as in drug resistance.

Hypoxia

Hypoxia, which is a common feature of solid tumors, results in tumor progression and treatment resistance. HIF-1 α is one of the most important regulators of the cellular response to hypoxia. HIF-1 α expression was found to be positive in 65.6% of gastric cancers. The overexpression of HIF-1 α was found to be an indicator of poor prognosis for patients with gastric cancer and was significantly correlated with histology, depth of invasion, VEGF expression, and MVD^[86]. It has also been reported that HIF-1 α expression could predict the response of patients with advanced gastric cancer to 5-FU-based adjuvant chemotherapy^[87]. Another study showed that HIF-1 α determines gastric cancer chemosensitivity through the modulation of p53 and NF-kappa B^[88]. Additional studies demonstrated that HIF-1 α overexpression increases the expression of BCL-2, decreases the expression of BAX, and also significantly induces the expression of ABCB1 and ABCC1. This indicates that HIF-1 α may confer hypoxia-induced drug resistance *via* the inhibition of drug-induced apoptosis and decreases in intracellular drug accumulation^[89].

Alterations of the extracellular matrix

The ECM is a complicated network of multifunctional molecules that influence major malignant phenotypes of cancer cells, including oncogenesis, progression and drug resistance. Laminin and collagen IV are natural basement membrane components that constitute a specific ECM that maintains malignant phenotypes in gastric adenocarcinoma cells^[90]. Recent findings showed that the adhesive ability of multidrug-resistant gastric cancer cells was significantly increased compared with parental cells, which were sensitive to chemotherapeutic drugs. The ECM component laminin increased the resistance of gastric cancer cells to vincristine and adriamycin by binding to the receptor MGr1-Ag/37LRP. This suggested that the chemoresistant phenotype of gastric cancer cells is associated with a state of increased cell adhesion. Laminin can modify the response to chemotherapeutic agents by various mechanisms, including regulation of MDR-related proteins (ABCB1 and ABCC1), apoptosis-related genes (BCL-2 and BAX), and signaling pathways (PI3K/AKT and MAPK/ERK)^[91,92]. It has been demonstrated that extracellular high mobility group box chromosomal protein 1 might promote drug resistance to adriamycin and vincristine *via* the up-regulation of ABCB1 in human gastric adenocarcinoma cells^[93].

Cytokines and growth factors

Soluble factors in the tumor microenvironment such as cytokines and growth factors exhibit key functions in chemotherapeutic resistance, as they maintain the activation of various survival-related signaling pathways. In a recent study, the serum levels of 52 types of cytokines and angiogenic factors were measured in 68 patients with gastric cancer who were treated with fluoropyrimidine and platinum combination chemotherapy. The following eleven cytokines and angiogenic factors were found to be independently correlated with poor overall survival: Interleukin-2 receptor-alpha, growth-regulated alpha protein, hepatocyte growth factor, macrophage colony-stimulating factor, stromal cell-derived factor, IL-6, IL-8, IL-10, interferon-gamma, vascular endothelial growth factor, and osteopontin^[94]. IL-33 has been reported to confer resistance to chemotherapy in gastric cancer cells through activation of the JNK signaling pathway^[95]. IL-6 can trigger the activation of STAT3 and has been found to be associated with acquisition of resistance of gastric cancer cells to trastuzumab^[96]. Tumor necrosis factor (TNF)-like weak inducer of apoptosis (TWEAK) is a member of the TNF superfamily of structurally related cytokines. It was revealed that TWEAK promotes resistance to 5-FU in gastric cancer cells through NF-kappa B activation^[97].

CONCLUSION

Resistance to chemotherapy is a major challenge for patients who currently undergo therapy for gastric cancer. A wide range of molecular mechanisms of chemoresistance has been implicated in gastric cancer, including reduced intracellular concentrations of drugs and alterations of drug targets. The dysregulation of cell survival and death signaling pathways can also lead to resistance to chemotherapeutic drugs. In addition, the interactions between cancer cells and the tumor microenvironment also plays an important role in chemoresistance in gastric cancer. These emerging findings are very helpful for the development of personalized therapies based on the prediction of the chemosensitivity of cancer cells as well as for the establishment of novel therapeutic strategies to reverse the chemoresistance of tumors. However, the mechanisms of chemoresistance are complex and multifactorial. The chemotherapeutic resistance of tumors may be caused by different molecular mechanisms in different patients due to tumor heterogeneity and drug variety. Therefore, more extensive studies are needed for a more comprehensive elucidation of the mechanisms of chemotherapy resistance in gastric cancer.

Abstract

Pancreatic cancer is the fourth leading cause of cancer-related death worldwide. Extensive research has yielded advances in first-line treatment strategies, but there is no standardized second-line therapy. In this review, we examine the literature trying to establish a possible therapeutic algorithm.

Key words: Nab-paclitaxel; Nal-iri; Pancreatic cancer; Second line; Algorithm

INTRODUCTION

Pancreatic cancer (PDA) is an emerging disease and is the fourth leading cause of cancer death worldwide^[1]. The prognosis is very poor; the 5-year survival rate is 5%, and the life expectancy of patients with metastatic PDA is approximately 2.8-5.7 mo^[2]. These poor outcomes are likely due to resistance to chemotherapy and PDA biology. PDA often presents with micro-metastatic lesions at diagnosis, which are subsequently confirmed by radiological evidence. The mechanisms underlying PDA development and progression have not been fully elucidated, hindering the development of

therapeutic strategies for disease management. National Comprehensive Cancer Network guidelines recommend 5-fluorouracil-oxaliplatin-irinotecan (FOLFIRINOX) or nab-paclitaxel plus gemcitabine as first-line therapy. Gemcitabine (alone or in combination) is recommended as second-line therapy, with capecitabine or fluoropyrimidine plus oxaliplatin as the final option^[3]. In fact gemcitabine seems to be more effective than fluoropyrimidine^[4]. Second-line therapy is not standardized and depends on patient performance status (PS) (which frequently worsens after first-line therapy), comorbidities, previous treatments, and residual toxicities. Notably, only 40% of patients can receive an additional line of therapy after the first treatment^[5].

However, active treatment has been linked to improved outcomes in PDA compared to best supportive care (BSC)^[6].

In this review, we focus on significant second-line studies and subsequently propose a therapeutic algorithm for PDA.

SECOND-LINE THERAPY

Although studies of efficient target therapies are promising, the backbone of second-line strategies for PDA involves a combination of chemotherapeutic agents. Currently, gemcitabine-based chemotherapy or fluoropyrimidine-based therapy, depending on previous drug regimens, remains the standard of care in the second-line setting.

Target therapy

PDA is a heterogeneous cancer and identifying plausible therapeutic targets is consequently difficult. The efficacy of a variety of drugs targeting different pathways has been evaluated, including targets in angiogenesis, farnesyl-transferases, cancer stem cells, hyaluronic acid, EGFR-MEK, m-TOR, and JAK-STAT pathways. Bevacizumab has been investigated in PDA therapy due to the favourable results achieved in other gastrointestinal cancers. Although the addition of bevacizumab to gemcitabine in first-line therapy failed to improve overall survival (OS), it has been evaluated in second-line settings. A small randomized trial comparing bevacizumab monotherapy to the combination of bevacizumab (10 mg/kg q14) plus docetaxel (35 mg-m² day 1.8.15 q 28) reported a detrimental effect of combination therapy^[7]. The only targeted therapy approved by the Food and Drug Administration for PDA treatment is erlotinib. This drug produced a small advantage in first-line treatment and also demonstrated activity (4.1 mo in OS) in second-line treatment^[8]. However, the combination of erlotinib with bevacizumab failed to improve patient outcomes^[9].

The EGFR and VEGFR pathways play major roles in PDA carcinogenesis and have been investigated as potential targets for second-line treatment. Inhibition of MEK1/2 by selumetinib failed to improve OS in gemcitabine-refractory patients compared to capecitabine^[10],

most likely due to activation of the EGFR pathway. On the contrary, a phase II trial with a small sample size, demonstrated that the combination of erlotinib and selumetinib achieved better outcomes (7.3 mo OS)^[11]. The EGFR inhibitor gefitinib failed to produce satisfactory results when used in combination with docetaxel using different schedules^[12,13]. The JAK-STAT inhibitor ruxolitinib achieved promising outcomes in preclinical and phase II trials^[14], but the subsequent phase III trial was terminated prematurely due to inefficacy. Instead encouraging results (median OS 9.8 mo) were reported with the use of olaparib, a poly (ADP-ribose) polymerase inhibitor, in BRCA1 and BRCA2 (BRCA1/2) mutated patients prior exposed to at least one line of therapy^[15]. Reni *et al.*^[16] investigated the maintenance with sunitinib in advanced PDA not progressed after six months of first line therapy, reporting an interesting result: An high 2-year OS, 22.9% vs 7.1% with sunitinib and placebo respectively.

Immunotherapy

Recent studies have focused on the new and attractive field of immunotherapy, which has achieved excellent results in the treatment of other malignancies. A variety of strategies had been tested in the following therapeutic settings: Vaccines, immune checkpoint blockade, anti-cytotoxic T-lymphocytes-associate protein 4 inhibitors, anti-PD-1 and anti-PDL1 inhibitors, and oncolytic virotherapy^[17]. Good outcomes have not been obtained, most likely due to the immune suppressive nature of the PDA microenvironment, which is characterized by desmoplastic reactions. Predictive biomarkers are not available but are actively being sought^[17].

Chemotherapy

Extensive data on potential treatments for gemcitabine-refractory patients are available because gemcitabine was previously the most frequently used agent for PDA. The roles of oxaliplatin and irinotecan in PDA have been evaluated due to the effectiveness of these drugs for other gastrointestinal cancers. Based on the promising results of a phase II trial^[18], three phase III randomized studies have investigated the efficacy of oxaliplatin-based regimens in gemcitabine-refractory patients. The CONKO-01 trial compared the efficacy of oxaliplatin, folinic acid (LLV), and 5-fluorouracil (5-FU) 24 h (OFF) with BSC. Although the patient cohort was small due to premature accrual closure, the study represents the first second-line trial demonstrating an advantage of chemotherapy over BSC (median OS 4.8 mo vs 2.3 mo). Patient randomization was terminated early because of the hesitation of the clinicians to administer BSC when a potentially active therapy was available^[19].

Afterwards in the CONKO-003 trial the OFF arm was compared to an active control arm (5-FU). The results of this study confirmed OFF schedule efficacy. OS increased significantly in the experimental arm (5.9 mo vs 3.3 mo), and there was a low rate of adverse events^[6]. These

data are more reliable than those of the CONKO-01 trial because of the high number of randomized patients (168). Smaller, non-randomized studies reported similar results (approximately 5 mo in OS) for combination oxaliplatin-capecitabine (xelox)^[20].

However, PANCREOX, which randomized 108 patients to oxaliplatin and 5-FU, the FOLFOX6m schedule, or 5-FU plus leucovorin, demonstrated a detrimental effect of FOLFOX6m on both OS and quality of life (median OS 6.1 mo vs 9.9 mo, $P = 0.02$), although the high OS in the 5-FU arm appears disputable^[21].

Other schedules after progression to gemcitabine-based therapy have been investigated in non-randomized studies. The combination of oxaliplatin plus raltitrexed^[22] or gemcitabine^[23] led to OS of 5.2 and 6 mo, respectively. A recent small phase II study reported outstanding OS (10.4 mo) for the combination of oxaliplatin and docetaxel^[24]. The use of docetaxel was suggested by the result of a previous retrospective trial that reported OS of 4.0 mo with docetaxel monotherapy^[25]. By contrast, the combination of docetaxel with irinotecan yielded disappointing outcomes, with OS of 4.1 mo, comparable to the median OS for other schedules in this setting^[26].

Limited experience with docetaxel^[27], paclitaxel^[28], and eribulin^[29] monotherapies has not yielded satisfactory results.

Similar to oxaliplatin, irinotecan has been evaluated in association with other agents such as raltitrexed, resulting in OS of 6.5 mo^[30]. Patients pre-treated with platinoid therapy frequently experienced peripheral neuropathy, limiting therapy options. Irinotecan monotherapy exhibited moderate activity and an acceptable safety profile as second-line treatment^[31]. A subsequent multicentre phase II study was conducted to investigate the combination of irinotecan with fluoropyrimidine using the FOLFIRI schedule (irinotecan 180 mg/m², leucovorin 200 mg/m², 5-FU 400 mg/m² bolus and 5-FU 600 mg/m² for 22 h). This schedule was well tolerated and led to acceptable outcomes (OS 5 mo)^[32].

Recent interesting data emerging from two relevant studies (PRODIGE 4, ACCORD 11) of FOLFIRINOX first-line therapy suggest an important impact of this schedule on OS; approximately 45% of patients underwent second-line therapy, despite the high rate of adverse events in the experimental arm compared to the gemcitabine control arm, including febrile neutropenia (5.4% vs 1.2%), neutropenia (45.7% vs 21%) and diarrhoea grade 3-4 (12.7% vs 1.8%)^[33].

The optimal treatment choice after FOLFIRINOX progression has not been established. The PRODIGE intergroup reported the most common second-line therapy administered to patients progressing in the FOLFIRINOX arm was gemcitabine (82.5%) or a gemcitabine-based combination (12.5%). Conversely, in the gemcitabine-resistant group, the second-line treatment was FOLFOX (49.4%), gemcitabine plus oxaliplatin (17.6%), fluorouracil and leucovorin plus cisplatin (16.5%) or FOLFIRINOX (4.7%)^[34]. Studies have also investigated nab-paclitaxel plus gemcitabine^[35,36]

and gemcitabine alone^[37] after first-line FOLFIRINOX. In gemcitabine-refractory patients, second-line therapy with FOLFIRINOX is marginally effective and less manageable in terms of toxicities^[38].

The most accepted hypothesis explaining rapid PDA progression during chemotherapy is the presence of a dense stroma surrounding the tumour cells that prevents drug activity. To overcome this obstacle, a new formulation of paclitaxel (nab-paclitaxel) was used in combination with gemcitabine as a first-line regimen^[39]. This combination exhibited activity in the second-line setting both in gemcitabine-refractory patients^[40,41] and after progression on FOLFIRINOX^[42]. Nab-paclitaxel exhibited a clinical benefit and is also feasible in elderly patients^[43]. Based on these results, irinotecan encapsulated in liposome nanoparticles was evaluated. A phase II trial of nanoliposomal irinotecan (nal-iri) monotherapy reported OS of 5.2 mo^[44]. The phase III study (NAPOLI-1) randomized (1:1:1) 417 patients worldwide to nanoliposomal irinotecan monotherapy, 5-FU and leucovorin, or nanoliposomal irinotecan plus 5-FU and leucovorin. The reported median OS was 4.9, 4.2 and 6.1 mo, respectively^[45]. This multicentre study had a large accrual, and nanoliposomal irinotecan plus 5-FU and leucovorin achieved the highest OS reported (Tables 1 and 2). Nanoliposomal irinotecan monotherapy was comparable to the combination of other chemotherapy agents.

All available agents have been tested in PDA therapy in different combinations and schedules. However, as in other cancers, the sequence of treatments and the optimization of the few efficient agents are critical. Therefore, it is very important to define an algorithm based on PS, patient age, and comorbidities for the first line decision (Figure 1).

To determine the first-line therapy, patients can be classified into three categories depending on age, PS, and comorbidities: Patients with PS 0-1 and < 65 years can be treated with FOLFIRINOX; patients with PS 0-1 and > 65 years can receive nab-paclitaxel; and patients with PS > 1 elderly patients, or patients with serious comorbidities receive gemcitabine monotherapy. The selection of subsequent therapies is affected by previous treatment and depends on residual toxicities, PS after first-line therapy, and patient preference.

Based on the literature, we hypothesize that patients treated with FOLFIRINOX can receive nab-paclitaxel plus gemcitabine or gemcitabine monotherapy. However, patients treated with first-line gemcitabine have additional options, including fluoropyrimidine and irinotecan.

There are currently no studies assessing treatment progression following nab-paclitaxel. However, if the patient recovers from peripheral neurotoxicity, we suggest platinoid-based chemotherapy or irinotecan-based therapy. A recent post hoc analysis of the MPACT trial showed that second-line therapy is feasible and more beneficial in patients previously treated with an efficient first-line treatment, particularly nab-paclitaxel plus gemcitabine, than in patients treated with gemcitabine

alone^[46].

Improved outcomes may be obtained by treatment with all active agents (nab-paclitaxel, gemcitabine, irinotecan, oxaliplatin, fluoropyrimidine) during the entire patient history.

CONCLUSION

Many drugs have been investigated for PDA treatment, but outstanding OS results have only recently been obtained in the second-line setting. The median OS remains approximately 5 mo that is a good results in comparison with that achieved by BSC. Current targeted therapies have not demonstrated efficacy in phase III trial, and future studies must strengthen the efficacy of current chemotherapy agents. Drugs such as nal-iri and nab-paclitaxel represent the first real change in this landscape and may provide new hope for PDA treatment.

Abstract

AIM

To determine whether there is an increased risk of gastric adenocarcinoma associated with vitamin D deficiency (VDd).

METHODS

A retrospective case control study was performed of all patients diagnosed with gastric adenocarcinoma between 2005 and 2015. After we excluded the patients without a documented vitamin D level, 49 patients were included in our study.

RESULTS

The average age of patients with gastric adenocarcinoma and documented vitamin D level was 64 years old (95%CI: 27-86) and average vitamin D level was 20.8 mg/dL (95%CI: 4-44). Compared to a matched control group, the prevalence of VDd/insufficiency in patients with gastric adenocarcinoma was significantly higher than normal vitamin D levels (83.7% vs 16.3%). Forty-one patients (83.7%) with adenocarcinoma showed VDd/insufficiency compared to 18 (37%) patients with normal vitamin D level without gastric cancer (OR: 8.8, 95%CI: 5-22, P value < 0.0001). The average age of males with gastric adenocarcinoma diagnosis was 60 years old vs 68 years old for females (P = 0.01). Stage

II gastric adenocarcinoma was the most prevalent in our study (37%).

CONCLUSION

We reported a positive relationship between VDd and gastric adenocarcinoma, that is to say, patients with decreased VDd levels have an increased propensity for gastric adenocarcinoma.

Key words: Gastric cancer; Adenocarcinoma; Vitamin D

Core tip: In recent years, vitamin D deficiency (VDd) has been associated with several gastrointestinal malignancies largely mediated by vitamin D receptors. It affects multiple cellular processes such as inhibiting differentiation, metastasis, proliferation and inducing apoptosis and cell cycle arrest. All these mechanisms support vitamin D's anti-cancer role. VDd removes the tumorigenic activity that it elicits from regulating cell cycle, inhibiting cellular proliferation, angiogenesis and molecular signaling. Several studies have revealed that vitamin D₃ substantially promotes apoptosis in undifferentiated gastric malignant cells, specifically HCG-27. A retrospective research was conducted to find an association between vitamin D serum levels and gastric cancer.

INTRODUCTION

Vitamin D is a fat soluble secosteroid responsible for enhancing intestinal absorption of several key nutrients such as calcium, magnesium, iron and phosphate. It is known to affect intestinal, skeletal and biologic pathways such as immune cells and tumor microenvironment. Vitamin D exists in two forms - vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol), which is obtained from foods such as fortified dairy products, eggs, fish and liver^[1]. The development of vitamin D₃ also stems from the conversion process of 7-hydrocholesterol in the dermis after exposure to sunlight (ultraviolet-B radiation)^[2]. Vitamin D₂ and D₃, whether from diet or dermal synthesis, is considered biologically inactive. The activation process begins in the liver where hydroxylation occurs by enzyme 25-hydroxylase, which results in 25-hydroxy vitamin D [25(OH)D]^[1-3]. Next, 25(OH)D travels to the kidneys to become the active form of vitamin D; 1,25(OH)₂D₃ by 1 alpha hydroxylase^[2,3]. Subsequently, vitamin D₃ is released to serum where it

acts on receptors of the intestine, bone and kidney to regulate calcium metabolism^[2,4,5].

Measurement of 25(OH)D level is the highly indicative for overall vitamin D status. 25(OH)D accounts for sunlight exposure, dietary intake and conversion from adipose tissue^[3,6,7]. Vitamin D deficiency (VDd) is defined as 25(OH)D < 15-20 mg/dL and sufficient range > 30 mg/dL.

In recent years, VDd has been associated with a multitude of gastrointestinal malignancies largely mediated by vitamin D receptors (VDRs). It affects multiple cellular processes such as inhibiting differentiation, metastasis, proliferation and inducing apoptosis and cell cycle arrest. All these mechanisms support vitamin D's anti-cancer role. Numerous studies have associated colon cancer with low vitamin D, however limited data suggests an association with gastric cancer^[8-11].

Gastric adenocarcinoma is considered the fourth most common cancer worldwide. A major risk factor for development of gastric adenocarcinoma is *Helicobacter pylori* (*H. pylori*) infection^[2]. Other risk factors include smoking and alcohol use. However, recent studies show that VDd is associated with poor prognosis in gastric adenocarcinoma^[3]. Recent cohort studies revealed that increased serum vitamin D levels are linked to a decreased risk of gastric cancer.

VDd removes the tumorigenic activity that it elicits from regulating cell cycle, inhibiting cellular proliferation, angiogenesis and molecular signaling^[12]. Current research illustrates that vitamin D₃ increases apoptosis in undifferentiated gastric malignant cells, specifically HCG-27 cell lines^[3]. In order to find a correlation between serum levels of vitamin D and gastric adenocarcinoma a retrospective research was conducted.

MATERIALS AND METHODS

Study design

A retrospective, single-centered study was performed of all subjects diagnosed with gastric adenocarcinoma between 2005 and 2015. This study was conducted at a tertiary medical center in one of the most diverse communities in the United States, which provided a significant cultural and epidemiological advantage. This study was approved by Icahn School of Medicine at Mount Sinai, Institutional Review Board.

Selection criteria

Among 3200 patients with gastrointestinal malignancies diagnosed between 2005 and 2015, 304 patients had gastric adenocarcinoma. Patients who did not have a vitamin D level were excluded. Of the 304 patients with gastric adenocarcinoma, 49 patients had documented vitamin D levels, documented gastric pathology by pathologist report and were over the age of 18. Vitamin D levels were defined as following: 25(OH)D deficiency (< 20 ng/mL), insufficiency (20-29 ng/mL) and normal 25(OH)D level (≥ 30 ng/mL).

Demographic data such as age, gender and ethnicity

Figure 1 Average vitamin D level in gastric adenocarcinoma vs control group. GA: Gastric adenocarcinoma.

Figure 2 Vitamin D level distribution among gastric cancer adenocarcinoma and control group.

Table 1 Baseline characteristics of gastric adenocarcinoma and control group

Characteristics	Case (gastric adenocarcinoma) (n = 49)	Control (n = 49)
Age, yr	63.9%	60.43%
Male	24 (49%)	24 (49%)
Female	25 (51%)	25 (51%)
Hispanic	30 (61.2%)	30 (61.2%)
Body mass index	24 kg/m ²	25 kg/m ²
	SD (22-27)	SD (23-28)
Vitamin D deficiency	19 (38.8%)	7 (14.3%)
Vitamin insufficiency	22 (44%)	24 (49.0%)
Combined vitamin D deficiency and insufficiency	41 (83.68%)	31 (63.27%)

as well as smoking, body mass index, *H. pylori* infection and stage of adenocarcinoma were assessed. Our cohort was compared to a matched control group of subjects who had no known history of cancers and with documented level of vitamin D (Table 1).

For all statistical analyses, the results were considered significant when two-tailed *P*-values were < 0.05. The distributions of demographic information and baseline comorbidity were compared between both groups.

RESULTS

The average age of patients with gastric adenocarcinoma and documented vitamin D level was 64 years old

(95%CI: 27-86) and average vitamin D level was 20.8 (95%CI: 4-44). Compared to the matched controls, the prevalence of VDd and vitamin D insufficiency in patients who had gastric adenocarcinoma was significantly higher than in patients with normal vitamin D levels (83.7% vs 63.27%). There were 41 gastric adenocarcinoma patients with VDd/insufficiency (83.7%) compared to 18 (37%) patients with normal vitamin D level without gastric adenocarcinoma (OR: 8.8, 95%CI: 5-22, *P* value < 0.0001) (Figure 1).

Furthermore, patients with VDd had an OR that was 2.7 times higher for gastric adenocarcinoma compared to the normal vitamin D population (95%CI: 1.4-5, *P* value 0.002), while patients with VDd had a 1.4 OR. However, endpoints did not achieve statistical significance (*P* value 0.1) (Figure 2).

Among gastric adenocarcinoma groups, stage II gastric adenocarcinoma was most common (37%) followed by stages III (25%), I (20%) and IV (18%). The vitamin D level did not differ between different cancer stages. There were higher rates of Hispanics (61%) followed by the East Asian population (13%) (Table 2). The average age in males with a gastric adenocarcinoma diagnosis was 60 years old vs 68 years old for females (*P* = 0.01). There was no significant difference in average vitamin D level (20 ng/mL in males vs 22 ng/mL in females) or stage of cancer (Figure 3).

We sub grouped the patients with an abnormal vitamin D values into VDd and insufficiency; the average age of gastric adenocarcinoma in the deficiency group

Table 2 Average vitamin D level, age and gastric adenocarcinoma cancer stage based on ethnicity

	Number of patients	Average vitamin D level	Average age	Average adenocarcinoma stage
Hispanic	30 (61%)	20	63	3
East Asian	13 (27%)	20	60	2
Middle Eastern	4 (8%)	21	70	3
Indian	2 (4%)	30	75	3

**Figure 3** The average vitamin D level, age and stage of gastric adenocarcinoma between males and females.**Figure 4** Vitamin D deficiency vs insufficiency among gastric adenocarcinoma group.

was 57.7 years old vs 65.5 years old in the insufficiency group ($P = 0.07$). There were no differences in gastric adenocarcinoma stage between the two groups (Figure 4).

DISCUSSION

In our study, our inclusion criteria were patients diagnosed with gastric adenocarcinoma with a vitamin D level. We had 49 patients as part of our cohorts. These cases were then matched to a cohort of similar age, gender and ethnicity with measured serum vitamin D level and no history of cancer. The mean age of the cases were 64 as opposed to the control group at 60. Gender ratio was similar - 49% male and 51% female. The predominant ethnicity was Hispanic, accounting for 61.2%. This can be attributed to the increased Hispanic patient population at Elmhurst Hospital Center. The diagnoses of gastric adenocarcinoma were by biopsy: 18% with stage IV, 25% with stage III, 37% with stage II and finally 20% with stage I. For our case group, the vitamin D value recorded was the one measured at the time of diagnoses and prior to repletion. We defined

vitamin D levels in association with widely accepted thresholds. VDd is defined as < 20 mg/dL, insufficiency 20-29 mg/dL and sufficiency was ≥ 30 mg/dL.

The prevalence of VDd was compared between the gastric adenocarcinoma group and matched control group, using ORs and 95%CI. Our finding showed an increased prevalence of VDd in the case group as compared to the matched group - 39% vs 14% respectively. The primary end point suggests an association between VDd and gastric adenocarcinoma; however, the study also found no correlation between the degree of deficiency and the stage of gastric adenocarcinoma.

In general, there is now accumulating evidence of VDd associated with multiple malignancies due to its anticancer effects. There has been increasing data for the association of VDd with colon cancer^[2,5,10]. More recently, there is some new research suggesting an association with esophageal, pancreatic and liver cancer as well^[2]. However, there is limited data showing gastric adenocarcinoma. The anticancer biochemical role of vitamin D is largely mediated by the VDR. VDR is a steroid in the thyroid hormone receptor family. Free

1,25 D₃ binds to the VDR causing phosphorylation of the receptor then the ligand activated VDR interacts with the retinoid X receptor (RXR) to form a heterodimer^[8,9,11-14]. Subsequently, the heterodimer 1,25-VDR-RXR complex translocate to the nucleus and thus binds to vitamin D response elements (VDREs) in multiple regulatory regions located in the promoters of target genes^[5,8,9,11-14]. The receptor signaling between RXR and VDR is a vital step for VDR transcriptional activity. VDREs are also utilized to initiate gene transcription. The RXR-VDR complex recruit specific coactivator molecules such as steroid receptor coactivators, histone acetyltransferases and its mediators. The significance of the RXR-VDR complex translocating to the nuclei and binding to VDREs is to allow for promotion or suppression of precise cellular events of tumorigenesis^[2,4,5,15].

The most common malignancy of the stomach is adenocarcinomas arising from gastric epithelium. Gastric adenocarcinoma is the fourth most common malignancy worldwide. In the United States, gastric adenocarcinoma accounts for 1.5% of new cancer cases and 1.8% of cancer deaths. The 5-year relative survival rate for gastric cancer increased from 14.3% in 1975 to 29.3% from 2006-2011^[16]. The 5-year observed survival rate for gastric adenocarcinoma patients after surgery ranges from 71% for stage IA to as low as 4% for stage IV^[17].

Most gastric cancer patients are elderly when diagnosed with a median age of 69 in the United States. Less than 2% of gastric cancer cases arise in patients under 35 years of age. Asia and South America have higher rates of gastric cancer than in the United States. Gastric adenocarcinoma is marginally more prominent in males in the United States, whereas in Japan, it is the most common cancer diagnosed in men. However, worldwide, gastric cancer rates are twice as high in men compared to women. American Cancer Society's estimates for stomach cancer in the United States for 2015 revealed that approximately 24590 cases will be diagnosed (15540 in men and 9050 in women) and that 10720 people will die from this type of cancer (6500 men and 4220 women).

Gastric adenocarcinoma is often asymptomatic, but some non-specific symptoms reported include indigestion, abdominal discomfort and appetite loss. Later in the disease phase there is bleeding which leads to anemia. Although causes of gastric cancer are multifactorial, *H. pylori* infections are an essential risk factor^[17]. However, only 2% of people with *H. pylori* infections develop stomach cancer^[18]. Duodenal ulcers are most likely due to inflammation of the pyloric antrum, whereas inflammation of the corpus causes gastric ulcers and gastric carcinoma^[19]. There is a counter correlation between low socioeconomic status and this disease due to factors such as poor nutrition, poor sanitation and scarce treatment and conservation of food and water. Individuals who maintain diets high in fruits, green vegetables, beta-carotene and ascorbic acid are less at risk. There is also research that indicates decreased use of nitrites in prepared foods reduces the

risk as well. It has also been well studied that dietary factors such as smoked foods and red meat^[20] also increase the risk. With respect to vitamin D, there is now supporting evidence for the association of deficient levels and an increase risk for gastric adenocarcinoma. Several *in vitro* studies proved that 1,25-dihydroxyvitamin D₃ has the anticarcinoma effects of anti-proliferation, promoting apoptosis^[9,20-22]. More specifically, it has been demonstrated that vitamin D₃ substantially stimulates apoptosis in the undifferentiated gastric cancer cell line HCG-27^[3,23]. Moreover, specific to gastric adenocarcinoma, vitamin D₃ inhibits gastric cancer cell growth and induces cell cycle arrest^[9,20,23]. Bao *et al.*^[12] found that direct usage of 1,25 dihydroxy vitamin D₃ induces cellular apoptosis in gastric cancer cells and also increases the expression of VDR, further supporting the antitumor role that vitamin D may activate in gastric adenocarcinoma^[2]. One of the limitations of our study is the small population number as not every patient with gastric adenocarcinoma had documented vitamin D level. Another limitation that must be addressed is the role malnutrition in cancer patients. There are several pathogenesis of cancer associated malnutrition. The primary reason is decreased food intake due to systemic effects of the disease, local tumor effects, psychological effects or adverse effects of treatment. Other contributing factor is the malignancy releasing inflammatory markers systemically such as procytokines have been linked to malnutrition and cachexia^[24]. However, this study is unable to assess the nutrition status of the patients included in this study but one must be aware malnutrition which includes low vitamin D could be a result of the malignancy itself.

The question becomes, can vitamin D supplementation decrease incidence of gastric adenocarcinoma? It is reasonable to suggest the role of supplementation of vitamin D in deficient patients because of indirect etiologies related to gastric adenocarcinoma. Patients who underwent gastrectomy subsequently altered vitamin D metabolism, especially amongst those who received total gastrectomy^[3,25]. Supplementation is also recommended for patients who have malnutrition and malabsorption disorders, which is a consequence of malignancy or diseases such as celiac sprue. Lastly, there is new evidence that high doses of vitamin D plus calcium show significant reduction in cancer incidence in women^[26]. With expanding evidence of vitamin D supplementation and its benefits as mentioned above, avoiding deficiency or adding vitamin D supplements might be an economical and safe way to reduce cancer incidence, or act as a supplement to chemotherapeutic agents^[9,11,24,27]. Overall, VDD can be easily corrected by taking supplements, changing dietary habits or increasing sunlight exposure, which is why it is a practical reason for clinicians to assess vitamin D status. To further assess this association, additional prospective research should be done to clarify the benefit of vitamin D supplementation and possible prevention of gastric adenocarcinoma.

In summary, there is increasing research on the role of vitamin D and gastrointestinal cancers, but there is still limited data on the association of vitamin D and gastric adenocarcinoma. Our study showed VDd has an increased predisposition for gastric adenocarcinoma. There is however no correlation between the severity of VDd and stage of gastric adenocarcinoma.

COMMENTS

Background

In recent years, vitamin D deficiency (VDd) has been associated with a multitude of gastrointestinal malignancies. It affects multiple cellular processes such as inhibiting differentiation, metastasis, proliferation and inducing apoptosis and cell cycle arrest. All these mechanisms support vitamin D's anticancer role. Numerous studies have associated colon cancer with low vitamin D, however limited data suggests an association with gastric cancer.

Research frontiers

Vitamin D is a fat soluble secosteroid that is known to affect intestinal, skeletal and biologic pathways such as immune cells and tumor microenvironment. Vitamin D is related to many cancers and the current research hotspot is the potential use of vitamin D screening and supplementation to prevent or slow the progression of malignancy.

Innovations and breakthroughs

Understand the pathogenesis of vitamin D anticancer role. Several studies have found a link between low vitamin D levels and gastrointestinal malignancy. However, there is limited data suggesting a relationship between VDd/insufficiency in gastric adenocarcinoma.

Applications

This study showed VDd has an increased predisposition for gastric adenocarcinoma. Further studies are warranted to assess this association and the possible risk stratification of vitamin D supplementation in preventing or slowing the progression of gastric adenocarcinoma.

Terminology

The anticancer biochemical role of vitamin D is largely mediated by the vitamin D receptor (VDR). VDR is a steroid in the thyroid hormone receptor family. Free 1,25 D₃ binds to the VDR causing phosphorylation of the receptor then the ligand activated VDR interacts with the retinoid X receptor to form a heterodimer. This allows for the suppression or promotion of specific cellular events of tumorigenesis.

Peer-review

It is interesting that the VDd is associated with gastric adenocarcinoma. The article fits in perfectly with the global trend.

Abstract

AIM

To investigate the prognostic effect of a delayed interval between neoadjuvant chemoradiotherapy (CRT) and surgery in locally advanced rectal cancer.

METHODS

We evaluated 87 patients with locally advanced mid- or distal rectal cancer undergoing total mesorectal excision following an interval period after neoadjuvant CRT at Şişli Hamidiye Etfal Training and Research Hospital, Istanbul between January 2009 and January 2014. Patients were divided into two groups according to the interval

before surgery: < 8 wk (group I) and \geq 8 wk (group II). Data related to patients, cancer characteristics and pathological examination were collected and analyzed.

RESULTS

When the distribution of timing between group I ($n = 45$) and group II ($n = 42$) was viewed, comparison of interval periods (median \pm SD) of groups showed a significant difference of as 5 ± 1.28 wk in group I and 10.1 ± 2.2 wk in group II ($P < 0.001$). The median follow-up period for all patients was 34.5 (9.9-81) mo. group II had significantly higher rates of pathological complete response (pCR) than group I had (19% *vs* 8.9%, $P = 0.002$). Rate of tumor regression grade (TRG) poor response was 44.4% in group I and 9.5% in group II ($P < 0.002$). A poor pathological response was associated with worse disease-free survival ($P = 0.009$). The interval time did not show any association with local recurrence ($P = 0.79$).

CONCLUSION

Delaying the neoadjuvant CRT-surgery interval may provide nodal down-staging, improve pCR rate, and decrease the rate of TRG poor response.

Key words: Rectal carcinoma; Pathological tumor response; Neoadjuvant chemoradiotherapy; Interval timing; Tumor down-staging

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Delaying the neoadjuvant chemoradiotherapy (CRT)-surgery interval for treatment of locally advanced rectal carcinoma may improve pathological complete response rates by providing nodal down-staging, as well as decreasing the rate of tumor regression grade (TRG) poor response. TRG may be an important predictive factor for disease-free survival. Extending the interval between CRT and surgery may improve the survival through tumor down-staging without increasing the rate of surgical complications.

Delaying surgery after neoadjuvant chemoradiotherapy improves prognosis of rectal cancer. *World J Gastrointest Oncol* 2016; 8(9): 695-706 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i9/695.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i9.695>

INTRODUCTION

Locally advanced distal and mid-rectal tumors are commonly treated with preoperative combined chemoradiotherapy (CRT) followed by total mesorectal excision (TME)^[1-3]. Previously conducted studies have recommended a treatment interval time between preoperative neoadjuvant CRT and surgery for the

treatment of locally advanced rectal cancer^[4,5]. The first prospective trial (The Lyon Trial R90-01), which assigned patients randomly to have surgery at two different time intervals following CRT, was conducted in 1999. That trial showed that a 6-8-wk treatment interval between radiotherapy and surgery improved tumor down-staging and yielded a higher pathological response rate compared with a 2-wk interval. Since then, a 6-8-wk interval has been accepted as the appropriate treatment interval between neoadjuvant therapy and surgery^[6]. However, a definite definition for an optimum interval period is still lacking in the medical literature. In addition, even though the known effect of an extended interval on pathological complete response (pCR), the impact of pCR on disease-free survival (DFS) and overall survival (OS) has not been clearly described^[7].

The aim of this study was to determine whether the interval time between preoperative neoadjuvant CRT and surgery affected the rates of pCR, perioperative surgical complications, sphincter-saving surgery, DFS and OS in locally advanced mid-or distal rectal cancer.

MATERIALS AND METHODS

Patients

This was a retrospective review of a series of 113 consecutive patients who underwent preoperative neoadjuvant CRT followed by radical resection with TME for curative intent of locally advanced mid- or distal rectal cancer between January 2009 and January 2014 at Şişli Hamidiye Etfal Training and Research Hospital, General Surgery and Oncology Departments. The study was approved by the local ethics committee. Written informed consent was obtained from all study participants, or their legal guardian for being included in the study. All patients included in the study (1) were aged \geq 18 years; (2) had pathological diagnosis of adenocarcinoma of mid-rectal (located between 5 and 10 cm from the anal verge) and distal rectal (situated in the first 5 cm from the anal verge, excluding the anal canal) tumors by endoscopic biopsy; (3) had tumors with T3/T4 stage or N (+) as demonstrated on pelvic phased-array magnetic resonance imaging; and (4) underwent TME after neoadjuvant CRT. Study parameters including interval period between neoadjuvant CRT and surgery, operation time and type, intraoperative and early postoperative morbidity and mortality, and hospital stay were recorded. Reports from pathological examinations were interrogated to extract data on total and metastatic lymph node numbers and surgical margins. Data on local recurrence, organ metastases that occurred during postoperative follow-up period, DFS and OS rates were also recorded. Postoperative anastomotic complications were defined according to severity grading of anastomotic leakage of the International Study Group of Rectal Cancer^[8]. Twenty-six patients, including those who had widespread metastasis at the time of diagnosis ($n = 3$), patients who underwent short-term radiotherapy (5×5 Gy)

($n = 7$), individuals with synchronized tumors or had treatment due to other malignancies with rectal cancer as secondary ($n = 5$), patients who could not tolerate neoadjuvant chemotherapy ($n = 3$), and patients who were lost to follow-up ($n = 8$) were excluded. The remaining 87 patients constituted the study population. The study patients were divided into two groups according to the interval time between neoadjuvant CRT and surgery: < 8 wk (group I) and ≥ 8 wk (group II).

In all patients, tumor localization and pathological diagnosis were made by using procto-sigmoidoscopy and endoscopic biopsy, respectively. Systemic staging was performed using thoracic and abdominal computed tomography (CT), while local staging was performed using phased-array magnetic resonance imaging. Preoperative neoadjuvant CRT was given for a total of 5 wk and it included 45-50.4 Gy radiotherapy (5×1.8 -2.0 Gy/wk) and concomitant 5-fluorouracil (180 mg/m² per day) for 5 d/wk. Surgery was performed in all patients at the earliest interval of 4 wk after neoadjuvant chemotherapy. The interval between neoadjuvant therapy and surgery varied according to logistics and scheduling preferences of the attending surgeon.

Postoperative follow-up protocol was performed every 3-4 mo during the first year, once every 6 mo during the second year, and once every year after the second year. During follow-up, local recurrences were determined using thoracoabdominal CT, positron emission tomography-CT or colonoscopy.

Pathological examination

Histopathological examination of the resected specimens including the mesorectum was performed to identify as many lymph nodes as possible. Evaluation of tumor regression grade (TRG) after CRT in the primary tumor of the rectal wall was performed by experienced pathologists according to the Ryan scheme for tumor regression score^[9], which was suggested by the College of American Pathologists protocol. The absence of viable cancer cells or acellular pools of mucin in resected specimens were considered as complete response (TRG 1). Single cells or microscopic foci of cancer cells in samples were assessed as near complete response (TRG 2). Residual cancer outgrown by fibrosis was considered as the minimal response (TRG 3). Minimal or no tumor kill, or extensive residual cancer in specimens were found as a poor response (TRG 4). T stage 0 was considered as complete tumor response in the rectal wall, while near complete, minimal or inadequate responses were examined at any T stage. In the present study, tumoral down-staging or pathological tumor response was expressed by TNM classification, according to American Joint Committee on Cancer, and pCR was defined as T stage 0 in the rectal wall without metastatic lymph node in the mesorectum.

Statistical analysis

Data were analyzed using SPSS for Windows, version

17.0 (SPSS, Chicago IL, United States) by the official biostatistician of the hospital. Continuous variables are represented as mean \pm SD and categorical variables as numbers and percentages. Intergroup analyses were performed using Students' *t* test and Mann-Whitney *U* test for continuous variables and χ^2 test and Fisher's exact test for categorical variables. The Spearman correlation test was used to investigate the relationship between continuous variables and intervals between CRT and surgery. Paired *t* and Wilcoxon tests were used to compare dependent groups. Oncological outcomes of patients were classified as 2-year and 5-year DFS and OS. The Kaplan-Meier test, log-rank test, and Cox regression analyses were used to determine the relationship between potential risk factors and DFS and OS. OS was defined as the period between diagnosis of the disease until death that occurred as a result of the disease. DFS was defined as the time between diagnosis of the disease until local recurrence or far-organ metastasis. Patients who died from other causes or died within the early postoperative period were censored. Results were evaluated between 95%CIs, and the level of statistical significance was set at $P < 0.05$.

RESULTS

A total of 87 patients who had locally advanced mid- or distal rectal cancer underwent surgical resection with TME after neoadjuvant CRT. Of these 45 (group I) had a treatment interval < 8 wk and 42 (group II) had an interval ≥ 8 wk. Patient demographics and clinical characteristics were comparable in both groups (Table 1). When the distribution of timing in both groups was viewed, comparison of interval periods (median \pm SD) between the groups showed a significant difference; as 5 ± 1.28 (2-7.8) wk in group I and 10.1 ± 2.2 (8.2-20.2) wk in group II ($P < 0.001$) (Figure 1).

Effect of interval period on preoperative variables

Statistical analysis did not show any correlation between treatment interval and respective preoperative and postoperative variables (operation time and type, diverting ileostomy dehiscence rate, intraoperative and postoperative complication rate, hospital stay and early postoperative mortality rate) (Table 2). Despite all patients being informed about surgical approach and necessity of diverting stoma, six had not given consent to have a diverting loop stoma. Therefore, 42 patients (93.3%) in group I and 39 patients (92.9%) in group II were diverted at the time of TME.

For patients who had distally located tumors, sphincter-saving surgery was performed in 17 (64.7%) in group I and 11 (63.6%) in group II ($P = 0.86$). Intraoperative complications occurred in four patients from group I, left ureter injuries in two patients (4.4%), and presacral significant bleeding in the other two (4.4%). In group II, there was right ureter injuries in two patients (4.7%) and bladder injury in one patient (2.3%) ($P = 0.48$). During

Figure 1 Distributions of groups with regard to interval time between neoadjuvant therapy and surgery. Median interval periods \pm SD were 5 ± 1.28 (2-7.8) wk in group I and 10.1 ± 2.2 (8.2-20.2) wk in group II ($P < 0.001$).

the postoperative period, complications occurred in 13 patients (28.9%) in group I and 11 patients (26.1%) in group II. Complications that occurred in group I were anastomotic leakage in five patients (11.2%) and wound infection in eight (17.8%). Surgical complications in both groups were comparable ($P = 0.42$).

Anastomotic complications were classified based

on the severity grading of anastomotic complications of the International Study Group of Rectal Cancer. In group I, three cases with diverting stoma developed perianastomotic abscess in the pelvis. These were classified as Grade B anastomotic complications, and managed successfully with percutaneous abscess drainage and antibiotics. Two cases that were not

diverted at the time of TME required reoperation for Grade C anastomotic leakages. Mortality occurred in 1 (2.3%) of the patients who had Grade C anastomotic leakage on postoperative day 18.

In group II, anastomotic leakage was observed in 8 patients (19%), wound infection in 3 (7.1%) and mortality in 2 (4.7%). Mortality was due to postoperative pulmonary emboli and myocardial infarction. Grade A anastomotic complications appeared in four patients with diverting ileostomy who were treated with antibiotics, without the need for invasive interventions or surgical procedures. Grade B anastomotic complications occurred in three cases, and one of them did not have a diverting stoma. These patients underwent percutaneous abscess drainage and were treated with antibiotics. One patient who was not diverted with a stoma at the time of TME developed Grade C anastomotic leakage, and surgery was performed in this case. There was no mortality associated with anastomotic leakage in group II patients. There were no significant differences between the groups in terms of anastomotic complications or early postoperative mortality ($P = 0.07$ and $P = 0.37$, respectively).

Effect of interval period on stage and pathological response

In both groups, there were no significant differences in terms of postoperative T stage ($P = 0.17$). However, histopathological examination of TME specimens showed different nodal complete response in both groups (46.7%

vs 81%, $P = 0.001$) (Table 3). The pathological tumor down-staging was found to be related to a decreased number of metastatic lymph nodes in the mesorectum. Tumor down-staging rate was 57.4%, as the pCR [Stage 0 (TON0)] rate was 13.8%. In group I, tumor down-staging occurred in 22 patients (48.9%), while no down-staging was obtained in 23 patients (51.1%); of whom 22 patients had Stage 3 disease and the remaining one had Stage 2 disease. The pCR rate in group I was 8.9%. In group II, 33 patients (78.5%) developed tumor down-staging and nine (21.4%) showed no down-staging. Eight of the patients who showed no down-staging had Stage 3 disease and the other one had Stage 2 disease. The pCR rate in group II was 19%. A significant decrease in postoperative stage was seen in patients who had a longer interval period. Patients in group II had significantly higher rates of pCR than their counterparts in group I (19% vs 8.9%, $P = 0.002$).

Significant predictors of pathological response such as age, gender, tumor localization, preoperative stage, preoperative T stage, and interval time were investigated by univariate and multivariate analyses. Except for pathological TRG and interval time, no positive correlation was noted between other predictive factors and pathological response. However, while rate of poor response TRG (TRG-4) was found to be 44.4% in group I, it was 9.5% in group II ($P < 0.002$). Although, an extended interval between CRT and surgery was found to increase rates of complete or near-complete TRG response, this rate was not significant when both groups were compared (Table 4).

A total of 60 patients who were diagnosed with Stage 2 or 3 disease after histopathological examination of TME specimens, including 30 patients in each group, were recommended for postoperative adjuvant therapy. However, 57 patients eventually received adjuvant therapy after surgery due to early postoperative mortality in three patients.

Factors predicting local recurrence, DFS and OS

The median follow-up period for all patients was 34.5 (9.9-81) mo. Median follow-up time for group I was 37.5 (9.9-74.5) mo and group II was 31.2 (10.7-81) mo. Median follow-up was comparable in both groups ($P = 0.59$).

Analysis of OS in group I showed median survival duration of 62.8 (95%CI: 55.8-69.7) mo, and a 24-mo

survival rate of 91.5%, and 60-mo survival rate of 79.1%. For group II, the median OS was 77.9 (95%CI: 72-81) mo. Twenty-four-month survival rate was 100%, and 60-mo survival rate was 94.4%. OS showed a significant difference when both groups were compared (*P* = 0.02). The median DFS duration in group I was 50.8 (95%CI: 43.4-58.2) mo. DFS rates were 76.4% at 24 mo and 55.3% at 60 mo. For group II, median DFS was 71.2 (95%CI: 63.1-79.2) mo. DFS rate was 85.1% at 24 mo and remained unchanged at 85.1% until 60 mo in group II. DFS rates differed significantly when both groups were compared (*P* = 0.01) (Figure 2).

When potential factors affecting OS and DFS were analyzed, nodal down-staging was found to have a positive correlation with OS and DFS (Table 5). OS and DFS were better in patients who achieved nodal down-staging (OS: 78% vs 52.1%, *P* = 0.001; DFS: 72.3% vs 43.1%, *P* = 0.001) (Figure 3).

After investigating the correlation between survival rates and pathological TRG, lower and moderate pathological regression grades (TRG 1-3) provided similar survival benefit, but only a poor pathological response (TRG 4) was associated with worse DFS

(*P* = 0.009). However, TRG scores did not show any association with OS and local recurrence (*P* = 0.06 and *P* = 0.39, respectively) (Figure 4).

Local recurrence was found to be 8.9% after a mean duration of 71.1 ± 2.3 mo in group I. Group II had a local recurrence rate of 7.1% after a mean duration of 72.4 ± 4.6 mo. The interval time did not show any association with local recurrence (*P* = 0.79) (Figure 5).

DISCUSSION

Since the initial description of the TME technique for rectal cancer by Heald, TME has become the standard surgical treatment for mid- and distal rectal cancer^[10-12]. Previous prospective studies have shown that surgery alone is not sufficient for local disease control, but its combination with preoperative CRT reduces local recurrence and increases DFS^[3,13-19]. The Lyon R90-01 Trial was the first randomized prospective study to compare the effects of short and long intervals after neoadjuvant therapy on pathological tumor down-staging, and found that a 6-8-wk treatment interval between radiotherapy and surgery improved tumor

down-staging and pCR. Since then, a 6-8-wk interval has been accepted as an appropriate interval between preoperative neoadjuvant therapy and surgery^[6].

In contrast, there have been rising concerns among surgeons regarding radiation-induced pelvic fibrosis that may occur as a result of a longer waiting period.

This is because fibrosis may cause operative difficulty and lead to an increased rate of surgical complications. Therefore, the issue of surgical timing has encouraged further studies to investigate the optimal interval time for surgical treatment in terms of oncological outcomes.

Several studies that have examined the effect of different intervals after neoadjuvant CRT on tumor response, pCR, local tumor control and survival have reported conflicting results (Table 6). Our study showed a higher rate of pCR among patients who had an interval > 8 wk. pCR was associated with a decreased number of metastatic lymph nodes in the mesorectum, which led to tumor down-staging. The only factor providing nodal down-staging was found to be interval period. In contrast, a shorter or longer interval time did not show any effect on T stage of the rectal wall. Specifically, a longer interval time was associated with a significant reduction in TRG 4 (poor response) rates. High TRG 4 rate (44%) in the shorter interval group in our study may be explained by performing surgery at 5 wk after neoadjuvant CRT in most patients.

It is questionable whether the poor tumor response

Figure 5 Local recurrences were similar in both interval groups. The interval duration did not show any association with local recurrence ($P = 0.79$).

also reduces DFS, while pCR is assumed as an indicator of improved DFS. Our findings established a negative correlation between TRG 4 (poor response) and DFS; an outcome that has not been mentioned in previous studies. Its clinical significance represents poor prognosis in terms of disease recurrence. Thus, the possibility of early recurrence of the disease should be considered in follow-up of patients who had TRG 4.

In a retrospective study by Wolthuis *et al*^[20], patients who underwent surgery after a treatment interval > 7 wk showed better pathological tumor response. However, pathological response in this study was evaluated based on the final pathological T staging of the rectal wall. In the Lyon R90-01 Trial by Francois *et al*^[6], despite the exclusion of preoperative chemotherapy, a longer interval time was again associated with better clinical tumor response. In another study, Kalady *et al*^[21] reported a pCR of 31.8% among patients who waited for > 8 wk before surgery and 16% in patients who had an interval < 8 wk. The authors further documented that an extended interval between completion of neoadjuvant therapy and surgery was the single most important determinant of better tumor response regarding final T stage in rectal wall as well as lymph nodes. Garcia-

Aguilar *et al.*^[22] in their prospective multicenter study investigated the effect of an extended interval between CRT and surgery on tumor response, CRT-related toxicity, and surgical complications. The authors also examined the impact of intense chemotherapy that was given during this interval period on pCR rates. They found that intense CRT in addition to increasing the time interval between neoadjuvant therapy and surgery may increase the pCR rate without significantly increasing CRT-related complications, operative difficulty or postoperative complications. Similarly, de Campos-Lobato *et al.*^[23] found an interval > 8 wk to be associated with a higher rate of pCR. In a recent study of predictive factors affecting pCR by Tulchinsky *et al.*^[24], neoadjuvant-surgery interval time was an independent predictive factor of tumor down-staging. In the largest and one of the most recent studies by the Dutch Surgical Colorectal Audit, a longer CRT-surgery interval of approximately 11 wk was related to the highest chance of pCR^[25]. Also, meta-analyses of several studies confirmed that an interval > 8 wk before surgery resulted in more tumor regression^[26,27].

In contrast, there have been studies reporting no correlation between duration of treatment interval and pCR. Findings from these studies have associated pCR with the longer period needed for a CRT response^[5,19,28-32]. In a study by Pucciarelli *et al.*^[33], tumor response was associated with preoperative chemotherapy regimen. A surgical interval > 6 wk was identified as a favorable prognostic factor for OS, although no differences were observed in pCR or DFS.

Our rates of tumor responses were lower than in the other studies. This was because of failure of tumor down-staging in half of the patients in group I. However, the longer interval group still had a better pCR than the shorter interval group had in the present study, and pCR rate was 19%, which was comparable with other studies. In the present study, tumor down-staging was related to a decrease in metastatic lymph nodes in the mesorectum, and a longer interval was needed for nodal down-staging.

A pCR is deemed to increase the chances of sphincter-saving surgery, decreases local recurrence, and has a positive prognostic impact on survival. Our study showed a positive correlation between pathological tumor response and OS and DFS. Patients who had an extended interval time had higher OS and DFS rates. These findings are in agreement with the study of Yeo *et al.*^[34]. In their multicenter retrospective study, which examined mesorectal nodal status in patients with T0 stage in the rectal wall after neoadjuvant therapy, nodal status was the most efficient independent prognostic factor for DFS and OS. Similarly, Abdul-Jalil *et al.*^[35] reported that pCR and nodal status after neoadjuvant therapy were important predictive factors for survival. Pucciarelli *et al.*^[33] showed that preoperative T staging was the only independent prognostic factor of DFS and OS; however, they reported that pathological tumor response did not affect survival. In the study by Francois *et al.*^[6] an extended interval time did not have any effect

on local recurrence and short-term survival. Also, in our study, rate of poor response TRG (TRG 4) was found to have negative effect on DFS, and was significantly lower in patients who had an extended interval before surgery. This shows the contribution of the prolonged interval to longer DFS. However, these factors were not associated with local recurrence. Similarly, Rödel *et al.*^[36] found that poor TRG was associated with worse DFS rate (63%), but not with local recurrence. In contrast, they found an association between TRG and presence of residual tumors in lymph nodes, but not between TRG and interval before surgery^[36]. In another study by Abdul-Jalil *et al.*^[35], TRG had no prognostic effect on survival.

Although it is suggested that neoadjuvant CRT increases the chances of sphincter-saving surgery, the benefit of extending the interval time from neoadjuvant therapy to surgery in reducing rates of abdominoperineal resection is controversial. Most studies investigating sphincter preservation rates by neoadjuvant therapy-surgery interval have reported no correlation between them^[5,6,22,24-26,29-31,37,38]. Our sphincter-saving surgery rates were similar in both groups, indicating no influence of neoadjuvant therapy-surgery interval. Also, its rate of 64% was comparable with the results of the other studies^[2,24,39].

One of the major concerns regarding extending the interval after neoadjuvant CRT is radiotherapy-induced fibrosis, which can lead to operative difficulty and an increased risk of intraoperative and postoperative morbidity. Current data on the effect of interval time and perioperative morbidity have varied. Buie *et al.*^[40] in their retrospective study of 246 patients, who underwent TME after neoadjuvant CRT, noted a significant increase in the rate of pelvic sepsis. In contrast, Martel *et al.*^[41] reported factors such as smoking, difficult anastomosis, and anastomosis located in the first 4 cm from the anal verge as significant predictors of pelvic sepsis, and not neoadjuvant CRT. In a recent prospective randomized study by Saglam *et al.*^[31], although overall surgical complication rate was higher in the short interval group, similar individual postoperative complications in both groups were observed. Similar findings were reported by Kerr *et al.*^[42] in another retrospective study that included 189 patients. Postoperative complication rates in that study were higher in patients operated on after < 8 wk delay, while the interval was not related to mortality. In contrast, several studies have shown no significant increase in postoperative complications by delaying surgery after neoadjuvant CRT^[6,20,22-24,30,32,43-45]. The findings of the present study have also shown similar postoperative complication rates in both short and long neoadjuvant therapy-surgery interval. Besides, we report a surgical complication rate of 26%-28%, which is considerably lower than the 40%-43% that previously reported^[24,39]. Our short-interval group had an anastomotic leakage rate of 11.1% compared with 19% in the long-interval group. The overall anastomotic complication rate in the present study was 14%, and did not differ significantly between the short- and

long-interval groups (11.1% and 19%, respectively). These findings were comparable with the results of other studies reporting an anastomotic leakage rate of 10%-20%^[4,6,24,40,46]. Our early postoperative morbidity rates also showed no significant difference between the groups.

The current study had several limitations. First, the retrospective nature of the study did not allow a comprehensive appraisal of the reported findings, and may account for the significant effect of the interval time on poor response TRG (TRG 4) and its effect on DFS. The other limitation was that the study did not allow a full analysis of long-term oncological results in all patients, because of the patients who did not complete the 5-year follow-up period.

The findings of the present study suggest that delaying the neoadjuvant CRT-surgery interval provides nodal down-staging and improves pCR rates, as well as decreasing the rate of TRG poor response. TRG may be an important predictive factor for DFS. Extending the interval between CRT and surgery may improve survival through tumor down-staging without increasing the rate of surgical complications. Studies investigating the optimal time between neoadjuvant CRT and surgery and its effect on pre- and postoperative outcomes should be encouraged for better oncological outcomes and lowest morbidity.

COMMENTS

Background

Today, locally advanced distal and mid-rectal tumors are commonly managed with preoperative combined chemoradiotherapy (CRT) followed by a waiting time before total mesorectal excision (TME). Previous studies have shown that a 6-8-wk interval between CRT and surgery improves tumor down-staging and provides a higher pathological response rate. However, the optimum interval is still lacking in the medical literature. In addition, even though the effect of an extended interval on pathological complete response (pCR) is known, the impact of pCR on disease-free survival (DFS) and overall survival (OS) has not been clearly described. Thus, interval before surgery is important in terms of tumor response and survival. The aim of this study was to determine whether the interval time between preoperative neoadjuvant CRT and surgery affects the rates of pCR, perioperative surgical complications, sphincter-saving surgery, DFS and OS in locally advanced mid- or distal rectal cancer.

Research frontiers

Although the concept of interval between CRT and surgery in the management of locally advanced rectal cancer is generally accepted, a clear and explicit waiting period before surgery is not defined. However, previous studies have shown that an extended interval time between CRT and surgery improve survival and tumor response rates without increasing surgical complications. Based on the current results, there is a trend towards extension of the interval to > 8 wk before surgery for locally advanced rectal cancer.

Innovations and breakthroughs

In this study, longer interval time was related to nodal down-staging and better pathological tumor response. pCR rate was 19% in the longer-interval group, comparable with other studies. Also, patients who had an extended interval had higher OS and DFS rates. However, in this study, poor response tumor regression grade (TRG) 4 had a negative effect on DFS and was significantly lower in patients who had an extended interval before surgery. This finding emphasizes the importance of the negative effect of poor TRG on DFS.

Applications

The present study suggests that an interval > 8 wk between CRT and surgery provides tumor down-staging and higher tumor response rates, and improves survival. Poor TRG is associated with shorter interval before surgery and related to worse DFS. If a patient has TRG 4 in his/her histopathological examination of the resected specimen, the possibility of early recurrence should be considered in follow-up of the patient.

Terminology

TME is a gold standard surgical technique for treatment of rectal cancer, first described by Bill Heald in 1982. A significant length of the bowel around the tumor together with mesorectum involving metastatic lymph nodes is removed *en bloc*. Neoadjuvant CRT is the administration of chemotherapeutic agents before surgery for locally advanced rectal cancer. The goals of neoadjuvant CRT are to reduce tumor size before radical surgical intervention, and provide local control of the disease. DFS is the length of disease-free time until the first relapse of the disease after curative treatment. OS is the length of time that patient is still alive, from the date of diagnosis or the start of treatment. TRG is a scoring system evaluating the response of the primary tumor of the rectal wall to CRT in resected specimens.

Peer-review

The authors have concluded that studies investigating the optimal time between neoadjuvant CRT and surgery and its effect on pre and postoperative outcomes should be encouraged for better oncological outcomes and lowest morbidity.

Abstract

AIM

To verify the current status of super-extended lymph node dissection for advanced gastric cancer according to a questionnaire survey.

METHODS

One-hundred and five institutions responded to the questionnaire. The survey included the following items: Number of experiences, whether performed prophylactically and/or therapeutically, whether preoperative chemotherapy was provided, number of preoperative chemotherapy rounds, and therapeutic options after chemotherapy.

RESULTS

Eighty-seven of the 105 institutions (83%) had performed D3 gastrectomy in the past or continued to perform D3 gastrectomy at present. However, D3 gastrectomy was rarely performed prophylactically in clinical practice. Seventy-eight institutions (74%) indicated that preoperative chemotherapy with curative intent was required for patients suspected of having para-aortic node (PAN) metastases. After chemotherapy, a D3 gastrectomy was scheduled for patients with a complete or partial response, stable disease, and progressive disease at 36 (46%), 28 (36%), and 13 (17%) of the institutions, respectively.

CONCLUSION

For patients with apparent PAN metastasis, a D3 gastrectomy is typically planned if a few courses of

preoperative chemotherapy yield at least a stable disease condition.

Key words: Questionnaire survey; Advanced gastric cancer; Radical surgery; Para-aortic nodal dissection; Preoperative chemotherapy

Core tip: In this paper, we discussed the current status of super-extended lymph node dissection (LND) for advanced gastric cancer based on the results of a questionnaire survey. A recent study has indicated that prophylactic super-extensive lymphadenectomy does not improve the survival rate in patients with curable gastric cancer. In another study, surgery with para-aortic dissection was effective with the addition of neoadjuvant chemotherapy. Although super-extended LND seems to be rarely accepted worldwide, the rigorous and careful selection of patients can provide long-term survival after systemic LND. Therefore, we present the current status of super-extended LND in Japan.

Morita S, Fukagawa T, Fujiwara H, Katai H. Questionnaire survey regarding the current status of super-extended lymph node dissection in Japan. *World J Gastrointest Oncol* 2016; 8(9): 707-714 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i9/707.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i9.707>

INTRODUCTION

Gastrectomy with D2 lymph node dissection (LND) has been the standard operation for advanced gastric cancer (AGC)^[1,2]. Although the efficacy of LND has been proven, patients with extensive nodal metastasis have a poor prognosis, even after R0 resection.

Lymphatic flow from the stomach streams into the perigastric nodes and then passes to the nodes around the celiac axis and its main branches. Following its influx into the para-aortic nodes (PANs), it finally joins the systemic circulation *via* the thoracic duct. Thus, the PANs have been regarded as the final nodal station requiring dissection to remove the threat of systemic metastases originating from the lymphatic system^[3]. Therefore, Japanese surgeons pursued a path of lymphadenectomy expansion with curative intent in the 1970s and 1980s. Although a super-extended dissection can be safely performed with acceptable operative risks, the long-term outcomes of patients with PAN metastasis have been less than spectacular, with reported 5-year survival rates of less than 30% and an incidence of PAN involvement from AGC of 10%-30%^[4-8]. To investigate whether para-aortic nodal dissection (PAND) for gastric cancer has a survival benefit in a large prospective study, the Japan Clinical

Oncology Group (JCOG) conducted a multi-institutional, randomized, controlled trial of D2 vs D2 plus PAND for patients with curable gastric cancer. This trial obtained evidence that the recommendation for extended D2 lymphadenectomy plus PAND should be withdrawn for the treatment of T2b, T3, or T4 curable gastric cancers^[8]. Critics have pointed out that PAN involvement indicates a systemic level of metastasis that is already outside the reach of surgical management, and dissecting these lymph nodes is not necessarily correlated with a better prognosis, at least in a preventative manner. In response to this result, the new Japanese Classification of Gastric Carcinoma (JCGC) excluded PAN from the regional lymph nodes of the stomach^[9]. Positive No.16 lymph nodes are treated as distant metastases, resulting in a Stage IV classification. Therefore, Japanese surgeons have revised their treatment strategy by focusing on highly effective treatments, such as a multimodal approach that includes chemotherapy to reduce recurrences after radical surgery. At present, surgical resection is the only way to remove tumors completely. We present an overview of the current status of PAND in Japan, having gathered information through a questionnaire survey.

MATERIALS AND METHODS

At the 2012 annual meeting of the Japanese Society for Gastro-surgical Pathophysiology, 13 data items, including PAND for patients with primary AGC, were collected retrospectively using a questionnaire survey. In this study, D3 gastrectomy was defined as D2 plus PAND, and the further dissection of other group 3 nodes described in the 13th JCGC was not necessarily required. The PANs, which are defined as the third tier, correspond to the No.16-a2 areas (nodes between the level of the celiac axis and the left renal vein) and the No.16-b1 areas (nodes between the left renal vein and the inferior mesenteric artery), based on the JCGC^[9]. The questionnaire contained questions regarding experience level, indications for prophylactic or therapeutic use, and data pertaining to preoperative chemotherapy (Table 1). Unexamined cases and patients with missing data were excluded when calculating the incidence.

RESULTS

The questionnaire was prepared and sent to 254 institutions. One hundred and five institutions (41.3%) responded to the survey. The geographical and functional distributions of the responding 105 hospitals are shown in Figure 1A. Fifty-two were academic medical centers and seventeen were cancer centers. The other 36 institutions were general hospitals.

Do you have any experience performing PAND?

Eighty-seven (83%) of all the responding institutions had experience performing PAND, and 28 institutions (17%) were still performing this procedure (Figure

PAND: Para-aortic nodal dissection.

1B). Fourteen institutions had each performed more than 100 procedures. Seven institutions had performed 50 or more procedures but less than 100 procedures. Forty-nine institutions did not have much experience, having performed less than 50 procedures (Figure 1C). Seventeen institutions did not provide a specific number of procedures on the questionnaire form.

When performing a distal gastrectomy, do you dissect the left upper lateral nodes ("No.16-a2-lat")?

For a distal gastrectomy, the dissection of the left upper lateral nodes ("No.16-a2-lat") has been regarded as optional because of the low incidence of metastasis. Twenty-six (30%) of the 86 respondents reported dissecting the a2 lat nodes even if the resected part was

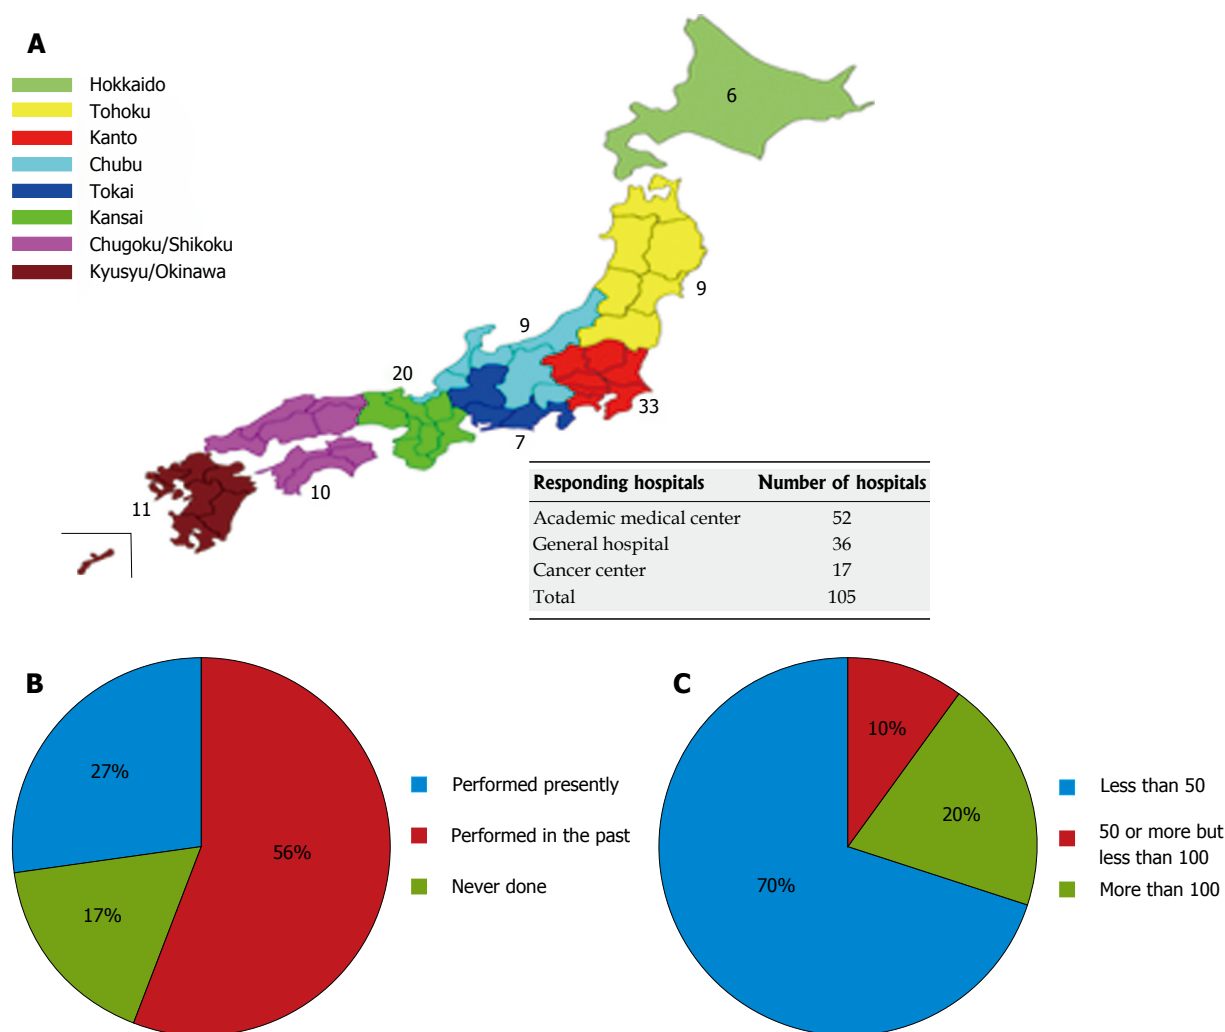

Figure 1 Geographical distribution, experiences and hospital volumes in the 105 responding hospitals. PAND: Para-aortic nodal dissection.

distal to these nodes; 40 institutions (47%) reported that they sometimes dissected these nodes, and 20 institutions (23%) reported that they never dissected these nodes.

Prophylactic PAND dissection

For cases with no preoperative evidence of metastasis in the PAN, almost all the institutions never performed a prophylactic D3 dissection. Six (6%) of the 105 respondents performed prophylactic D3 dissections for staging purposes or in the case of nodal swelling in the supra-pancreatic area (Figure 2A). Only 21 institutions (20%) performed sampling at this site. Of the 21 institutions, 8 (38%) performed an additional dissection of the para-aortic area, if the examination of frozen samples was positive.

Therapeutic PAND dissection

For cases with apparent preoperative metastasis in the PAN, 78 (74%) of the 105 respondents reported performing preoperative chemotherapy, and 7 institutions

(7%) reported performing a D3 dissection without other therapies. The remaining institutions performed systemic chemotherapy in such cases (Figure 2B).

Preoperative chemotherapy

The most common preoperative chemotherapy regimen was a combination of S1 and cisplatin, which was selected by 57 (73%) of the 78 respondents. A triple-drug combination of S1, cisplatin and docetaxel was the second most common combination, selected by 20 institutions (26%). Two cycles of preoperative chemotherapy were selected by 62 institutions (79%), and three cycles were selected by 7 institutions (9%). If a complete or partial response was achieved after chemotherapy, 35 institutions (45%) provided additional chemotherapy for up to six cycles.

For cases with a PR or CR, the performance of an additional D3 dissection was selected by 36 (47%) of the 77 respondents, while a D2 dissection plus sampling was selected by 34 institutions (44%). Seven institutions (9%) limited the extent of LND to a D2 dissection. For

Figure 3 Results for the question regarding treatment options after preoperative chemotherapy in patients with obvious para-aortic nodal metastasis.

SD cases, the performance of an additional D3 dissection was selected by 27 institutions (35%), while a D2 dissection plus sampling was selected by 39 institutions (51%). Four institutions (5%) selected non-surgical treatment. For PD cases, 13 institutions (17%) still perform D3 dissections, although 36 institutions (47%) select a D2 dissection plus sampling and 19 institutions (25%) select a D2 dissection. Eight institutions (10%) have abandoned surgical treatment (Figure 3). Operations without preoperative chemotherapy were only performed at 7 institutions (7%) overall.

DISCUSSION

The 2008 annual report of the JGCA showed that D3 dissection was only performed in 7.2% of all surgically treated patients^[10]. In our data set, about 26% of the institutions that responded are still performing D3 gastrectomy. Overall, the number has been declining. The main reasons for this decrease are generally attributed to the following three aspects. First, the survival benefit for patients treated with a super-extensive LND has reached a plateau with the technical evolution and systemization of the surgical procedure. Basically, Japanese surgeons have adhered to the traditional

concept of a lymphadenectomy, which offers the best chance for the removal of involved lymph nodes and the treatment of AGC. However, metastasis to the para-aortic lymph nodes is correlated with a significantly poor prognosis, even after the complete surgical removal of these lymph nodes. Several reports have shown that the probability of PAN involvement is 30% at most^[11]. Several theories regarding the optimal level for extensive LND exist, and a uniform strategy has not yet been formulated.

The second reason is that only patients with PAN involvement and neither peritoneal seeding nor liver metastasis are candidates for this treatment. With advances in mass-screening and imaging equipment, early gastric cancer now accounts for nearly 50% of all gastric cancers in Japan^[10]. Moreover, obtaining multiple slices on computed tomography and/or diagnostic laparoscopy has further reduced the number of patients who meet the selection conditions^[12,13]. Thus, only a very few patients are likely to be candidates for this procedure, and such patients are rarely encountered in clinical practice.

Thirdly, a large randomized clinical trial had a considerable influence on the present results. A report by the JCOG showed that there was no survival benefit for a prophylactic D2 lymphadenectomy plus PAND (70.3%), compared with a D2 dissection alone (69.2%), in patients with AGCs^[8]. Our data shows that prophylactic dissection is not popular in Japan. The results of the above-mentioned clinical trial have contributed to the recent reduction in procedures. Some institutions perform PAND prophylactically, although they are few in number. However, the purpose of such procedures is only for staging, and not for curative intent. About two thirds of institutions (62%) do not perform complete PAND even if the frozen examination of PAN is positive. Similarly, a few institutions (7%) plan to dissect these nodes during their first attempt in cases with apparent PAN swelling preoperatively. Regardless of surgical treatment, the number of institutions performing chemotherapy as the initial treatment has been

increasing. This trend suggests that PAN involvement is regarded as being almost systemic, and the dissection of these lymph nodes is not necessarily related to a better prognosis, at least in a preventative manner. This situation emphasizes the importance of multidisciplinary therapies^[14-16].

Several selected phase I and II trials of preoperative chemotherapy in patients with resectable gastric cancer have been performed since the 1990s^[17-27]. The current practice for the treatment of patients with gastric cancer in Europe is now surgery with perioperative chemotherapy, after promising results were obtained in two major randomized control trials^[15,28]. In Japan, two selected phase II trials of neoadjuvant chemotherapy followed by a D2 gastrectomy with PAND for resectable gastric cancers have been reported^[27,29]. Although one trial was terminated because of treatment-related deaths, the other showed both the feasibility and the effectiveness of S-1 plus cisplatin followed by a D2 gastrectomy with PAND. In our data, around three-fourths of the institutions responded that they used the SP regimen for preoperative therapy. About one-fourth added one more agent, docetaxel, to the SP regimen. A neoadjuvant setting for tumor down-staging to improve resectability is considered to be required for the treatment of apparent PAN involvement, although some theoretical disadvantages do exist, such as tumor progression, oncological emergency, and a high perioperative morbidity^[30]. Further consideration will be needed to select the most effective regimen.

Finally, the JCOG9501 study also reported a paradoxical interaction in that the survival rates were better for those patients assigned to D2 plus PAND than for those assigned to D2 alone among cases with pathologically negative nodes^[8]. This result may indicate the effectiveness of an extended lymphadenectomy in cases that have responded well to preoperative chemotherapy. Our study showed a pronounced propensity for patients with a good clinical response (at least more than stable disease after chemotherapy) to have undergone a D3 dissection. The determination of the optimal extent of LND (D2 or D3) in cases with a complete response after chemotherapy is still a matter of debate. On the other hand, a considerable number of SD or PD cases had undergone D3 including PAND. Kurokawa *et al.*^[31] reported that the histological response rate seems to be a better surrogate endpoint for overall survival than radiologic response rate in studies of neoadjuvant therapy for gastric cancer. At the least, diagnostic laparoscopy should be a recommended preoperative examination for staging. Regarding the poor radiologic response to chemotherapy, careful handling is required after excluding apparent PD cases. To settle this important matter, further prospective validation is needed.

The main limitation of this study was that the intended group was confined almost exclusively to patients with PAN involvement. In addition, this highly targeted group needed to meet stringent requirements consisting of

the absence of peritoneal seeding and liver metastasis. Therefore, it should be noted that the response rate was comparatively low, given that mainly specialized institutions were included, and that biases in the data were unavoidable because of problems such as the limited number of patients from small and medium-sized hospitals.

In conclusion, preoperative chemotherapy with curative intent is almost essential for patients with PAN involvement. However, this does not deny that super-extended LND may play a certain role in the course of radical therapy. This procedure should be confined exclusively to specialized institutions, since eligibility is limited and a high surgical proficiency is required.

COMMENTS

Background

Super-extended lymph node dissection (LND), including the para-aortic area, is a controversial issue in the treatment of patients with advanced gastric cancer (AGC). The Japanese Society for the Study of Postoperative Morbidity after Gastrectomy conducted a nationwide questionnaire survey to clarify the current status of para-aortic LND for AGC.

Research frontiers

The long-term outcomes of patients with para-aortic node (PAN) metastasis have been less than spectacular. Positive No.16 lymph nodes are treated as distant metastases. The results of this study contribute to clarifying the current status of super-extended LND in Japan.

Innovations and breakthroughs

Platinum doublet chemotherapy, S1 plus CDDP, is widely used as a neoadjuvant chemotherapy for AGC with PAN metastasis. The study showed a pronounced propensity for patients with a good clinical response to have undergone a D3 dissection.

Applications

This large survey suggested that D3 dissections are not performed for prophylactic purposes. For patients with apparent PAN metastasis, a D3 gastrectomy is usually planned if a few courses of preoperative chemotherapy yield at least a stable disease condition.

Terminology

D3 dissection: Super-extended LND including perigastric, supra-pancreatic and para-aortic areas for AGC with a risk of extensive nodal involvement.

Peer-review

This manuscript deals with questionnaire survey on super-extended lymph-node dissection in patients with AGC. The conclusion of this manuscript seems to agree with the general consensus of current Japanese surgical oncologists, and could be acceptable for publication.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Narikazu Boku, MD, PhD, Professor, Division of Gastrointestinal Oncology, Shizuoka Cancer Center, Shizuoka 4118777, Japan

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Despite the considerable amount of research in the

field, the management of locally advanced rectal cancer remains a subject to debate. To date, effective treatment centers on surgical resection with the standard approach of total mesorectal resection. Radiation therapy and chemotherapy have been incorporated in order to decrease local and systemic recurrence. While it is accepted that a multimodality treatment regimen is indicated, there remains significant debate for how best to accomplish this in regards to order, dosing, and choice of agents. Preoperative radiation is the standard of care, yet remains debated with the option for chemoradiation, short course radiation, and even ongoing studies looking at the possibility of leaving radiation out altogether. Chemotherapy was traditionally incorporated in the adjuvant setting, but recent reports suggest the possibility of improved efficacy and tolerance when given upfront. In this review, the major studies in the management of locally advanced rectal cancer will be discussed. In addition, future directions will be considered such as the role of immunotherapy and ongoing trials looking at timing of chemotherapy, inclusion of radiation, and non-operative management.

Core tip: Numerous controversies exist within the treatment of locally advanced rectal cancer. This review article summarizes the relevant evidence for rectal cancer treatment and offers opinions on how to interpret the data in clinical practice. Additional information is provided on novel areas of interest that are being actively explored such as the role of immunotherapy, the need for biomarkers, and the non-operative management.

INTRODUCTION

Over the last several decades, the approach to treat locally advanced rectal cancer has become more complex. Surgical and pathologic advances as well as multimodality approaches combining surgery, chemotherapy, and radiation therapy (RT) have decreased recurrence rates and improved quality of care. The mainstay of treatment to date has been surgical resection, and total mesorectal excision (TME) is the current standard. The goal of adjuvant therapy (radiation and chemotherapy) is to further decrease the rate of local and distant recurrences. Fluoropyrimidine-based chemotherapy both sensitizes the tumor cells to radiation as well as eliminates micrometastatic disease. However, despite refinements in the treatment of locally advanced rectal cancer, substantial controversies remain: Among them, the optimal course of radiation, sequencing of therapy, and surgical approach to clinical complete responses to neoadjuvant therapy. In this article, we highlight several of the prominent controversies in the treatment of locally advanced rectal cancer and provide a platform for discussion of evolving areas of interest within the field.

TIMING OF RADIATION AND SHORT COURSE RADIATION VS LONG COURSE CHEMORADIATION

The use of radiation therapy prior to surgery, rather than after surgery, is currently the standard of care for locally advanced rectal cancer. This is based on two large studies showing decreased local recurrence when radiation is used in the neoadjuvant setting (Table 1). In the Dutch TME trial, patients were randomized to RT and TME or to TME alone. This study showed an overall 5-year local recurrence rate of 4.6% in patients treated with radiation and TME and of 11% in the TME group ($P < 0.0001$) with no statistical significant difference in the rate of distant metastases^[1,2]. In the German CAO/ARO/AIO-94 phase III trial, patients were randomly assigned to preoperative or postoperative chemoradiation (CRT). Although the 5-year local relapse rate was better in the preoperative RT group (13% vs 6%, $P = 0.006$)^[3], the updated follow-up showed no statistical difference in the 10-year cumulative incidence of local relapse, disease-free survival or distant metastases^[4].

Both short course radiation therapy and long course CRT have been found to be effective in this setting, but no agreement exists in regards to the ideal method of neoadjuvant radiation-based treatments despite the publication of randomized, prospective data.

Neoadjuvant short course RT and long course CRT have been compared in three randomized, prospective trials (Table 1). The Trans-Tasman Radiation Oncology Group randomized cT3N0-2M0 rectal cancer patients (within 12 cm from the anal verge) to pre-operative short course radiation of 5x5Gy/fraction or CRT to a total dose of 50.4 Gy (28 fractions). The patients in the short course randomization proceeded to surgery within 3-7 d after radiation completion and were treated with 6 monthly cycles of adjuvant fluorouracil (425 mg/m²) 4-6 wk after surgery. The patients in the CRT group were treated with continuous infusion FU (225 mg/m²) daily for the duration of the radiation, followed by surgery 6 wk later and four monthly cycles of adjuvant fluorouracil (425 mg/m²). Interestingly, there was no significant difference in three-year local recurrence rate (7.5% vs 4.4%, $P = 0.24$) or five-year distant recurrence rate (27% vs 30%, $P = 0.92$) between the two groups. However, pathologic downstaging was significantly more common in the CRT than in short course group (45% vs 28%, $P = 0.002$), but there was no difference in organ sparing surgeries, nor any difference in late toxicities (5.8% vs 8.2%, $P = 0.53$)^[5]. The authors concluded that long course CRT may be more effective than short course for distal tumors, based on a trend toward decrease in local recurrence. In a similar design, the Polish Colorectal Study Group randomized patients with cT3-4 resectable rectal cancer to either CRT (50.4 Gy in 28 fractions with bolus 5-fluorouracil and leucovorin) followed by surgery 4-6 wk later or to short course radiation (25 Gy in 5 fractions) followed by surgery 7 d later. As seen in the Trans-Tasman Radiation Oncology Group there was no statistical significant difference in the 4-year local recurrence rate (10.6% in the short course group vs 15.6% in the CRT group, $P = 0.21$). However, there was a significant difference in the pathologic complete response (pCR) in favor of the CRT group, and the short course group was significantly more likely to have a positive surgical margin^[6]. Although intriguing, this is likely due to the early surgery in the short course group rather than type of radiation as a longer interval before surgery has been shown to increase the rate of pCR^[7]. There was no difference in the rate of sphincter preservation, overall survival, or the incidence of late toxicity at a median follow up of 4 years incidence between the two groups^[6]. The Polish Colorectal Study Group most recently reported on a study randomizing patients to preoperative short course RT with consolidation FOLFOX4 for 3 cycles or to preoperative CRT. There was no statistical difference in rate of pCR between the short course consolidation and CRT groups (16% vs 11.5%, $P = 0.19$) and no difference at 3 years in overall survival, disease-free survival, and cumulative incidence of local failure^[8].

Although preoperative radiation is shown to be superior to postoperative radiation in terms of improving local recurrence rate, it remains unclear whether short course RT or long course CRT is preferable. The use of

LR: Local recurrence; DR: Distant recurrence; RT: Radiation therapy; TME: Total mesorectal excision; CRT: Chemotherapy radiation therapy.

CRT did improve downstaging in both of these studies, but this is likely due to the difference in timing between completion of radiotherapy and surgical resection between the two groups. The advantages of short course RT include reduced duration and cost of therapy, but there remains concerns about late toxicity. In addition, it remains unclear whether CRT provides any meaningful long term advantages given lack of benefit in controlling distant metastases or improving overall survival.

CHEMOTHERAPY COMPONENT OF CHEMORADIATION: WHICH AGENTS?

Standard neoadjuvant CRT includes a fluoropyrimidine as the chemotherapy component, primarily due to the radiation sensitization activity of these drugs. Capecitabine, an oral prodrug converted to 5-fluorouracil (5-FU) by intracellular thymidine phosphorylase, has been shown to be non-inferior to infusional 5-FU for this indication^[9,10]. It is unclear, however, whether multi-agent chemotherapy regimens combined with radiotherapy can improve outcomes. Several studies (Table 2) have investigated the addition of oxaliplatin to fluorouracil-based neoadjuvant CRT including the NSABP R-04^[9], the STAR-01^[11], the ACCORD 12/0405-ProDIGE 2^[12], and the PETACC-6^[13]. These studies added weekly oxaliplatin to either infusional fluorouracil or capecitabine in combination with preoperative radiation. The results of these studies showed no difference in therapeutic outcomes, including pathologic complete response, locoregional control, and survival outcomes, and there was an increase in grade 3-4 treatment toxicities in patients treated with oxaliplatin. In contrast, the results of the German CAO/ARO/AIO-04 suggest a

possible benefit with the addition of oxaliplatin to CRT. In this trial, patients with T3-4 or cN+ rectal cancer were randomized to preoperative long course CRT with infusional fluorouracil (1000 mg/m² days 1-5 and 29-33) followed by surgery and four cycles of adjuvant bolus fluorouracil (500 mg/m² days 1-5 and 29) or to preoperative CRT with infusional fluorouracil (250 mg/m² days 1-14 and 22-35) and oxaliplatin (50 mg/m² days 1, 8, 22, and 29) followed by surgery and eight cycles of adjuvant infusional fluorouracil (2400 mg/m² days 1-2 and 15-16), leucovorin (400 mg/m² days 1 and 15), and oxaliplatin (100 mg/m² days 1 and 15). Patients in the investigational arm had a higher pathologic complete response rate (17% *vs* 13%, *P* = 0.038) and a higher disease free survival (DFS) at 3 years (75.9% *vs* 71.2%, *P* = 0.03), without increases in overall toxicity^[14,15]. The results should be interpreted with caution given that different fluorouracil dosing and regimens were used in the two treatment arms. It is also unclear whether the improved DFS is attributable to the adjuvant inclusion of oxaliplatin. Moreover, the patients in the oxaliplatin arm were treated with eight cycles of adjuvant chemotherapy, but the control patients only received four cycle. Thus, this difference in protocol may contribute to the difference in disease free survival.

ADJUVANT CHEMOTHERAPY: WHAT AND WHEN?

Modern surgical techniques combined with radiotherapy have dramatically improved locoregional control of locally advanced rectal cancer, but systemic control remains a significant issue. Distant relapse is now the main driver of adverse survival outcomes in this disease. The rationale for adjuvant chemotherapy in surgically resected rectal

Used concomitant bolus FU dosing not commonly utilized in the United States, and only four cycles of adjuvant chemotherapy

^a*P* < 0.01 any chemo *vs* no chemo. LR: Local recurrence; DR: Distant recurrence; TME: Total mesorectal excision; CRT: Chemotherapy radiation therapy.

cancer is largely extrapolated from colon cancer data^[16], but is also supported by a meta-analysis of randomized trials that compared surgery with or without adjuvant chemotherapy for rectal cancer^[17]. The European Organization for Research and Treatment of Cancer (EORTC) 22921 phase III trial randomized patients with clinical stage II or III resectable rectal cancer to preoperative radiation with or without concomitant fluorouracil (350 mg/m² IV bolus over 5 d) with leucovorin (20 mg/m² IV) followed by either surveillance or four cycles of adjuvant fluorouracil/leucovorin^[18]. There was no difference in the 10-year overall survival between patients getting adjuvant chemotherapy or not (51.8% *vs* 48.4%, *P* = 0.32). Additionally, the rate of

distant metastasis between all arms had no significant difference (34.1%-39.6%). However, the three arms receiving any chemotherapy (neoadjuvant only, adjuvant only, or both) had significant reduction in local recurrence (11.8%-14.5%) compared to those treated with radiation alone (22.4%, *P* = 0.0017), but this did not translate to an overall survival advantage^[19]. Notably, the EORTC 22921 trial incorporated a concomitant bolus fluorouracil dosing not commonly utilized in the United States, and only four cycles of adjuvant chemotherapy were given. Moreover, there were significant deviations from planned treatment, with 26.9% in the adjuvant group never initiating adjuvant therapy, most commonly due to post-operative complications, and less than 43% of

patients received the planned dose within the scheduled time interval^[18]. Despite the controversial results of the EORTC 22921, there remains substantial interest in the use of systemic chemotherapy, both as adjuvant therapy and as CRT, to decrease distant metastatic disease and improve survival^[20]. The theoretical advantages of systemic chemotherapy include eradicating distant micrometastases and providing ideal systemic treatment prior to a large and potential debilitating surgery (and thus a less fit patient)^[21].

Given the difficulties with adherence to postoperative chemotherapy, there is now significant interest in the utility of administering chemotherapy preoperatively (Table 2). In the phase II TIMING trial, stage II and III rectal cancer patients were treated with CRT, and those patients with evidence of clinical response 4 wk after CRT received two cycles of modified FOLFOX-6 followed by TME 3-5 wk later. The remainder of the patients proceeded to TME 6 wk after completion of CRT. The preliminary results from this study showed pathologic complete response of 25% in those treated with the upfront modified FOLFOX-6 compared to 18% in those who proceeded to surgery directly, but this result did not reach statistical significance^[22]. Memorial Sloan-Kettering Cancer Center (MSKCC) reported on its institutional experience offering upfront FOLFOX for patients with high-risk locally advanced rectal cancer. Sixty-one patients received induction FOLFOX (median 7 cycles), and of the 49 patients who proceeded to TME all had R0 resections and 47% had greater than 90% tumor response, with 27% pathologic complete responses^[23]. Despite the encouraging results of this trial, it should be interpreted with caution given the small sample size, the retrospective nature of the analyses, and the lack of randomization.

Several non-randomized studies have been conducted to investigate the use of neoadjuvant chemotherapy. Calvo *et al.*^[24] reported on patients with locally advanced rectal cancer treated with two cycles of induction FOLFOX-4 (oxaliplatin 85 mg/m² D1, 5-FU 400 mg/m² IV bolus and 600 mg/m² IV continuous in 22 h on D1 and D2, folinic acid 200 mg/d IV D1 and D2) followed by immediate CRT. Compared to patients treated with preoperative CRT alone, there was no significant difference in toxicities and patients treated with the induction chemotherapy had significantly more ypT0 (29% vs 8%, $P = 0.006$)^[24]. Chau *et al.*^[25] reported on 77 consecutive patients with MRI-defined poor-risk locally advanced rectal cancer treated with 12 wk of neoadjuvant chemotherapy (CAPOX: Oxaliplatin 130 mg/m² every 3 wk with capecitabine 2000 mg/m² 14 d on with 7 d off) followed by CRT with TME 6 wk after completion of CRT. All but one of the patients had R0 resections, pCR was seen in 16 patients, and an additional 32 patients had only microscopic tumor foci^[25]. Schou *et al.*^[26] report on 84 consecutive patients with locally advanced rectal cancer treated with two cycles of CAPOX before CRT followed by TME 6 wk later. An R0 resection was seen in 94% of patients, a pCR was seen in 23% of patients, and T downstaging occurred in

69%^[26]. Additional phase II studies examining the benefit of neoadjuvant chemotherapy have been reported. Marechal *et al.*^[27] reported on a phase II study of patients with T2-T4/N+ locally advanced rectal cancer who were randomly assigned to preoperative CRT (continuous infusion fluorouracil) or to oxaliplatin, folinic acid, and 5-FU followed by CRT and surgery. There was no difference in rate of patients with ypT0-1N0 (32.1% for patients with treated with neoadjuvant chemotherapy vs 34.5% for patients treated with CRT alone, $P = 0.85$), and there was no difference in pCR between the two groups. The patients treated with induction chemotherapy had significantly more grade 3-4 toxicities than those treated with CRT (35% vs 7%, $P = 0.017$). The results of these non-randomized studies show improved local control with neoadjuvant chemotherapy as well as good tolerance.

CAN RADIATION BE OMITTED?

Given potential improved pathological and clinical responses and good treatment tolerance with the incorporation of neoadjuvant systemic chemotherapy, some have questioned whether radiation can be omitted completely. The GEMCAD 0801 phase II trial included 46 patients with resectable T3N0-2 rectal adenocarcinoma and treated with four cycles of neoadjuvant capecitabine and oxaliplatin with bevacizumab (for the first 3 cycles) before TME. Pathologic CR occurred in 20% and T downstaging was observed in 48% of patients. It was noted that there was a 13% rate of anastomotic leak, which is higher than expected, and could be attributed to bevacizumab^[28]. Another phase II trial that was conducted at MSKCC administered six cycles of FOLFOX with bevacizumab for cycles 1-4 to newly diagnosed stage II-III rectal cancer. Patients with progression were treated with CRT followed by TME, and those that had stable disease or better proceeded directly to TME. All patients except 2 underwent surgery and they all had R0 resections with a 25% pCR rate, with no local recurrence at 4 years^[29]. Based on these results, the PROSPECT (Preoperative Radiation or Selective Preoperative Radiation and Evaluation Before Chemotherapy and TME) trial was launched^[30]. The PROSPECT trial is a phase II/III randomized trial designed to address whether preoperative radiation therapy can be used more selectively in locally advanced rectal cancer (Figure 1). Patients with T2N1 or T3N0-1 rectal cancer are randomized to either standard CRT or to six cycles of FOLFOX. Patients on the investigational arm undergo repeat staging prior to surgery, and those who fail to have a response of at least 20% per RECIST criteria proceed to treatment with CRT prior to surgery. Adjuvant chemotherapy with FOLFOX is suggested but not required. The outcomes of this study may change the paradigm of rectal cancer neoadjuvant treatment.

NON-OPERATIVE APPROACH

Neoadjuvant CRT results in significant downstaging of

Figure 1 Preoperative radiation or selective preoperative radiation and evaluation before chemotherapy and total mesorectal excision trial investigating rectal cancer treatment without radiation. TME: Total mesorectal excision; MRI: Magnetic resonance imaging. Adapted from Clinicaltrials.gov.

locally advanced rectal cancer, and 15%-27% of patients will have a pathologic complete response (pCR)^[31]. The main question is whether patients who achieve pCR could be monitored rather than operated on in order to avoid the post-surgical comorbidities. Complete pathological response was found to correlate with 5-year DFS in a meta-analysis of patients with locally advanced rectal cancer treated with preoperative CRT (5 year DFS for patients with a pCR was 83.3% compared to 65.6% for those without pCR, $P < 0.0001$)^[31]. For those patients with a pCR to neoadjuvant treatment, a nonoperative approach has been investigated in several case series^[32-34]. Habr-Gama *et al.*^[33-35] reported on patients with clinical T2-4, N0-1 rectal cancer treated with CRT followed by assessment for clinical response 8 wk later. In this trial, 26.8% of the patients had a complete clinical response (cCR) based on exam, imaging, and endoscopy (including biopsies) and were subsequently monitored expectantly. The first year of surveillance included monthly physical exam, digital rectal exam, proctoscopy, and serum CEA levels as well as CT scans of the abdomen and pelvis every six months. Follow up visits were spaced to every two months for the second year and to every six months for the third year. Two patients developed local recurrence 56 and 65 mo after completion of CRT and were treated successfully with transanal full-thickness excision and salvage brachytherapy, respectively. Three patients developed systemic metastases for an overall recurrence rate of 7%, and no cancer related deaths occurred with a median follow up of 57.3 mo^[33]. Subsequent publications from this group showed similar results^[34]. A large phase II trial by MSKCC (Figure 2) is underway to further investigate the efficacy and safety of a non-operative approach. Patients with T3-4N0-1 locally advanced rectal cancer by MRI all receive neoadjuvant CRT and 4 mo of chemotherapy (CAPOX or FOLFOX), with randomization of the sequence of receipt. Patients with a cCR or near-cCR on follow-up examination will proceed to nonoperative expectant

management every 3 mo for two years and every 6 mo thereafter^[36,37]. This investigated approach may save patients the comorbidities associated with surgical intervention. However, if this approach is proven to be effective there needs to be a standard approach to surveillance. A small study reported data on the utility of combining clinical assessment (DRE and endoscopy) with T2W-MRI and diffusion-weighted MRI as having a 98% posttest probability for a cCR^[38].

Clinical downstaging from neoadjuvant therapy has instigated interest in other surgical management options; though TME has significantly improved outcomes, it is associated with considerable morbidity, including long term consequences such as fecal incontinence, urinary dysfunction, sexual dysfunction, and permanent ostomy^[39]. These issues can significantly impair patients' quality of life. Case series and retrospective data have indicated that carefully selected patients may have good oncologic outcomes from less aggressive surgical procedures^[40,41]. A prospective study of 10 patients with T3 rectal cancer who were deemed unfit for a radical surgical excision with TME or refused large surgery, were treated with CRT followed by transanal excision with no recurrence at 24 mo follow up^[42]. Another small but prospective and randomized study compared 100 patients with cT2N0 rectal cancer treated with CRT and randomized to either TME or endoluminal locoregional resection by transanal endoscopic microsurgery. There was no difference in local recurrence or metastatic recurrence, but these findings are limited by the small number of patients and that the patients were early stage and not being the definition of locally advanced disease^[43]. More recent evidence comes from a non-randomized, phase II trial of 79 patients with cT2N0 distal rectal cancer treated with neoadjuvant CRT followed by local excision. The primary endpoint, 3-year DFS, was 88.2%, and eight (10%) patients had recurrence (5 distant and 3 local)^[44]. This study shows that patients with cT2N0 distal rectal cancer may be treated with local excision, but is limited by lack of comparative results.

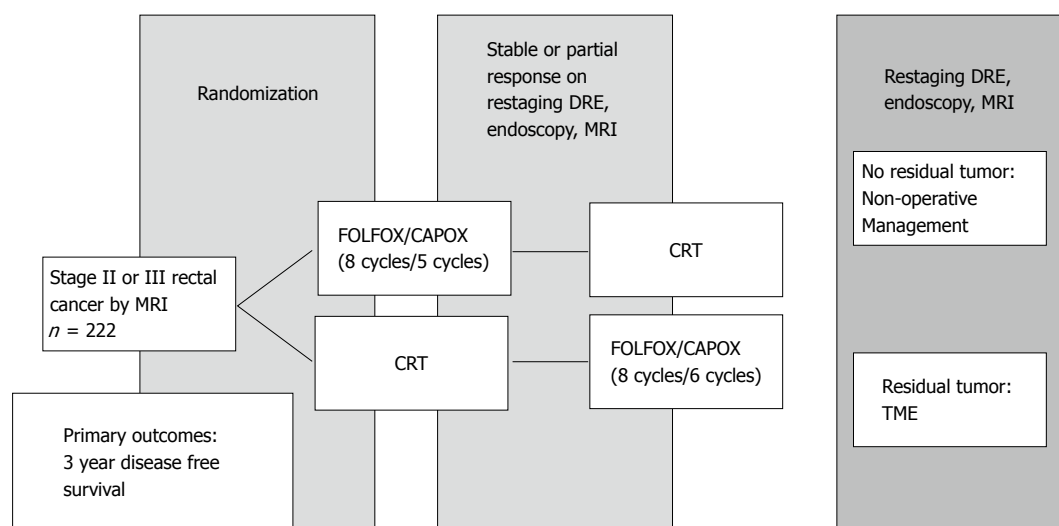

Figure 2 Memorial Sloan-Kettering Cancer Center phase II study of non-operative approach. TME: Total mesorectal excision; MRI: Magnetic resonance imaging. Adapted from Clinicaltrials.gov.

Local excision is an option for patients who cannot tolerate a major surgery, but it remains uncertain if this approach results in similar oncologic outcomes particularly in locally advanced stages of disease.

CONCLUSION

Despite considerable advances in rectal cancer treatment over the last two decades, controversies remain. The current standard is to treat patients with preoperative radiation, but the optimal course (CRT or 5×5 Gy) is not known. Studies suggest that the addition of oxaliplatin to CRT does not provide significant additional benefit and adds toxicity. As new approaches to chemotherapy are investigated, the inclusion of RT is being questioned. However, the optimal approach and timing for systemic chemotherapy in locally advanced rectal cancer has not been answered. Even the role of surgery, the traditional sine qua non of rectal cancer therapy, is being questioned, with non-operative approaches to management demonstrating excellent outcomes without the consequences of surgery.

Further refinements in approach may rely on the identification of predictive biomarkers in this disease. Advances in genomic and molecular tumor profiling have facilitated this search. Biopsy specimens from 52 patients with rectal cancer planned for preoperative radiotherapy were submitted to gene expression profiling using DNA microarray analysis (U95Av2 Gene Chip). The profiles of radiation responders and non-responders were compared, and thirty-three novel genes were identified with differential expression; these genes could predict response with an accuracy of 88.6%^[45]. Similar studies have been conducted to predict response to CRT^[46-49]. DNA microanalysis has identified genes predictive of response, but no genes were reported consistently across the studies. Nishioka *et al.*^[48] attempted to identify a candidate gene using immunohistochemistry (IHC) to

validate the DNA microarray results. Among 20 patient biopsies, 17 potentially predictive genes were identified. Matrix metalloproteinase-7 (MMP7) was identified as the gene with the largest difference between responders and non-responders and was analyzed with IHC. MMP7 was found to be overexpressed by IHC in 4 out of 10 responders and 0 out of 7 non-responders. Watanabe *et al.*^[49] used DNA microanalysis to identify four genes (LRRIQ3, FRMD3, SAMD5, and TMC7) expressed in responders to CRT with 89.1% prediction accuracy and validated the gene expression by RT-PCR analyses. While these results are intriguing, widespread clinical application remains limited by lack of reproducibility and the need for independent validation across separate cohorts.

Another area of investigation is the tumor micro-environment and how it interacts with the immune system. Immunologic features of tumor microenvironment may predict tumor response to therapy as well as form the basis for innovative treatment strategies. Studies of colorectal cancer showed that the patterns of immune cell infiltration within tumors had prognostic significance and lead to the development of the Immune Score^[50-52]. The densities of CD45RO⁺ memory T-cells and CD8⁺ cytotoxic T-cells tumor infiltrating lymphocytes (TILs) were determined for patients with stage I and II colorectal cancer. Higher densities at both the center of the tumor and the invasive margin were predictive of superior patient outcomes including disease free, disease specific, and overall survival ($P < 0.001$)^[52]. Not only does the number of CD8⁺ TILs correlate with survival, but it has been shown to have superior prognostication than the TNM staging^[53]. Although it is evident that colorectal tumors are infiltrated by the immune cells, mainly T-cells, this infiltration is not sufficient to induce tumor response. This may be due in part to the immune suppression provided by the activation of immune checkpoints, such as PD-L1/PD-1 pathway. Examination of colorectal tumors showed

PD-L1 expression in 37% of mismatch repair (MMR)-proficient tumors and in 29% of MMR-deficient tumors, with a strong correlation between PD-L1 expression and infiltration with CD8⁺ T-cells in the MMR-proficient tumors ($P = 0.0001$)^[54]. However, treatment with PD-L1 monoclonal antibody nivolumab showed no objective responses in 18 patients with colorectal cancer^[55]. More recent data revealed that high microsatellite instable tumors selectively exhibit upregulated expression of immune checkpoints including those being studied as drug targets: PD-1, PD-L1, CTLA4, LAG-3, and IDO^[56]. Accordingly, microsatellite stability may be a biomarker for immunotherapy in colorectal cancer, given the fact that tumors with microsatellite instabilities tend to have higher mutational loads leading to a better recognition by the immune system. Another area of active investigation is combination therapy of immunotherapy and CRT. Based on preliminary data showing that neoadjuvant CRT can lead to increase T-cells in rectal cancer^[57], we are currently in the process of conducting a phase II study investigating neoadjuvant CRT and pembrolizumab (anti-PD-1) in patients with stage II and III rectal cancer cancer^[58]. Furthermore, novel clinical trial designs need to be implemented in the neoadjuvant setting in colorectal cancer. The National Cancer Institute is planning to launch a large clinical trial to evaluate 3-year DFS in patients managed with total neoadjuvant therapy and TME or non-operative management, compared with standard historical controls managed according to standard of care (CRT and TME followed by adjuvant chemotherapy). The historical control arm continues to enroll patients while the adaptive trial design allows the addition of other investigational arms. This novel trial design and others will bring more advances to the field that may change the paradigm of rectal cancer treatment.

Abstract

Tumors of the pancreas, the ampulla of Vater, and the extrahepatic and intrahepatic bile ducts have significant histological similarities due to the common embryonic origin of the pancreatobiliary system. This obviates the need for discovery of biomarkers with diagnostic and prognostic value for these tumors. Mucins, especially MUC-1, -2, -4 and -5AC, are important candidates for developing into such reliable biomarkers. Increased expression of MUC1 occurs in pancreatic ductal adenocarcinomas and is associated with increased degrees of dysplasia in pancreatic intraepithelial neoplasia (PanIN). Positive expression of MUC2 in intraductal papillary mucinous neoplasms (IPMN) of the intestinal type indicates high potential progression to invasive carcinoma with *de novo* expression of MUC1, while absence of MUC2 expression in IPMNs of gastric type implies low potential to malignant evolution. *De novo* MUC4 expression correlates to the severity of dysplasia in PanIN and is associated with a poor prognosis in patients with pancreatic ductal adenocarcinomas. In biliary intraepithelial neoplasia (BilIN), increased expression of MUC1 is associated with higher degrees of dysplasia. Intrahepatic cholangiocarcinomas (ICC) are characterized by increased expression of all glycoforms of MUC1. Positive MUC2 expression in intraductal papillary neoplasm of the bile ducts (IPNB) of the intestinal type indicates high malignant potential with *de novo* expression of MUC1 in the invasive element. Absent MUC2 expression in any degree of BilIN may prove useful in differentiating them from IPNB. *De novo* expression of MUC4 is associated with poor prognosis in patients with ICC or carcinoma of the extrahepatic bile ducts (EHBDC). High *de novo* expression of MUC5AC is found in all degrees of BilIN and all types of IPNB and ICC. The MUC5AC is useful in the detection of neoplastic lesions of the bile duct at an early stage. Increased expression of mucin MUC1 in carcinoma of the ampulla of Vater associated with unfavorable behavior of the tumor, such as lymph node metastasis, infiltration of the pancreas and duodenum, advanced TNM classification and worse prognosis. Patients with

intra-ampullary papillary-tubular neoplasm (IAPN) of the pancreatobiliary immunophenotype did not show MUC2, while those of the intestinal immunophenotype are MUC2 positive. The expression of MUC4 is associated with poor prognosis in patients with carcinoma of the ampulla of Vater favoring metastasis and making them resistant to apoptosis. Moreover, it appears that MUC4 positivity correlates with recurrence of the tumor. Expression of MUC5AC is associated with the invasive potential of the tumor.

Key words: Ampulla Vater neoplasms; Biliary system neoplasms; Mucins; Pancreatic neoplasms

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The combined status of mucin expression may be useful in the differential diagnosis of pancreatobiliary neoplasms, the detection of pre-malignant lesions and the evaluation of their malignant behavior. Besides their diagnostic and prognostic role, their involvement in carcinogenesis reveals their importance as putative therapeutic targets in the future.

INTRODUCTION

All mucosal surfaces of the human body are covered by a thick viscous layer which protects them from external insults. A major component of this defensive barrier is a class of epithelial-derived glycoproteins known as "mucins". The structural signature of a mucin is a dense network of oligosaccharide side chains comprising of N-acetyl-galactosamine, which bind *via* an O-glycosidic linkage to specific amino acid residues (serine, threonine and proline), that occur in repetitive short stretches in the protein backbone termed "tandem repeats"^[1,2]. The side chains make up to 50%-90% of the weight of a mucin. Mucins are distinguished from proteoglycans (another major class of glycoproteins) by the lack of uronic acid and xylose and the presence of the aforementioned O-glycosidic links.

Genes encoding for the protein backbone of mucins are denoted by the three letter code "MUC", followed by a number (MUC1-21), which corresponds to the chronological order of discovery^[3]. Mucins are classified according to their structure and function as either "membrane bound" or "secreted"^[4]. The first class includes mucins MUC1, MUC3, MUC4, MUC12, MUC13, MUC16, MUC17, and MUC21. These mucins possess a large N-terminal extracellular portion, a transmembrane part

and a small C-terminal cytoplasmic one. The cytoplasmic segment is important for signal transduction, as it contains several phosphorylation sites that are important for interaction with other scaffolding and signaling proteins. The extracellular portion of mucins includes several specific domains of unknown function, which include epidermal growth factor (EGF)-like, AMOP (adhesion associated domain in MUC4 and other proteins), VWD (Factor Von Willebrand), SEA (sea-urchin sperm protein enterokinase and agrin) and NIDO (Nidogen-like)^[5]. Another unique feature of the membrane bound mucins is the existence of multiple isoforms with modified structure and function, which are generated by alternative splicing^[4].

Secreted or gel-forming mucins are encoded by genes located contiguously on chromosome 11 and include MUC2, MUC5AC, MUC5B, MUC6 and MUC7. This genetic clustering indicates a close functional association of the relevant proteins. Secreted mucins also have "tandem repeats", the number of which is a unique feature with potential diagnostic, prognostic and possibly therapeutic significance^[6]. Two unique domains that characterize secreted mucins are the VWD domain and the cysteine knot (CK) motif^[7]. The first appears to be important for connecting the mucins into oligomeric structures, while the second for the formation of mucin homo- or heterodimers.

EXPRESSION OF MUCINS IN NORMAL PANCREATOBILIARY SYSTEM

The mucin profile in normal pancreatobiliary system has been identified mostly through immunostaining studies with the use of mucin-specific antibodies. However, it should be noted, that different antibodies have been used across separate studies, leading to heterogeneous expression patterns. A typical example is the work of Yamashita *et al*^[8] who reported that immunoexpression of MUC1 in normal bile duct was dissimilar between three separate MAbs (DF3, MUSE11 and 139H2), that were tested. In particular, MUC1/139H2 was expressed in normal bile ducts of any size at the luminal surface of the biliary cells and/or in the cytoplasm. MUC1/MUSE11 was detected only in small-sized ducts (S < 100 μm), predominantly in the apical surface of the cells, while MUC1/DF3 was undetectable in normal biliary epithelium. In the same study, MUC2 staining in normal bile ducts also varied and was dependent upon the use of the specific antibody (polyclonal anti-MUC2/MRP or monoclonal CCP58 antibody). MUC2/anti-MRP was not expressed in normal bile duct epithelium, whereas MUC2/CCP58 exhibited supranuclear expression in 60% of the cases^[9]. Finally, MUC4 was undetectable in normal bile ducts, while MUC5AC immunostaining was present in a small number of cases^[9].

In another study, it was shown that in normal pancreatic tissue, MUC1 and all of its glycoforms were expressed at the apices of centroacinar cells, intercalated and intralobular ducts, and focally in the interlobular pancreatic ducts. MUC1 and MUC1 glycoforms were

Table 1 Expression of various glycoforms of mucin 1 in normal pancreatic tissue

Main pancreatic ducts	-	-	-	-

MUC: Mucins.

undetectable in the main pancreatic duct^[10]. In the same study there was no detectable pancreatic expression of MUC2, MUC4, and MUC5AC. The expression of various glycoforms of MUC1 (MUC1/CORE, MUC1/DF3, sialylated MUC1/MY.1E12 and fully glycosylated MUC1/HMFG-1) in normal pancreatic tissue, is summarized in Table 1^[11].

EXPRESSION OF MUCINS IN PANCREATOBILIARY NEOPLASMS

Pancreatic carcinogenesis develops through the accumulation of several genetic and epigenetic lesions, some of which affect genes encoding for mucins. It has been shown that certain mucins are expressed *de novo* during neoplastic transformation of the epithelium, while specific mucin patterns have been recognized in different pre-malignant and malignant neoplasms of ductal origin. In recent years, mucins have gained significant value for the diagnostic approach to pancreatic neoplasms. At the same time, their high specificity has rendered them potential candidates for therapeutic interventions^[12]. Finally, mucin expression patterns have become a major criterion for the subclassification of intraductal papillary mucinous neoplasms (IPMN).

According to the WHO classification of 2010, IPMNs are histologically classified as pancreatobiliary, intestinal, gastric or oncocytic type^[13]. Distinction of IPMN subtypes is very important from the clinical perspective, because they demonstrate differences in their malignant potential. IPMN of pancreatobiliary type with MUC1 expression and intestinal type with MUC2 expression are located mainly in the main pancreatic duct and exhibit a high frequency of carcinoma development^[11]. In contrast, IPMN of gastric type with MUC5A expression is usually located in the pancreatic branch ducts and rarely shows malignant transformation. These findings are consistent with the clinicopathological description of the "International guideline for management of IPMN/MCN". According to this classification, IPMNs are classified as "IPMN-main duct type" and "IPMN-branch duct type"^[14].

A similar subclassification based on the aforementioned parameters (cell type, mucin profile and prognostic data), has been introduced for biliary and ampullary neoplasias. According to the WHO classification of 2010, intraductal papillary neoplasm of the bile ducts (IPNB)

are classified as pancreatobiliary, intestinal and gastric type, while the oncocytic type is referred as a variant of the pancreatobiliary^[15]. The most frequent histopathologic types are pancreatobiliary and intestinal.

MUC1

In 1993 it was reported for the first time, that pancreatic ductal adenocarcinomas (PDAC) with aggressive biological behavior usually express MUC1^[16]. Furthermore, the pattern of MUC1 expression in PDAC is different from that in the normal pancreas. In well differentiated PDAC, MUC1 is detected not only along the luminal cell surface of glandular formations, but also in the baso-lateral surface. In poorly differentiated PDAC, cytoplasmic expression of MUC1 is demonstrated^[17]. In addition, PDAC show high expression rates for MUC1 glycoforms (MUC1/CORE 66%, MUC1/DF3 96%, MUC1/MY.1E12 98%, MUC1/HMFG1 76%)^[18]. Regarding pancreatic intraepithelial neoplasia (PanIN), the expression profile of MUC1 is associated with the grade of dysplasia^[19]. Indeed, increase of MUC1 expression has been correlated with increase of PanIN grade^[20].

MUC1 is exclusively associated with pancreatobiliary type IPMN and its malignant variant^[13,21]. Moreover, underglycosylated MUC1 is absent or rarely seen in IPMN-intestinal type and IPMN-gastric type. On the other hand, glycosylated MUC1 is undetectable or occasionally detectable in IPMN-intestinal type, but is frequently observed in IPMN-gastric type^[11]. The invasive carcinomas, which develop in intestinal type IPMN, show *de novo* MUC1 expression^[20,22].

There are only few references to the expression of MUC1 in mucinous cystic neoplasms (MCN), oftentimes with conflicting results. In one study, MUC1 appeared to be rarely expressed in MCN^[23], while in another the majority of MCN was found positive for MUC1/DF3^[24]. On the other hand, MUC1 expression is detectable in up to 90% of intraductal tubulopapillary neoplasms (ITPN)^[25].

Regarding the mucin expression in neoplasms of the biliary system, MUC1 profile in biliary intraepithelial neoplasia (BiIN) was similar to that in PanIN, characterized by progressive increase with increasing severity of dysplasia^[26]. In the intraductal papillary neoplasm of the bile ducts (IPNB) of pancreatobiliary type, MUC1 expression rates were high in invasive, but low in non-invasive lesions^[9]. On the other hand, IPNB-intestinal type showed *de novo* expression of MUC1, particularly in cases with frequent invasive growth and significant poorer survival^[9].

Intrahepatic cholangiocarcinoma (ICC) with aggressive biological behavior and poor outcome usually presents a MUC1+/MUC2- profile, while bile duct cystadenocarcinoma (BDCC) with moderate aggressiveness and favorable prognosis demonstrates a MUC1-/MUC2+ pattern^[8]. The frequency of expression of MUC1 in ICC was significantly higher than that in BDCC^[27]. In general, positive staining for MUC1 has been associated with poor prognosis, regardless of the glycosylation status, in both ICC and

BDCC^[27].

The expression pattern of MUC1 in tumors of the ampulla of Vater appears to have predictive value based on results of recent studies^[28,29]. In particular, MUC1 positivity was associated with unfavorable behavior of the tumor, such as lymph node metastasis, vascular invasion, infiltration of the pancreas and duodenum, advanced TNM classification and worse prognosis^[29].

Utility of MUC1 as biomarker in pancreatobiliary neoplasia:

A strong association has been observed between elevated expression of MUC1 in pancreatic neoplasms and decreased survival. The negative predictive value was high (95%), as 19 out of 20 patients with no MUC1 expression survived more than 30 mo^[30]. Out of 13 candidate genes, only those of MUC1, mesothelin (MSLN), and MUC2 showed statistically significant differences in the expression pattern between the groups with aggressive and less aggressive carcinomas^[31]. Mesothelin/MSLN is a protein that is present on normal mesothelial cells and is overexpressed in mesothelioma and ovarian and pancreatic adenocarcinoma. Both MSLN and MUC1 appeared to be strong predictors of survival thus acquiring prognostic significance. In fact, the prognostic significance of MUC1 positivity exceeded that of conventional pathological features^[31]. Accordingly, the National Cancer Institute has identified MUC1 and MSLN among the most promising targets for cancer vaccine development^[32]. A radiolabeled monoclonal antibody against MUC1 was investigated recently in a phase I / II trial, and phase III study will follow^[33]. Finally, promoter-driven gene therapy, which exploits overactive MUC1 and MSLN promoters in various cancer types has been extensively studied in pre-clinical cancer models using viral vectors^[34].

Much of the oncogenic role of MUC1 may be attributed to the participation of the small cytoplasmic tail of MUC1 (MUC1.CT) in signal transduction and transcriptional events^[35]. MUC1.CT regulates the recruitment and activity of transcription factors, thereby regulating transcription of the corresponding genes^[36]. Other studies have implicated MUC1 in tumour growth, invasion and metastasis in pancreatic cancer^[37]. MUC1 participates in the regulation of pancreatic cancer cell metabolism^[38]. It was shown, that MUC1 physically occupies the promoter regions of genes involved in glycolysis and glucose metabolism in pancreatic cancer cells. The MUC1 selectively enhances the transcription of some of the glycolytic genes and this effect is more pronounced under conditions of hypoxia in a HIF-dependent manner. Furthermore, MUC1 expression is associated *in vivo* with increased glucose uptake in xenograft model of orthotopic implantation of pancreatic cancer. Increased tumour cell metabolism has been identified as a hallmark of cancer requirements for rapid cell growth and is consistent with previous studies which consider MUC1 as a modulator of growth and invasive properties in multiple cancer types^[39].

An association of MUC1 with Platelet-Derived Growth Factor-A (PDGF-A) has also been reported^[38]. PDGF-A

is one of the several regulators of tumor growth, angiogenesis and metastasis in pancreatic carcinoma. MUC1 regulates the expression and secretion of PDGF-A. In particular, the increase of MUC1 expression induces expression of PDGF-A in multiple human and mouse cell lines *in vitro* and *in vivo*, as well as in pancreatic cancer models with or without expression of MUC1. Both PDGF-A and MUC1 are considered unfavorable prognostic markers and potential targets for therapeutic intervention in pancreatic cancer. Moreover, expression of hypoxia-inducible factor 1- α (HIF1- α) as a marker of pancreatic cancer progression correlates with the expression of PDGFA and with poor prognosis^[40]. Therefore, it is hypothesized, that MUC1 promotes nuclear translocation of this transcription factor, which is a known regulator of PDGFA^[41].

MUC2

MUC2 is not expressed in PDAC^[16]. This was originally reported in 1993^[17] and was later confirmed by immunohistochemistry^[18]. Similarly, MUC2 was not detected in PanIN independently of the grade of dysplasia^[19]. In contrast, MUC2 expression has been reported in IPMNs. More specifically IPMN-intestinal type, that expresses MUC2, is primarily located at the main pancreatic duct and shows high frequencies of malignant transformation and invasive carcinoma (usually mucinous/colloid carcinoma)^[11]. On the other hand, MUC2 has not been detected in MCN^[23,24].

Regarding expression in biliary neoplasms, in an important study by Zen *et al.*^[26], MUC2 expression was absent in all BilIN, while it was expressed in the majority of IPNB. In a more recent study, it was also reported that MUC2 was detectable in 50% of IPNB^[15], although quantitative data on the relation to specific subtypes are missing. This was however addressed in another study, in which MUC2 expression was observed in 95% of IPNB intestinal type and in 50% of IPNB pancreatobiliary type^[9]. Expression of MUC2 in extrahepatic bile ducts carcinoma (EHBDC) was related to tumor progression and the expression of the mucins was associated with poor prognosis^[42]. ICC with aggressive biological behavior and poor outcome usually demonstrates a MUC2 negative profile while BDCC with moderate aggressiveness and favorable prognosis exhibits MUC2 positive profile^[8,26]. Overall, MUC2 expression is considered to be a favorable prognostic marker in neoplastic lesions of the bile ducts^[26,27]. Regarding the carcinoma of ampulla of Vater, expression of MUC2 is associated with non-invasive pancreatobiliary papillary neoplasia of intestinal subtype which is more frequently associated with invasive neoplasia^[43]. In a study of 105 adenocarcinomas of the ampulla of Vater, intestinal immunophenotype was characterized by MUC2 and caudal-related homeobox transcription factor-2 (CDX2) positivity, while pancreatobiliary immunophenotype was characterized by MUC2 and CDX2 negative expression^[43].

MUC4

Recently, it was found that high expression of MUC4 was an independent poor prognostic factor in adenocarcinomas of the pancreas and bile ducts^[9]. In a study of 135 PDAC, MUC4 was expressed in 32% of the cases while intense expression was associated with significantly poorer survival^[29]. In the studies of Swartz *et al* and Park *et al* MUC4 was detected in 89% and 79% of PDAC respectively^[44,45]. These discrepancies may be ascribed to the application of a lower threshold-value for MUC4 positivity in the latter two studies. There are no current data available regarding the expression of MUC4 in IPMN and MCN. In sharp contrast, PanIN is associated with *de novo* expression of MUC4. Moreover, MUC4 expression intensity increases in parallel with the degree of dysplasia^[44,45].

MUC4 is also expressed in neoplasms of the biliary system. In one study MUC4 was expressed in 63% of IPNB. The MUC4 showed more frequent expression in IPNB-intestinal relative to IPNB-pancreatobiliary type^[9]. In intrahepatic and in extrahepatic cholangiocarcinoma MUC4 is expressed *de novo* mainly in the cytoplasm of cancer cells and is correlated with poor prognosis. The survival rate of patients with MUC4 positivity is significantly poorer compared to patients with negative MUC4 expression^[9,46]. There is no information concerning MUC4 expression in BDCC.

MUC4 is less frequently expressed in the normal epithelium of the ampulla and is an independent marker of the pancreatobiliary type adenocarcinoma of the ampulla^[28] associated with poor prognosis and recurrence of the tumor^[28,47].

Utility of MUC4 as biomarker in pancreatobiliary neoplasia: MUC4 expression is associated with poor prognosis in patients with pancreatobiliary neoplasia. There has been a strong correlation between the expression of MUC4 and carcinoma recurrence^[28,47]. In a retrospective study of biliary tract carcinoma in 2006, it was observed that patients with positive MUC4 in bile had reduced survival (5.0 mo vs 11.5 mo)^[46], while a similar difference in survival rate has been reported in a Japanese population, which underwent surgery for extrahepatic biliary tract carcinoma^[46].

MUC4 is a membrane associated mucin which inhibits intercellular adhesion and adhesion between cells and stroma favoring extravasation and metastasis^[48,49]. It has also been implicated as promoter in infiltrative growth and metastasis of pancreatic cancer by facilitating cancer cell motility^[50-52]. In various *in vitro* and *in vivo* studies, selective suppression of MUC4 expression highlighted its role in cell adhesion and epithelial mesenchymal transition^[53] and in restriction of cancer cell growth and metastasis^[54]. In pancreatic tumor cells selective downregulation of MUC4 led to suppression of pERK1/2 and increased expression of E-cadherin. These findings suggest that MUC4 inhibits the function of E-cadherin as well as of N-cadherin and EGFR1 by activation of Akt and

JNK/2 signaling pathways, respectively^[55]. Decreased expression of matrix metalloproteinase-9 (MMP-9) has also been identified after downregulation of MUC4^[56]. Inversely, activation of ERK1/2 signaling pathway *via* MUC4, activates MMP-9, which in turn causes degradation of E-cadherin resulting in alteration of intercellular contacts. These data demonstrate that MUC4-mediated repression of E-cadherin may enhance the invasive capacity of tumor cells. Suppression of MUC4 is also correlated with changes in the shape of cancer cells indicating its involvement in epithelial-mesenchymal transition^[56,57]. Finally, cells expressing MUC4 are resistant to immune mediated apoptotic cell death by natural killer cells (NK)^[58]. Mucins, including MUC4, which are connected with cell membrane, have become a point of interest as they act as endogenous ligands and modulators of the tyrosine kinase receptor ErbB2^[59], which is part of an antiapoptotic pathway utilized by most common epithelial tumors^[60]. The therapeutic blockage of ErbB2 with the monoclonal antibody trastuzumab improves the effectiveness of chemotherapy and survival in breast cancer^[61]. In breast carcinoma cells, MUC4 has anti-aggregatory action and appears to promote tumor growth^[62]. These oncogenic properties of MUC4 point out its significance as a potential therapeutic target.

MUC5AC

High *de novo* expression of MUC5AC has been observed in many types of pancreatobiliary neoplasms including all grades of PanIN^[19,22] and BilIN^[26], PDAC^[11], ICC^[15], as well as all types of IPMN^[11] and IPMB^[9]. In particular, IPMN of gastric type with MUC5AC expression is usually located in the pancreatic branch ducts, and rarely shows malignant transformation^[14]. Since MUC5AC is not expressed in normal pancreatobiliary epithelium^[26], it seems to be a specific marker of early neoplastic lesions of the pancreatobiliary system^[11,26] which correlates with poor prognosis^[63]. Diverse expression rates (37.5% vs 100%) have been reported in MCN and are attributed to the use of different antibodies^[23,24].

MUC5AC expression was frequent in both BilIN and IPNB^[26] and showed high expression in both IPNB-intestinal and IPNB-pancreatobiliary type^[9,15]. In a study in Northern Thailand, a region with high incidence of BTC (biliary tract cancer), MUC5AC protein was detected in the serum of 63% of the patients with BTC, whereas it was absent in healthy controls^[64]. In the same study in benign biliary epithelium MUC4 and MUC5AC were undetectable. There are no literature data for MUC5AC expression in BDCC.

Expression of MUC5AC in neoplasias of the ampulla of Vater depends on the histological subtype. Positive expression of MUC5AC is related to the pancreatobiliary phenotype and participates in subsequent stages of carcinoma extension such as invasion and metastasis^[65,66]. In intestinal type carcinomas a weak expression of the neoplastic epithelium was observed. In very few cases it was also detected in the center of the tumor, while in

lymph node metastases and vascular infiltrates it was mostly absent^[67].

Utility of MUC5AC as biomarker in pancreatobiliary neoplasia: In a study from Thailand^[63], detection of MUC5AC in cholangiocarcinomas was associated with larger-sized tumors (> 5 cm), and advanced-stage of disease. Patients who had positive serum MUC5AC status had a significantly poorer prognosis compared to patients with undetectable serum MUC5AC ($P < 0.001$). Multivariate analysis showed that patients with positive serum MUC5AC status had a 2.5-fold higher risk of death compared to patients who had negative serum MUC5AC status ($P < 0.001$). Moreover, the diagnostic specificity of MUC4 and MUC5AC for BTC was found superior of CA19-9 (93% MUC4, 96% MUC5AC vs 65% CA19-9)^[68]. This high specificity, however, was weakened by the comparatively low sensitivity (27% MUC4 and 44% MUC5AC), which increased to 58% by combining MUC4 and MUC5AC^[68].

MUC5AC has been shown to be a major component of gastric and bronchial mucous, while in other normal tissues the expression is low or absent. MUC5A is known to be a marker of and associated with poor prognosis in diffuse type gastric carcinoma^[69].

According to a recent study in MUC5AC knockdown human pancreatic cancer cell lines that were generated by the introduction of siRNA, ectopic expression of MUC5AC did not affect cell proliferation *in vitro*, but was directly involved in tumor progression *in vivo* by dramatically reducing growth and metastatic potential^[70].

All the results described above concerning the expression of mucins 1, 2, 4 and 5AC in neoplasms of pancreas, biliary system and ampulla Vater are formatting in Tables 2-4 respectively.

Other mucins

MUC3: MUC3 is a predictor of poor prognosis in gastric and breast cancer. In pancreatobiliary neoplasms, a strong independent association was identified in the setting of periampullary carcinomas between cytoplasmic expression of MUC3 and favorable prognosis, in contrast to poor outcome of carcinomas showing membranous expression^[71]. The cysteine-rich domains within MUC3 are able to inhibit apoptosis and promote migration of MUC3-expressing cells, favouring cancer progression^[72]. However, neither vascular nor perineural invasion correlated with membranous expression of MUC3, suggesting that an alternative mechanism may be responsible for poor survival in these patients^[71].

MUC6: MUC6 had no effects on survival of patients with pancreatic cancer^[73].

MUC16 (CA 125): MUC16 (CA 125) is known as a tumor marker in ovarian and pancreatic cancer. Studies have investigated the expression of MUC16 in the initiation, progression and metastasis of pancreatic cancer^[74-76]. Its participation in the diagnosis, prognosis and treatment of

pancreatic cancer and its relation to the stage and degree of differentiation has also been explored. MUC16 is not expressed in the normal pancreatic ducts, but it was detected in pancreatitis^[74]. It was also detected in pre-cancerous lesions, suggesting that its overexpression is already detectable at the early stages of carcinogenesis. In one study 20% of PanIN- I, 28% of PanIN- II and 42% of PanIN- III were found positive^[75]. The expression of MUC16 was significantly higher in high-grade dysplasia PanIN- III compared to low grade dysplasia, while there was no significant difference in MUC16 expression between PanIN- I and II^[75]. The expression of MUC16 seems to be stronger in metastatic foci as compared to the primary tumor, thus, possibly playing an important role in metastasis of adenocarcinoma^[74].

In the same study MUC16 was detected in 65% of pancreatic carcinomas. Progressive increase of expression was found to be parallel to the loss of tumor differentiation with positivity being 50% in well differentiated, 59% in moderately differentiated and 66% in undifferentiated adenocarcinomas^[74]. Whereas the expression of MUC16 was not significantly different between the three degrees of differentiation, the expression was significantly higher in moderately differentiated and undifferentiated carcinomas compared with the well differentiated. The observation that MUC16 is overexpressed in pancreatic carcinoma may be associated with a similar upregulation of other mucins associated to the cell membrane such as MUC4 and MUC1^[1,76]. Overall, these results suggest a possible involvement of MUC16 in the pathogenesis of pancreatic adenocarcinoma and provide the basis for future studies aimed at unraveling the role of this glycoprotein.

CONCLUSION

Mucins in epithelial neoplasias of the pancreatobiliary system, in particular MUC-1, 2, 4 and 5AC are gaining importance due to their potential roles as diagnostic, predictive and prognostic markers.

In pancreatic neoplasms, increased expression of MUC1 occurs in pancreatic ductal adenocarcinomas and correlates with increasing degree of dysplasia in PanIN. Positive expression of MUC2 in IPMN-intestinal type indicates high biological potential for progression to invasive carcinoma with *de novo* expression of MUC1. IPMN-gastric type with negative MUC2 expression implies low probability for malignant evolution. *De novo* MUC4 expression seems to increase with enhancement of dysplasia in PanIN and is related to poor prognosis in patients with pancreatic ductal adenocarcinomas.

In biliary carcinogenesis expression of MUC1 correlates with the degree of BilIN dysplasia while increased expression of all MUC1 glycoforms was observed almost uniformly in ICC. Positive MUC2 expression in IPNB-intestinal type indicates high malignant potential associated with *de novo* expression of MUC1 in the invasive component. Absence of MUC2 in BilIN may be useful in the differential diagnosis from IPNB. Appearance of MUC4 in patients with ICC or EHBDC is associated

Table 2 Mucins expression in pancreatic neoplasms

	Normal	PanIN			PDCA	IPMN				MCN	ITPN
		PanIN- I	PanIN- II	PanIN- III		Gastric-type		Intestinal-type			
						Non-invasive	Invasive	Non-invasive	Invasive		
MUC1	2	2	3	4	4	1	4	1	4	CR	4
MUC2	1	1	1	1	1	1	1	4	4	1	1
MUC4	1	2	3	4	4	NA	NA	NA	NA	NA	NA

NA: Non available data; CR: Conflicting results; PanIN: Pancreatic intraepithelial neoplasia; IPMN: Intraductal papillary mucinous neoplasms; MCN: Mucinous cystic neoplasms; ITPN: Intraductal tubulopapillary neoplasms; MUC: Mucins. 1: No expression; 2: Low expression; 3: Moderate expression; 4: High expression.

Table 3 Mucins expression in neoplasms of biliary system

	BilIN			EHBDC	IPNB			
	BilIN- I	BilIN- II	BilIN-III		Pancreatobiliary-type		Intestinal-type	
					Non-invasive	Invasive	Non-invasive	Invasive
MUC1	2	3	4	4	2	4	1	3
MUC2	1	1	1	3	NA	4	NA	3
MUC4	NA	NA	NA	4	NA	4	NA	3
MUC5AC	4	4	4	4	4	4	4	4

NA: Non available data; BilIN: Biliary intraepithelial neoplasia; EHBDC: Extrahepatic bile ducts; IPNB: Intraductal papillary neoplasm of the bile ducts; MUC: Mucins. 1: No expression; 2: Low expression; 3: Moderate expression; 4: High expression.

Table 4 Mucins expression in ampulla Vater neoplasms

	Ampulla vater	
	Pancreatobiliary-type	Intestinal-type
MUC1	4	4
MUC2	1	4
MUC4	4	4
MUC5AC	4	3

MUC: Mucins. 1: No expression; 2: Low expression; 3: Moderate expression; 4: High expression.

with poor prognosis. *De novo* expression of MUC5AC occurs in all grades of BilIN and in all types of IPNB and ICC. MUC5AC is useful in detection of bile duct neoplastic lesions at early stage.

Finally, in carcinoma of the ampulla of Vater, increased expression of mucin MUC1 is associated with unfavorable behavior of the tumor, such as lymph node metastasis, infiltration of the pancreas and duodenum, advanced TNM classification and worse prognosis. IAPN with pancreatobiliary-immunophenotype show no MUC2 expression while those with intestinal-immunophenotype are positive. The expression of MUC4 is linked with poor prognosis in patients with carcinoma of the ampulla of Vater favoring metastasis and tumor recurrence. Expression of MUC5AC correlates with carcinoma invasive capacity.

In conclusion, the combined status of mucin expression may be useful in the differential diagnosis of pancreatobiliary neoplasms, the detection of pre-

malignant lesions and in the evaluation of their malignant behavior. Besides their diagnostic and prognostic role, their involvement in carcinogenesis reveals their importance as putative therapeutic targets in the future. Further studies are needed to clearly define the exact positioning of these evaluations in the diagnostic and therapeutic algorithms of neoplastic lesions of the pancreas and biliary system.

Abstract

Cancer stem cells (CSCs) constitute a small proportion of the cancer cells that have self-renewal capacity and tumor-initiating ability. They have been identified in a variety of tumors, including tumors of the digestive system. CSCs exhibit some unique characteristics, which are responsible for cancer metastasis and recurrence. Consequently, the development of effective therapeutic strategies against CSCs plays a key role in increasing the efficacy of cancer therapy. Several potential approaches to target CSCs of the digestive system have been explored, including targeting CSC surface markers and signaling pathways, inducing the differentiation of CSCs, altering the tumor microenvironment or niche, and inhibiting ATP-driven efflux transporters. However, conventional therapies may not successfully eradicate CSCs owing to various problems, including poor solubility, stability, rapid clearance, poor cellular uptake, and unacceptable cytotoxicity. Nanomedicine strategies, which include drug, gene, targeted, and combinational delivery, could solve these problems and significantly improve the therapeutic index. This review briefly summarizes the ongoing development of strategies and nanomedicine-based therapies against CSCs of the digestive system.

Key words: Nanomedicine; Cancer stem cells; Digestive system; Drug delivery; Gene delivery

Nanomedicine strategies for sustained, controlled, and targeted treatment of cancer stem cells of the digestive system. *World J Gastrointest Oncol* 2016; 8(10): 735-744 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i10/735.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i10.735>

INTRODUCTION

Currently, gastrointestinal cancer is the second leading cause of cancer-related deaths worldwide. Despite some progress achieved in cancer treatment, the current therapies have limitations with respect to their ability to prevent tumor metastasis and relapse. Recent scientific studies have found that a small proportion of cancer cells (0.01%-4%) can proliferate indefinitely. These cells are similar to adult stem cells with respect to their proliferation, self-renewal, and differentiation into other cells; therefore, they were named cancer stem cells (CSCs)^[1]. CSCs were first isolated from acute myeloid leukemia by Bonnet *et al*^[2] in 1997. It was not until 2003 that CSCs in solid tumors were studied when Al-Hajj *et al*^[3] identified CSCs with a phenotype of CD44⁺/CD24^{-/low}/Lineage⁻ in breast cancer. This provided strong evidence for the existence of CSCs in solid tumors and theoretically supported the possible identification of CSCs in other solid tumors. Subsequently, CSCs were identified in a variety of tumors, including tumors of the digestive system, such as gastric cancer^[4], liver cancer^[5], and colon cancer^[6-9].

CSCs have many characteristics similar to those of stem cells, for example, the self-renewal and differentiation abilities, and some common signaling pathways, including the Wnt/ β -catenin, Notch, and Hedgehog pathways^[10-13]. However, CSCs also exhibit some unique characteristics because of abnormally regulated genetic mechanisms: (1) quiescence, conventional anticancer therapies always kill rapidly proliferating cancer cells, but have less effect on quiescent CSCs^[1,14,15]; (2) high tumorigenicity, only a handful of CSCs can lead to tumor development, whereas the same number of non-CSCs are unable to form clones or tumors *in vivo*^[16,17]; (3) resistance, CSCs highly express membrane transport proteins of the ATP binding cassette (ABC) family, which can transport and efflux a variety of materials, including metabolites, drugs, toxic substances, endogenous lipids, peptides, nucleotides, and sterols, which accounts for the drug efflux and drug resistance of CSCs^[18,19]; (4) high levels of anti-apoptotic molecules^[1]; and (5) enhanced DNA repair ability^[20-23]. Conventional

therapies including chemotherapy, radiotherapy, biotherapy, and thermal therapy mainly focus on the differentiation and proliferation of cancer cells rather than those of CSCs, resulting in an increase in the CSCs fraction, which can lead to metastasis and recurrence^[24,25]. Consequently, the development of effective therapeutic strategies against CSCs plays a key role in increasing the efficacy of cancer therapy.

In recent years, the applications of nanomaterials and nanotechnology in CSC-targeted therapy have received more and more attention. As an emerging interdisciplinary field, nanotechnology can provide materials and tools with unique physical and chemical properties and biological functions for CSC-targeted therapy. In this review, we briefly discussed the properties of CSCs and the conventional strategies against CSCs of the digestive system, as well as a summary of the latest achievements in the nanomedicine approaches for CSC therapy in the digestive system.

CANCER STEM CELLS OF THE DIGESTIVE SYSTEM

Normal gastrointestinal tissues comprise a specific class of stem cells, named gastrointestinal stem cells, which are adult stem cells, with a capacity to self-renew and replicate. They can differentiate into any type of cells in the gastrointestinal tract and play an important role in the regeneration of gastrointestinal mucosa and maintenance of tissue homeostasis. It seems that gastrointestinal stem cells may undergo mutation and can transform into CSCs, which, in turn, participate in the initiation and progression of the gastrointestinal tumors^[26]. However, Houghton found that *Helicobacter pylori* induced chronic inflammation in the gastric tissue of C57BL/6 mice and this inflamed tissue included bone marrow-derived cells, which could develop into intraepithelial carcinoma through dysplasia^[27]. The exact origin of gastrointestinal CSCs is unknown: They may be derived directly from the mutation of normal stem cells, or it may be that mature cells acquire tumor formation potential and transform into CSCs.

The identification of CSCs plays an important role in the evaluation of the prognosis of patients and serves to guide treatment. Currently, the main method used for the isolation of CSCs is based on the surface markers (such as membrane proteins, adhesion molecules, and receptors) that distinguish CSCs from non-CSCs, which can be sorted by flow cytometry or magnetic-activated cell sorting (MACS). In recent years, great progress has been made in the study of gastrointestinal CSCs and their markers, which can theoretically support the diagnosis and treatment of gastrointestinal tumors. In addition, the identification of specific cellular markers of gastrointestinal CSCs has become a research focus. So far, some possible markers of gastrointestinal CSCs have been evaluated, such as CD24, CD133, CD44, CD166, stage-specific embryonic antigen (SSEA), Oct-4,

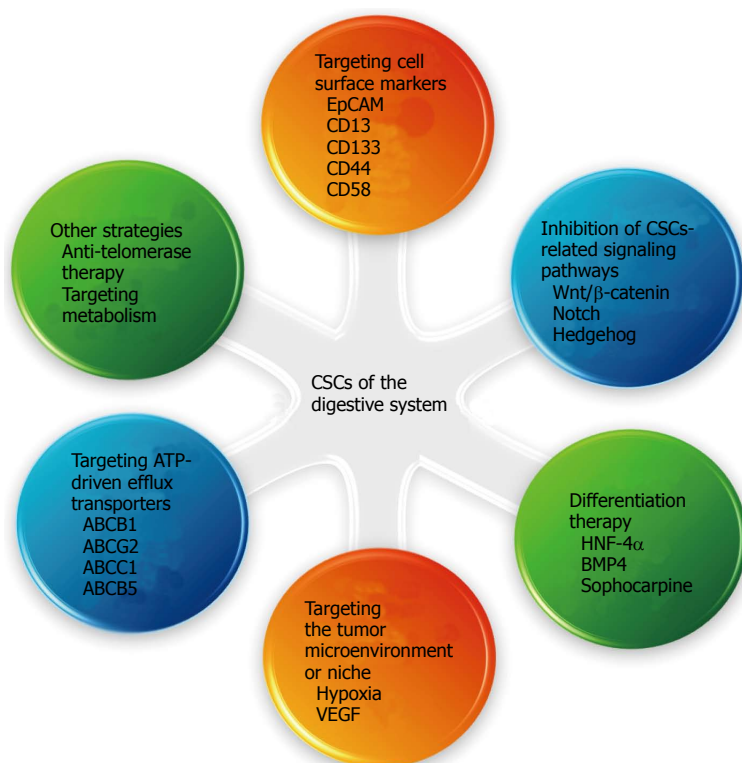

Figure 1 Possible therapeutic strategies that can eliminate cancer stem cells of the digestive system. CSC: Cancer stem cells; VEGF: Vascular endothelial growth factor; HNF-4 α : Hepatocyte nuclear factor-4 α ; BMP: Bone morphogenetic protein.

and Sox-2. CD133 and CD44 are the main markers of gastrointestinal CSCs. However, recent studies of CSC phenotypes have presented a new challenge^[28,29]; CSCs are of different phenotypes and it is urgent and necessary to target all subsets of CSCs within the tumor to prevent a relapse. Thus, there is a need to investigate more cell surface markers in addition to CD133 and CD44, for the identification of gastrointestinal CSCs.

STRATEGIES AGAINST CSCs OF THE DIGESTIVE SYSTEM

The current failure in the treatment of gastrointestinal cancer is attributable to drug resistance and recurrence after therapy in most cases, in which CSCs are thought to play a crucial role. Therefore, strategies targeting CSCs may bring new hope for the treatment of gastrointestinal cancer^[19,30]. Currently, several strategies have been proposed to target CSCs of the digestive system (Figure 1). For example, specific surface markers and altered signaling pathways are attractive therapeutic targets. Induction of the differentiation of CSCs and targeting of the tumor microenvironment or the niche supporting the CSCs are also efficient strategies. Inhibition of ATP-driven efflux transporters that are overexpressed on the CSCs surface, is believed to increase the sensitivity of the tumor to chemotherapeutic drugs. Other strategies, such as anti-telomerase therapy and modulation of abnormal metabolism, are also worth evaluating.

Targeting cell surface markers

CSCs express some unique surface markers that

distinguish them from other cells; therefore, strategies targeting these specific surface markers can eradicate CSCs of the digestive system, which is an effective approach for the treatment of gastrointestinal cancer. Aptamers, which are oligonucleotide or peptide molecules that can specifically bind to a desired site and penetrate the cancer cells, have been found to target the CSCs surface markers. Shigdar *et al.*^[31] isolated the first RNA aptamer against epithelial cell adhesion molecule (EpCAM), a putative marker of gastric, colorectal, and liver CSCs. In addition, monoclonal antibodies have been developed to block CSC surface markers. Haraguchi *et al.*^[32] demonstrated that CD13 is a marker for liver CSCs and treatment with anti-CD13 antibody suppressed the self-renewal and tumor-initiating ability of dormant CSCs. Smith *et al.*^[33] reported that a murine anti-human CD133 antibody conjugated to a potent cytotoxic drug, monomethyl auristatin F, selectively targeted CD133⁺ cells, which is a marker for gastric and liver CSCs. Other surface markers, including CD44^[34] and CD58^[35], have been also utilized to specifically eradicate the CSCs of the digestive system.

Inhibition of CSCs-related signaling pathways

The normal function of stem cells depends on the normal regulation of a variety of signaling pathways. Dysregulation of the signaling pathways results in abnormal proliferation and differentiation. Therefore, inhibition of CSCs-related signaling pathways is an effective method for cancer therapy. The common CSCs-related signaling pathways include: (1) Wnt/ β -catenin pathway: Implicated in the maintenance and proliferation of CSCs^[36]. Cai *et al.*^[37]

suggested that the Wnt/ β -catenin pathway is essential for the self-renewal of cancer stem-like cells in human gastric cancer. Another study also suggested the same role for the Wnt/ β -catenin pathway in gastric CSCs and showed that salinomycin (SAL) could inhibit gastric tumor growth by suppressing Wnt/ β -catenin signaling in CSCs^[38]. The Wnt/ β -catenin pathway plays an important role not only in gastric CSCs, but also in colon and liver CSCs^[39,40]. Song *et al.*^[39] demonstrated that small molecules could target the Wnt signaling pathways in CSCs for the treatment of colorectal cancer; (2) notch pathway: Required for the maintenance of gastrointestinal stem cells^[41]. Luo *et al.*^[42] suggested that the Notch pathway promotes CSCs activity in hepatocellular carcinoma (HCC). Wang *et al.*^[40] demonstrated that the Wnt/ β -catenin and Notch signaling pathways play important roles in the activation of liver CSCs; and (3) hedgehog pathway: Implicated in the unchecked self-renewal and the development of metastatic tumors^[43]. Song *et al.*^[44] suggested that the Sonic Hedgehog pathway is essential for the maintenance of the cancer stem-like cells in human gastric cancer. A study that investigated the molecular mechanisms of curcumin and curcumin analogs against colorectal CSCs suggested the involvement of signaling pathways, including Wnt/ β -catenin, Sonic Hedgehog, Notch, and PI3K/Akt/mTOR^[45].

Differentiation therapy

Differentiation therapy of tumors refers to treatment of malignant tumors *via* induction of cell differentiation. The abnormal differentiation of CSCs is one of the important causes of cancer development, thus, inducing the differentiation of CSCs is an important method for cancer therapy^[46]. Hepatocyte nuclear factor-4 α (HNF-4 α), a central regulator of differentiated hepatocyte phenotype, suppresses tumorigenesis and tumor development by inducing the differentiation of the hepatocarcinoma cells, especially CSCs, into mature hepatocytes^[47]. Lombardo *et al.*^[48] found that bone morphogenetic protein 4 (BMP4) induces the differentiation of colorectal CSCs and increases the antitumor effects of 5-fluorouracil and oxaliplatin. Zhang *et al.*^[49] verified that sophocarpine has the ability to suppress HCC and CSCs and could act as a differentiation therapy drug.

Targeting the tumor microenvironment or niche

The microenvironment is an important condition for the survival of cells, which plays an important role in the regulation of the proliferation and differentiation of cells. The stem cell microenvironment, called niche, includes the niche cells, extracellular matrix, and soluble factors derived from the niche cells. CSCs are also believed to reside in niches, which maintain the principle properties of CSCs, preserve their phenotypic plasticity, protect them from the immune system, and facilitate their metastatic potential^[50]. Targeted therapy against this microenvironment is of great significance for the treatment of cancer. Vermeulen *et al.*^[51] proposed that

colon cancer stemness was partly orchestrated by the microenvironment. Hypoxia, which influences the liver CSC microenvironment, has been identified as a major cause of hypervascularization in HCCs^[52]. Targeting hypoxia is an effective strategy to manipulate the niche of the quiescent, drug-resistant cells. Several studies have indicated that angiogenesis can be related to CSC survival and drug resistance and shown that vascular endothelial growth factor (VEGF) is one of the most specific and critical regulators of angiogenesis, which promotes CSC activity by governing both the microvasculature formation and the intrinsic self-renewal pathways^[53-55]. Targeting VEGF with inhibitors or antibodies can lead to normalization of the tumor vasculature, disruption of the CSC niche, and inhibition of tumor growth^[56-58].

Targeting the ATP-driven efflux transporters

CSCs express high levels of ABC transporters, such as ABCB1, ABCG2, and ABCC1, which represent the three principal multidrug-resistance (MDR) genes that have been identified in tumor cells^[19,59]. These transporters actively efflux the drugs outside the cells, conferring resistance to chemotherapeutic drugs^[59]. Xie *et al.*^[60] suggested that the overexpression of ABCG2 is responsible for chemotherapy failure in colon cancer. Inhibition of ABCB1 (MDR1) expression, which encodes P-glycoprotein (Pgp), can increase the sensitivity of HCC cells to anticancer drugs, such as doxorubicin and daunorubicin^[61]. Pgp's cousin, ABCB5, is another ABC transporter implicated in the drug resistance of CSCs in different tumor types. For example, Cheung *et al.*^[62] found that the expression of granulins-epithelin precursor (GEP) and ABCB5 in liver CSCs was associated with chemoresistance and reduced the survival rates of patients with HCC. However, inhibition of ABC transporters is likely to have significant side effects^[63], and the ability to overcome MDR clinically is rather limited^[64]. Therefore, targeted and combined therapy may be required to circumvent drug resistance and nanomedicine may show tremendous potential to overcome MDR.

Other strategies

Anti-telomerase therapy: Telomerase activation leads to telomere maintenance, which plays an important role in the immortality of CSCs. Compared to the normal cells, the telomerase activity in CSCs is higher and the length of the telomere is shorter. Anti-telomerase therapy can specifically shorten the CSCs telomere, causing replicative senescence, apoptosis, and cell cycle arrest with little damage to the normal cells. Several anti-telomerase agents, such as the antisense oligonucleotide inhibitor GRN163L and immunotherapies that use dendritic cells (GRVAC1), hTERT peptide (GV1001), or cryptic peptides (Vx-001), are currently in clinical trials for treatment of various tumors and are speculated to efficiently target CSCs^[65,66]. A recent study has implied that co-inhibition of telomerase and tankyrase 1, which elongates the telomere, may be a rational strategy for telomere-directed gastric cancer therapy^[67].

Targeting the metabolism: Recently, there is growing evidence that metabolism and stemness are highly intertwined processes in tumors^[68]. For example, gastrointestinal CSCs showed higher inducible nitric oxide synthase (iNOS) expression, lower reactive oxygen species (ROS) production, and a different metabolic profile with respect to non-CSCs. Aerobic glycolysis blockade, oxidative stress-based therapies, and nitric oxide synthase inhibition target the gastrointestinal CSCs and could have profound anticancer effects^[69].

NANOMEDICINE-BASED THERAPIES AGAINST CSCs OF THE DIGESTIVE SYSTEM

As discussed above, conventional therapies may not successfully eradicate CSCs owing to various problems, including solubility, stability, rapid clearance, poor cellular uptake, and unacceptable cytotoxicity. Thus, more and more attention has been drawn to the application of nanomedicine^[70-72]. Nanomedicine can be defined as the application and further development of nanotechnology to solve the problems faced in medicine, *i.e.*, to diagnose, treat, and prevent diseases at the cellular and molecular levels^[73-75]. Nanomedicine is characterized by a size of less than 200 nm in general, which is smaller than the traditional medicine, thus, it has the advantages of large specific surface area, high surface reaction activity, and high adsorption capacity. Moreover, it can be optimized in the aspects of drug loading, pharmacokinetic properties, and biocompatibility by different modifications of the particle surface. In conclusion, nanomedicine has the following characteristics: Sustained, controlled, and targeted drug delivery, improved drug stability, prolonged half-life of drugs, good biocompatibility, *etc.* Consequently, nanomedicine strategies for sustained, controlled, and targeted treatment of CSCs of the digestive system may offer superior outcomes leading to efficient cancer therapy (Figure 1).

Drug delivery

One important application of nanomedicine is the transport of chemotherapeutic drugs with poor solubility, stability, or severe side effects. For example, the monocarboxylic polyether antibiotic, SAL, which primarily functions as a highly selective potassium ionophore, has been shown to affect various CSCs, including liver, gastric, and colorectal CSCs^[76-79]. However, it exhibits poor aqueous solubility and severe nervous and muscle toxicity, which hinder its clinical applications^[80,81]. Therefore, various studies incorporate SAL into nanocarriers to address these issues. For instance, Yao *et al.*^[82] developed a gastric CSC-targeted drug delivery system (SAL-SWNT-CHI-HA complexes), which could enhance the bioavailability and cytotoxic activity of SAL. In our previous study, we developed novel iRGD (internalizing Arg-Gly-Asp peptide)-conjugated DSPE-PEG2000

nanomicelles (M-SAL-iRGD) for delivery of SAL to both liver cancer cells and CSCs. M-SAL-iRGD possessed a small size of around 10 nm and a drug encapsulation efficacy higher than 90%. It showed a superior tumor penetrating ability and therapeutic efficacy^[83]. Similarly, curcumin has extraordinary anticancer properties; however, it has limited application in the treatment of cancer owing to its insolubility, instability, and poor pharmacokinetics, which greatly hamper its *in vivo* efficacy^[84-86]. Wang *et al.*^[87] developed a novel nanoparticle formulation in which curcumin was encapsulated in stearic acid-g-chitosan oligosaccharide (CSO-SA) polymeric micelles to overcome these hurdles. Curcumin-loaded CSO-SA micelles could increase curcumin accumulation in cancer cells and were effective in inhibiting colorectal CSCs both *in vitro* and *in vivo*. In another study, Wang *et al.*^[88] used the CSO-SA micelles to deliver a standard chemotherapy for colorectal cancer treatment (oxaliplatin). This could also increase oxaliplatin accumulation in both colorectal cancer cells and tissues and could effectively eradicate colorectal CSCs.

Gene delivery

Nucleic acids, especially small interfering RNAs (siRNAs) and microRNAs (miRNAs), can effectively target genes overexpressed in CSCs and involved in the maintenance of stemness and tumorigenicity. However, their characteristics, such as negative charge, high molecular weight, and low stability, limit their application. Therefore, nanomedicines have been developed to condense them for effective delivery. For instance, a novel non-cytotoxic and pH-sensitive anti-EpCAM monoclonal antibody-labeled CSCs-targeted block copolymer vesicle was synthesized as a nanocarrier for anticancer drugs and siRNA. The polymer vesicles showed good pH-regulated drug release capability and excellent stability in water, PBS, and 40% fetal bovine serum. The EpCAM-positive CSC-targeted vesicles showed a high delivery efficacy of both the anticancer drug, doxorubicin hydrochloride (DOX-HCl), and siRNA to the CSCs^[89]. Similarly, Kim *et al.*^[90] developed a tumor-targeted nanodelivery platform (scl) and showed that systemic administration of scl carrying the wtp53 gene was able to induce tumor growth inhibition and promote the death of both CSCs and non-CSCs in subcutaneous colorectal cancer xenografts. Nanomedicine for siRNA delivery can also sensitize CSCs to chemotherapeutic drugs. For example, Liu *et al.*^[91] designed a novel siRNA delivery carrier system with multidrug resistance gene (MDR1)-targeted siRNA (siMDR1) and showed that it effectively reduced the expression of MDR1 in human colon CSCs, resulting in a significant increase in the chemosensitivity to paclitaxel.

Recent studies have indicated that miRNAs are important regulators of CSCs^[92]. For example, miR-34, a transcriptional target of p53, inhibits the biological properties of gastric CSCs. Restoration of miR-34 expression in gastric CSCs inhibits sphere formation *in vitro* and tumor regeneration *in vivo*^[93]. Liu *et al.*^[94] developed gelatinase-stimulated PEG-Pep-PCL nanoparticles to

Table 1 Nanomedicine-based therapies against cancer stem cells of the digestive system

Tumor types	Nanomedicine	Ref.
Drug delivery		
Gastric cancer	SAL-loaded carbon nanotubes functionalized with HA	[82]
Liver cancer	SAL-loaded iRGD-conjugated DSPE-PEG2000 nanomicelles	[83]
Colorectal cancer	Curcumin-loaded CSO-SA micelles	[87]
	Oxaliplatin-loaded CSO-SA micelles	[88]
Gene delivery		
Liver cancer	anti-EpCAM-monoclonal-antibody-labeled block copolymer vesicle	[89]
Colorectal cancer	Wtp53 gene loaded scL nanocomplex	[90]
Colon cancer	MDR1 siRNA loaded lipid nanoparticles	[91]
Gastric cancer	miR-200c loaded gelatinase-stimuli PEG-Pep-PCL nanoparticles	[94]
Targeted delivery		
Gastric cancer	SAL-loaded carbon nanotubes functionalized with HA	[82]
Liver cancer	anti-CD44 antibody-mediated liposomal nanoparticle loaded of doxorubicin	[96]
	CD90-targeted thermosensitive magnetoliposomes-encapsulated 17-AAG	[97]
Combinational delivery		
Gastric cancer	Nanoparticle co-loaded miR-200c and DOC	[99]
Liver cancer	micellar nanoparticle co-delivering platinum (IV) prodrug and siNotch1	[100]
Colorectal cancer	Liposomes co-encapsulated irinotecan and floxuridine	[101]
Colon cancer	Nanoliposomes co-encapsulated vincristine and topotecan	[102]

deliver miR-200c, which were reported to inhibit CSC-like properties. The miR-200c nanoparticles enhanced the radiotherapy efficacy, reduced the expression of CD44, and the percentage of CD44⁺ gastric cancer cells. Meanwhile, other CSCs properties, including invasiveness and resistance to apoptosis, could be suppressed by miR-200c nanoparticles.

Targeted delivery

In addition to its ability to improve drug stability and biocompatibility, nanomedicine can also be modified to direct or guide the therapeutic agents to CSCs. Since CSCs express specific cell surface biomarkers, it may be a promising strategy to use these biomarkers for targeted drug delivery. Hyaluronic acid (HA), a glycosaminoglycan widely found in the extracellular matrix, can specifically recognize its receptors, CD44, and has been identified as a potent targeting ligand to tumors possessing CD44-overexpressing cells^[95]. Yao *et al.*^[82] developed SAL-loaded chitosan (CHI)-coated single-walled carbon nanotubes (SWNTs) functionalized with HA, which facilitated the uptake of SWNTs into the gastric CSCs *via* CD44 receptor-mediated endocytosis. In addition, anti-CD44 antibodies could also be used for CSC-targeted therapy. Wang *et al.*^[96] developed doxorubicin-loaded anti-CD44 antibody-functionalized liposomal nanoparticles, which specifically targeted CD44⁺ cells of HCC to mitigate the side effects of conventional chemotherapy. In a recent study, CD90⁺ LCSCs were isolated by magnetic-activated cell sorting from HCC cells. Therefore, Yang *et al.*^[97] prepared a CD90-targeted thermosensitive magnetoliposomes (TMs)-encapsulated 17-allylamino-17-demethoxgeldanamycin (17-AAG), which is a heat-shock protein 90 (HSP90) inhibitor, to sensitize the CD90⁺ LCSCs to magnetic hyperthermia and enhance its antitumor effects *in vitro* and *in vivo*.

Combinational delivery systems

As described above, nanomedicine-based single drug delivery systems are effective in targeting the CSCs in the digestive system. However, various CSCs-targeted drugs that are not highly cytotoxic as compared to the conventional chemotherapeutic drugs, are not very effective in reducing the bulk cancer cells, which can spontaneously and stochastically turn into CSCs again^[98]. Therefore, combinational delivery of chemotherapeutics and CSC-specific agents for eliminating both the cancer cells and CSCs is a promising method to improve cancer treatment. Liu *et al.*^[99] co-loaded miR-200c and docetaxel (DOC) into an intelligent gelatinase-stimulated nanoparticle, which exhibited synergetic effects on the inhibition of both CSCs and non-CSC cancer cells. The miR-200c/DOC nanoparticles prominently suppressed the *in vivo* tumor growth. Shen *et al.*^[100] developed a micellar nanoparticle to deliver platinum (IV) prodrug and siNotch1 into both non-CSCs and CSCs of SMMC7721. The combined drug delivery system could remarkably augment drug delivery into tumor tissues, thus, substantially suppressing the tumor growth (Table 1).

Additionally, nanomedicine is crucial for the delivery of dual drugs with predictable ratios at the tumor site to achieve a synergistic effect. Mayer *et al.*^[101] co-encapsulated irinotecan and floxuridine at a 1:1 molar ratio inside 100-nm-diameter liposomes composed of distearoylphosphatidylcholine/distearoylphosphatidylglycerol/cholesterol (7:2:1 molar ratio). The liposomes maintained the drug ratio in the plasma after injection, and delivered the formulated drug ratio directly to the tumor tissue of the colorectal cancer. In another study, vincristine and topotecan were successfully co-encapsulated at therapeutically relevant levels in the same nanoliposome (LipoViTo). The nanoliposomes controlled the drugs' "biofate" and maintained a fixed drug ratio *in*

vivo, displaying an enhanced therapeutic efficacy against colon cancer^[102].

CONCLUSION

The CSCs theory revealed more facts about cancer, but the CSCs in the digestive system are still not fully understood. There is a need for further investigation of the new markers, abnormal metabolism, and signal transduction pathways of CSCs, which will improve our strategies to target CSCs. In this review, we summarized the current strategies against CSCs of the digestive system. Nanomedicines have been shown to effectively deliver drugs and genes to target CSCs of the digestive system. A number of studies have shown that there is a significant increase in the therapeutic outcome with nanomedicine. However, there are still great challenges limiting the effective application of nanomedicine in clinical practice. One of the most important challenges is the biological safety issues. There is still no clear evidence that the nanomaterials can be effectively metabolized *in vivo* and will not accumulate to cause side effects. In addition, it is difficult to determine the safe dose of nanomedicine because of the lack of clear evaluation criteria.

Although there are still some difficulties preventing the wide application of nanomedicine in clinical practice, there is a reason to believe that, with the progress of nanotechnology and the in-depth research of CSCs, the unique advantages of nanomedicine will create good conditions for the development of personalized therapy for cancer patients and will finally be capable of conquering cancer of the digestive system.

Abstract

Ampullary carcinoma (AC) is a rare gastrointestinal tumor without clear treatment recommendations. The management of this tumor is usually extrapolated from the treatment of pancreatic, biliary duct and intestinal cancers. Few papers have studied the AC as an independent entity and yet succumbs to several limitations. These studies were retrospective single institutional experiences with limited sample sizes recruited over a long period of time. Unlike metastatic ACs where chemotherapy is the only recommended option, localized AC once excised may be approached by either chemotherapy alone or concomitant chemoradiation therapy. In this review, we report the overall survival and recurrence factors of more than 1000 patients from all the studies treating exclusively ACs. We also review the medical treatment of this tumor and conclude to the necessity of multi-institutional randomized controlled studies for AC exclusively.

Key words: Ampullary cancer; Prognostic factors; Treatment; Review; Novel therapies

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This paper is a minireview outlining the actual knowledge concerning the treatment of ampullary carcinoma. After a brief review of the prognostic factors and current treatment options for localized and advanced ampullary carcinoma, we discuss the new molecular targets and report on the potential novel therapies.

INTRODUCTION

Ampullary carcinoma (AC) is an uncommon tumor accounting for approximately 0.2% of gastrointestinal malignancies and 7% of periampullary tumors^[1]. It is continuously increasing in frequency and actually is the second most common of periampullary tumors after pancreatic cancers^[1,2]. Adenocarcinomas are the most common tumors of the ampulla and may be subdivided pathologically into intestinal and pancreaticobiliary subtypes for potential prognostic purposes^[3]. Few trials have studied the AC as an independent entity. It is frequently seen as a subgroup of pancreatic and biliary tract cancer trials even though ACs have a better prognosis and constitute a confounding factor in these studies. In comparison to pancreatic adenocarcinomas, prognostic factors are in favor of the ampullary tumors. The tumor size and staging at diagnosis, the positivity of lymph nodes (LN), the vascular and neural invasions were lower in ACs^[4]. Nevertheless, trials treated ACs as pancreatic cancers. This dilemma probably stands essential for the absence of any guidelines from both the National Cancer Network (NCCN) and the European Society for Medical Oncology (ESMO) concerning the treatment of advanced ACs^[5,6]. In this paper we report on the recurrence factors and overall survival (OS) of patients with AC. We also review the position of chemotherapy in this setting.

PROGNOSTIC FACTORS IN AC

Although localized AC is known for its high rates of resectability and good long term OS, most of the series report a high proportion of recurrent disease. However, these series are of small numbers which disables any statistical OS analysis^[1]. LN spreading and number of resection LV^[7-12], the vascular, nervous and pancreatic invasion^[7,11-15] along with the unresectability of the tumor and positive margin status after resection^[9,10,13,16], and intraoperative transfusions^[7,11,17] are the most consistent survival factors throughout the studies of localized AC.

Several studies tried to establish the risk factors for the recurrences of excised ACs. Todoroki *et al.*^[14] in 2003 did not experience locoregional failure with pancreaticoduodenectomy. Recurrences occurred distally and were affected by lymphatic and venous invasion with a mean time to relapse of 13 mo. Perioperative blood transfusion, LN spreading and pancreatic invasion increased the risk of recurrence^[7,11,17].

Very few studies elaborated the prognostic factors of

advanced ACs. These factors can be extrapolated from studies of unresectable pancreatic and periampullary cancers. Negative prognostic factors include weight loss, abdominal pain, peritoneal dissemination and liver metastasis. Older age is also a negative prognostic factor except in white younger women characterized by a worse prognosis than older ones^[18,19].

EVOLUTION OF TREATMENTS

Tumor resection is the mainstay in the treatment of localized AC. Current surgical options prefer radical pancreaticoduodenectomy over local resection despite its higher morbidity^[7]. The conventional local regional resection technique considers a transduodenal approach. The extraduodenal technique is a potential alternative that offers a complete removal of the tumor with concurrent excision of retropancreatic LN^[20]. Preoperative endoscopic biliary drainage is not widely acceptable among pancreatic surgeons in view of the increased morbidity and delays of definite treatment^[21]. However, the only study involving exclusively AC showed that preoperative biliary drainage reduces postoperative wound infection without influencing mortality^[22].

The role of chemotherapy for both local and advanced AC is not yet clearly established in view of the rarity of the disease. The only relevant data is commonly found in series combining patients with small bowel, pancreatic or biliary tract tumors. Tables 1 and 2 report the response rate, time to progression and OS of 10 retrospective single institutional experience of small sample sizes varying between 26 and 186 patients with AC that were recruited over periods ranging from 5 to 33 years.

While reviewing the localized AC studies, most of the series used a pancreatic cancer chemotherapy regimen that consisted of fluorouracil and radiotherapy to treat ACs^[23-29]. Regimens also combined gemcitabine and radiotherapy after the introduction of the first in 1997^[30]. The ESPAC-3 trial by Neoptolemos *et al.*^[31] in 2012 included the largest sample of AC patients; 297 of the 428 patients enrolled in this trial had AC. Participants were divided into three subgroups: The control group consisted of 144 patients, the fluorouracil and the gemcitabine subgroups contained 143 and 141 patients respectively. Overall, the increase in median OS in the chemotherapy group was not statistically significant (43.1 mo vs 35.2 mo; $P = 0.25$)^[31]. By analyzing exclusively AC data, the median OS of the gemcitabine and the fluorouracil subgroups were 71 mo and 57.8 mo respectively in comparison to the 41 mo of the control arm group^[31]. In opposition, Jiang *et al.*^[30] in 2013 showed a trend toward increased OS in the fluorouracil group.

Papers reporting treatments of advanced ACs are fewer, only two papers were published to date^[32,33]. The first introduced in 2010 platinum for the first time in the treatment of AC; the regimens consisted of a combination of cisplatin with either gemcitabine or

Table 1 Response rate, time to progression and survival in patients with localized ampullary carcinoma

fluorouracil but failed to establish any OS difference between the two protocols^[32]. In opposition, Shoji *et al*^[33] showed more OS benefit in the gemcitabine group. This study reported 26 advanced AC patients receiving chemotherapy without tumor resection. The fluorouracil and gemcitabine based protocols had a response rate of 7.7% and an OS of 9.1 mo (OS = 9 and 12.3 mo respectively). It is of particular importance to note a phase II trial by Overman *et al*^[34] that recruited 30 patients among which 40% had advanced AC. Patients received a treatment with capecitabine and oxaliplatin (CAPOX) and had an overall response rate of 33% (95%CI: 10%-65%)^[34].

TREATMENT MODALITIES IN LOCALIZED AC

In the absence of solid data, neither NCCN nor ESMO established standard chemotherapy regimens for patients with ACs^[5,6]. Effectively, the Americans approach this tumor differently than the Europeans (Figure 1)^[35].

In discordance with the European treatment regimens that extrapolate chemotherapy protocols from pancreatic tumor trials^[30,31,36], the American treatment regimen is supported by the result of RTOG 9704 trial^[37]. As of stage IB of AC, the treatment approach is identical to resectable pancreatic adenocarcinomas with a sequence of gemcitabine and concurrent infusional fluorouracil and radiotherapy. Though the optimal sequencing is not clear, an acceptable protocol includes gemcitabine 1000 mg/m² for 3 weekly followed by conformal radiotherapy with concurrent infusional fluorouracil 250 mg/m² daily, and after 3 to 5 wk gemcitabine is reintroduced at 1000 mg/m² for 3 of every 4 wk for 3 mo^[38]. As with pancreatic cancer, the infusion protocol of fluorouracil is not clear yet.

CHEMOTHERAPY REGIMENS

TREATMENTS IN ADVANCED AC

As with localized AC, the optimal chemotherapy is not yet elucidated. The concurrent chemotherapy regimen recommended in advanced AC is an association of

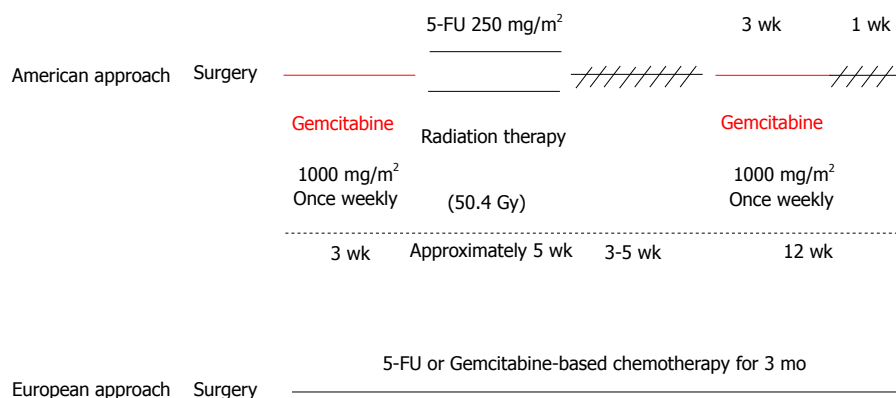

Figure 1 Concurrent American and European approach for the treatment of localized ampullary carcinoma^[35]. 5-FU: 5-fluorouracil.

cisplatin and gemcitabine^[38]. Other acceptable regimens adopted from the pancreatic chemotherapy treatment panel are fluorouracil or gemcitabine associated with oxaliplatin^[37-40]. An interesting approach in this context considers the pathologic subtype as an indicator for a potential chemotherapy regimen where fluorouracil-based therapy is used for intestinal ACs and gemcitabine-based therapy for pancreaticobiliary ACs^[34].

NOVEL THERAPIES

Given the rarity of the disease, the performance of well-powered randomized controlled clinical trials is very difficult. Multiple phase II trials including targeted therapies are actually ongoing among which a combination of CAPOX and bevacizumab (NCT01208103), CAPOX and panitumumab (NCT01202409), gemcitabine-oxaliplatin (GEMOX) and erlotinib (NCT00832637). The only study ongoing in the adjuvant setting is evaluating the role of high volume washing of the abdomen in increasing survival after surgery in patients with pancreatic and peripancreatic tumors (NCT02757859).

The ongoing studies seem promising but recruit also other peripancreatic tumors besides AC. A recent-genomic sequencing study of AC identified severe genetic aberrations with deleterious mutations and deletions in KRAS, SMAD4 and PTEN. This genomic profile suggests that the oncogenesis of ACs differs from both biliary tract and pancreatic cancers. The combination of these genomic aberrations suggests a therapeutic approach by mTOR/PI3K inhibition for patients with AC^[41]. Moreover, another genomic analysis revealed mutations in the WNT signaling pathway with high frequency inactivating mutations of ELF3 and a high rate of microsatellite instability. Such findings coupled with small-molecule inhibitors of β -catenin would be of particular interest to be evaluated in clinical trials^[42]. The only ongoing genetic analysis-guided dosage treatment study of patients with advanced gastrointestinal cancer include a combination of nab-paclitaxel, fluorouracil, leucovorin and irinotecan (FOLFIRABAX) (NCT02333188).

CONCLUSION

Given the rarity of the ACs, the published literature lacks well-powered randomized controlled trials. Effectively, the published data is limited to single institutional retrospective studies with small sample sizes. These studies recommend gemcitabine monotherapy or in combination with conformal radiotherapy for the treatment of localized AC and the combination of gemcitabine and cisplatin for the treatment of advanced AC. While analyzing these data, one should be aware to the selection bias of retrospective studies. Moreover, the results of single institutional studies are not to be extrapolated to community hospitals where the surgeons are less experienced in the management of this rare disease. Any effort for future therapeutic development should consider multi-institutional randomized controlled studies recruiting exclusively AC.

Abstract

Irreversible electroporation (IRE) is a non-thermal ablation technique used especially in locally advanced pancreatic carcinomas that are considered surgically unresectable. We present the first case of acute superior mesenteric artery (SMA) occlusion secondary to pancreatic IRE procedure that has not been reported before in the literature. A 66-year-old man underwent neoadjuvant chemoradiotherapy for locally advanced pancreatic ductal adenocarcinoma. IRE procedure was applied to the patient during laparotomy under general anesthesia. After finishing the procedure, an acute intestinal ischemia was detected. A conventional vascular angiography was performed and a metallic stent was successfully placed to the SMA and blood flow was maintained. It is important to be careful in such cases of tumor involvement of SMA when evaluating for IRE procedure of pancreatic tumor.

Key words: Irreversible electroporation; Mesenteric artery occlusion; Locally advanced pancreatic cancer; Superior mesenteric artery

Core tip: Irreversible electroporation (IRE) is a non-thermal ablation technique is a hope for patients who have unresectable locally advanced pancreatic carcinomas; especially, when any vascular surgical approach is impossible because of the tumor involvement. We encountered superior mesenteric artery occlusion after IRE procedure for locally advanced pancreatic cancer. We suggest that treating physicians should keep in mind that kind of mortal vascular complications of IRE. Stent placement *via* angiography could be the lifesaving treatment choice for vascular occlusions due to IRE procedure.

locally advanced pancreatic cancer. *World J Gastrointest Oncol* 2016; 8(10): 751-756 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i10/751.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i10.751>

INTRODUCTION

The majority of the pancreatic adenocarcinomas are diagnosed at an advanced stage, with resectable tumors being identified in only 10%-20% of the cases at the time of first admission^[1]. Involvement of the celiac trunk, superior mesenteric artery or portal vein without distant metastasis is observed in 40% of cases with stage 3 disease^[2,3]. For these patients, a 5-year survival rate of 6.8% has been reported following surgical resection^[4]. These patients are now classified as locally advanced stage pancreatic cancer (LAPC), and their survival rates are reportedly better compared to patients with distant metastasis. The probability of surgical resection following neoadjuvant treatment is higher in these patients^[5]. Nowadays, different ablation techniques are being studied in combination with neoadjuvant treatment^[6]. Some thermal ablation techniques such as radiofrequency ablation (RFA), cryoablation and microwave ablation have been developed and defined for tumor ablation. Thermal ablation methods are reported to cause necrosis during treatment for LAPC through thermal injury in the peripancreatic fatty tissue, main vascular structures, pancreatic tissue, duodenum and biliary tract^[7]. These morbid complications are limitations of these techniques for pancreatic tumors.

Irreversible electroporation (IRE) creates pores in cell membrane by transmitting short electrical currents at high voltage^[8]. As a result, the phospholipid membrane of the cell is permanently damaged, and the apoptosis and necrosis complex is observed due to the impairment of cellular homeostasis. Since IRE is not a thermal ablation technique, it is assumed that it is affected to a lesser extent from the vascular flow surrounding the tissue^[9]. No decrease in ablation energy is observed, due to the effect on the main vascular blood flow. Also, due to the shorter duration of treatment, a larger affected tissue volume, and a lower pain response, this technique is considered to be superior to other ablation techniques^[10]. Previous studies demonstrated that IRE use in the treatment of locally advanced pancreatic cancer was safe, since it resulted in no harm to the peripancreatic tissues and did not affect the superior mesenteric artery, porta hepatis and biliary tract^[11]. Metallic stent removal is recommended prior to the use of IRE in cases where a metallic stent is applied in the biliary tract for biliary obstruction. It is believed that the presence of a metallic stent in the field of electrical flow within the duodenum may result in damage to the adjacent structures^[12].

Studies conducted in various centers around the world have reported the short and long term protocol of IRE to be effective in the treatment of LAPD. In these

Figure 1 Coronal plain computerized tomography. Locally advanced pancreatic malignant mass of 45 mm in diameter surrounded and narrowed superior mesenteric artery (arrow).

studies no important morbid complication was reported like SMA occlusion. However, in this case report, we draw attention to a previously unpublished complication of IRE in LAPC.

CASE REPORT

A 66-year-old man with locally advanced pancreatic head adenocarcinoma diagnosed by fine-needle aspiration biopsy 6 mo ago was admitted to our institution. Tumor markers were measured, with CA 19-9 = 4801 IU/mL and CA 125 = 161 IU/mL. After diagnosis, a plastic stent was placed in ductus choledocus with ERCP. Immediately afterwards, chemoradiation was administered to the patients [5 cycles of chemotherapy consisting of Folfox + 5-FU + Oxaliplatin every 14 d, for 28 d RTA (28 fractions 50, 4 gray IMRT received)]. After admission to our hospital, computerized tomography (CT) examination was performed to the patient, and a malignant mass of 45 mm in diameter was observed at the pancreatic head level (Figure 1). It was noted that the tumor had surrounded the superior mesenteric artery 360 degrees, the affected segment of SMA was 40 mm. The tumor had apparently reduced the SMA diameter by 3 mm (Figure 1). Main pancreatic duct was markedly dilated, and the diameter was measured as approximately 7 mm. There was no metastasis and the tumor was stable after neoadjuvant chemotherapy.

The patient was referred to our hospital with a diagnosis of LAPC. Irreversible electroporation for pancreatic tumor and simultaneous gastrojejunostomy was planned. The abdomen was opened with a median incision above the umbilicus and abdominal exploration was performed. During the exploration, no distant metastases were identified anywhere in the abdomen. Intraoperative liver ultrasonography was used to detect possible metastasis to liver. The patient was under general anesthesia, surgery was performed in the supine position. The gastro-colic omentum was opened to reach and expose the pancreatic tumor. Electroporation was performed in accordance with the procedural instructions.

Figure 2 Conventional angiography of superior mesenteric artery immediately after irreversible electroporation. Angiography revealed that there is occlusion in superior mesenteric artery (red arrow) and also occlusion in hepatic artery (white arrow) originated from superior mesenteric artery.

Figure 3 Conventional angiography of superior mesenteric artery after stent placement. After the stent placement superior mesenteric artery recanalized and intestinal blood flow was maintained (arrow shows the recanalized superior mesenteric artery).

IRE was performed using the Nanoknife System (Angiodynamics, Lanthan), as described in the previous manuscript on IRE for the pancreas. High definition intraoperative ultrasound imaging was used in all cases, which is required to demonstrate non-traumatic precise needle placement and also for continuous ablation assessment during IRE. In sum, 3 monopolar probes with 2-cm spacing will deliver an electroporation defect of approximately 3.5 cm axial, 2.5 cm anterior-posterior, and 2.5 cm cranial-caudal. This electroporation procedure is achieved through a maximum of 1.5 cm exposure, 1500 V/cm, and 100 s wavelength. The procedure was performed in 45 min. After IRE procedure a gastrojejunostomy completed. After completing gastrojejunostomy anastomosis, a color change was concurrently observed in the small intestine. Based on a suspicion of SMA occlusion, arterial pulse was checked in the small bowel mesentery. No pulse was obtained in this area. The abdomen of the patient was closed, and he was taken to the angiography unit because SMA occlusion developed in the tumor surrounded segment. In angiography images, it was observed that a short segment after the origin of SMA, right hepatic artery was arising. Even after 1 cm distal to right hepatic artery origin there was no blood flow in the SMA (Figure 2). First of all, occluded segment was dilated with a 3 mm balloon. After dilatation a 4 mm and 3 cm length metallic stent was placed to this dilated segment (Figure 3). There were no complications in the postoperative follow-up. The patient was discharged without any complication the sixth day postoperatively.

DISCUSSION

Nearly 30% to 40% of patients with pancreatic adenocarcinoma have a locally advanced disease with stage III at the time of diagnosis and half of the tumors involved celiac axis and SMA. Autopsy studies have demonstrated that 30% of the patients with pancreatic cancer are in locally advanced stage with no distant metastasis^[13]. Chemoradiotherapy used in the conventional treatment

of such patients is of limited efficacy. In the past, hepaticojejunostomy or gastrojejunostomy were commonly used in the palliative surgical treatment of patients with LAPC. IRE is a new hope for the patients' with LAPC in locally control of pancreatic cancer with survival benefits. We perform IRE for LAPC invaded or encapsulated superior mesenteric artery in the absence of distant metastasis. We perform 3 to 5 per annually IRE since 2013 in our institution.

In the classical surgical approach, pancreaticoduodenectomy (PD) is preferred in resectable pancreatic carcinomas. Although acute occlusion or thrombosis in the hepatic artery, portal vein, SMA or celiac artery are rarely observed following this operation, they are still considered as the most significant causes of mortality. Gaujoux *et al*^[14] preoperatively evaluated 545 patients who underwent PD, by arterial reconstruction, examining SMA and celiac artery stenosis with CT, and detecting hemodynamically significant stenosis is 27 (5%) of the patients. On the other hand, five patients died due to undetectable stenosis and ischemic complications. Stent placement and bypass procedures were preoperatively performed in those patients, with an effort being made to prevent postoperative ischemic complications. Overall, the rate of complications was reported as 2.6%. It was observed that 36% of these complications were ischemic complications associated with undetectable stenosis^[14]. Other studies in the literature recommend the application of CT, angiography or intraoperative Doppler ultrasonography, and clamping the gastroduodenal artery for the diagnosis of SMA occlusion^[15]. Median arcuate ligament compression, atherosclerotic stenosis or fibromuscular dysplasia and tumor involvement of SMA might be the cause of acute occlusion of SMA in patients with pancreatic cancer^[16]. Recommended treatment modalities in acute SMA occlusion include thrombectomy, revascularization with side-to-side or end-to-side anastomosis, and stent application by angiography^[17]. While SMA occlusion is rarely observed during PD, acute SMA occlusion has never been previously reported in the literature

in patients who underwent IRE. The impaired blood supply in the jejunal segments, which was noticed intraoperatively in our case presented here, enables the detection of SMA occlusion. Since access to the occluded segment in our case would be easier by vascular angiography, stent placement was preferred for treatment choice. Accessing the SMA surgically, on the other hand, was not possible because of tumor involvement. Therefore, by using angiography, diagnosis and treatment were both performed at the same time.

Owing to the imaging techniques used today, LAPC can be diagnosed preoperatively. Endoscopically applied biliary and/or duodenal stents provide a chance for palliative treatment by eliminating the risk of surgical morbidity for the patient^[18]. Currently defined thermal ablation techniques are known to be inefficient for adequate ablation of tumor cells adjacent to vascular structures due to the heat sink effect. IRE provides non-thermal ablation in tumor cells through the short electrical currents with high amplitude. Therefore, it can be applied in LAPC without being affected from the flow in portal vein, celiac artery, biliary tract or SMA. However, IRE modulates vascular smooth muscle cells to apoptosis; but it has been demonstrated that elastin and collagen in particular, which are present in vascular structures, have been affected from this ablation technique^[19]. After IRE blood flow is intact and vascular smooth muscle cells repopulate in a short time period^[19]. The method's efficacy was demonstrated in studies performed on large tumor areas, where its application was associated with shorter times and lesser complications. Folfirinox or gemcitabine based chemotherapy is used for approximately 4 mo in the first line treatment of LAPC, and its efficacy is approved by the National Comprehensive Network Guideline^[20].

In a study by Martin *et al*^[21], 54 patients who underwent IRE were compared with 85 patients who were admitted for standard chemotherapy. At the end of the study, no significant differences were found in overall survival and progression-free survival between patients who underwent systemic chemotherapy for 4 mo and who underwent IRE treatment^[21]. The overall survival results of the IRE applied to 200 patients revealed no significant differences with patients receiving chemoradiotherapy and it was recommended that chemoradiotherapy, is used along with IRE as part of a triple treatment protocol. In this multicenter study, minor complications were observed among those 200 patients, but no case of acute vascular occlusion was encountered^[22]. Other studies with large series demonstrated that application of IRE was safe and efficient around vascular structures^[23].

Unexpected complications are being reported as clinical studies are continuing. Following application of this technique, various complications have been reported secondary to electrical transmission, especially in patients with metallic biliary stents or enteric stents^[12].

In the review of the literature, we did not encounter any study on SMA occlusion following IRE application, as

was the case with our patient presented herein. A recent systematic review reported an IRE-related complication rate of 13%, with an IRE-related mortality of 2%^[24]. Martin *et al*^[22], in a recent study with a population of 200 patients suffering from LAPC treated with IRE, showed an overall rate of adverse events of 37% (74 patients with 149 overall complications) and a mortality rate of 2%. The most common complications (including both percutaneous and open techniques) described after the use of IRE on pancreas are pancreatitis, pneumothorax, hematoma, abdominal pain, bile leakage, pancreatic leakage, duodenal leakage, duodenal ulcer, deep vein thrombosis/pulmonary embolism and superior mesenteric venous occlusion.

In healthy individuals average diameter of SMA was reported between 7.3 and 5.9 mm^[24]. The measured diameter of SMA in this case with CT scan was 3 mm. The tumor involved the artery and decreased its diameter nearly 50%. After the IRE procedure edema may developed around the ablation area or at the wall of the artery may especially cause an SMA occlusion. SMA occlusion and intestinal ischemia was noticed earlier in the present case, since IRE was applied simultaneously with open surgery, and this condition was treated by an angiographically applied vascular stent before necrosis developed in the jejunal segments. It is more important to be careful in percutaneous IRE procedures for LAPC because it is difficult to diagnose intestinal ischemia such a short time period.

The anatomy of the hepatic artery varies substantially. Reported rate of replaced right hepatic artery from SMA ranges from 5% to 25%^[25]. A variant artery is an important risk factor when the surgeon unaware of this anomaly. It is possible to progress the thrombosis to the stump of right hepatic artery in such cases. This is another possible fatal complication of SMA occlusion when hepatic artery arises from SMA. The liver and gut will become necrotic within a few hours.

Recently, percutaneous IRE application has been tried and its results in terms of overall survival were observed to be positive^[26]. Placement of probes could be both percutaneous and surgical; it depends on localization of the lesion and experience of the team. One should pay attention to acute vascular occlusions that might develop in such cases. It is also necessary to bear in mind that acute vascular occlusions might develop during percutaneous or surgical IRE application in LAPC.

IRE expands the scope of treatment of lesions that is near to major vascular/biliary/urinary structures. Because of this adjacency, these lesions are not suitable for local ablative therapies and could only be try to treat with some forms of external beam radiation therapy. In order to prevent injury of these major structures by displacement of electrodes, there is a need for general anesthesia (deep paralysis)^[23]. The only contraindication of IRE is patients with pacemakers or with cardiac arrhythmias^[27]. IRE is mostly applied for locally advanced tumors invaded to adjacent structures.

As in our case, if there is a severe vascular invasion is decreasing the diameter more than 50%, a coated vascular stent could be placed to the narrowed segment before applying IRE.

In conclusion, we present a new and fatal complication of IRE procedure for LAPC. In our patient, the diameter of SMA was decreased over 50% when compared with a healthy individuals SMA. We think that both arterial narrowing and IRE depend tissue edema are affective factors for acute SMA occlusion. However, it might also be speculated that the monopolar probes itself caused direct SMA injury or induced, *e.g.*, a small hematoma in the vicinity of the SMA, resulting in occlusion of the already narrowed vessel.

COMMENTS

Case characteristics

A 66-year-old man presented with locally advanced pancreatic head adenocarcinoma.

Differential diagnosis

Chronic inflammation, desmoids reaction around the tumor.

Laboratory diagnosis

Tumor markers were measured, with CA 19-9 = 4801 IU/mL and CA 125 = 161 IU/mL.

Imaging diagnosis

Computerized tomography examination revealed a malignant mass of 45 mm in diameter was observed at the pancreatic head level and the tumor had surrounded the superior mesenteric artery 360 degrees.

Treatment

The patient received systemic chemotherapy following irreversible electroporation.

Related reports

This case is a unique case of superior mesenteric artery occlusion as a complication of irreversible electroporation.

Term explanation

Irreversible electroporation creates pores in cell membrane by transmitting short electrical currents at high voltage. As a result, the phospholipid membrane of the cell is permanently damaged, and the apoptosis and necrosis complex is observed due to the impairment of cellular homeostasis.

Experiences and lessons

While a general clinical decision making algorithm would not be appropriate and each clinical situation needs to be individualized. As in this case, if there is a severe vascular invasion is decreasing the diameter more than 50%, a coated vascular stent could be placed to the narrowed segment before applying irreversible electroporation.

Peer-review

The manuscript by Ekici *et al* describes a case of arterial complication following irreversible electroporation (IRE) for locally advanced pancreatic cancer. IRE is one of the new methods for local therapy of non-metastatic but locally advanced pancreatic cancers. The present case report is both timely and important, highlighting a potential adverse event using this technique.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Isabelle Van Seuning, PhD, Director, Inserm UMR-S 1172 Team "Mucins, epithelial differentiation and carcinogenesis", Jean-Pierre Aubert Research Center, Lille cedex 59045, France

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Laparoscopic rectal surgery has demonstrated its superiority over the open approach, however it still has some technical limitations that lead to the development of robotic platforms. Nevertheless the literature on this topic is rapidly expanding there is still no consensus about benefits of robotic rectal cancer surgery over the laparoscopic one. For this reason a review of all the literature examining robotic surgery for rectal cancer was performed. Two reviewers independently conducted a search of electronic databases (PubMed and EMBASE) using the key words "rectum", "rectal", "cancer", "laparoscopy", "robot". After the initial screen of 266 articles, 43 papers were selected for review. A total of 3013 patients were included in the review. The most commonly performed intervention was low anterior resection (1450 patients, 48.1%), followed by anterior resections (997 patients, 33%), ultra-low anterior resections (393 patients, 13%) and abdominoperineal resections (173 patients, 5.7%). Robotic rectal surgery seems to offer potential advantages especially in low anterior resections with lower conversions rates and better preservation of the autonomic function. Quality of mesorectum and status of and circumferential resection margins are similar to those obtained with conventional laparoscopy even if robotic rectal surgery is undoubtedly associated with longer operative times. This review demonstrated that robotic rectal surgery is both safe and feasible but there is no evidence of its superiority over laparoscopy in terms of postoperative, clinical outcomes and incidence of complications. In conclusion robotic rectal surgery seems to overcome some of

technical limitations of conventional laparoscopic surgery especially for tumors requiring low and ultra-low anterior resections but this technical improvement seems not to provide, until now, any significant clinical advantages to the patients.

Key words: Robotic surgery; Robotic rectal surgery; DaVinci rectal surgery; Robotic rectal cancer; Robotics for rectal cancer; Robotic rectal resection

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Laparoscopic rectal surgery has progressively expanded. However it has some technical limitations. The need to overcome these limitations leads to the development of robotic platforms. Although the positive feedback is by the surgeons, there is still no evidence in literature about the superiority of robotic rectal surgery when compared to traditional laparoscopy.

Staderini F, Foppa C, Minuzzo A, Badii B, Qirici E, Trallori G, Mallardi B, Lami G, Macri G, Bonanomi A, Bagnoli S, Perigli G, Cianchi F. Robotic rectal surgery: State of the art. *World J Gastrointest Oncol* 2016; 8(11): 757-771 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i11/757.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i11.757>

INTRODUCTION

Laparoscopic colorectal surgery has progressively expanded since a number of randomized controlled trials (RCTs)^[1-3], review articles^[4,5], meta-analysis^[6] and case series^[7] have demonstrated its better postoperative outcomes when compared to open surgery. However, laparoscopic surgery has some technical limitations such as poor ergonomics, 2-dimension view, coning and fulcrum effect, that may influence surgery in narrow anatomical fields such as in the pelvis during rectal surgery. The need to overcome these limitations leads to the development of robotic platforms. The da Vinci robotic surgical system is the only totally robotic platform available. After approval by Food and Drug Administration in 2000, its use progressively spreaded as demonstrated by the increasing number of publications. Three-D high definition vision, wrist-like movement of instruments (endowrist™), stable camera holding, motion filter for tremor-free surgery and improved ergonomics for the surgeon are the advantages of the robotic system that may make rectal surgery more affordable and theoretically should provide better outcomes for the patient. Although the positive feedback is by the surgeons, there is still no evidence in literature about the superiority of robotic rectal surgery when compared to traditional laparoscopy. The aim of this study was to review the rapidly expanding literature in order to focus on the current state and assess any

benefits of robotic rectal cancer surgery.

RESEARCH AND LITERATURE

A review of the literature examining robotic surgery for rectal cancer during the period from 2000 to 2015 was performed. Two reviewers independently conducted a search of electronic databases (PubMed and EMBASE) using the key words "rectum", "rectal", "cancer", "laparoscopy", "robot". The reference lists provided by the identified articles were additionally hand-searched to prevent article loss by the search strategy. This method of cross-references was continued until no further relevant publications were identified. The last search was performed on December 2015. Inclusion criteria were prospective, retrospective, randomized, comparative studies about robotic rectal surgery for cancer including anterior resections, low anterior resections, ultralow anterior resections, abdominoperineal resections, proctectomies, proctocolectomies. Exclusion criteria were: Abstracts, letters, editorials, technical notes, expert opinions, reviews, meta-analysis, studies reporting benign pathologies, studies in which the outcomes and parameters of patients were not clearly reported, studies in which it was not possible to extract the appropriate data from the published results, overlap between authors and centers in the published literature, non-English language papers.

The literature search yielded 266 papers, the process is listed in Figure 1. After the 1st filtering, the remaining 60 studies were 33 comparative, 26 case series, and 1 RCT. Then 17 studies were excluded due to duplicated data. They were 7 comparative and 9 case series. After this process a total of 43 papers, 27 comparative including only 1 RCT and 16 case series were included and reviewed.

STUDIES OVERVIEW

The number of publications about robotic rectal surgery for cancer has been constantly increasing. Among the papers we included there was only 1 paper per year published in 2006, 2007, 2008, 3 papers in 2009, 2 in 2010, 5 per year in 2011 and 2012, 10 in 2013 and 15 in 2014. With regard to the nationality of the 1st author there were 16 studies in the South Korea (37.2%), 11 in the United States (25.5%), 4 in Italy (9.3%), 2 in Turkey (4.6%), 2 in the Singapore (4.6%), 1 in Japan (2.3%), 1 in Denmark (2.3%), 1 in Spain (2.3%), 1 in Romania (2.3%), 1 in Brazil (2.3%), 1 in Canada (2.3%), 1 in Taiwan (2.3%), 1 in China (2.3%) (Table 1).

Surgical technique

A total of 3013 robotic operations were performed. Sixteen studies^[10,12,14,16,17,22,23,25,27,28,37,38,40-42,48] (1257 patients) reported a totally robotic procedure which was carried out with either a single^[10,16,17,22,23,25,27,28,37,38,40-42,48] or a double docking^[12,28] technique. In 22 studies^[8,13,15,18,20,21,25,26,30-34,36,39,43-47,49,50] (1384 patients) an

Figure 1 Flow diagram of literature search.

hybrid robotic technique was performed: The inferior mesenteric vessels ligation and splenic flexure mobilization were performed laparoscopically whereas pelvic dissection and total mesorectal excision were performed robotically. In 5 studies^[9,11,19,29,35] (372 patients) the robotic technique was not specified. Laparoscopic procedures described in the 27 comparative studies^[8-33] were performed in the same manner as robotic surgery using laparoscopic instruments (Table 1).

Demographics and preoperative data

Most of patients were male (1911, 63%), the mean age was 58, the mean BMI was 26.6. Nine hundred-eight patients (20%) underwent a neoadjuvant chemotherapy, 71 (2.3%) a neoadjuvant chemo-radiotherapy and 8 (0.2%) radiotherapy only. With regard to the type of operation, 1450 (48.1%) were low anterior resections, 997 (33%) were anterior resections (AR), 393 (13%) ultra-low anterior resections (ULAR) and 173 (5.7%) abdominoperineal resections (APR). In the studies where the type of operation was not specified and where it was stated that a TME was performed^[27,29,41] we assumed that all operations were low anterior resections (LAR) (Table 2)

Operative data

The mean robotic operative time ranged from 202 min^[31] to 485.8 min^[17]. For the 1345 laparoscopic patients in the selected comparative studies the mean operative time ranged from 158.1^[30] to 374.3 min^[17]. This difference was statistically significant in 12 comparative studies^[10,14,17-24,27,28,30] with a longer time for robotic surgery. Levic *et al.*^[9] were the only authors that reported

a longer laparoscopic operative time ($P = 0.055$), but all interventions were performed with a single port technique (Table 3).

The estimated blood loss (EBL) was not reported in 14 studies. The mean value ranged from 17 mL^[36] to 280 mL^[14] with the robotic approach and from 59.2^[18] to 271.4^[15] in the laparoscopic group. Among 16 comparative studies^[8-10,12-15,17,19-21,23,24,29,31,33] that evaluated the EBL only Kang *et al.*^[23] and Erguner *et al.*^[21] reported a significantly lower EBL with the robotic approach when compared to the laparoscopic one.

Thirty seven studies reported the conversion rate to open surgery. Three^[8,22,31] out of 22 comparative studies^[8-15,17,19-25,28-33] showed a significantly lower conversion rate in the robotic series when compared to laparoscopy. The difference in overall conversion rate reported by Ielpo *et al.*^[14] was not statistically significant. However, when data were analyzed according to the tumor location (upper, mid, lower rectum), the conversion rates between robotic and laparoscopic procedures for lower rectal cancers were respectively 1.8% and 9.2% ($P = 0.04$).

The rate of patients that underwent a protective ileostomy creation ranged from 0%^[30] to 100%^[10] both in the robotic and laparoscopic group. The difference in protective ileostomy creation was statistically significant in 5 studies. Kuo *et al.*^[17] reported a lower rate in the robotic vs the laparoscopic group whereas Saklani *et al.*^[19], Erguner *et al.*^[21], Kim *et al.*^[25], Baek *et al.*^[29] showed a lower rate in the laparoscopic vs the robotic group.

Postoperative data

The mean postoperative day to first flatus ranged from 1.9^[48] to 3.2^[30] d in the robotic cases and from 2.4^[23] to 3.4^[17] in the laparoscopic ones. No statistically significant difference between robotic and laparoscopic cases was reported in any of the articles reviewed (Table 4).

The day of first postoperative liquid diet was available in 11 studies^[6,22,27,29,34,36,43,45,47,48,50] ranging from 1^[16] to 3.9^[45] d in the robotic cases. Only two^[22,29] comparative studies reported the first postoperative liquid diet in their robotic and laparoscopic series, in one^[22] of these the difference was statistically significant in favour of robotic surgery (3 d vs 5 d, $P = 0.005$).

The day of first postoperative solid diet was available in 11 studies^[8,10,13,17,19,23-25,30,34,37] ranging from 2.58^[10] to 7.5^[18] d in the robotic cases and from 2.48^[10] to 7.7^[18] d in laparoscopic cases. Among 9 comparative studies^[8,10,13,17,19,23-25,30] only Kang *et al.*^[23] reported a significant earlier oral intake in the robotic group (4.5 d vs 5.2 d, $P = 0.004$) when compared to the laparoscopic one.

The mean length of hospital stay ranged from 4.5^[33] to 14.2^[17] and from 3.6^[33] to 15.1^[17] d after robotic and laparoscopic surgery respectively. Among 8 comparative studies, Tam *et al.*^[15], Levic *et al.*^[9] and Park *et al.*^[30] reported a shorter length of stay in their laparoscopic series whereas 5^[8,22-24,32] studies reported a significant

Tot rob: Totally Robotic; DV: Da Vinci; NS: Not specified.

shorter length of stay after robotic surgery.

No statistically significant differences in the overall 30 d mortality between the robotic and laparoscopic approach was found among 15 comparative studies^[8-11,13,14,19-24,29-31] (0.10% and 0.45% respectively).

Twenty-three studies reported the reintervention rate. In the robotic series it ranged from 0%^[8,22,32,33,42,48] to 15%^[20] whereas it ranged from 0%^[32,33] to 15.7%^[11] after laparoscopic surgery. The most common cause of reintervention was anastomotic leak in both the robotic and laparoscopic groups. No statistically significant differences were found in any of the 12 comparative studies^[11-15,20-24,32,33].

The overall complication rate in the robotic and laparoscopic groups was 24.5% and 27.7% respectively. No significant differences in this parameter

were reported between the robotic and laparoscopic series^[8-11,13-15,19-25,28-33]. The most frequent complication in both the robotic and laparoscopic cases was anastomotic leak followed by bowel obstruction and urinary complications (Table 5). Thirteen studies^[10,18,19,22-24,26,31,37,38,40,44,45] reported urinary and sexual dysfunction after rectal surgery, 9 of these were comparative. Park *et al*^[18] reported an earlier and significant restoration of erectile function after robotic surgery when compared to the laparoscopic one. Kim *et al*^[26] observed an earlier recover of urinary function after robotic intervention within six months from the operation ($P = 0.001$). After 6 mo the difference was no more statistically significant.

Table 6 shows the studies which classified complications according to the Clavien Dindo Scoring System. Clavien-Dindo 1 and 2 were the most frequent

¹9 hartmann; ²1 Posterior pelvic exenteration; ³1 hartmann. AR: Anterior resections; ULAR: Ultra-low anterior resections; APR: Abdominoperineal resections; CHT: Chemotherapy; BMI: Body mass index; ASA: American society anesthesiologists.

complications in both groups (13.8% robotic vs 12.4% laparoscopic).

Oncological outcome

The mean number of harvested nodes ranged from 10^[14] to 20.6^[48] and from 9^[14] to 21^[10] in the robotic and laparoscopic cases respectively. Three of 22 comparatives^[8-15,17,19-25,28-33] studies reported a statistically significant difference in the number of harvested nodes between the robotic and laparoscopic approach: Levic *et al*^[9] and D'Annibale *et al*^[22] showed an higher number of examined nodes after robotic surgery whereas Yoo *et al*^[10] showed an higher number of examined nodes after laparoscopic surgery (Table 7).

The mean length of distal resection margins

after robotic rectal surgery was available in 20 studies^[8-10,13,15-17,19,21-38,40,41,43,45,48,50]. It ranged from 13.3 mm^[10] to 460 mm^[15]. Tumor involvement rate of distal margins was available 21 studies^[8,9,11,12,15,17,20,21,23,25,26,28-30,34,36,37,39,46,48,50] and ranged from 0%^[8,15,17,20,21,25,26,28-30,34,36,37,48,50] to 2.6%^[39] of patients. An involvement of distal resection margin was found in 6 (0.47%) out of 1257 patients operated on with the robotic technique.

The mean length of distal resection margins after laparoscopic rectal surgery was available in 19^[8-10,13,15,17,19,21-26,28-33] studies. It ranged from 13 mm^[25] to 510 mm^[15]. The involvement of distal margins was available in 14 studies^[8,9,11,12,15,17,20,21,23,25,26,28-30] and ranged from 0%^[8,9,11,12,15,21,23,25,26,28-30] to 5%^[15] of patients. A distal margin positivity was reported in 3 (0.3%) out of 857

¹Values are expressed as mean, solid diet includes soft diet. SBO: Small bowel obstruction; RME: Robotic mesorectal excision; LME: Laparoscopic mesorectal excision; OME: Open mesorectal excision; POD: Post operative day.

patients. Among the 19 comparative^[8-10,13,15,17,19,21-26,28-33] studies only Park *et al*^[24] reported a longer distal margin in the robotic than in the laparoscopic group ($P = 0.04$). No significant difference in distal margins tumor involvement was reported when the robotic and laparoscopic approaches were compared.

Mean circumferential resection margins (CRM) after robotic rectal surgery were reported in 9 studies^[9,13,17,21,25,30,43,44,47] ranging from 1.8 mm^[43] to 11 mm^[44]. CRM tumor involvement was available in 32 studies^[8,10-12,14-17,19,20,22-30,35-37,39,40,42,44-50] and ranged from 0%^[15,16,20,22,36,42,44,46,49,50] to 11.1%^[17] of patients with a 2.94 overall rate (76 out of 2583 patients).

Mean CRM after laparoscopic rectal surgery were reported in 6^[9,13,17,21,25,30] comparative studies. It ranged

from 4 mm^[21] to 8.2 mm^[30]. CRM involvement was reported in 17 studies^[8,10-12,14,15,17,19,20,22-26,28-30] and occurred in 51 out of 1158 patients (4.4%) Where the 2 procedures were compared only D'Annibale *et al*^[22] observed a significantly greater number of patients with positive CRM in the laparoscopic series when compared with the robotic one.

Only in 11 papers^[9,11,13,20,21,26,32,34,36,41,44] reported the quality of mesorectum. Complete mesorectum excision ranged from 100%^[11,36] to 60%^[9] in the robotic series and from 100%^[11] to 40.6%^[9] after laparoscopy. Total mesorectal excision was achieved in 83.62% of robotic cases vs 77.22% of laparoscopic ones. None of the 7 comparative studies showed a significant difference in the quality of mesorectum between the 2 procedures.

Short-term oncologic outcomes

Only 11 authors^[8-10,16,19,25,28,31,38,42,47] reported short term oncologic outcomes (Table 8). The main drawback is the heterogeneity of the length of follow up ranging from 1 mo^[9,42] to 80 mo^[8] making results difficult to compare. The disease free survival in the laparoscopic group ranged from 75%^[10] to 89.2%^[31] with local recurrence ranging from 0%^[9,42] to 16.6%^[8] and an overall survival ranging from 88.5%^[10] to 98%^[24]. The disease free survival in the robotic group ranged from 70.4%^[16] to 100%^[31,42] with local recurrence ranging from 0%^[9,31,42] to 12.8%^[10] and an overall survival ranging from 85%^[16] to 100%^[42].

CONCLUSION AND DISCUSSION

Robotic rectal surgery is constantly increasing over the years. Previous reviews have already demonstrated its safety and feasibility^[51-53], although there are not published studies demonstrating its superiority over the laparoscopic approach mainly due to the lack of randomized control trials. This lack of evidence about the effectiveness of robotic rectal surgery is in contrast with the overall opinion of surgeons that report an easier surgical approach especially to narrow and difficult anatomic spaces such as the pelvis. Several authors^[52-54] reported 3D high definition vision, wrist-like movement

of instruments (endowrist™), stable camera holding, motion filter for tremor-free surgery and improved ergonomics as major improvements in rectal surgery but it seems that these technical benefits have not reflected better clinical outcomes yet. This review aimed to analyze robotic rectal surgery from the first report to nowadays in order to focus on the current state and assess any benefits of robotic rectal surgery and its evolution through the years.

A well-established finding of this review is the longer operative time of robotic surgery when compared to the laparoscopic one. This is most likely due not to longer dissection but to non-surgical technical time. In fact in the totally robotic approach the docking and undocking has to be performed twice and in the hybrid approach there is the need to switch from laparoscopy to robot. A totally robotic technique without undocking is feasible, but this approach is technically much more difficult and as a consequence, a longer operative time is needed^[10,12,14,16,17,22-24,27,28,37,38,40-42,48]. Traditionally, longer operative time is related with increased morbidity, most likely related to the difficulty of the operation^[53]. However prolonged times in robotic surgery are not associated with an increased complication rate as demonstrated by this review and previously published review and meta-analysis^[55].

In our review 2^[21,23], out of 16 comparative studies reported a significantly lower estimated blood loss after robotic rectal surgery confirming that there is still no evidence that robotic rectal surgery for cancer may be associated with a lower intraoperative blood loss.

As regards conversion rates to open surgery, 3^[8,22,31] out of 22 comparative studies reported significant lower complication rates in robotic patients. Many authors associated these results to better visualization, 3D view, endowrist™ technology and stable camera holding

resulting in an easier dissection in narrow anatomical fields such as the pelvis^[56]. Even the results reported by Ielpo *et al*^[14] suggest that the robotic approach has lower conversion rates when the tumor location requests a low anterior resection and as a consequence, when the operations is technically more challenging. Since converted cases are associated to greater morbidity and tumor recurrence^[57], robotic surgery could provide better oncologic long term results as well as a decreased perioperative morbidity.

The difference in protective ileostomy creation observed in this review can be related to several factors: The surgeon's habit, the tumor location, the surgeon's learning curve. Moreover, a trend toward an increasing stoma creation after robotic surgery could have been verified because of the initial worries about the new technique. On the bases of our findings the robotic approach seems associated with a higher rate of protective stoma creation.

One of the main benefits of minimally invasive surgery is the early recover. In this review we were unable to draw definitive results about any benefit of the robotic technique over conventional laparoscopy. Length of hospital stay, day of 1st flatus, 1st solid diet and 1st liquid diet were substantially similar in both the robotic and laparoscopic series even if some authors reported some advantages for either the robotic or the laparoscopic technique^[8,9,15,22-24,30,32].

Anastomotic leak is the most severe surgical complication in rectal surgery. Well known risk factors for anastomotic leak are represented by cancers located less than 6 cm from anal verge, neoadjuvant radio-chemotherapy, obesity and intraoperative blood transfusions^[58-63]. In this review the overall anastomotic leak rates in the robotic and laparoscopic series were similar (7.3% vs 7.6%) with no comparative study

reporting any significant difference between the 2 types of procedure. All together these results demonstrate that robotic surgery does not reduce the anastomotic leak rate. Nevertheless results of comparative studies are contradictory since 9^[11,15,19,20-22,23,25,30] of these reported less anastomotic leaks in the robotic group and 9^[8-10,14,17,24,28,29,31] in the laparoscopic one, but none of these results was significant. Looking at intraoperative complications, only Levic *et al.*^[9] reported a significant, higher rate in the robotic patients (4.48% vs 0%). However it must be considered that in this study there were more obese patients in the robotic group and all robotic and laparoscopic operations were performed in 2 different hospitals.

The number of harvested and examined lymph nodes is pivotal in the postoperative tumor staging whose accuracy increases with the number of nodes retrieved within the surgical specimen. The robotic platform with its 3D high definition vision and wrist-like movement of instruments should improve the lymph nodes retrieving. Nevertheless, the difference between the mean harvested lymph nodes in the robotic and laparoscopic series was not substantial in our review (15.1 vs 15.7 respectively) and only 2 authors^[9,10] reported a significant higher number of retrieved lymph nodes in the robotic group.

The length of tumor involvement of both the distal and circumferential resection margins is considered an important parameter in evaluating the treatment of rectal cancer. Findings from the present review seems to determinate the lack of any advantages of robotic surgery over the laparoscopic approach. This issue might be explained by the likely surgeon's trend to prefer robotic approach in more advanced and distal tumors because of the theoretical superiority of this technique in pelvic dissection. In this review indeed 7 authors^[10,11,15,20,22,25,31] reported a significant lower distance of the tumor from anal verge when the robotic approach was compared with the laparoscopic one. Two comparative studies^[13,22] reported even a significant wider CRM in their robotic series when compared to the laparoscopic ones. However a possible bias in the evaluation of this parameter is the non-uniform recording of data: some authors report median values, others the mean values making data not comparable. Even definition of circumferential resection margin is still not clear as it is currently considered as positive as positive if < 1 mm^[8,11,14,19,24,25,30,35,64] by some authors and < 2 mm^[10,12,15-17,20,22,23,26-29,36,37,39,40,42,44-50] by others.

Thanks to its technical characteristics the robot platform should help in performing total and complete mesorectal excision that is an important target in rectal surgery since it potentially reflects the radicality of the operation. Unfortunately even if this is a major parameter in evaluating the radicality of the intervention, only 11 out of 43 studies in this review have addressed this important parameter. On the basis of our results any superiority of robotic mesorectal excision over the laparoscopic one cannot be demonstrated.

Robotic surgery may help in the identification and preservation of autonomic nerves due to high definition 3D image. Common sites of potential nerve damage are the superior hypogastric plexus, leading to ejaculation dysfunction in males and impaired lubrication in females, and the pelvic splanchnic nerve/pelvic plexus leading to erectile dysfunction in men. According to results of the CLASSIC trial^[59] the risk of an autonomic injury with sexual dysfunction in males is significantly higher in laparoscopic surgery when compared to the open approach. The perceived advantages of robotic surgery may translate to decreased incidence of urinary dysfunction and erectile dysfunction in males. Although some preliminary results suggested that robotic assisted rectal surgery is superior to conventional laparoscopic surgery in preventing sexual or urinary dysfunction^[63,64], we cannot provide definitive results since only few studies addressed this issue with high heterogeneity in the scores systems used for the analysis. Furthermore not all the patients in the studies agreed in answering questionnaires and this could lead to a possible type II error. Some authors^[26,18] reported an earlier recovery of erectile, sexual desire and urinary function when the robotic group was compared with the laparoscopic one but they did not report any difference in long-term follow-up.

In conclusion, results from the present review show that robotic surgery is as feasible and safe as conventional laparoscopy in the treatment of rectal cancer, with the only drawback of longer operative time. The magnified view, the improved ergonomics and dexterity might improve the diffusion of minimally invasive approach in the treatment of rectal cancer. Potential clinical benefits of the robotic technique must be demonstrated, if any, only by RCTs.

Abstract

Gastrointestinal malignancies are among the leading causes of cancer-related deaths worldwide. Like all human malignancies they are characterized by accumulation of mutations which lead to inactivation of tumor suppressor genes or activation of oncogenes. Advances in Molecular Biology techniques have allowed for more accurate analysis of tumors' genetic profiling using new breakthrough technologies such as next generation sequencing (NGS), leading to the development of targeted therapeutical approaches based upon biomarker-selection. During the last 10 years tremendous advances in the development of targeted therapies for patients with advanced cancer have been made, thus various targeted agents, associated with predictive biomarkers, have been developed or are in development for the treatment of patients with gastrointestinal cancer patients. This review summarizes the advances in the field of molecular biomarkers in tumors of the gastrointestinal tract, with focus on the available NGS platforms that enable comprehensive tumor molecular profile analysis.

Key words: Predictive biomarkers; Targeted therapy; Next generation sequencing; Gastrointestinal tract; Somatic mutations; Liquid biopsy

Core tip: Gastrointestinal cancers are among the leading causes of cancer morbidity and mortality worldwide. So far, various targeted agents associated with predictive biomarkers are available or are under development for the selection of treatment in patients with gastrointestinal cancer. Advances in high-throughput technologies such as next generation sequencing and the use of noninvasive

materials for tumor characterization, such as liquid biopsies, will facilitate tumor molecular profiling and lead to the establishment of further targeted treatment therapies.

INTRODUCTION

The comprehension of the importance of tumor biology has led to the development of new drugs that target specific molecules involved in carcinogenesis. The efficacy of such targeted therapies often depends on the presence or absence of gene alterations that encode for the protein-target or for proteins involved in the molecular pathway targeted by the specific medication. This targeted therapeutical approach is based on the tumor's molecular analysis in order to select patients with increased probability to respond to the treatment given. Advances in Molecular Biology techniques have permitted comprehensive tumor genomic profiling using new breakthrough technologies such as next generation sequencing (NGS)^[1-3].

Nowadays, biomarkers are used in the management of patients with cancer and can be divided into predictive and prognostic. Prognostic biomarkers are defined as those that provide information on the possible outcome of cancer in a particular patient regardless of treatment. Predictive biomarkers provide information on the potential benefit of the administrated treatment (whether this relates to the tumor's volume shrinkage or survival). Predictive biomarkers can be used to identify subpopulations of patients that are likely to respond to a particular treatment^[1]. They can be subdivided in positive and negative predictive biomarkers. The first are used for positive selection of patients who are likely to benefit from targeted therapy, whereas the latter for resistance prediction^[1].

The number of genes involved in targeted therapy (predictive biomarkers), is increasing continuously. The simultaneous analysis of these biomarkers is feasible using molecular biology technologies that allow accurate, fast and cost effective genomic analysis with limited requirements concerning the quantity of the biological material used^[1,4]. NGS has all the features required to carry out such analysis and provides simultaneous information on a large number of actionable alterations in tumor tissues and thus a more precise molecular characterization of the tumor. The massive amount of genetic information produced is the main advantage of this technology. However, it also constitutes its main

challenge, requiring usage of appropriate software and bioinformatics tools, along with web-based tools for data analysis, management and interpretation^[5].

The human gastrointestinal (GI) tract is an organ system which includes all structures between mouth and anus and is divided into upper (buccal cavity, pharynx, esophagus, stomach and duodenum) and lower (small and large intestine) GI tracts. GI cancers are complex diseases and refer to malignant conditions that affect the digestive system. The current review will focus on the advances in the field of molecular biomarkers and the application of high throughput technologies, in the most common tumors of the gastrointestinal tract.

Esophageal cancer

Esophageal cancer is one of the most aggressive malignancies with a rapidly increasing incidence rate in the recent decades. There are two predominant histological types: Esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC) of the distal esophagus and the gastroesophageal junction. Smoking and heavy alcohol consumption are associated with increased risk of ESCC, while gastroesophageal reflux disease and Barrett esophagus may increase the risk of EAC^[6].

TP53 mutations are identified in about 50% of esophageal cancers and are associated with poorer survival^[7]. Apart from mutations in *TP53* ESCC and EAC seem to differ significantly in the genetic alterations pattern. Agrawal *et al.*^[8] using NGS reported a substantial disparity in the spectrum of mutations, with more insertions/deletions in ESCCs, A:T>C:G transversions in EACs, and C:G>G:C transversions in ESCCs. Inactivating mutations of *NOTCH1* are identified in about 20% of ESCCs but not in EACs. Somatic aberrations in EACs are mainly identified in the Wnt, cell cycle and Notch pathways^[9,10]. A number of genes that can be used as predictive markers for targeted therapy have been explored for somatic mutations in esophageal adenocarcinoma, including genes of the RAF/MEK/ERK (MAPK) kinase pathway such as *EGFR*, *BRAF*, *KRAS*, *PIK3CA*^[11]. However the reported frequency of somatic mutations identified appears to be low and this is obvious when accessing data from the Catalogue of Somatic Mutations in Cancer database (COSMIC, cancer.sanger.ac.uk) (Figure 1), which is currently the most comprehensive global resource accessing the world literature on somatic mutations in human cancer^[12]. In a recent study, NGS-based comprehensive genomic profiling was used to analyze ESCC and EAC tumors^[13]. The analysis showed that the esophageal histotypes differ significantly in genomic alterations profile, with *KRAS* and *ERBB2* far more frequently altered in EAC compared to ESCC. In contrast, genes of the mechanistic target of rapamycin (MTOR) pathway (*PIK3CA* and *PTEN*) and *NOTCH1* are more frequently altered in ESCC compared to EAC. They also have different amplification patterns (Figure 2).

ESCC and EAC also differ in the gene amplification

Figure 1 Bar chart showing the most frequently mutated genes in esophageal cancer according to catalogue of somatic mutations in cancer database. In the Y-axis the percentage of observed mutation frequency is represented. In the X-axis the most frequently mutated genes are listed. A: Top 30 mutated genes in esophageal adenocarcinoma; B: Top 30 mutated genes in esophageal squamous cell carcinoma.

and/or protein (over)expression of the receptor tyrosin kinases (RTKs) EGFR and HER2 making them possible prognostic markers and as therapeutic targets^[7,14]. EGFR is frequently overexpressed in ESCCs, while HER2 overexpression occurs mainly in EACs. Thus the trastuzumab-platinum regimen is currently used for the 15% of the EACs patients that test positive for HER2 (ERBB2) amplification or overexpression^[13,14].

Numerous preclinical studies addressed EGFR and HER2 inhibition in esophageal cancer cell lines and there are various phase II/III clinical trials testing EGFR, HER2, and VEGF targeting therapies for esophageal cancer^[7,15]. However, the results obtained to date do not allow the use of these agents in clinical practice. Upon trial completion several clinical studies have concluded, that in order to select patients who will respond to RTK-targeted therapy, there is a need for molecular patient stratification before treatment.

In a disease with historically poor outcomes and limited options, comprehensive genomic profiling of relapsed and refractory cancers, including distinct evaluation for EAC and ESCC has led to promising information suggesting targeted therapies for future consideration.

Gastric cancer

Gastric cancer (GC) develops from the inner lining of the stomach and is a very aggressive malignancy, with poor prognosis and very high cancer related mortality. The high mortality rate is largely due to the late stages of cancer diagnosis and to the lack of effective medical

treatment for advanced stages of this disease^[16,17]. The majority of these cancers are adenocarcinomas and can be further classified as diffuse (poorly differentiated) or intestinal (well-differentiated) types that have distinct molecular profiles^[16,17].

Concerning the causes of GC, it can be viewed as a multifactorial disease since many inherited and environmental factors play a role in its development. Infectious agents such as *Helicobacter pylori* and EBV, dietary habits and the genetic background are considered as causative agents^[17].

Given the variety of causes of the disease, it is not surprising that these tumors present a high level of biological heterogeneity, with distinct molecular profile for each patient. Genetic and epigenetic alterations play important role in GCs therefore, targeted therapy based on the biology of the individual patient could improve treatment outcome^[17-19].

ERBB2 amplifications occur frequently in gastric tumors (2%-27%)^[12,20]. Trastuzumab, a monoclonal antibody against HER2/neu receptor, was the first targeted agent to be used in the treatment of ERBB2-positive advanced gastric and gastroesophageal junction (GEJ) adenocarcinoma^[20]. Several molecular targeted agents associated with a survival benefit in other cancer types are now under clinical investigation for the treatment of gastric cancer, including inhibitors of EGFR, MET, FGFR, VEGF, and PI3K^[18,20]. Additionally, *CDH1* gene mutations at the somatic level are considered of prognostic significance^[19].

Several studies have investigated gastric cancer's

Figure 2 Bar chart showing the copy number variations in esophageal cancer according to the study performed^[13]. In the Y-axis the percentage of CNV frequency is represented. In the X-axis the most frequently altered genes are listed. A: Genes most commonly affected by CNV (amplification or loss) in esophageal adenocarcinoma; B: Genes most commonly affected by CNV (amplification or loss) in esophageal squamous cell carcinoma. CNV: Copy number variation.

molecular profile using whole genome as well as targeted NGS approaches^[19,21-23]. The presence of somatic mutations and copy number variations (CNV) in many cancer driver genes has been revealed. Among the cancer genes frequently mutated in gastric cancer *P53*, *ARD1A*, *CDH1*, *PIK3CA*, *APC*, *CTNNB1*, *ERBB3*, *ATM*, *KRAS* are the most important prognostic and/or predictive markers (Figure 3)^[12]. Consequently, molecular profile-directed therapy seems to be a promising strategy for the improvement of standard chemotherapy effectiveness.

CNVs have been observed for *HER2*, *FGFR2*, and *MET* that represent viable treatment targets for which therapeutics are already approved or are currently under investigation^[24] (Figure 4).

The high heterogeneity of these tumors triggered scientists to attempt their molecular characterization. In a study conducted by The Cancer Genome Atlas, molecular classification four major genomic subtypes of gastric cancer were defined: EBV-infected tumors; MSI tumors; genomically stable tumors; and chromosomally unstable tumors^[21].

In a recent study, Li *et al.*^[19], using whole genome

NGS data were able to classify gastric cancers into regular (86.8%) and hyper-mutated (13.2%) subtypes based on mutation burden. Additionally, in the "regular" mutated cohort a further classification, using 40 significantly mutated genes, could be obtained, separating the patients to S1 and S2 subtypes with distinct prognostic outcomes.

Gastrointestinal stromal tumors

Gastrointestinal stromal tumors (GISTs) are rare tumors of the gastrointestinal tract. They are mesenchymal in origin and are characterized by overexpression of the KIT protein^[25]. Morphological diagnosis based on microscopic examination is the standard for GIST diagnosis. They occur anywhere within the GI tract, but they are most common in the stomach (60%) or small intestine (30%)^[26]. Their diagnosis is based on the expression of the transmembrane tyrosine kinase (TK) receptor, KIT, since 95% of GISTs express CD 117 antibody. In 80% of the cases, somatic mutations in the *ckIT* gene are observed, resulting in constitutive receptor activation. Additionally, in 5%-10% of the cases without *ckIT* mutations, the TK receptor *PDGFRA* is

Figure 3 Bar chart showing the most frequently mutated genes in gastric cancer according to catalogue of somatic mutations in cancer database. In the Y-axis the percentage of observed mutation frequency is represented. In the X-axis the genes are listed.

Figure 4 Copy number variation in the most important treatment targetable genes in gastric cancer. In the Y-axis the percentage of observed CNV is represented. In the X-axis the genes are listed. CNV: Copy number variation.

mutated^[27]. The mutation spectrum of these tumors is very limited as we observe in COSMIC database (Figure 5)^[12]. Tyrosine kinase inhibitors (TKIs) like imatinib, sunitinib, and more recently regorafenib, have proven effectiveness in suppressing the growth of metastatic GISTs, allowing patients to live far longer than during the previous era of ineffective chemotherapy^[28-30]. The response to targeted therapy with TKIs is mainly dependent on the presence and type of mutation. Patients with mutations in exon 11 of the *ckit* are highly responsive to imatinib, while the presence of a mutation in exon 9 of this gene implies intermediate response rates and necessitates a double dose of drug administration. Furthermore, resistance mutations to imatinib are also observed in the *ckit*/*PDGFRA* genes. These mutations can be present in the primary tumor or arise as a result of the drug administration (secondary mutations)^[29].

Colorectal cancer

The cancer of colon and rectum (colorectal, CRC) is the third most common cancer worldwide with 95% of these tumors being classified as adenocarcinomas. It's a leading cause of cancer related deaths; however, colorectal cancer mortality is declining in the last decades, mainly due to early diagnosis and the presence of new therapy strategies^[31,32]. This malignancy is one of the

first paradigms of the benefits that can be derived from the application of personalized treatment in cancer therapy^[33-35].

Genetic alterations in colorectal cancer include mainly single-base substitutions (SBS). Nevertheless, small insertions and deletions (indels), amplifications, homozygous deletions and translocations can also be observed^[36].

Five hundred and seventy-two cancer relevant genes are included in the Catalogue of Somatic Mutations in Cancer (COSMIC, cancer.sanger.ac.uk)^[12]. Somatic mutations in CRC cancer are observed in the majority of these genes. The pattern of genomic alterations was identified through Massively Parallel Sequencing studies, revealing the inter- and intra-tumor genetic heterogeneity of these tumors^[37-39]. Apart from single base substitutions, gene amplifications are also observed (Figure 6). Mutations in many important biologic pathways occur. In Table 1 the frequency of mutations in important molecular signaling pathways and the related therapies are represented. The gene mutation frequency is calculated using data from samples analysed by whole genome screening in the COSMIC database. The information concerning the therapies targeting each pathway was retrieved from MyCancer Genome knowledge database (www.mycancergenome.org/), that provides reliable information concerning

Figure 5 Bar chart showing the most frequently mutated genes in gastrointestinal stromal tumors according to catalogue of somatic mutations in cancer database. Figure 6 Copy number variation in the most important treatment targetable genes in colorectal cancer. CNV: Copy number variation.

important cancer related genes and their correlation with treatment options (Table 1)^[40].

The *RAS* proto-oncogenes (*HRAS*, *KRAS* and *NRAS*) encode a family of highly homologous proteins. They participate in a signal transduction cascade, namely the *RAS*/*RAF*/*MEK*/*ERK* pathway, which regulates the growth and survival properties of the cells. They are controlled by extracellular signals transmitted by the transmembrane receptor tyrosine kinase (TK), *EGFR*^[34]. This TK and the *RAS*/*RAF*/*MEK*/*ERK* pathways it controls, play an important role in colorectal carcinogenesis, making it a good target for biological therapy of this disease.

Two monoclonal antibodies were designed as effective inhibitors of *EGFR*. Cetuximab (Erbix, Merck KGaA, Darmstadt, Germany) is a chimeric mouse/human antibody, and Panitumumab (Vectibix, Amgen Thousand Oaks, CA, United States), is a fully human antibody^[33-35]. They both target the extracellular domain of the *EGFR* protein and compete with ligands, blocking ligand induced intracellular signal transmission. However, anti-*EGFR* treatment is not effective in patients harboring activating mutations in genes that participate in the intracellular transduction *RAS*/*RAF*/*MEK*/*ERK* pathway. This is due to the constitutive, independent of ligand, activation of the mutated proteins^[33].

In total, activating mutations in the *RAS* genes, mainly in codons 12, 13 or 61, occur in approximately

20% of all human cancers. Mutations in *KRAS* account for about 85% of all *RAS* mutations in human tumors, *NRAS* for about 15%, and *HRAS* for less than 1%^[41,42]. Which particular *RAS* gene is mutated seems to be tumor specific. Colonic, pancreatic and lung cancers have high frequencies of *KRAS* mutations^[41,42].

Acquired mutations in *KRAS* and *NRAS* are commonly used to identify colorectal cancer patients who are unlikely to benefit from anti-*EGFR* therapy. Approximately 40% of colorectal cancer tumors harbor mutations in the *KRAS* gene, with the majority of the mutations occurring in codons 12, 13 and 61. In 5% of the colorectal cancer cases a mutation occurs in the *NRAS* gene^[35,41].

Another important gene of the *RAS*/*RAF*/*MEK*/*ERK* pathway is *BRAF*. Mutations in the *BRAF* gene (exons 11 and 15) have been detected in about 12% of colorectal cancers and are mutually exclusive with *RAS* mutations^[12,43,44]. The *BRAF* activating aberrations, result in constitutive *BRAF* kinase activity, *ERK* signaling, proliferation and transformation^[44]. The majority of *BRAF* mutations are observed in exon 15 (codon 600) and a minority of mutations are observed in exon 11^[44,45].

Several studies have reported that patients with metastatic CRC (mCRC) that harbor *BRAF* mutations do not respond to the anti-*EGFR* antibody agents cetuximab or panitumumab^[43,46,47]. However it is unclear if the presence of *BRAF* mutations in CRC cancer can be

Table 1 Overall gene mutation frequency in each molecular signaling pathway

Biologic pathway	Frequency of mutation in genes involved in each pathway	Therapies that target the pathway
Beta-catenin/WNT signaling	75%	FZD, GSK inhibitors
Cell cycle control	68%	CDK, CDK1, CDK2, CDK4/6 inhibitors
Receptor tyrosine kinase/growth factor signaling	67%	Therapeutic antibodies/tyrosine kinase inhibitors
MAP kinase signaling	61%	BRAF, ERK, MEK AND SRC inhibitors
PI3K/AKT1/MTOR	52%	Allosteric mTORC1 inhibitors/mTORC1/2 catalytic inhibitors
DNA damage/repair	48%	PARP INHIBITORS
TGFbeta signaling	37%	TGFBRI inhibitors
Chromatin remodeling/DNA methylation	32%	DNMT inhibitors, Histone deacetylase
Immune checkpoints	26%	Anti-CTLA4 antibodies, anti-PD-1 antibodies, Anti-PD-L1 antibodies, Immunotherapies
JAK/STAT signaling	23%	JAK inhibitors
Hedgehog signaling	12%	SMO inhibitors

The information concerning therapies that target each molecular pathway was retrieved for MyCancer Genome Site (Available from: URL: <http://www.mycancergenome.org/>).

used as a predictive marker or if it has only a prognostic value, independent of treatment, since different studies arrive at controversial conclusions concerning its clinical significance^[45,48].

The *PIK3CA* gene encodes the catalytic subunit of phosphatidylinositol 3-kinase while belongs to a family of lipid kinases. These kinases regulate a diverse range of cellular processes including cell proliferation, adhesion, survival, and migration^[49]. Mutations in *PIK3CA* stimulate downstream AKT-mTOR signaling pathways, thereby promoting growth-factor independent growth, cell invasion and metastasis. *PIK3CA* mutations have been reported in multiple malignancies, including approximately 25% of gastric, 4% of lung, 25% of breast, and 20% of colorectal cancers^[50]. The majority (80%) of *PIK3CA* mutations cluster in 2 "hotspot" regions, the helical domain (exon 9) and the kinase domain (exon 20). Concomitant *PIK3CA* mutations in exons 9 and 20 seem to be linked to significantly worse cancer-specific survival^[51]. *PIK3CA* mutations may also be associated with clinical resistance to EGFR-targeted monoclonal antibodies, but there have been conflicting results^[52-55]. A meta-analysis comprising 864 patients, from 11 studies, with colorectal cancer treated with cetuximab or panitumumab-based therapy showed that *PIK3CA* mutations, particularly in exon 20, are significantly associated with worse response and shorter progression-free and overall survival^[51]. Somatic *PIK3CA* mutations have also been associated with superior colorectal cancer-specific survival in patients who regularly intake aspirin after diagnosis^[56]. *PIK3CA* activating mutations may also predict sensitivity to inhibitors of the PI3K-AKT-mTOR pathway^[57]. Inhibitors of mTOR, PI3K, and AKT, alone or in combination with other therapies are in clinical trials in solid tumors^[58,59].

A number of rare gene mutations occurring in the PI3K/AKT/mTOR pathway are potentially actionable in colorectal cancer. *PTEN* is a key negative regulator of the PI3K pathway. *PTEN* gene mutations occur in about 5% of colorectal cancers^[12,60,61]. *PTEN* inactivating mutations and *PTEN* loss have as a consequence the

upregulation of the PI3K/ AKT pathway^[54,61].

Currently, the prognostic and predictive significance of *PTEN* mutations or *PTEN* loss of expression is under investigation. In retrospective studies, *PTEN* loss was associated with decreased sensitivity of colorectal cancer tumors to anti-EGFR antibodies^[60-62]. Preclinical data and *in vitro* studies suggest that it may be associated with sensitivity to PI3K and mTOR inhibitors. Based on these data, several PI3K and mTOR inhibitors are currently in clinical trials for the treatment of patients with *PTEN*-deficient cancers^[61,63].

AKT (Protein kinase B, PKB) is a serine/threonine kinase that is encoded by three genes *AKT1*, 2 and 3. Somatic mutations in the *AKT1* gene occur in colorectal cancer in about 1% of the cases according to the COSMIC database^[12]. The only mutation observed is the activating mutation *E17K*, which is also observed in other types of cancer^[64]. *AKT1* is a critical component of the PI3K/AKT/mTOR pathway, thus it has become an attractive target for therapeutic intervention^[49,65]. *AKT1 E17K* mutations have also been associated with primary resistance to cetuximab^[66].

In colorectal cancer, DNA mismatch repair (MMR) system deficiency occurs frequently and leading to microsatellite instability (MSI). These are small changes in the DNA sequence that occur during DNA replication and are usually additions or deletions of one or two nucleotide bases^[67,68]. This phenomenon is most common in areas of the genome that contain repetitive DNA sequences with a repeat unit, from one to four bases, and are known as Microsatellite regions^[67,69]. The presence of microsatellite instability (MSI High) is a good prognostic marker^[67,70]. It is found in 90% of cases of tumors arising patients with hereditary Lynch syndrome and in 10%-15% of the sporadic cancers^[71]. Sporadic MSI-H tumors can be distinguished from the hereditary ones through somatic mutation analysis of the *BRAF* gene or loss of *MLH1* expression^[72,73]. Somatic mutations in the *BRAF* gene occurs only in sporadic MSI-H tumors but not in Lynch-associated CRC cancers. Similarly, *hMLH1* promoter methylation rarely occurs in

Lynch syndrome-associated cancers, while is common in sporadic MSI-high cancers^[73].

Recent studies have indicated that MSI high tumors, both sporadic and hereditary, are less aggressive and are related with low probability of lymph node and distant recurrences^[70]. In addition they respond differently to chemotherapy, since they are less sensitive to Topoisomerase inhibitors and to the treatment with 5-fluorouracil^[74-76]. Additionally, it has been proposed that MMR-deficient tumors are more responsive to PD-1 blockade than the mismatch repair-proficient tumors^[77].

Gene expression profiling (GEP) is an emerging tool which aims to identify differentially expressed subsets of genes (gene signatures) in groups of patients with distinct clinical outcomes. Several commercial GEP tests are currently available for stage II/IIIa colorectal cancer patients. Oncotype DX[®] Colon Cancer Assay (Genomic Health, Inc., Redwood City, CA) and ColoPrint (Agendia, BV, Amsterdam, Holland) are the most promising gene signature tests^[78]. Both tests provide a risk of recurrence, but OncotypeDx has the advantage of being applicable to Formalin Fixed Paraffin Embedded (FFPE) tissue for analysis, while ColoPrint requires fresh tissue which is not easily available. Oncotype DX[®] Colon Cancer Assay is a quantitative reverse transcription polymerase chain reaction (RT-qPCR) assay on RNA extracted from FFPE tumor tissue, used to assess risk of recurrence in stage II colon cancer patients at three years after surgery^[79-81]. The test uses gene expression profiling of 12 genes that include seven prognostic genes and five reference genes, in order to provide a Recurrence Score (RS). The RS allows patients and physicians to determine the risk of developing a distant metastasis. In a retrospectively performed study by Yothers *et al.*^[82], RS was the strongest predictor of disease recurrence independent of other factors, such as T-stage, mismatch repair status, number of nodes examined, tumor grade, and lymphovascular invasion. The greatest utility of this test seems to be in the prediction of recurrence risk in T3, mismatch repair-proficient (MMR-P) stage II colon cancer patients^[82]. However, it has also been validated in stage III patients with very promising results^[83]. The continuous RS predicted recurrence as well as disease free survival (DFS) and overall survival (OS) in all three patient subgroups (stage II, IIIA/B, and IIIC). The use of this assay could lead to overall reduction in adjuvant chemotherapy use in this subgroup of stage II/III colon cancer patients^[83].

LIQUID BIOPSY

Until recently, the best material for somatic mutation analysis was considered formalin fixed paraffin embedded (FFPE) tumor tissue. FFPE tissue is a widely available material, easy to use and maintain. In addition, the cancer tissue can be selected and mutation analysis

can be performed without contamination by normal tissues^[42]. This increases the sensitivity of mutation detection assays which is very important because, due to tumor heterogeneity, somatic mutations can sometimes be present at a very low percentage. However, FFPE tissue material also has several disadvantages^[84,85]. First of all in some cases it is not available. This is the case of non-operable tumors. Furthermore, the examination of a limited tumor area present in a paraffin block doesn't take into account tumor molecular heterogeneity and does not necessarily reflect the molecular profile of other tumors or metastasis that are eventually present in the patient's body^[85]. Additionally, the genetic material obtained, due to the paraffinization process, is sometimes of very bad quality and not suitable for molecular analysis^[86]. Most importantly, tumor molecular profile is altered mainly following therapy and those alterations cannot be detected by analyzing the primary tumor material^[87].

Nowadays, the presence of cell-free tumor derived nucleic acids (ctDNA/ctRNA) in cancer patients body fluids (plasma, serum, Broncho-alveolar, urine, stool, etc.) is well documented^[84]. The term Liquid Biopsy has emerged indicating the use of these noninvasive materials for tumor characterization. The mutation status detected in a liquid biopsy reflects the status present in the patient's tumor. Furthermore Liquid Biopsy analyses take into account intra-tumor or inter metastatic heterogeneity and could eventually detect more tumor alterations compared with the analysis of a specific area in a FFPE tissue^[83,84]. A variety of sensitive methods can be used for the detection of ctDNA in plasma samples, including digital PCR, Real time PCR, Arms PCR and NGS^[84].

The utility of liquid biopsy analysis has been proven in many studies that used ctDNA for the detection of tumor specific alterations in plasma with prognostic and/or predictive significance^[87-98]. A liquid biopsy analysis can be performed before treatment as well as for patients monitoring during therapy. It is also very helpful in the detection of secondary mutations that arise due to targeted therapy. The detection of secondary mutations in plasma can modify the treatment strategy for those patients (Table 2).

NGS METHODOLOGIES

NGS is a general term referring to all post-Sanger sequencing technologies that are able to massively sequence millions of DNA segments^[99,100]. The goal of these technologies is to increase sequencing capacity and speed at a lower cost. Furthermore, the sensitivity obtained is superior to that of the conventional sequencing technology, making possible the detection of mutations that are present at very low percentages in a background of normal DNA, which is very important for somatic mutation detection. Currently the most widely used platforms are those offered by Illumina, Inc. (United States); Thermo Fisher Scientific, Inc. (United

Table 2 Gene mutations identified in ctDNA of patients with tumors of the gastrointestinal tract and their correlation with possible clinical implications

Gene	Mutation type	Tumor type	Possible clinical implications	Ref.
KRAS/NRAS	Point mutation/amplification	Colorectal/pancreatic cancer	Resistance to anti-EGFR therapy/sensitivity to MEK inhibitors	[88-90]
BRAF	Point mutation	Colorectal cancer	Resistance to anti-EGFR therapy/sensitivity to MEK inhibitors	[88,91]
MET	Amplification/alteration	Colorectal/esophageal cancer	Resistance to anti-EGFR therapy/sensitivity to MEK inhibitors	[92-94]
HER2	Amplification	Colorectal/gastric cancer	Resistance to anti-EGFR therapy/sensitivity to Anti HER2 inhibitors	[95,96]
EGFR	Point mutation	Colorectal/pancreatic cancer	Panitumumab	[97,98]
PIK3CA	Point mutation	Colorectal/pancreatic cancer	mTOR inhibitor	[89]
Ckit	Point mutations	GISTS	Imatinib or dose escalation or alternative TKIs	[99,100]
PDGFRA	Point mutations	GISTS	Imatinib or dose escalation or alternative TKIs	[99,100]

TKI: Tyrosine kinase inhibitors; GIST: Gastrointestinal stromal tumors; EGFR: Epidermal growth factor receptor; mTOR: Mechanistic target of rapamycin.

Sates) and Roche Holding AG (Switzerland)^[101-103]. The first NGS platform was created by Roche and used emulsion PCR (emPCR) to clonally amplify the fragments that are then sequenced *via* sequencing-by-synthesis (SBS) technology^[101]. The Illumina platform is currently widely used in the NGS market and involves bridge amplification, of a solid surface-bound DNA, to clonally amplify the fragments that are then sequenced using SBS chemistry^[102]. Unlike the previous two technologies, the Life technology platform uses Ion semiconductor sequencing, instead of fluorescence based sequencing, detecting the protons released as nucleotides are incorporated during synthesis^[103,104].

The past years have seen an accelerating outbreak of publications in which NGS is applied for a variety of goals such as full-genome resequencing or more targeted mutation detection. Worldwide collaborative efforts, such as COSMIC database, International Genome Consortium (ICGC) and The Cancer Genome Atlas (TCGA) project, enabled to catalogue NGS data of thousands of cancer genomes across many disease types^[105,106]. Targeted NGS, involving gene panels, is a quicker and cost effective alternative to whole genome sequencing or exome sequencing. Targeted NGS panels for somatic mutation detection include actionable cancer genes and allow the determination of the patient's tumor molecular profile. The goal of their use is to increase the percentage of patients with detected actionable alterations and with copy number data, allowing them to be included in clinical trials^[107-109].

Such panels are currently available or can be custom made. They exhibit high rates of sensitivity, specificity and repeatability; therefore they are optimal for diagnostic use. Benchtop NGS sequencers are now offered by both Illumina (MiSeq) and Thermo Fisher (PGM™ and Ion Proton™). The availability of the equipment required and the cost effectiveness of the analysis allows its implementation in local specialized laboratories^[108,109]. However, the reliability of these tests should be reassured. Thus, NGS performing laboratories should have specialized personnel and equipment which will provide adequate data analysis management and interpretation with the aid of appropriate software and bioinformatics tools. Importantly, these tests should be

operated under the guidelines of a quality assurance system^[110,111].

Concerning the selection of the appropriate sequencing platform, it should be based on the individual laboratory's needs. All NGS platforms have advantages and disadvantages and the choice of the platform used should be based on the application for which it is required. For example, the MiSeq platform (Illumina) has lower error rates especially in the homo-polymer regions compared to both Ion Proton and PGM (Life Technology). However it requires higher DNA concentration and quality, which is not always available when the starting material is FFPE tissue. On the other hand, the NGS platforms offered by Thermo Fisher provide a fast and cost-effective sequencing solution with good analytical performance. Additionally, they more compatible with low DNA concentrations and partially degraded poor quality DNA from FFPE samples^[107-109,112]. Consequently, they provide an attractive option of clinical utility for the detection of cancer hotspot mutation analysis.

CONCLUSION

This review summarizes the use of biomarkers in the most common cancers of the GI tract. They are used for positive selection of patients who are likely to benefit from targeted therapy or for resistance prediction. Biomarker based targeted treatment is established in a subset of patients with gastrointestinal cancer. Meta-analysis studies have shown that biomarker based treatment is a promising approach and is associated with improved treatment outcome^[113-115]. However, ongoing clinical trials, identification of novel biomarkers as well as further advances in high-throughput technologies will hopefully result in further development of therapeutic targets, treatment strategies and improved survival for these patients in the near future.

Abstract

A perioperative multimodal strategy including combina-

tion chemotherapy and radiotherapy, in addition to surgical resection, has been acknowledged to improve patient prognosis. However chemotherapy has not been actively applied as an immunomodulating modality because of concerns about various immunosuppressive effects. It has recently been shown that certain chemotherapeutic agents could modify tumor microenvironment and host immune responses through several underlying mechanisms such as immunogenic cell death, local T-cell infiltration and also the eradication of immune-suppressing regulatory cells such as regulatory T cells (Tregs) and myeloid-derived suppressor cells. With the better understanding of the cell components in the tumor microenvironment and the effect of chemotherapy to improve tumor microenvironment, it has been gradually clear that the chemotherapeutic agents is two-edged sword to have both immune promoting and suppressing effects. The cellular components of the tumor microenvironment include infiltrating T lymphocytes, dendritic cells, regulatory T cells, tumor associated macrophages, myeloid derived suppressor cells and cancer associated fibroblasts. Based on the better understanding of tumor microenvironment following chemotherapy, the treatment protocol could be modified as personalized medicine and the prognosis of pancreas cancer would be more improved utilizing multimodal chemotherapy. Here we review the recent advances of chemotherapy to improve tumor microenvironment of pancreatic cancer, introducing the unique feature of tumor microenvironment of pancreatic cancer, interaction between anti-cancer reagents and these constituting cells and future prospects.

Clinical impact of chemotherapy to improve tumor microenvironment of pancreatic cancer. *World J Gastrointest Oncol* 2016; 8(11): 786-792 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i11/786.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i11.786>

INTRODUCTION

Pancreatic carcinoma is an extremely aggressive malignant tumor and the fifth leading cause of death worldwide and is expected to be the second by 2030 in Western countries^[1,2]. The only curative option is surgical resection, but the 5-year overall survival (OS) rate still needs to be improved from the current 10%-15% even after curative resection^[1,3]. A perioperative multimodal strategy including combination chemotherapy and radiotherapy, in addition to surgical resection, has been acknowledged to improve patient prognosis. New cytotoxic agents such as gemcitabine, Tegafur-gimeracil-oteracil potassium (TS-1) and combination chemotherapy with 5-fluorouracil (5-FU), oxaliplatin, and irinotecan along with perioperative chemoradiotherapy before and after surgery have recently been widely investigated^[4,5]. Chemotherapy, usually a standard treatment option for cancer, has not been actively applied as an immune-modulating modality because of concerns about various immunosuppressive effects. However, certain chemotherapeutic agents have recently been shown to improve host immune responses and even break immune tolerance^[6]. Several underlying mechanisms have been clarified, including immunogenic cell death^[7,8], local T-cell infiltration and also the eradication of immune-suppressing regulatory cells such as regulatory T cells (Tregs) and myeloid-derived suppressor cells (MDSCs), all of which are associated with cells in the tumor microenvironment^[9]. On the other hand, care must be taken that chemotherapy-induced cancer metastasis does occur during treatment through non-immunological pathways^[10].

We review recent advances in chemotherapeutic regimens to improve the tumor microenvironment for pancreatic cancer, and introduce unique features of the tumor microenvironment for pancreatic cancer, interactions between anti-cancer reagents and the constituent cells, and future prospects.

OVERVIEW OF STANDARD CHEMOTHERAPY AND CHEMORADIATION THERAPY FOR PANCREATIC CANCER

Although the only curative option is surgical resection, with the advances in perioperative strategy for pancreatic carcinoma, many cytotoxic agents have proven effective in treating this disease. Chemoradiation therapy had been also adopted aiming at locoregional response and additional effects outside the field of irradiation (abscopal effects)^[11].

Representative cytotoxic agents include historical 5-FU monotherapy, gemcitabine monotherapy, and gemcitabine-based combination therapies^[4]. The following randomized controlled trials are investigations recently undertaken try to improve the chemotherapeutic strategy for pancreatic cancer. Burris *et al.*^[12] had shown for the first time that gemcitabine was superior to 5-FU in terms of overall survival, thus suggesting gemcitabine as a key drug in advanced pancreatic cancer. In 2011, FOLFIRINOX (5-FU, leucovorin, irinotecan and oxaliplatin) had been shown to have survival benefit over gemcitabine alone in patients with metastatic pancreas cancer^[13]. Recently Nab-paclitaxel plus gemcitabine have been reported to have superior efficacy compared with gemcitabine monotherapy in metastatic pancreas cancer (MPACT trial)^[14]. However, MPACT trial, consisting of Gem + Nab-paclitaxel had OS of 8.5 mo compared to 6.7 mo in patients treated with gemcitabine alone) suggesting minimal improvement of survival by current chemotherapy regimens and requiring for further developments.

Taken together, overall survival of patients with metastatic disease extended to nearly 1 year from around 6 mo in the preceding two decades, thanks to recent therapeutic advances. However, although these reagents are promising, median progression-free survival remains limited and the 5-year survival rate of patients is still unsatisfactory, at around 15%-20%, even with these multimodal treatment strategies. This is due in part to dose limiting toxicity of side effects such as neuropathy and bone marrow suppression and due also to chemoresistance, relapse and metastasis even after surgical resection.

TUMOR MICROENVIRONMENT OF PANCREATIC CANCER

Tumor cells alone were initially considered the specific target of chemotherapy, leading to a focus on the cytotoxicity of agents inhibiting DNA repair, tubulin formation and cell proliferation^[15]. However, recent research has identified the tumor microenvironment as comprising tumor cells, host immune cells such as T cells, Tregs and MDSCs, and cancer-associated fibroblasts or stromal cells that support or suppress each

Table 1 Targets of chemotherapy to improve tumor microenvironment

Cellular components	Target molecules	Chemotherapeutic agents	Underlying mechanism	Ref.
TIL	CD4, CD8 positive T lymphocytes RAS/MAPK	GEM, TS-1, MEK inhibitor, PD1/PDL1 immune checkpoint inhibitors	Increase lymphocyte infiltration	[22] [24]
DC		GEM	Proliferation of DC and CTL	[26]
Treg	CD4 and FoxP3 positive T lymphocytes	GEM, cyclophosphamide	Depletion	[21]
MDSC	CCL2, CCR2, GM-CSF	GEM, 5-FU	Increase differentiation	[34,35]
			Depletion	[5]
CAF	Palladin positive fibroblasts	GEM	Depletion	[38]
	mTOR/4E-BP1 pathway	GEM, Pasireotide	Reduce tumor growth and chemoresistance	[39]

TIL: Tumor infiltrating lymphocytes; DC: Dendritic cells; Treg: Regulatory T cells; TAM: Tumor associating macrophages; MDSC: Myeloid derived suppressor cells; CAF: Cancer associated fibroblasts; Gem: Gemcitabine; 5-FU: 5-fluorouracil.

other^[9]. Each of these cellular components contributes to treatment response and patient prognosis, with tumor cells forming a network through direct interactions and cytokines providing important signals to initiate cell invasion into vessels and lymph nodes, leading to distant metastasis. Desmosomes are also one of the specific features of pancreas carcinoma that make drug delivery so difficult and prevent immune cells from infiltrating to tumor nests^[16].

These evidences collectively indicate that tumor cells are thought to grow, interacting with the micro-environment, highlighting the need to clarify the specific mechanisms by which each chemotherapeutic agent improves the tumor microenvironment to contribute to treatment efficacy.

The following sections are arranged to describe recent evidence for the effects of chemotherapeutic agents on the cellular components of the tumor micro-environment (Table 1).

INFILTRATING T LYMPHOCYTES

A number of reports have suggested that the accumulation of CD4 and CD8 lymphocytes in solid tumors offers a good prognostic indicator for patient survival^[17,18]. In terms of pancreatic cancer, Tewari *et al.*^[19] demonstrated a positive correlation between prognosis and the presence of tumor infiltrating T cells. Although the clinical relevance differs among types of cancer, in association with the HLA class I expression level^[20], some agents have been reported to induce T-cell infiltration into pancreas cancers^[21]. Homma *et al.*^[22] showed that CD4⁺ and CD8⁺ cells were significantly increased after neoadjuvant chemotherapy comprising gemcitabine and TS-1 followed by radiotherapy (NACRT), and a high accumulation of CD4⁺ cells offered a good prognostic marker for pancreas carcinoma after NACRT. Teng *et al.*^[23] recently classified the types of tumor microenvironment based on the presence or absence of T-cell infiltration and expression of PD1 along with patient prognosis.

Loi *et al.*^[24] recently suggested that therapeutic cooperation of MEK and PD-1/PD-L1 immune check point inhibitors could increase tumor-infiltrating lympho-

cytes through RAS/MAPK pathways in breast cancer. Great expectations are held for increased control of the tumor microenvironment, especially with tumor-infiltrating lymphocytes enabling further improvements in patient prognosis associated with immune check point inhibitors.

DENDRITIC CELLS

Dendritic cells are the most potent antigen presenting cells and play a crucial part in the initiation, programming, and regulation of antitumor immunity, directing cytotoxic T lymphocytes and natural killer cells to become potent antitumor effectors capable of eradicating malignant cells^[25,26]. Recently it had been reported that dendritic cells are impaired in number and display maturation defects disable to function as antigen presenting cells in pancreatic cancer due to the inflammation of the disease^[27]. Meanwhile, chemotherapy can promote immunogenic cell apoptosis enhancing immunogenicity and mediating efficient phagocytosis by dendritic cell^[7]. Moreover, gemcitabine can enhance the cross presentation of tumor associated antigens by dendritic cells and as well as inducing the proliferation of DC and CTL^[26]. Those strategies utilizing chemotherapeutic agents might be useful to overcome negative microenvironment.

REGULATORY T CELLS

Tregs are defined as T cells expressing both CD4 and forkhead box P3 (FoxP3), and are usually associated with poor prognosis and immunosuppression in various cancers. Transcriptional FoxP3 is a crucial intracellular marker and also a key developmental and functional factor for CD4⁺FoxP3⁺ Tregs^[28]. In terms of pancreatic cancer, multimodal chemotherapy including GEM, cyclophosphamide, and taxane has been demonstrated to decrease Tregs in the tumor microenvironment^[5]. Low Treg percentage in circulation at 1 year after PC resection had been correlated with improved survival^[29]. We have also previously shown that neoadjuvant treatment of pancreatic ductal adenocarcinoma with chemotherapy and chemoradiotherapy can alter the

local Treg balance in favor of antitumor immunity in resected human sections^[21]. Another paper by Keenan *et al*^[30] showed that immunization of mice with *Listeria* Monocytogenes engineered to express k-ras along with depletion of Treg cells reduced progression of early stages PanINs. Also, Shibuya *et al*^[31] recently reported that CD8 effector T cells show marked accumulation in the tumor microenvironment, but are suppressed by Tregs and PD-L1 expressed on T cells. These findings have therefore led to expectations for novel strategies of multimodal chemotherapy in combination with immune checkpoint inhibitors reducing Tregs.

TUMOR-ASSOCIATED MACROPHAGES

Tumor-associated macrophages (TAMs) are derived from CCR2⁺ monocytes in the spleen and peripheral blood, infiltrating into the tumor and developing into macrophages on stimulation by the releasing hormone CCL2 and colony-stimulating factor 1 (CSF-1)^[32,33]. TAMs have recently been reported to limit the effects of chemotherapy and promote tumor chemoresistance^[34]. Michem *et al.* reported that targeting TAMs by inhibiting CSF1R or C-C chemokine receptor 2 (CCR2) could decrease the number of pancreatic tumor-initiating cells and improve chemotherapeutic efficacy *in vivo*. The Denargo group reported that the combination of cytotoxic chemotherapy and blockade of CSF1R, which is prominently expressed by monocytes, Mo-MDSC and macrophages, resulted in improved anti-tumor T-cell responses^[32]. Furthermore, Sanford *et al*^[33] reported that the CCL2/CCR2 chemokine axis plays a crucial role in the recruitment of inflammatory monocytes from bone marrow to peripheral sites of inflammation and an increased ratio of inflammatory monocytes in blood compared to bone marrow offers a novel predictor of decreased patient survival following tumor resection. These lines of evidence clearly show that chemotherapy combined with chemokine blockade might reduce the chemoresistance associated with the exclusion of TAMs.

MYELOID DERIVE SUPPRESSOR CELLS

MDSCs are heterogeneous populations of immune cells derived from progenitor cells in bone marrow. MDSCs with a phenotype of CD33⁺HLA-DR^{low} that are lineage-negative (CD14⁻, CD15⁻) are well described as immunosuppressive in cancer patients contributing to tumor progression by damping T-cell immunity and promoting angiogenesis^[35,36]. Many chemotherapeutic drugs have long been thought to exclude MDSCs from various cancers. Zheng *et al*^[5] showed that GEM and 5-FU have a direct killing effect on MDSCs. In contrast, Takeuchi *et al*^[36] reported that GEM could increase MDSC numbers through increases in GM-CSF levels, converting M2 macrophages into suppressive MDSCs. Therefore MDSC in peripheral blood might be a possible predictive biomarker of chemotherapy failure in PC patients^[37]. Also, GEM and 5-FU have been reported to

activate NLRP3 inflammasomes in MDSCs, leading to interleukin-1 β release, which restrains their antitumor efficacy^[38]. More recently, Hu *et al*^[39] reported TNFB2R as important for its suppressive function. Uniquely, Sanford *et al*^[40] recently reported the clinical utility of zoledronic acid. This agent is usually utilized to improve calcium imbalances in patients osteoporosis, but also prevents tumor-mediated myelopoiesis associated with the generation of MDSC. Further studies are warranted to adjust the balance between direct reduction of MDSCs and indirect promotion of MDSCs by chemotherapy in combination with the multimodal strategies described above.

CANCER-ASSOCIATED FIBROBLASTS

Fibrous stroma associated with cancer in the tumor micro environment has increasingly been recognized as involving cancer-associated fibroblasts (CAFs). These cells are reported to contribute to poorer survival in various tumors, including pancreatic ductal adenocarcinoma, which has been reported to contain large numbers of CAFs^[41]. The characteristically dense desmosome in pancreatic cancer acts as a barrier to drug delivery, thus contributing to chemoresistance^[4]. Among the many markers of CAFs, Sato *et al*^[41] reported that palladin, a CAF marker, could represent an independent marker of poor prognosis and a biomarker to predict the efficiency of chemotherapy or even disease recurrence. Duluc *et al*^[42] recently revealed one of the underlying mechanisms abrogating pancreatic cancer chemoresistance through the mTOR/4E-BP1 pathway, allowing GEM-based chemotherapy combined with sst1 receptor-activating pasireotide to reduce tumor growth and chemoresistance. This kind of anti-stromal targeted therapy could be expected in addition to host immune cell-targeted therapy, as an adjunct to direct killing of cancer cells.

DISCUSSION

With our developing understanding of the cell components in the tumor microenvironment and the effects of chemotherapy in improving this environment, chemotherapeutic agents have gradually been revealed to represent a two-edged sword with effects that both promote and suppress immunity^[5]. Such therapies deplete one factor of immune suppression while at the same time inducing another mechanism to inhibit host immune responses. Some experimental data in this paper show that these problems might be overcome by multimodal combination chemoimmunotherapy in addition to standard chemotherapy, blocking antibodies for cytokine release or utilizing immune checkpoint inhibitors. Beaty *et al*^[43] reported combining chemotherapy with the agonist CD40, as a member of the TNF receptor superfamily, for surgically incurable PDA and observed tumor regression in some patients. Takeuchi *et al*^[36] likewise reported that anti-GM-CSF

antibody blocking could accelerate the formation of immunosuppressive myeloid cells in the tissue microenvironment of human pancreatic cancer.

Chemotherapeutic protocols including timing and dose might also be further explored and modified based on both reductions in tumor size and the induction of anti-tumor-specific immunity. Metronomic chemotherapy or low-dose chemotherapy has been reported to induce anti-tumor T-cell immunity *in vivo*^[44]. One of the underlying mechanisms might be that such low-toxicity doses of cytotoxic agents induce minimal suppression of tumor cells while concomitantly inducing minimal suppression of immune-promoting cells based on altered immune balance.

Lastly, future evidence should be accumulated regarding these balances in the tumor microenvironment during multimodal chemotherapy by measuring biomarkers locally and systematically. Biopsy specimens provide information of infiltrating T lymphocyte levels in the tumor microenvironment, offering possible predictors of beneficial response to chemotherapy in breast and pancreas cancers. SPARC expression levels in the stroma could represent a target for nab-paclitaxel. Although data must continue to be accumulated, miRNA might reflect changes in immune balances and predict the efficacy of chemoimmunotherapy^[45]. Taking all these lines of evidences together in combination with the properties of emerging agents, current problems seem likely to be overcome, at least in part, and the prognosis of pancreas cancer can be expected to continue improving in the coming decades.

CONCLUSION

The chemotherapeutic agents have both immune promoting and suppressing effects in the tumor microenvironment of pancreatic cancer. Based on the better understanding of tumor microenvironment following chemotherapy, the treatment protocol could be modified as personalized medicine and the prognosis of pancreas cancer would be more improved utilizing multimodal chemotherapy.

Abstract

Colorectal cancer (CRC) has become the third most common cancer in the world. Screening has been shown to be an effective way to identify early CRC and precancerous lesions, and to reduce its morbidity and mortality. Several types of noninvasive tests have been developed for CRC screening, including the fecal occult blood test (FOBT), the fecal immunochemical test (FIT), the fecal-based DNA test and the blood-based DNA test (the SEPT9 assay). FIT has replaced FOBT and become the major screening test due to high sensitivity, specificity and low costs. The fecal DNA test exhibited higher sensitivity than FIT but its current cost is high for a screening assay. The SEPT9 assay showed good compliance while its performance in screening needs further improvements. These tests exhibited distinct sensitivity and specificity in screening for CRC and adenoma. This article will focus on the performance of the current noninvasive *in vitro* diagnostic tests that have been used for CRC screening. The merits and drawbacks for these screening methods will also be compared regarding the techniques, usage and costs. We hope this review can provide suggestions for both the public and clinicians in choosing the appropriate method for CRC screening.

Key words: Colorectal cancer; Adenoma; Fecal immunochemical test; Fecal DNA; SEPT9; Septin 9

Core tip: The choice of colorectal cancer (CRC) screening methods is crucial for screening validity and compliance. Currently, the fecal immunochemical test (FIT), fecal DNA and the blood-based SEPT9 assays are the three *in vitro* diagnostic tests for CRC screening. In this article, we reviewed the current application of the three types of assays and compared their performance

in CRC screening. FIT is still the cheapest method with high screening validity, and fecal DNA tests also exhibit high validity but its price is high. In contrast, the SEPT9 assay showed high compliance with acceptable performance. The choice of screening test may depend on the balance of performance, compliance and costs.

INTRODUCTION

Colorectal cancer (CRC) has become the second and the third leading cause of new cancer cases in Europe and in the United States, respectively^[1]. There were approximately 142820 new cases with 50830 deaths in the United States in 2013, and approximately 447000 new cases of CRC and 215000 deaths in European countries in 2012^[1,2]. The new cases for CRC are approximately 400000 in China in 2012, and it has become the third leading cause of death in the country^[3].

Regular screening can achieve early CRC detection and early treatment. However, 60%-70% of patients are found at middle- or late-stage CRC when they are diagnosed^[4]. Approximately 60% CRC deaths could be avoided and the average 5-year survival rate could be increased from 46% to 73% if healthy people carry out a regular periodic screening each year^[5]. Therefore, an effective early screening method for CRC can reduce CRC morbidity and mortality.

There are four *in vitro* diagnostic (IVD) screening method currently available for CRC screening, including the fecal occult blood test (FOBT), the fecal immunochemical test (FIT), the fecal DNA test and the plasma SEPT9 gene methylation test. This review will provide a detailed analysis on the performance of these tests, and compare their merits and drawbacks in CRC screening. It is our aim for this review that the public and the professionals can choose the appropriate methods for CRC screening.

STOOL-BASED TESTS FOR CRC SCREENING

The FIT test

The guaiac FOBT test (gFOBT) has been used for a long time as a screening test for CRC. It exhibited a sensitivity of 12.9%-79.4% with a specificity of 86.7%-97.7% for CRC screening in many studies^[6-13]. However, its sensitivity and specificity for CRC detection is lower than the more specific FIT (previous called iFOBT) test. This is because the gFOBT relies on peroxidase-like activity

between heme and guaiac, which can be affected by many factors in daily diet without distinguishment between upper and lower gastrointestinal (GI) tract bleeding, while the FIT test targets the hemoglobin in the lower GI tract, as hemoglobin from upper GI tract will be degraded when it arrives at lower GI tract. This characteristic allows FIT test to specifically detect the bleeding from lower GI tract, and therefore detect the diseases with bleeding, such as adenoma, polyps, inflammatory diseases and CRC, etc. As the gFOBT test has many drawbacks in CRC screening, FIT is used more commonly in current CRC screening. We therefore focus on the performance of FIT test in this review.

The performance of FIT test in CRC screening in asymptomatic, average-risk adults has been listed in Table 1. Data from 19 studies showed that the overall sensitivity for CRC was 0.79 (95%CI: 0.69-0.86) and the overall specificity was 0.94 (95%CI: 0.92-0.95)^[12,14-31]. This includes a total of 113360 subjects with 437 CRC cases confirmed by colonoscopy or 2-year follow-up. As the overall sensitivity and specificity are satisfactory for a cancer screening test with low costs, FIT is currently the most commonly-used method for CRC screening. The overall CRC positivity rate of 0.39% (437/113360) appeared to be significantly lower than the other two screening reports with asymptomatic, average-risk adults using fecal DNA (0.65%, 65/9989; $\chi^2 = 15.93$, $P < 0.001$)^[32] and SEPT9 gene methylation assay (0.67%, 53/7941; $\chi^2 = 14.66$, $P < 0.001$)^[33], respectively, indicating that the use of 2-year follow-up as a confirmatory methods may result in underestimation of CRC cases.

The use of qualitative FIT or quantitative FIT has always been an issue in choosing the FIT test for screening. A strip test (colloidal gold immunochromatographic method) is currently the main technique for qualitative FIT. It does not need specific instruments and the interpretation of test results relies on human recognition of test bands, although instruments are available to digitize the chrominance of the bands. In contrast, immunoturbidimetry is the main method for quantitative FIT, and the current devices include automated instrument for samples processing and colorimetry. Therefore, the current qualitative FIT appears to be faster, more convenient, less costly while more subjective than the quantitative FIT.

The performance between the qualitative and quantitative FIT showed significant differences. As shown in Table 1, the overall sensitivity of the qualitative FIT was 0.82^[12,15-21], which was significantly higher than that of the quantitative FIT (0.73) ($\chi^2 = 3.933$, $P = 0.047$)^[22-31], while the qualitative FIT exhibited significantly lower specificity than the quantitative FIT (0.93 vs 0.95) ($\chi^2 = 81.64$, $P < 0.001$), although the difference was small. This comparison needs to be interpreted with caution, as different studies used different cutoff values and resulted in distinct sensitivity and specificity. Ideally, they should be compared under the same cutoff value so that the sensitivity and specificity can be directly

Table 1 The sensitivity and specificity of qualitative and quantitative fecal immunochemical test

Table 2 Comparison of sensitivity and specificity between Cologuard and fecal immunochemical test

Pathological categories		Cologuard	FIT
Sensitivity ^[32]	CRC	92.3%	73.8%
	Advanced precancerous lesions	42.4%	23.8%
	Polyps with high-grade dysplasia	69.2%	46.2%
	Serrated sessile polyps	42.4%	5.1%
Specificity ^[32]	Nonadvanced or negative findings	86.6%	94.9%
	Negative results on colonoscopy	89.8%	96.4%

CRC: Colorectal cancer; FIT: Fecal immunochemical test.

compared. The pooled data analyzed here provides a reference for comparing the two types of FIT tests. It can be suggested that the quantitative FIT may be a good choice for CRC screening tests that do not need high accuracy or are performed in hospitals where automated instruments are not available.

However, it should be mentioned that the cutoff value for qualitative FIT is preset, while the cutoff value for quantitative FIT can be adjusted to balance the sensitivity with specificity. Therefore, the data format for qualitative FIT is "positive" or "negative" without traceability, while the results from quantitative FIT are digitized with traceability. This is extremely useful when the relationship between the amount of bleeding in a certain disease and the population/personal information (such as diet, age, habit, sex, etc.) is investigated. Future model for predicting CRC incidence might partially relies on the data from quantitative FIT.

The fecal DNA test

The detection of abnormal DNA or epigenetic markers from colorectal lesions is based on natural exfoliation of cancerous or precancerous cells into the colorectal tract. The fecal DNA test aims at detecting the DNA mutations, microsatellite instability, impaired DNA mismatch repair and abnormal methylation. There are many studies focusing on the detection of CRC by fecal DNA markers^[34,35], and the overall sensitivity for CRC

detection by various fecal DNA marker combinations ranged from 53% to 87%, with specificities beyond 76%^[34,35]. Although there are a large number of fecal DNA markers available in these studies, the first commercial fecal DNA test was not available until the approval of Cologuard (Exact Sciences, Madison, WI, United States) by the United States FDA in 2014. Imperiale *et al*^[32] published the leading study on Cologuard in 2014. By randomizing subjects to Cologuard or FIT screening, it showed that the sensitivity of Cologuard was superior to that of FIT in CRC, advanced precancerous lesions, polyps with high-grade dysplasia and serrated sessile polyps, while its specificity appeared to be lower than that of FIT (Table 2).

The Cologuard DNA test includes quantitative molecular assays for KRAS mutations, aberrant NDRG4 and BMP3 methylation, and β -actin, plus a hemoglobin immunoassay. As the hemoglobin immunoassay is essentially a FIT test, Cologuard is actually a combination of gene mutation, methylation and occult blood tests. The multitarget stool DNA test provides a new way that combines various detecting technology to detect CRC and early colorectal lesions with high sensitivity and specificity. The high detection of precancerous lesions, HGD and serrated sessile polyps is extremely useful for a screening test, as these lesions may develop into CRC if they are not resected. The only obstacle for broad application of Cologuard is the cost, as the detection of multitargets increased the cost of the test. Its current expense of \$599 per test is high for a routine screening assay.

BLOOD-BASED TESTS FOR CRC SCREENING

The plasma SEPT9 gene methylation assay

An ideal screening test for cancer could be a simple blood test in the foreseeable future. The plasma SEPT9 gene methylation test Epi proColon (Epigenomics AG, Berlin, Germany) is currently the only commercially

available blood-test for CRC early detection and screening, and was approved recently by the United States FDA as a CRC screening test for average-risk population over 50 years old. Many clinical studies have proved the test to be a method with acceptable sensitivity and specificity for CRC detection^[33,36-49]. The test was firstly developed by Lofton-Day *et al*^[36] in 2008 as a research kit, and was commercialized by Epigenomics AG as its first generation assay Epi proColon 1.0. At the same time, ARUP lab also developed its SEPT9 assay as a lab-developed test^[40]. Abbott developed its real-time mS9 CRC assay, but there was only one report on its performance and the sensitivity of 36.3% was much lower than other SEPT9 tests^[47]. The 2nd generation test (Epi proColon 2.0) was launched in 2011-2012 with better performance. Till today, most reports on the SEPT9 assay appeared to be case-control study or cohort study investigating the test performance in selected population, exhibiting a sensitivity of 36.6%-95.6% with a specificity of 81.5%-99.0% using 1/3, 2/3, 1/2 or 1/1 algorithm^[33,36-49]. In contrast, there is only one study (the PRESEPT trial) investigating the application of the assay in CRC screening in average-risk population, exhibiting a sensitivity of 48.2% and 68.2% with a specificity of 91.5% and 80.0% using 1/2 or 1/3 algorithm, respectively^[33,43].

Detection of early stage CRC is crucial for early intervention and reduction of mortality. The positive detection rate (PDR) of the SEPT9 assay for stage I, II, III and IV was 26.3%-84.0%, 36.7%-100.0%, 25.0%-100.0% and 64.7%-100.0%, respectively, depending on different algorithm, exhibiting a huge variation for each stage. As 1/3 and 2/3 algorithm are the most commonly used methods for result interpretation, we calculated the PDR for each stage using the two algorithms. The pooled PDR for stage I, II, III and IV was 58.3%, 73.3%, 70.8% and 87.7%, respectively, using 1/3 algorithm (Table 3), and was

51.2%, 71.7%, 80.5% and 84.2%, respectively, using 2/3 algorithm (Table 4)^[36-47]. No statistical difference in PDR in any stage between the two algorithms has been found. It can be clearly seen that the PDR for early stage CRC (stage I) was above 50% and fell into 70%-80% for stage II and III, which is acceptable for a blood-based CRC test. However, these PDRs were from case-control or cohort studies, and more studies should be performed at screening settings.

Although the SEPT9 assay was designed for CRC detection, researchers also studied its detection sensitivity for precancerous adenoma. The pooled PDR for non-advanced adenoma and advanced adenoma (AA) was 10.0% and 18.2%, respectively, from six studies, in which the PDR for AA was significantly higher than the PDR of normal control group (11.8%, χ^2 test, $P < 0.001$)^[30,33,37,40,43,46]. However, as PDR of 18.2% was still too low for an effective test, the SEPT9 assay may not be applicable in adenoma detection.

The SEPT9 assay exhibited high compliance in screening. One recent report showed that 63% of subjects in a CRC screening study refused colonoscopy. 97% of subjects who refused colonoscopy accepted a noninvasive screening test, and 83% chose the SEPT9 test and 15% chose FIT test. The majority of patients who refused colonoscopy chose the SEPT9 assay due to its convenience and less time-consuming procedure^[50].

CEA and other serum glycoprotein markers

CEA and carbohydrate antigen 199 (CA199) are the two most common serum-based glycoprotein CRC markers, however, they are not appropriate for CRC screening due to their low sensitivity and the lack of CRC specificity, especially for early-stage CRC^[41,51-53]. For example, CEA test exhibited a sensitivity of 40.9%-51.8% and a specificity of 85.2%-95% for CRC detection in three studies^[41,51,52]. Therefore, it is more appropriate to be used in monitoring the CRC recurrence or response from

Table 5 Sensitivity and specificity of fecal immunochemical test, fecal DNA and SEPT9 tests in colorectal cancer and advanced adenoma screening

	FIT ^[12,15-31]	Fecal DNA ^[32]	SEPT9 ^[43]
Sensitivity (CRC)	79%	92%	68%
Specificity	94%	87%	80%
Sensitivity (AA)	24%	42%	18%

FIT: Fecal immunochemical test; CRC: Colorectal cancer; AA: Advanced adenoma.

patients to surgical or systemic therapy, rather than screening^[53].

The main drawback of serum glycoprotein markers in CRC screening is that the sensitivity and specificity of any single marker is not high enough to make it a reliable indicator. These markers have been found in various cancers other than CRC with low sensitivity for early stage lesions. Combined use of multiple markers may be a way to achieve diagnostic significance in CRC detection. In one report, five glycoprotein markers, including CEA, CA199, CA242, CA72-4, and CA125, are used together as indicators for CRC. It showed that the sensitivity of any single marker was low (18.8%–52.2%) for detecting CRC in stages I and II, while the combination of the five exhibited a sensitivity of 85.3% at the specificity of 95%^[54].

COMPARISON OF NONINVASIVE TESTS FOR CRC SCREENING

The sensitivity for CRC and AA, and the specificity in asymptomatic average-risk population for FIT, fecal DNA and SEPT9 tests are shown in Table 5. It can be seen that the fecal DNA test exhibited the best performance in terms of sensitivity for CRC and AA, while its specificity was slightly lower than that of the FIT. It is noteworthy that the fecal DNA test can detect 42% AA, which may reduce the number of subjects progressing to CRC, *i.e.*, reducing the CRC morbidity. The SEPT9 assay is the only blood-base CRC screening assay currently. Although its screening performance was not satisfactory at the moment, it showed very high compliance^[50]. The blood-based CRC screening assay may be more popular if the sensitivity and specificity in screening setting could be improved to the level of those in case-control studies (ideally sensitivity > 70% and specificity > 90% for CRC screening).

The current costs for FIT, fecal DNA and the SEPT9 test are \$10-50, \$599 and approximately \$170, respectively. As the recommended screening frequency for FIT, fecal DNA and the SEPT9 is once per year, once per three years and once per year, respectively, FIT might be the cheapest test considering the balance between performance and costs. However, the quality adjusted life year of the three tests should be compared under the same setting to evaluate the cost-effectiveness of them, although some studies have been performed for each

Table 6 Positive detection rate of SEPT9, fecal immunochemical test and carcino-embryonic antigen tests and various combined tests

SEPT9 alone	FIT alone	CEA alone	SEPT9 + FIT	SEPT9 + CEA	FIT + CEA	SEPT9 + FIT + CEA

individual method in different settings, such as different health systems.

CRC SCREENING WITH COMBINED TESTS

The combination of fecal DNA (mutation and methylation) with a hemoglobin immunoassay in Cologuard has provided a good example for CRC screening when multiple markers are analyzed together to enhance the detection sensitivity. There are merits and drawbacks for this strategy. First, combination of multiple markers enhances sensitivity at the price of reducing specificity. The number of false positive cases will increase with the increased number of markers. Therefore, to identify the markers with high sensitivity and specificity and to find the best combination of markers remain a challenge for combined screening test development. Ideally, the number of markers should be kept to minimum, while the sensitivity and specificity can be balanced to provide the best performance. Secondly, the detection of multiple markers with distinct methods increases the technical difficulties in an assay. For example, the detection of mutation in Cologuard may use sequencing or PCR method, while the detection of methylation needs to use the methylation specific PCR method containing bisulfite conversion. In contrast, immunoassay is used in the detection of hemoglobin. Furthermore, the sample preparation procedure may also be different for detecting different abnormalities. Therefore, a good combined test needs not only optimization of each individual test, but also an accurate algorithm to maximize the performance of each test. The optimization and interpretation of the combined test must come from clinical trials with large number of cases. Thirdly, a screening test should be accurate, fast, convenient, simple and cheap. These features allow large-scale screening in a certain period of time, and allow easy test in areas where test instruments are not available. In addition, low costs ensure screening tests for average-risk population, in which the CRC incidence could be lower than 1% in people over 50 years old. All the above considerations need to be addressed in future development of combined screening test.

As FIT, SEPT9 and CEA tests are all CRC detection tests with high specificity, the combination of them may provide higher sensitivity with no significant compromise

in specificity. We recently tested this assumption in an opportunistic screening setting, in which blood and stool samples were collected from outpatients and inpatients coming to the GI departments of three Chinese hospitals^[55]. Table 6 shows the test results from the screening. SEPT9, FIT or CEA alone detected 77.0%, 74.6% and 41.3% of CRC cases, respectively, while the combination of the three increased the sensitivity to 97.2%, and SEPT9 plus FIT exhibited a sensitivity of 94.4%. Since CEA is more sensitive to late-stage CRC than early-stage CRC, and no significant difference was found between SEPT9 + FIT + CEA and SEPT9 + FIT, we recommend SEPT9 + FIT as a routine method for CRC screening.

CONCLUSION

The FIT, fecal DNA and the SEPT9 tests are IVD tests currently used for CRC screening. FIT tests exhibited satisfactory sensitivity and specificity with low costs and therefore become the major screening test for CRC at the moment. The sensitivity of the fecal DNA test appeared to be very high due to combination of multiple methods while its high cost is an obstacle preventing the test from broad use. Both sensitivity and specificity for the SEPT9 test in CRC screening were lower than those of the FIT and fecal DNA test, but it showed high compliance with promising future if its accuracy can be improved. Combined tests with multiple markers should be a future direction in CRC screening, however, some hurdles, such as technical integration, test/interpretation optimization, and high costs, etc, need to be overcome before they can be used in large-scale CRC screening aiming at asymptomatic average-risk population.

Abstract

A 48-year-old woman presented with bilateral enlarged ovaries, ascites, bilateral pleural effusion, and advanced gastric cancer. Pleural fluid cytology did not reveal malignant cells. Oophorectomy, performed as a palliative procedure, was followed by rapid resolution of the pleural effusion and ascites. The patient was diagnosed with pseudo-Meigs' syndrome, and underwent chemotherapy followed by partial gastrectomy. At the last follow-up, 84 mo following oophorectomy, she was alive, and free of disease recurrence, despite not receiving any further treatment. Pseudo-Meigs' syndrome should be considered in patients with bilateral ovarian tumors, ascites and pleural effusion, and treatment such as oophorectomy may result in symptomatic improvement and better prognosis in similar patients.

Key words: Pseudo-Meigs' syndrome; Ovarian tumor; Gastric cancer; Pleural effusion; Ascites

Core tip: In general, the prognosis of gastric cancer with distant metastases is poor. On the other hand, oophorectomy for gastric cancer-related metastatic ovarian tumors may improve survival, especially in the absence of metastasis to other organs. We here report a long-term survival case of pseudo-Meigs' syndrome caused by gastric cancer following oophorectomy. We conclude that pseudo-Meigs' syndrome should be considered in patients with gastric cancer with enlarged

ovaries, pleural effusion, and ascites.

Case of pseudo-Meigs' syndrome caused by gastric cancer-related metastatic ovarian tumor with prolonged survival. *World J Gastrointest Oncol* 2016; 8(11): 801-804 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i11/801.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i11.801>

INTRODUCTION

Meigs' syndrome is defined as the presence of pleural effusion and ascites in association with benign ovarian tumors such as fibromas. In these patients, pleural effusion and ascites typically disappear following oophorectomy. Pseudo-Meigs' syndrome is similar to Meigs' syndrome, except that the ovarian tumor may be malignant rather than benign. Pseudo-Meigs' syndrome caused by gastric cancer with metastatic ovarian tumors is very rare. Herein, we report a case of pseudo-Meigs' syndrome caused by gastric cancer with metastatic ovarian tumors, with prolonged survival following oophorectomy.

CASE REPORT

A 48-year-old woman was admitted to our hospital with a 3-mo history of lower abdominal fullness. She had no significant medical history. She smoked half a pack of cigarettes and consumed 1 L of beer a day for 28 years. On physical examination, her height and weight were 161 cm and 49 kg, respectively. Her blood pressure (103/60 mmHg), pulse rate (92 beats/min), body temperature (37.3 °C), and arterial oxygen saturation at room air (96%) were almost normal. The right chest breath sounds were decreased, her abdomen was distended, and a hard fist-sized mass was palpable in her lower abdomen. Her serum levels of carbohydrate antigen 19-9 and carbohydrate antigen 125 (CA 125) were elevated at 170.4 U/mL (normal, < 35 U/mL) and 897 U/mL (normal, < 37 U/mL), respectively. Computed tomography demonstrated bilateral enlarged ovaries, ascites, and bilateral pleural effusion (Figure 1). Upper gastrointestinal endoscopy revealed an ulcerated lesion with raised margins on the greater curvature of the body of the stomach (Figure 2). Biopsy of this lesion confirmed the diagnosis of poorly differentiated adenocarcinoma. Based on the above findings, a diagnosis of gastric cancer with metastatic ovarian tumors, malignant ascites, and pleural effusion, was made, although pleural fluid cytology failed to identify any malignant cells. Consequently, bilateral oophorectomy was performed as a palliative procedure. The resected ovarian tumors measured 15 cm (right) and 8 cm (left) in diameter. The tumors were solid with multiple mucus-containing cysts (Figure 3A and B). There was no evidence of tumor dissemination in

Figure 1 Whole body computed tomography-scan demonstrating bilateral enlarged ovaries, ascites and bilateral pleural effusion.

Figure 2 Upper gastrointestinal endoscopy revealing an ulcerated lesion with raised margins on the greater curvature of the body of the stomach.

the abdomen and the ascitic fluid was negative for cancer cells on cytology. Histological examination of the resected ovarian specimens confirmed that the tumors comprised poorly differentiated adenocarcinoma similar to the gastric tumor (Figure 3C), suggesting that the bilateral ovarian tumors were secondary to the gastric cancer (Krukenberg tumors).

The patient's pleural effusion and ascites resolved completely within 2 wk of her surgery. In view of these findings, we considered a diagnosis of pseudo-Meigs' syndrome. Following the oophorectomy, she received chemotherapy with docetaxel and S-1, with one course comprising docetaxel 40 mg/m² as an intravenous

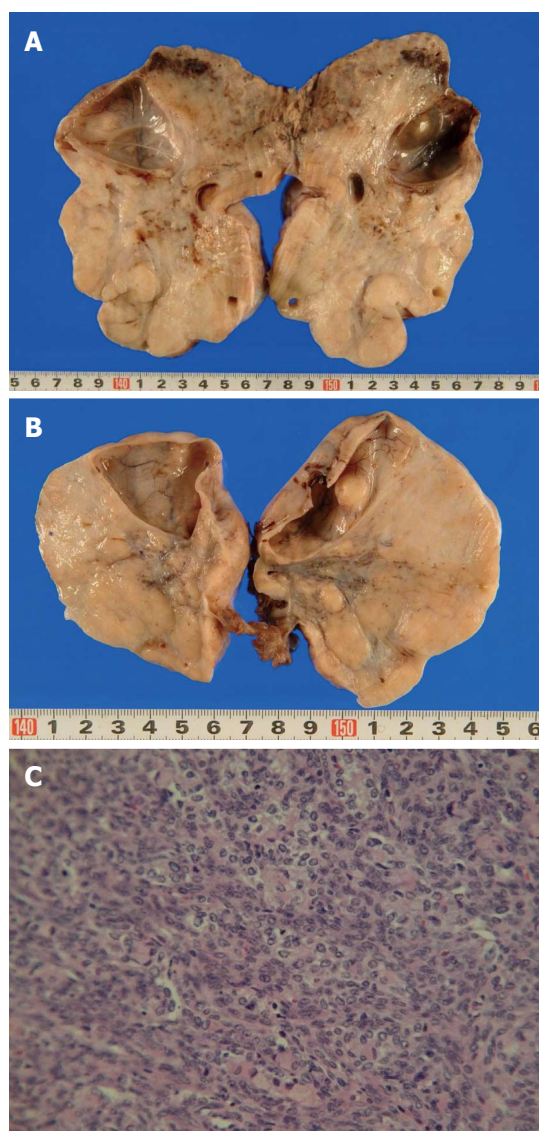

Figure 3 Resected ovarian tumors measured 15 cm (right) (A) and 8 cm (left) (B) in diameter. The tumors were solid with multiple mucus-containing cysts. Histological examination of the resected ovarian specimens confirmed that the tumors were composed of poorly differentiated adenocarcinoma similar to the gastric tumor (C).

infusion on day 1 and oral S-1 80 mg/m² on days 1-14 of a 21-d cycle. After 10 cycles of chemotherapy, approximately 9 mo after her first hospital visit, since no further metastases were detected, she underwent distal gastrectomy. The final pathological diagnosis was Stage IV [pT3, pN1, cM1(Ovary)] according to the TNM classification of gastric carcinoma (UICC fifth edition). At the last follow-up, 84 mo following oophorectomy, she was alive and free of disease recurrence, despite not receiving any further treatment.

DISCUSSION

In 1937, Meigs and Cass^[1] first reported a case series of seven patients with ovarian fibroma with pleural effusion and ascites, in whom the pleural effusion and

ascites disappeared following removal of the ovarian tumors. Subsequently, Rhoads *et al.* reported similar cases and coined the term "Meigs' syndrome"^[1,2]. A similar presentation associated with primary malignant or metastatic ovarian tumors, instead of benign ovarian tumors, is referred to as pseudo-Meigs' syndrome^[3].

Ascites may be secondary to ovarian tumors or fluid secretion from the peritoneum, develop as a result of tumor stimulation or in response to cytokines, or may be secondary to tumor-related lymphatic obstruction^[4]. Pleural effusion is explained as occurring secondary to the movement of ascitic fluid to the pleural cavity *via* transdiaphragmatic lymphatics and diaphragmatic foramen^[5]. It is uncommon for malignant tumor cells to be identified in the pleural or ascitic fluid in patients with pseudo-Meigs' syndrome.

Metastatic ovarian cancer comprises 6%-30% of all ovarian malignancies. The most common primary sites are the gastrointestinal tract, breast, and reproductive organs. In Japan, gastric cancer is the most common primary site because of its relatively high prevalence^[6]. Pseudo-Meigs' syndrome is more frequently caused by primary ovarian malignant tumors than ovarian tumors metastases from gastrointestinal cancer, and gastric cancer as the primary source for pseudo-Meigs' syndrome is particularly rare. In fact, to our knowledge, only 10 cases have been described so far, including five in the literature^[5,7-10] and five in Japanese conference proceedings. The mean age of the patients in the published reports was 51.8 (range, 32-76) years. Two and three cases had unilateral and bilateral ovarian metastases, respectively, and the ovarian tumor size ranged from 10 to 25 cm in diameter. Pleural effusion was bilateral in three cases and unilateral in two. Moreover, the serum CA 125 levels are often elevated in patients with Meigs' syndrome and decrease following oophorectomy, as in the present case. Benjapibal *et al.*^[11] explained that CA 125 may be produced from the peritoneal epithelium by a biomedical factor, secondary to mechanical irritation by a large tumor, or owing to an increase in the intra-peritoneal pressure related to the large volume of ascites.

The prognosis of gastric cancer with distant metastasis is poor, with a median survival time of 8.6-13.8 mo when treated by chemotherapy alone or in combination with molecular targeted therapy^[12]. On the other hand, Lu *et al.*^[13] reported that oophorectomy for gastric cancer-related metastatic ovarian tumors may improve survival, especially in the absence of metastasis to other organs. The overall survival times of patients who did and did not undergo metastasectomy were reported as 14.1 and 8 mo, respectively, in their study. Furthermore, Briau *et al.*^[14] reported that oophorectomy along with current chemotherapy regimens, such as taxane- or platinum-based therapy, improved survival even if the patients had extra-ovarian metastatic sites. In the present case, we selected a docetaxel and S-1 combination regimen with the expectation of efficacy for non-measurable lesions other than in the ovaries^[15,16].

The increased survival of the patient reported herein may be owing to her oophorectomy in conjunction with chemotherapy. Accordingly, this case emphasizes the need to be aware of pseudo-Meigs' syndrome, and supports the recommendation of oophorectomy in cases where metastases are limited to the ovaries.

COMMENTS

Case characteristics

A 48-year-old woman with a 3-mo history of lower abdominal fullness.

Clinical diagnosis

Gastric cancer with metastatic ovarian tumors, malignant ascites, and pleural effusion.

Differential diagnosis

Gastric cancer with primary ovarian cancer, reactive ascites and, pleural effusion.

Laboratory diagnosis

The serum levels of carbohydrate antigen 19-9 and carbohydrate antigen 125 were elevated, at 170.4 U/mL (normal, < 35 U/mL) and 897 U/mL (normal, < 37 U/mL), respectively.

Imaging diagnosis

Computed tomography demonstrated bilateral enlarged ovaries, ascites, and bilateral pleural effusion.

Pathological diagnosis

The resected ovarian specimens comprised poorly differentiated adenocarcinoma, similar to the gastric tumor, suggesting that the bilateral ovarian tumors were secondary to the gastric cancer; there was no evidence of tumor dissemination in the abdomen and the ascitic fluid was negative for cancer cells on cytology.

Treatment

Oophorectomy and gastrectomy in conjunction with chemotherapy.

Related reports

Gastric cancer, as the primary source for pseudo-Meigs' syndrome, is particularly rare. This case is one of only a few reports of pseudo-Meigs' syndrome caused by gastric cancer with prolonged survival.

Term explanation

Meigs' syndrome is defined as the presence of pleural effusion and ascites in association with benign ovarian tumors such as fibromas. In these patients, pleural effusion and ascites typically disappear following oophorectomy. Pseudo-Meigs' syndrome is similar to Meigs' syndrome, except that the ovarian tumor may be malignant rather than benign.

Experiences and lessons

The authors experienced a long-term survival case of pseudo-Meigs' syndrome caused by gastric cancer. If the metastases are limited to the ovaries, it is important not to automatically assume that the tumor is unresectable.

Peer-review

This is an interesting case report in terms of the disappearance of ascites and pleural effusion after oophorectomy, and prolonged survival despite of the extent of the disease at diagnosis.

World Journal of *Gastrointestinal Oncology*

World J Gastrointest Oncol 2016 December 15; 8(12): 805-839

Editorial Board

2016-2019

The *World Journal of Gastrointestinal Oncology* Editorial Board consists of 420 members, representing a team of worldwide experts in gastrointestinal oncology. They are from 42 countries, including Argentina (2), Australia (11), Austria (1), Belgium (5), Brazil (2), Canada (5), Chile (2), China (55), Czech Republic (1), Denmark (1), Finland (2), France (8), Germany (23), Greece (13), Hungary (2), India (9), Iran (3), Ireland (2), Israel (4), Italy (39), Japan (44), Kuwait (2), Mexico (1), Netherlands (8), New Zealand (2), Norway (1), Poland (3), Portugal (4), Romania (1), Saudi Arabia (1), Serbia (2), Singapore (4), South Korea (29), Spain (10), Sweden (5), Switzerland (2), Syria (1), Thailand (1), Turkey (6), United Arab Emirates (1), United Kingdom (12), and United States (90).

World Journal of Gastrointestinal Oncology
Volume 8 Number 12 December 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Haiyong Han, PhD, Associate Professor, Clinical Translational Research Division, The Translational Genomics Research Institute (TGen), Phoenix, AZ 85004, United States

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

It is well established that colorectal cancer develops

from a series of precursor epithelial polyps, including tubular adenomas, villous/tubulovillous adenomas (VA/TVA), sessile serrated adenomas (SSA) and traditional serrated adenomas (TSA). Of these, TSAs are least common and account for only 5% of all serrated polyps. TSAs are characterised by the presence of a "pinecone-like" architecture, granular eosinophilic cytoplasm, luminal serrations, ectopic crypt foci (ECF) and elongated, pencillate nuclei. However, the distinct slit-like luminal serrations, reminiscent of small bowel mucosa, appear to be the most unique and reproducible feature to distinguish TSAs from other polyps. There is a contention that TSAs are not inherently dysplastic and that the majority do not show cytological atypia. Two types of dysplasia are associated with TSA. Serrated dysplasia is less well recognised and less commonly encountered than adenomatous dysplasia. In addition, it is now becoming increasingly evident that TSAs can be admixed with HP, SSA and VA/TVA. At a genetic level, polyps may switch phenotype as they accumulate genetic changes, evolving from a serrated pathway to a more conventional one, which could be the basis for a spectrum theory starting out with a TSA with serration and ECF evolving into a TSA with conventional dysplasia and, eventually, to a well-developed conventional adenoma. Nevertheless, there is an exigency for future studies to provide further illumination and bridge the gaps in our present understanding.

Key words: Serrated polyps; Traditional serrated adenoma; Tubulovillous adenoma; Serrated pathway; Fusion pathways

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Traditional serrated adenoma (TSA) is the least common type of the serrated polyps and is characterized by a constellation of distinct cytomorphological features. TSAs are thought to be precursors to the biologically aggressive, *BRAF* mutated, microsatellite stable,

colorectal cancer. It is becoming increasingly evident that TSAs can co-exist with other serrated polyps including hyperplastic polyps and sessile serrated adenomas. In addition, TSAs may also be seen with adenomatous polyps. In this review, we wish to highlight the issues around nomenclature, diagnostic criteria, coexistence with other polyp types, the occurrence of dysplasia and molecular pathways involved in the neoplastic progression of TSAs.

Kalimuthu SN, Chelliah A, Chetty R. From traditional serrated adenoma to tubulovillous adenoma and beyond. *World J Gastrointest Oncol* 2016; 8(12): 805-809 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i12/805.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i12.805>

INTRODUCTION

It is well established that colorectal cancer (CRC) develops from a series of precursor epithelial polyps^[1-5], which include conventional adenomas, incorporating tubular adenomas and villous/tubulovillous adenomas (VA/TVA) and serrated polyps, incorporating hyperplastic polyps (HP), sessile serrated adenomas (SSA) and traditional serrated adenomas (TSA)^[1,2,4,6,7]. CRC is known to develop through three putative molecular pathways with the conventional adenoma-carcinoma sequence (chromosomal instability pathway), the mismatch repair and serrated pathways, accounting for the molecular pathogenesis of most CRCs^[2,4]. VA/TVAs are thought to be the advanced precursors in the "adenoma-carcinoma" pathway^[2]. Conversely, CRCs arising from serrated polyps (which can be visible at the edge or intimately associated with the invasive tumour), are thought to be portentous of the "serrated pathway"^[1,4,8-10]. All three serrated polyps stay true to their epithet by characteristically demonstrating luminal serrations. Of these, TSAs are the least common and account for only 5% of all serrated polyps^[1].

NOMENCLATURE AND CLINICOPATHOLOGICAL CRITERIA

The historical provenance and journey taken to recognise TSAs in their present guise has been an interesting one. TSAs were first recognised by Longacre and Fenoglio-Preiser^[11,12] and were grouped together under the broad term of "serrated adenomas", as these polyps were thought to be conventional adenomas with a serrated luminal profile. Torlakovic *et al.*^[13] further refined this definition by appending the term "traditional" to the appellation, specifically to distinguish TSAs from SSAs and later highlighted several distinct morphological features specific to TSAs^[14].

TSAs are equally distributed between the genders and usually present in the sixth to seventh decade of

life^[11]. They range from 9-14 mm in maximum dimension and endoscopically have a pinecone-like appearance or may exhibit a fernlike/stellate pit pattern on chromoendoscopy^[11].

TSAs can be both sessile and pedunculated, the former being more common in the more proximal lesions^[11]. Histologically, TSAs are exemplified by a constellation of characteristic cytomorphological features, which include a tubulovillous, "pinecone-like" architecture, striking granular eosinophilic cytoplasm, presence of ectopic crypt foci (ECF), distinct luminal serrations, elongated, pencillate nuclei with evenly dispersed chromatin and small inconspicuous nucleoli and haphazardly distributed goblet cells (Figure 1)^[2,4,6,9,10,14]. Of these lineaments, the distinct slit-like luminal serrations with mushroom/jigsaw puzzle-like broad luminal fronds, reminiscent of small bowel mucosa, appear to be the most unique and reproducible feature to distinguish TSAs from other polyps^[6,8,11]. Interestingly, Bettington *et al.*^[5] have recently described a "serrated" TVA, which occurs more frequently in a proximal location and in essence, morphologically resembles a conventional TVA but at least > 50% of the polyp displays prominent serrations. The authors argue that this represents a distinct entity, with more frequent *KRAS* mutations and CpG island methylation; however, we surmise that the "undulating" or "maze-like" serrations described may merely represent a morphological spectrum seen within TVAs and could possibly be secondary to mechanical compression due to luminal spatial constriction. This latter conjecture could possibly elucidate why this particular type of serration may, at least focally, be observed in larger polyps harbouring a villous configuration, albeit almost never seen in TSAs. Nevertheless, it is important to distinguish serrated TVA from TSA, particularly in the scenario when TSAs co-exist with conventional TVAs^[6].

ECF have been defined as abnormal development of crypts, secondary to inactivating mutations in the bone morphogenetic protein 4 signalling pathway, causing loss of orientation towards the muscularis mucosae resulting in these short disorientated abortive crypts that fail to reach the muscularis mucosae (Figure 1)^[2,6,14]. ECF were previously touted to be a prerequisite for the diagnosis of TSA^[14]. However, these "maelstrom-like" or whorled clusters may not always be seen in TSAs^[2,6,8,15], particularly in smaller lesions (< 10 mm) and have also been documented in VA/TVAs (34%)^[2], albeit to a lesser frequency than observed in TSAs.

TSA WITH OTHER COEXISTENT POLYPS

When most of the aforementioned hallmark features are represented, a diagnosis TSA can be made with minimal difficulty. However, it is becoming increasingly evident that TSAs can be admixed with HP, SSA and VA/TVA^[1,2,6,16,17]. The documented rate of co-existent HP/SSA and VA/TVA with TSA range from 31%-52%,

Figure 1 Traditional serrated adenoma. A: Traditional serrated adenoma (TSA) demonstrating an arborizing, "pinecone-like" pattern; $\times 12.5$; B: TSA replete with abortive crypts or ectopic crypt foci (ECF) (arrowhead); $\times 100$; C: Characteristic slit-like luminal serrations with deep clefts and indentations, resulting in mushroom-like or jigsaw puzzle-like appearance, which resemble the apical brush border of small bowel; $\times 200$; D: The epithelial cells have intensely eosinophilic cytoplasm with centrally located palisaded, regular, pencil nuclei and nuclear grooves. In addition, there are haphazardly distributed goblet cells with apical mucin and basally located nuclei; $\times 400$ (all H and E).

Figure 2 Sessile serrated adenoma with the characteristic dilated crypts. It is a horizontal growth along the muscularis mucosa and deep serration, seamlessly merging with foci of traditional serrated adenomas like areas (arrow); $\times 100$, H and E.

14%-17% and 17%-43%^[1,2,15,16], respectively. There is presently sufficient evidence to suggest that a significant proportion of TSAs contain precursor lesions in the form SSAs (Figure 2)^[3,4,17], the former being more common of the two. These lesions are often seen intimately associated with the TSA. In contrast, the adenomatous polyps are sharply delineated from the TSAs and appear separate and morphologically distinct (Figure 3A). It is important not to over-document a co-existent adenomatous component when adenomatous

dysplastic glands occur within a TSA (Figure 3). It is helpful to recognise that dysplastic glands in TSAs more or less retain the characteristic serrations and will be more replete with ECFs than expected in VA/TVAs.

TSA AND DYSPLASIA

The subject of dysplasia in TSA has long been a contentious one. Historically, TSAs were considered to be inherently dysplastic, owing to the close cytological resemblance to tubular adenomas or TVA^[12]. However, this axiom has since been challenged and there is an alternate view proposed^[8,10,11,15]. TSAs are unquestionably neoplastic; however, the absence of overt cytological atypia, infrequent or absent mitoses, low Ki-67 proliferation index, consistent B-catenin and p53 negativity, and retention of p16 staining, suggest TSAs are not intrinsically dysplastic^[6,10,11,15]. Instead, the cells of TSAs may represent metaplastic or senescent cells^[10,15]. It is noteworthy that there are two forms of dysplasia that can occur in TSAs and indeed in the other two serrated polyps^[4,9,10,17]. The first is the well-accepted conventional adenomatous dysplasia, which can be readily recognised with minimal difficulty. The second, less well recognised and controversial, is serrated dysplasia. Serrated dysplasia manifests secondary to activation of the serrated pathway, which is initiated by *BRAF* mutations^[4,7,10,11,18]. Similar to

Figure 3 Traditional serrated adenoma and dysplasia. A: Traditional serrated adenoma (TSA) (arrow), sharply demarcated from more a more conventional tubulovillous adenoma (TVA) (arrowhead); $\times 100$; B: TSA with conventional dysplasia with some preservation of the characteristic architecture; $\times 200$ (both H and E).

adenomatous dysplasia, this form of can be graded as low grade and high grade based on both cytological and architectural features. Low grade serrated dysplasia can be subtle and is characterised by ovoid enlarged nuclei, vesicular dispersed chromatin with low mitotic activity. In addition, scattered dystrophic goblet cells may also be observed^[6,1,18]. In contrast, high grade dysplasia is readily recognisable as a result of severe cytological and architectural atypia. Currently, the biological significance of low grade serrated dysplasia is poorly understood. As such, in practice, it is recommended that only high grade serrated dysplasia be reported.

While the majority of the adenomatous polyps encountered may only display a single phenotype, in our experience, closer scrutiny often reveals isolated TSA-like glands or SSA/HP like areas. However, from a practical point of view, the sensible approach would be to name the polyp after the most dominant histological type, followed by any secondary or tertiary component identified with an accompanying comment as to the presence or absence of dysplasia.

MOLECULAR PATHWAYS

At a molecular level, the morphological alteration in phenotype may possibly be secondary to the transition from the serrated pathway to a more conventional one. For example, when conventional dysplasia ensues in a TSA, it is possible that the Wnt signalling pathway typically associated with chromosomal instability alters its morphology^[4]. Hence, the classic TSA with serrations and ECF, evolves into a TSA with conventional dysplasia and eventually, focally or entirely, resembling a conventional well-differentiated adenoma. This presupposes that molecular aberrations result in consistent morphological appearances. Jass *et al*^[3] was the first to propose the theory where separate to the adenoma-carcinoma and serrated pathway, there may be “fusion” pathways that combine mechanisms associated with both adenomatous and serrated polyps^[3,4]. However, further studies are required to consolidate this assertion.

CONCLUSION

Overall, it stands to reason that there is a considerable morphological overlap between different polyp types, albeit the molecular basis to which remains to be elucidated. Although conjectural, recent evidence raises the important question as to whether these polyps truly represent separate entities or are they merely manifestations at different stages of a morphological and/or molecular continuum. Nevertheless, there is an exigency for future studies to provide further illumination and bridge the gaps in our present understanding.

Abstract

The gradual elucidation of the underlying biology of colorectal cancer has provided new insights and therapeutic options for patients with metastatic

disease which are selected according to predictive biomarkers. This precision medicine paradigm, however, is incomplete since not all eligible patients respond to these agents and prognostic stratification is largely based on clinicopathologic variants. Importantly, no robust data exist to help properly select patients with localized disease at high risk for recurrence and most likely to benefit from adjuvant chemotherapy. There is a rapidly expanding body of literature regarding the role of the qualitative and quantitative analysis of circulating free DNA in various neoplasms, which consistently outperforms traditional tumor markers both as a predictive and as a prognostic marker. Several lines of evidence suggest that circulating free DNA may exhibit a complementary role to existing modalities for the early diagnosis of colorectal cancer, the selection of patients for adjuvant chemotherapy, for the follow-up of treated patients, for the selection of treatment for advanced disease and the assessment of response and for determining the prognosis of patients. These data, which are reviewed here, illustrate the important role that circulating biomarkers may soon have at the daily clinical practice.

Core tip: Published studies clearly indicate that cell-free DNA levels and the detection of specific molecular events in the plasma of colorectal cancer patients is a relevant prognostic and predictive biomarker, with clinically meaningful value at various disease settings such as asymptomatic screening, follow-up after curative surgery and metastatic disease. Further randomized studies are needed before these techniques are implemented at the daily practice.

INTRODUCTION

Globally, colorectal cancer (CRC) is the third most commonly diagnosed cancer in males and the second in females; there is a significant regional variation in incidence and mortality rates in Western countries, especially the United States, where both are decreasing as a result of the widespread adoption of effective screening policies and of the evolution of treatment strategies at the adjuvant setting. Approximately 8% of cancer deaths are caused by CRC^[1,2]. Twenty percent of newly diagnosed patients have *de novo* clinically overt metastases; moreover, 10% of patients diagnosed with local and 30% with regional disease will eventually relapse, most commonly with disseminated disease^[3]. These patients presumably already harbor occult micrometastases, thus identifying them and administering systemic treatment following local excision may improve their chance for cure. Moreover, despite significant advances in the understanding of underlying molecular mechanisms and in the development and regulatory approval of several active agents during the past 15 years, 5-year survival rates of patients with metastatic CRC (mCRC) remain poor at 13%^[3], with the majority of these patients receiving palliative systemic treatment without a curative intent. Thus, it is clear that earlier diagnosis when interventions may be curable and also better predictive and prognostic biomarkers both for localized and advanced disease are highly needed.

Liquid biopsy is a minimally invasive process based on a simple venipuncture that potentially addresses several issues, since it can be safely implemented on a wide scale basis and can be repeated with minimal risks for the patient. Moreover, liquid biopsy may illustrate the molecular diversity of the underlying disease process and serial testing facilitates the monitoring of its spatial and temporal genomic evolution and at the same time it circumvents the need for re-biopsy, which is invasive, cumbersome and not always feasible^[4]. Moreover, re-biopsy is subject to sampling bias and it may not be representative of the intratumoral heterogeneity. These biomarkers may be protein-based, such as cancer antigens [carcinoembryonic antigen (CEA)], cell-based, such as circulating tumor cells (CTC) and disseminated tumor cells and nucleic acid-based, such as circulating cell-free DNA (cfDNA) and micro RNAs. CEA has been the only circulating biomarker in clinical use for decades, but its usefulness is limited by suboptimal sensitivity and specificity^[5].

CIRCULATING cfDNA

cfDNA may originate from normal or from tumor

cells and it can be detected in healthy subjects, with increased levels noted in benign conditions such as inflammatory processes and infections^[6]. Necrotic and apoptotic cells may release DNA fragments passively, depending on the tumor burden, its growth kinetics and the effects of antineoplastic treatment, but it is also believed that cfDNA may be actively shed by tumor cells with the goal to transform cells in distant sites^[7]. Finally, CTCs and micrometastases may also be the source of cfDNA, along with the primary tumor.

Several technical challenges hamper the ability to standardize the identification and measurement of cfDNA in oncology patients. First of all, the low concentration of highly fragmented DNA molecules renders their identification, amplification and quantification rather challenging^[8]. Several DNA extraction methodologies have been developed with no one appearing to clearly improve yields and pre-analytical sample processing and storage could potentially influence results. Moreover, the abundance of available methodologies such as digital polymerase chain reaction (PCR), real-time quantitative PCR (qPCR) and emerging next-generation sequencing technologies result in a lack of comparability between results reported in various translational and clinical studies^[9,10]. Despite these challenges, an exponentially increasing body of literature has clearly demonstrated the promise that the measurement of cfDNA holds in various clinical settings and in multiple different neoplasms and advances in technology aim to tackle both the problems of detecting diluted tumor DNA and determining its origin based on the presence of known aberrations found on the primary tumor.

EARLY DIAGNOSIS OF COLORECTAL CANCER

Screening for CRC has been consistently shown to reduce disease specific mortality^[11]. An abundance of screening modalities is available and recommended by clinical practice guidelines, which implies that no one is clearly superior to the others since no randomized comparisons have been performed^[11,12]. Colonoscopy is regarded as the preferred technique^[13]. However, it is costly and invasive. Thus, enriching the population that undergoes colonoscopy with subjects at the highest risk for the development of CRC with a minimally invasive selection procedure is a matter of active research.

A large number of studies, reviewed elsewhere^[14], have evaluated the efficacy as screening tools of the detection of several molecular events, such as kirsten rat sarcoma viral oncogene homolog (KRAS), adenomatosis polyposis coli, TP53 and mismatch repair genes (*MMR*) mutations, DNA methylation and miRNA signatures in body fluids, mainly stool but also plasma and serum. In summary, the reported sensitivity and specificity rates vary widely, owing to the small quantity of hyperfragmented DNA, often of low quality, retrieved from body fluids (especially stool) and the different

techniques and biomarkers tested. Regarding plasma cfDNA, preliminary results are promising. In a high risk population with positive fecal occult blood test that subsequently underwent colonoscopy, Perrone *et al.*^[15] demonstrated that the quantification of cfDNA by qPCR was predictive for CRC but not premalignant lesions (area under curve, 0.709; 95%CI: 0.508-0.909). This important finding clearly illustrates that cfDNA can have a complementary role to traditional screening modalities for CRC. In the same study, the detection rate of KRAS mutations in the plasma by mutant-enriched PCR was low at 3%, compared to tissue-based analysis (45%). However, KRAS mutations can also be detected in patients with inflammatory bowel disease, complicating the interpretation of its significance^[16]. Significant barriers to the implementation of cfDNA-based strategies include the relatively low sensitivity especially for premalignant lesions and the probability of over-diagnosis.

MONITORING MINIMAL RESIDUAL DISEASE

Following curative surgery for localized CRC, approximately 50% of stage III patients according to the American Joint Committee on Cancer (node-positive disease) and 20% of stage II patients (T3N0 and T4N0) are expected to experience disease relapse without adjuvant chemotherapy, possibly due to the presence of occult micrometastases. Therefore, identifying these high risk patients could optimize adjuvant treatment strategies. The benefit derived from chemotherapy is well established for stage III patients, with the results of large, well-conducted randomized trials demonstrating a benefit for overall survival (OS) for patients treated with the combination of a fluoropyrimidine (5-fluorouracil or capecitabine) and oxaliplatin (FOLFOX and XELOX, respectively)^[17,18]. The management of stage II patients is much more controversial, as clinical trials and meta-analyses indicate that the absolute risk reduction is marginal and sometimes non-significant^[19-21]. Clinical practice guidelines recommend the use of clinic-pathological risk factors for the selection of eligible patients for adjuvant chemotherapy, such as T4 stage, perforation, obstruction, number of lymph nodes resected, presence of lymphovascular or perineural invasion, poor grade, preoperative CEA levels and positive or indeterminate margins^[22-24]. Additionally, molecular markers such as the presence of microsatellite instability^[25] and gene signatures^[26] have also been shown to have prognostic and/or predictive value. These data clearly underscore that robust decision making tools are needed for the selection of patients that will enjoy improved outcomes from additional chemotherapy, thus sparing from its toxic effects those not likely to benefit. Consequently, cfDNA has been evaluated in this setting. Reinert *et al.*^[27] recently showed that using droplet digital PCR-based (ddPCR)

personalized assays, the quantification of plasma cfDNA had almost 100% sensitivity and specificity for the prediction of relapse after surgery, with a mean lead time of 10 mo. Furthermore, the value of cfDNA measurement specifically in stage II CRC patients is being prospectively evaluated, with preliminary results showing that 7.7% of patients who had detectable cfDNA after curative surgery had higher relapse rates, 5/6 patients with detectable and 5/72 of those with undetectable cfDNA^[28]. The selection of the proper mutation markers to be monitored in cfDNA is as yet unresolved. Sato *et al.*^[29] monitored preoperative and postoperative cfDNA levels based on a panel of 50 genes, using ddPCR; only markers with an allele frequency above 0.1% in plasma DNA correlated with the clinical course. Interestingly, cfDNA has also been shown to be useful in the early detection of relapse after metastasectomy of liver metastases, significantly outperforming both CEA and imaging in one study^[30].

PREDICTION OF RESPONSE TO TREATMENT

The demonstration of the efficacy of monoclonal antibodies (moAbs) targeting the epidermal growth factor receptor (EGFR), such as cetuximab and panitumumab, in specific molecular subtypes of mCRC, marked a significant breakthrough towards the delivery of precision medicine. V-Ki-ras2 KRAS has a critical role in EGFR signaling transduction. Activating KRAS mutations at exon 2 are detected in approximately 40%-45% of patients with CRC and have been shown to confer resistance to treatment with cetuximab^[31,32] and panitumumab^[33]. Moreover, less common KRAS mutations at exons 3 and 4 and NRAS mutations at exons 2, 3, 4 identified at a further 17% of patients have been shown to also correlate with resistance to anti-EGFR moAbs^[34]. On the other hand, mutations at the B-Raf proto-oncogene, serine/threonine kinase (BRAF), which is further downstream at the mitogen-activated protein kinase (MAPK) pathway have been shown to have significant prognostic, but not predictive value as a marker of poor response to anti-EGFR antibodies when combined with chemotherapy, although evidence for the latter is not compelling due to the small number of patients and low statistical power of these analyses^[35,36]. To further complicate matters regarding the role of BRAF mutations, several lines of evidence suggest that their presence is a marker of resistance to monotherapy with anti-EGFR moAbs^[37-39].

Availability of adequate tissue is rarely a problem in CRC patients. Additionally, there is a high rate of concordance between the primary tumor and metastases regarding the mutational status of mCRC but, importantly, approximately 10% of patients with KRAS wild type (WT) primary tumors have KRAS mutated metastases and *vice versa*^[40]. Qualitative analysis of cfDNA for the presence of activating mutations is an

emerging method which has been consistently shown to closely correlate with the primary tumor status. For example, Morgan *et al*^[41] utilized a commercial PCR kit and demonstrated that the detection of KRAS mutations in cfDNA is highly concordant with their presence at the primary tumor and they could also be detected in the plasma of a patient with KRAS WT primary. Accordingly, Thierry *et al*^[42] showed in a prospectively evaluated patient cohort that qPCR-based detection of KRAS and BRAF mutations in mCRC patients is exquisitely sensitive and specific when using the primary tumor status as a reference standard, results that have been confirmed by others^[30]. Taken together, these data clearly imply that the detection of predictive molecular events in mCRC patients is an excellent surrogate for their presence at the primary tumor and could be used in cases where archival tumor is not available or when the acquisition of fresh tissue is not feasible.

MONITORING RESPONSE TO THERAPY

The quantitative measurement of a known aberration in the plasma may be used for disease monitoring of mCRC patients while under treatment and data show that cfDNA levels robustly correlate with tumor burden and response to treatment, raising the possibility of its use at the near future as an adjunct to anatomical imaging. Several investigators have established the correlation between tumor burden, cfDNA and levels of specific mutations such as KRAS in circulation^[42-44]. Moreover, high levels of cfDNA were shown to be predictive for diminished disease control rates when mCRC patients were treated with irinotecan and cetuximab in a study by Spindler *et al*^[43]. In a prospective trial of mCRC patients undergoing first-line chemotherapy, a 10-fold or higher reduction in circulating tumor DNA (ctDNA) before cycle 2 correlated well with CT imaging at 8-10 wk while lesser degrees of reduction were associated with a trend for improved progression free survival (PFS)^[45]. Although the quantification of cfDNA levels and their temporal changes seem appealing for clinical use, two issues need to be considered: First of all, benign conditions such as infections may also lead to raised cfDNA levels. Also, the genomic evolution of the tumor could potentially lead to alterations in cfDNA levels regardless of tumor burden. Until more specific and sensitive methods that measure ctDNA are available, it is prudent that cfDNA levels are used in combination with imaging scans for response assessment.

DETECTION OF RESISTANCE

Despite appropriate patient selection according to molecular testing, approximately 10% of treatment naïve patients experience disease progression as best response when receiving first line treatment with a chemotherapy doublet and an anti-EGFR antibody^[46];

importantly, virtually all patients will eventually develop disease progression while receiving such treatment. The resistance mechanisms of mCRC to anti-EGFR moAbs can be broadly categorized in three categories and it should be mentioned that there is significant overlapping between primary and secondary resistance, with a few notable exceptions: (1) events that disrupt the binding of cetuximab or panitumumab at the EGFR. These events may be point mutations, with the best characterized being the S492R mutation which interferes with the binding of cetuximab but not panitumumab^[47], a decrease of EGFR copy number or differential expression of the EGFR ligands epiregulin and amphiregulin^[48]; (2) activation of downstream kinases, effectively bypassing the inhibition of EGFR. The best described events include the KRAS, NRAS and BRAF mutations whose role at the primary resistance was previously described. Although less common, KRAS gene amplification has also been implicated in the development of resistance to cetuximab and panitumumab^[49]; and (3) activation of parallel, bypassing pathways. The most commonly described mechanisms are phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha exon 20 mutations in approximately 10%-15% of patients and phosphatase and tensin homolog (PTEN) mutations in 18%, both leading to activation of the PI3K/AKT/mTOR pathway^[39,50]. However, since these mutations frequently coexist with other resistance mechanisms such as KRAS mutations, it is difficult to establish a potentially direct causative role. Other genomic events that have been implicated in the development of secondary resistance are HER2 amplification^[51], IGF-1R activation^[52] and MET amplification^[53].

It is clear that CRC exhibits significant spatial and temporal heterogeneity while under the selective pressure of treatment, which is further complicated by the extensive crosstalk, shared downstream pathways and bypass signaling that is activated during treatment with anti-EGFR moAbs which allows pre-existing resistant clones to emerge. The early recognition of these molecular mechanisms, before disease progression is clinically or radiologically apparent, may offer a better chance at intercepting them, thus improving patient outcomes.

The best studied in cfDNA mechanism of acquired resistance is the emergence of KRAS mutations, which has been shown to occur while under treatment both with cetuximab^[54] and panitumumab^[55]. Notably, in a series of CRC patients receiving treatment it was shown that KRAS mutations developed in 38% of patients previously responding to anti-EGFR moAbs, 96% had newly acquired activation of the MAPK pathway and 70 new somatic mutations were described in total^[56]. Interestingly, in a series of 108 mCRC patients pretreated with a fluoropyrimidine, irinotecan and oxaliplatin, who received irinotecan and cetuximab, Spindler *et al*^[57] demonstrated that the emergence of detectable KRAS mutations in the plasma may precede

radiological progression and that patients with a KRAS mutant primary but no detectable mutations in the plasma could benefit from treatment despite previous exposure to and progression after irinotecan.

Apart from KRAS mutations, other molecular events that emerge under the selective pressure of anti-EGFR treatment and that drive resistance to these agents have been detected in cfDNA, such as EGFR mutations^[58] and MET amplification^[53]. The relative importance of each specific aberration, in light of the frequent co-existence of several mechanisms in a single patient^[59] needs to be elucidated in further studies.

CELL-FREE DNA AS A PROGNOSTIC MARKER

The prediction of survival in mCRC patients relies heavily on clinic-pathologic characteristics, such as hepatic tumor burden, node positive primary, CEA levels, microsatellite stability status, BRAF mutation status, resectability of metastatic disease and tumor grade^[60]. Objective and reproducible biomarkers are needed in order to optimize risk stratification and guide treatment decisions. The prognostic capacity of quantitative and qualitative cfDNA characteristics have been investigated in several studies. cfDNA levels were indeed shown to correlate with survival in mCRC^[56], including at the second line setting where increased cfDNA levels predicted shorter PFS and OS compared to lower levels, with a hazard ratio (HR) of 1.4 (95%CI: 1.1-1.7, $P = 0.03$) for PFS and 1.6 (95%CI: 1.3-2.0, $P < 0.0001$) for OS for each quartile of increase^[61]. Qualitative characteristics, such as methylated cfDNA levels have also been shown to independently predict OS in mCRC^[62]. In the largest published prospective mCRC patient cohort ($n = 97$), El Messaoudi *et al.*^[63] used qPCR and showed that cfDNA levels, higher specific mutation loads and the level of cfDNA fragmentation are strong prognostic factors; cfDNA levels were independent prognostic factors for the entire patient cohort and the level of fragmentation only for the KRAS/BRAF mutated subset. Specifically, a difference in OS of 10 mo was reported between the groups of high vs low cfDNA levels (18.07 mo vs 28.5 mo respectively, $P = 0.0087$)^[63]. Finally, Spindler *et al.*^[64] compared the prognostic value of the detection of KRAS mutations in the plasma compared to the primary tumor with the use of qPCR, with the former being an independent predictor for OS (HR = 2.98, 95%CI: 1.53-5.80, $P = 0.001$) and PFS (HR = 2.84, 95%CI: 1.46-5.53, $P = 0.002$), whereas the latter had no correlation with outcomes, which underscores the value of cfDNA qualitative testing.

DISCUSSION

There is enormous interest for the discovery, development, clinical evaluation and standardization of

circulating biomarkers in oncology, since liquid biopsy offers the possibility of real-time monitoring of the disease trajectory. Due to the absence of large scale comparisons of the relative efficacy of cfDNA and CTCs and the lack of standardization of clinical assays, no clear recommendations can be made on which is the superior biomarker and published literature suggests that they may be complementary^[65,66]. For example, CTCs have been shown to be useful in determining the level of heterogeneity of the disease, with significant differences compared to the primary tumor demonstrated in single cell whole genome analysis. Moreover, the phenotypic and genotypic characterization of CTCs could be a powerful tool aiding treatment planning and determining the likelihood of drug resistance^[67]. However, the large number of CTC capture and enrichment techniques, which are based on antibody selection or on the physical properties of CTCs and the often times low quantity and quality of DNA extracted from these rare cells represent significant drawbacks^[68].

Contrary, cfDNA exhibits several important advantages: Its extraction is less cumbersome compared to CTCs, but the preanalytical process is equally non-standardized. Also, multiple studies across various neoplasms have shown that its qualitative and quantitative measurement is representative of the overall tumor burden and of the mutational load of the disease and its heterogeneity. Therefore, its future potential role as a complement in asymptomatic screening and disease staging, as a tool for disease monitoring even without the use of anatomic imaging, as a prognostic marker and for the long term follow-up of disease free patients with CRC is exciting^[69]. Nevertheless, the aforementioned lack of standardization is a significant obstacle for the commercialization and widespread adoption of cfDNA in oncology. Moreover, cfDNA, in contrast with CTCs, does not provide information regarding RNA and protein profiling of the tumor. However, sensitivity may be improved since cfDNA has been detected both in patients with and without detectable CTCs, but CTCs were not detected in the absence of cfDNA^[56]. These observations clearly hint towards a combinatory approach to circulating biomarkers.

It is conceivable that in the near future serial cfDNA testing will become a component of routine clinical practice regarding the management of CRC. Its already established prognostic power may be integrated in novel staging schemes and its predictive capacity may influence treatment decisions. Importantly, its use may spare patients from unnecessary toxicity caused by ineffective treatments. It is imperative, however, that cost-effectiveness analyses be conducted since these costly techniques require specific equipment and are often labor-intensive.

CONCLUSION

cfDNA has already shown promise in CRC in multiple

clinical settings. Its prospective evaluation in randomized trials is of paramount importance before it can be considered as standard practice and cost-effectiveness analyses are also needed. Until then, translational studies continue to underscore its clinical utility and offer insights on the continuously evolving understanding of the disease complexity.

Abstract

AIM

To elaborate about this peculiar variant from a tertiary cancer center from India.

METHODS

It's a retrospective study (2011-2014) of all patients diagnosed with signet ring colo-rectal cancer (SRCC). Various clinico-pathological variables were studied.

RESULTS

One hundred and seventy consecutive patients with SRCC were diagnosed (11.4% of all colorectal cancers). Median Age of the cohort was 41 years. Most common location was recto-sigmoid area (54.7%). Majority patients presented in stage III and IV (91.2%). Most of the stage IV patients had isolated peritoneal metastases (86.5%). Colonic tumors had higher incidence of peritoneal metastases (91.8% vs 83.3%) as well as isolated peritoneal recurrences (37.5% vs 16.7%) than rectal primaries. Thirty-seven point five percent of patients recurred after curative surgery. Amongst them 63.63% patients had isolated peritoneal recurrences. Circumferential resection margin (CRM) was involved in 17.9% patients. Median relapse free survival (RFS) and overall

survival (OS) of the cohort were 14.9 and 18.13 mo respectively. CRM involvement, colonic primary were associated with poorer RFS and OS.

CONCLUSION

SRCC has predilection for peritoneal dissemination. More aggressive and/or extended chemotherapy schedules as well as prophylactic hyperthermic intra-peritoneal chemotherapy at the time of primary surgery may be attempted in these patients.

Key words: Colorectal cancer; Signet ring cell carcinoma; Peritoneal metastases; Hyperthermic intra-peritoneal chemotherapy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The incidence of Signet Ring Colo-Rectal Cancer appears to be higher in Indian subcontinent than the world literature. It has predilection for peritoneal lining. It affects younger age group. Majority cases present in stage III and IV. Recto-sigmoid region is affected commonly. The most common metastatic site and site of recurrence is peritoneal cavity. Probably it should be treated with a different protocol than the conventional adenocarcinoma with focus on aggressive peritoneal cytoreductions and hyperthermic intra-operative intraperitoneal chemotherapy (HIPEC). Further research is needed to evaluate molecular biology of this variant and utility of prophylactic HIPEC during curative surgery.

Tamhankar AS, Ingle P, Engineer R, Bal M, Ostwal V, Saklani A. Signet ring colorectal carcinoma: Do we need to improve the treatment algorithm? *World J Gastrointest Oncol* 2016; 8(12): 819-825 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i12/819.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i12.819>

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers worldwide^[1]. There are three subtypes described in the literature based on the amount and location of mucin in the tumor. These are conventional adenocarcinoma (AC), mucinous carcinoma (MC) and signet ring cell carcinoma (SRCC)^[2,3]. SRCC constitutes 1% of all colorectal carcinomas^[4-9]. It is an aggressive variant which affects younger population and has poorer prognosis^[5]. The literature explaining the biology as well as the optimum treatment algorithm of this particular variant is scarce due to its low incidence. So we look into the incidence, demographics, clinico-radiological presentation and outcome of treatment of this peculiar variant from a tertiary cancer centre from India (Tata Memorial Centre, Mumbai).

MATERIALS AND METHODS

All patients diagnosed with colorectal carcinoma from 1st January 2011 to 31st December 2013, registered under the Department of Gastro-intestinal Oncology services, Tata Memorial Centre, were included. The data was collected retrospectively from Electronic database as well as case files from Department of Surgical Oncology. The histopathology specimens of all these patients were reviewed at Department of Surgical pathology, Tata Memorial Centre. Signet ring cell colorectal cancers were defined as per WHO criteria (AC with more than 50% of signet-ring cells). Patients were staged as per AJCC classification (7th edition). Response to neoadjuvant chemoradiotherapy (NACTRT) was assessed as per RECIST criteria. The decision about the same was taken in the multidisciplinary meeting held for every patient. Pathological complete response was defined as absence of viable tumor cells in the primary, the lymph nodes and peri-rectal soft tissue. Circumferential resection margin (CRM) positivity was defined as presence of viable tumor cells at or within 1 mm of it. Follow up data was obtained from electronic medical records and/or telephonic questionnaire. Recurrences were based on biopsy or strong clinico-radiological evidence. Peritoneal metastases or recurrences constituted peritoneal deposits, malignant ascites, omental deposits and ovarian deposits. Relapse free survival (RFS) was assessed from the date of cancer directed surgery to date of recurrence. Overall survival (OS) was measured from the date of diagnosis of malignancy to date of death. SPSS-21 (IBM corporation) was used for the statistical analysis. Categorical variables were compared with χ^2 test. Survival functions were analyzed with Kaplan Meir curves and compared with log rank test.

RESULTS

From 1st January 2011-31st December 2013, 1487 patients with colorectal cancer got registered under the department of Gastrointestinal Services Tata Memorial Centre. Amongst them, signet ring cell carcinoma was diagnosed in 170 consecutive patients (11.4%). Follow up of 18 of 170 patients (10.58%) was inadequate (< 1 mo) (Table 1). Median Age of the cohort was 41 years. Males were affected nearly twice more than females (M: F = 1.8:1). Most tumors were located in the rectum and sigmoid colon (Rectum: 41.2% and Sigmoid: 13.5%). Majority patients presented in stage III (51.8%) and stage IV (39.4%). Most of the stage IV patients had isolated peritoneal metastases (58/67, 86.5%) (Table 2). Curative surgery was feasible only in 51.76% (88/170) patients. Thirty-seven point five percent (33/88) patients recurred after curative surgery. Twenty-one thirty-thirds (63.63%) patients had isolated peritoneal recurrences (Table 3). Most patients had high nodal burden, pN1 being 23.2% (22/95), pN2 being 57.9% (55/95). Amongst node positive patients, 66.3% (53/77)

Table 1 Demographic parameters

Parameter	Statistics
Total No.	170
Sex ratio	
Male	110
Female	60
Age (median), yr	41
Stage, <i>n</i> (%)	
II	6 (3.5)
III	88 (51.8)
IV	67 (39.4)
Not available	9 (5.3)
Location, <i>n</i> (%)	
Right colon	49 (28.8)
Transverse colon	13 (7.6)
Descending colon	11 (6.5)
Sigmoid colon	23 (13.5)
Rectum	70 (41.2)
Appendix	1 (0.6)
Not available	3 (1.8)

Table 2 Pattern of metastases in stage IV patients

Site of metastases	<i>n</i> (%)
Liver	1 (1.5)
Lung	1 (1.5)
Isolated peritoneal	58 (86.5)
Retropitoneal lymphnodes	2 (3.1)
Others	5 (7.4)

had perinodal extension. The rate of lymph node metastases and lympho-vascular invasion increased progressively with increasing pathological T stage.

Median RFS and OS of the cohort were 14.9 mo and 18.13 mo respectively. OS of peritoneal and non-peritoneal metastases were equivalent (16 mo vs 13 mo, $P = 0.729$) (Table 4).

Forty-eight rectal cancers were operated. Data for patients undergoing NACTRT was available for 37 cases only. Pathological complete response was seen in 21.6% (8/37) patients. CRM was involved in 17.9% (7/39) patients (data on CRM was not available for 9 cases). CRM involvement was associated with poorer RFS (15 mo vs 37.2 mo, $P = 0.060$) and OS (19.9 mo vs 41.5 mo, $P = 0.018$) as compared to patients with uninvolved CRM (Tables 4 and 5).

The location of primary had a significant impact on the clinico-pathological outcome of the patient. As compared to rectal primaries, colonic tumors had higher incidence of peritoneal metastases (83.3% vs 91.8%, $P = 0.074$) as well as isolated peritoneal recurrences (16.7% vs 37.5%, $P = 0.062$). Colonic primaries were associated with poorer OS than rectal tumors after curative resection (32.298 mo vs 40.089 mo, $P = 0.058$) and RFS (24.74 mo vs 34.02 mo, $P = 0.048$) (Table 6).

DISCUSSION

CRC is one of the most common cancers worldwide. Worldwide, it leads to 10% and 9.2% of cancers in

males and females respectively. It is a cause of 8% and 9% of cancer related deaths in males and females respectively^[1]. Several histological subtypes have been reported^[2,3]. It has two different subgroups apart from classical AC. They are classified based on varying amounts of signet-ring cell and/or mucinous component. Signet-ring cell carcinoma (SRCC) is characterized by intra-cytoplasmic mucin which displaces the nucleus aside. MC is characterized by extracellular mucin pools. SRCC or MC (defined as carcinoma with more than 50% of signet-ring cells or mucinous component, respectively as per WHO classification) constitutes approximately 1% or 5%-15% of CRC cases, respectively in the world literature^[4-9]. As compared to the world literature, the incidence of SRCC is much higher in our study (11.4% vs 1%). The median age of the cohort in our study was also lower than world literature (41 years vs 50-55 years)^[5,6,10,11]. This could represent either a referral bias being a tertiary cancer centre in India or definite distinct disease biology in the Indian population. Further studies regarding the demographic profile of this particular variant in Indian population are under consideration currently.

The literature is divided about the most common site of colorectal cancer in young population with some indicating proximal colon^[12] and others suggesting it to be recto-sigmoid region^[13,14]. In our study, rectum and sigmoid colon region was most commonly affected. This may be related to preferential referral of locally advanced rectal cases to our institute. One of the studies has shown that colorectal cancers affecting younger age group (< 40 years) have significantly higher incidence of signet ring cell cancer. Such tumors also affect rectosigmoid area more commonly than rest of the colon in

Table 5 Factors affecting relapse free survival in operated patients

young patients^[15].

SRCC has been associated with peculiar genomic changes such as high-degree microsatellite instability (MSI-high) (up to 40%), high-frequency of CpG island methylator phenotype, higher methylation level of long interspersed nucleotide element-1 and frequent BRAF mutation and low COX-2 expression^[8,16-20]. Due to high frequency of MSI-H mutations^[21] and associated poor prognosis, tumors with signet ring histo-morphology are recommended to be screened for MSI-H mutations as per revised Bethesda guidelines^[22]. The serrated adenoma-carcinoma pathway has been proposed for development of these tumors. Terada *et al*^[23] found that epithelial membrane antigen was downregulated in colorectal SRCC. Kim *et al*^[24] showed that focal loss of epithelial cell adhesion molecule was associated with development of SRCC in colonocytes. These molecular changes may be related to preferential peritoneal spread of this subtype. Currently the studies are under consideration at our institute to assess genomic changes related to this specific phenotype which may be the cause of higher incidence of signet ring colorectal cancer in Indian population than the world literature.

Our study revealed that, though SRCC has an aggressive biology in general, it seems to respond well to NACTRT with pathological complete response rate of 21%. Literature assessing response of SRCC to NACTRT is scarce due to low incidence worldwide. Jayanand *et al*^[25] showed that these tumors respond well to RT with high pathological complete response rates. It may be related to their aggressive nature and higher mitotic index. So potentially NACTRT should be included in the treatment protocol of rectal SRCC for improved outcomes.

Patients with SRCC are more likely to present in advanced stages (Stage III/IV) than AC. SRCC patients more often present with metastatic disease and are more likely to develop peritoneal metastases. This may be related to their peculiar molecular origin which is yet to be proven. It is also shown that SRCC metastasizes to the lymph nodes, whereas AC metastasizes primarily to the liver^[6,9,11]. Our study also showed similar findings.

SRCC has been associated with a poor prognosis compared with AC^[5,6,10,11]. Studies have shown that peritoneal metastases of SRCC are associated with a poorer prognosis, and survival is even worse if other

Table 6 Impact of location on outcome

Parameter	Colon	Rectum	Significance
Recurrence after curative resection			
Peritoneal, <i>n</i> (%)	15/40 (37.5)	8/48 (16.7)	0.062

OS after curative surgery (mo)	32.298	40.089	0.058

RFS: Relapse free survival; OS: Overall survival.

organs are also affected^[26]. But in our study, patients with peritoneal metastases had similar OS as compared to those with non-peritoneal metastases. This may be due to small sample size of the study. Often, these metastases cannot be treated with curative intent. As of now, curative surgery is an option mainly limited to liver and lung metastases, which are the most common metastatic sites in AC patients. Systemic chemotherapy for peritoneal metastases may not yield the same results compared with hematogenous metastases due to blood-peritoneal barrier. As a result, outcome is poor in advanced SRCC cases^[27].

The incidence of synchronous and metachronous peritoneal metastases in colorectal carcinoma (AC) seems to be in the range of 4%-5% (much lower than with SRCC)^[26,28]. Studies have revealed that peritoneal carcinomatosis among patients with metastatic colorectal cancer is associated with a 30% reduction in overall survival (10.7 mo vs 17.6 mo)^[29]. The overall survival of these patients is found to be less than 6 mo despite the use of 5FU and leucovorin based chemotherapy^[30,31]. But palliative surgery and systemic chemotherapy, together have been shown to improve survival upto 12 mo in patients with isolated peritoneal metastases^[29,32].

Hyperthermic intra-operative intra-peritoneal chemotherapy (HIPEC) has shown promising results for peritoneal metastases of colorectal origin^[29]. Verwaal *et al*^[29] reported outcome of 1427 patients with peritoneal metastases of colorectal origin treated with cytoreductive surgery (CRS) and HIPEC. Peri-operative morbidity and mortality were 34% and 3% respectively. Median hospital stay was 16 d. Median PFS was 15 mo and OS was 33 mo. Three- and five-year survival rates were 46% and 31% respectively. So authors concluded that CRS and HIPEC seems to be safe and beneficial in peritoneal metastases of colorectal origin^[33]. But literature assessing benefit of HIPEC for SRCC is scarce and controversial with studies denying^[34,35] and implying^[36] benefit of HIPEC in this subgroup. But these reports are retrospective and are fraught with small sample sizes.

Recently, Hao *et al*^[37] have proposed a study assessing the benefit of monoclonal antibody blocking EpCAM in CRC. This may be relevant in the further management

of SRCC as EpCAM also has altered expression in this subtype.

Klaver *et al.*^[38] have proposed a randomized controlled trial (COLOPEC) for assessing benefit of prophylactic HIPEC in patients at high risk of peritoneal carcinomatosis. They have included patients (non-metastatic) with T4 disease or on table tumor site perforation for prophylactic HIPEC followed by routine adjuvant chemotherapy. It has been postulated in assumption that very few patients with peritoneal carcinomatosis become eligible for CRS and HIPEC; as a result they have poor prognosis. So if a prophylactic HIPEC reduces the occurrence of peritoneal metastases in future, it may result in benefit in OS. The investigators have not considered signet ring cell pathology as inclusion criteria for the study; probably because of low incidence (1%-2%) of it in the western literature. A similar study may be considered in Indian patients with signet ring cell carcinoma to assess benefit of prophylactic HIPEC at the time of primary surgery as it has a peculiar tendency for isolated peritoneal recurrences and the incidence of this particular histopathological subtype seems to be higher in them (11.4%) as suggested by present study.

It is unclear whether different histological subtypes should influence treatment decisions, since it is often not addressed in clinical trials. In the literature, studies concerning outcome after adjuvant or palliative chemotherapy for SRCC are rare. However, due to the aggressive behavior and high incidence of SRCC in young patients, it is imperative to develop understanding of potential adjuvant treatment options as it is likely to alter quality of life and have significant socio-economic impact. Colonic SRCC are more likely to have peritoneal dissemination and poorer survival than rectal SRCC. So more aggressive treatment options, like HIPEC may be useful in these patients at the time of primary surgery or after peritoneal limited recurrence in order to improve survival and quality of life. This can only be addressed in a randomized control trial setting. Due to high nodal disease burden and high incidence of failure after curative surgery (up to 40%), more extended and/or aggressive adjuvant chemotherapy options should also be explored in this subset of population which is younger and is likely to tolerate the aggressive treatment better.

Signet ring colorectal cancer has poor prognosis. It has a higher incidence in Indian subcontinent. It affects young patients and has predilection for peritoneal dissemination.

Isolated peritoneal metastases as well as isolated peritoneal recurrences are very frequent in these patients. SRCC responds well to radiation. So whenever indicated, neoadjuvant radiation should be included in the treatment protocol for rectal SRCC.

More aggressive and/or extended chemotherapy schedules as well as prophylactic HIPEC at the time of primary surgery, especially for colonic tumors, should be explored in a trial setting in order to improve dismal

survival in these patients.

COMMENTS

Background

Signet ring colorectal cancer (SRCC) is a subtype of colorectal adenocarcinoma. It tends to affect younger age group. Most of the patients present in stage III or IV. The most common site affected is rectosigmoid region. It has a peculiar affection for peritoneal lining. Most of the metastases and recurrences happen exclusively in the peritoneal cavity. Visceral metastases are rare. Average prognosis of these patients is poor. There is no effective adjuvant or palliative treatment for this entity. Early studies in the field of cytoreduction and hyperthermic intra-operative intraperitoneal chemotherapy (HIPEC) have shown promising results and prolongation of survival in peritoneal carcinomatosis of colorectal cancer. The trials are underway to test the impact of prophylactic HIPEC during primary surgery for cT4N1/2 diseases. Since SRCC has a different natural course than the conventional adenocarcinoma of colon, it may be worthwhile to evaluate the possible role of extended chemotherapy or prophylactic HIPEC at the time of curative surgery for SRCC.

Research frontiers

Currently trials are underway (COLOPEC and Prophylchip) to assess efficacy of prophylactic HIPEC in high risk colorectal cancers to prevent occurrence of peritoneal metastases and prolongation of survival. Though aggressive, SRCC has shown its peculiar nature to remain confined to peritoneal cavity in majority patients. This makes it a potential target for peritoneum directed therapies (Cytoreduction and HIPEC). Also monoclonal antibodies blocking EpCAM are being evaluated in CRC. This may be relevant in the further management of SRCC as EpCAM also has altered expression in this subtype.

Innovations and breakthroughs

Cytoreduction and HIPEC has shown survival benefit in peritoneal carcinomatosis of colorectal origin in a large randomized trial by Verwaal *et al* SRCC has not been evaluated widely in the western literature, probably due to lower incidence. But in Indian subcontinent, the incidence of this disease entity appears to be higher than rest of the world. It also affects younger population; as a result has significant bearing on the socioeconomic outcome of entire family. There is a strong need to develop a modified treatment protocol for this disease than conventional adenocarcinoma as the disease biology appears to be different and standard chemotherapy doesn't act well on the peritoneal disease. Certain molecular abnormalities are also noted in SRCC such as high microsatellite instability, EpCAM mutations, high-frequency of CpG island methylator phenotype, higher methylation level of long interspersed nucleotide element-1 and frequent *BRAF* mutation and low COX-2 expression. Further research needs to be carried out to understand the biology of this disease entity well which might give us an insight into potential treatment options for the same.

Applications

To summarize, SRCC seems to be a suitable target for peritoneum directed therapies which include aggressive cytoreduction and HIPEC. Extended/modified chemotherapy protocols may improve survival. Further understanding of molecular biology of this disease may open new methods for its treatment.

Peer-review

It is a retrospective study of an uncommon subtype of colorectal carcinoma. The author statized some information of this cancer including the age, location, stages, metastasis, recurrence and survival.

Abstract

AIM

To review the evidence on the association between specific colon adenoma features and the risk of future colonic neoplasia [adenomas and colorectal cancer (CRC)].

METHODS

We performed a literature search using the National Library of Medicine through PubMed from 1/1/2003 to 5/30/2015. Specific Medical Subject Headings terms (colon, colon polyps, adenomatous polyps, epidemiology, natural history, growth, cancer screening, colonoscopy, CRC) were used in conjunction with subject headings/key words (surveillance, adenoma surveillance, polypectomy surveillance, and serrated adenoma). We defined non-advanced adenomas as 1-2 adenomas each < 10 mm in size and advanced adenomas as any adenoma ≥ 10 mm size or with > 25% villous histology or high-grade dysplasia. A combined endpoint of advanced neoplasia included advanced adenomas and invasive CRC.

RESULTS

Our search strategy identified 592 candidate articles

of which 8 met inclusion criteria and were relevant for assessment of histology (low grade *vs* high grade dysplasia, villous features) and adenoma size. Six of these studies met the accepted quality indicator threshold for overall adenoma detection rate > 25% among study patients. We found 254 articles of which 7 met inclusion criteria for the evaluation of multiple adenomas. Lastly, our search revealed 222 candidate articles of which 6 met inclusion criteria for evaluation of serrated polyps. Our review found that villous features, high grade dysplasia, larger adenoma size, and having ≥ 3 adenomas at baseline are associated with an increased risk of future colonic neoplasia in some but not all studies. Serrated polyps in the proximal colon are associated with an increased risk of future colonic neoplasia, comparable to having a baseline advanced adenoma.

CONCLUSION

Data on adenoma features and risk of future adenomas and CRC are compelling yet modest in absolute effect size. Future research should refine this risk stratification.

Key words: Colon adenoma; Colorectal cancer screening; Surveillance; Colonoscopy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The data on adenoma size, adenoma multiplicity and serrated polyps in terms of risk for future adenomas and colorectal cancer are compelling, however, the absolute effect size is relatively modest. Current guideline recommendations to perform colonoscopy surveillance at 3-5 years after baseline adenomas and serrated polyps appear appropriately tailored to the risk of future neoplasia.

Colon adenoma features and their impact on risk of future advanced adenomas and colorectal cancer. *World J Gastrointest Oncol* 2016; 8(12): 826-834 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i12/826.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i12.826>

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer death among men and women in the United States^[1]. The lifetime probability of developing CRC is approximately 5%, with 90 percent of cases occurring after age 50. In 2016, an estimated 134500 people will be diagnosed with CRC and 49200 will die of the disease^[1].

The vast majority of CRCs arise from a histologically-specific type of colon polyp, the adenoma, which forms as a result of sporadic mutation in the adenomatous polyposis coli pathway or DNA mismatch repair and by definition contains low-grade dysplasia. Over many

years, a minority of adenomas may grow in size and progress from low-grade dysplasia to high-grade dysplasia, to carcinoma-*in-situ* to invasive carcinoma. More recently, serrated adenomas (named for the "sawtooth" pattern in the crypts) have been identified as accounting for approximately 20%-30% of CRCs. In this review, we will use the term "adenoma" to describe adenomatous and serrated colon polyps and "serrated polyps" to specify polyps with serrated histology.

Colonoscopy is the most widely used modality for CRC screening^[2,3]. Advantages of colonoscopy include the ability of endoscopists both to identify and remove adenomas, which decreases the risk of subsequent CRC^[4]. By definition, "screening colonoscopy" occurs in patients without a history of adenomas and "surveillance colonoscopy" occurs at set intervals (usually 3-5 years) in patients with a history of adenomas to survey for new adenomas^[5]. It is important to understand the existing evidence upon which surveillance colonoscopy recommendations are made to help inform shared decision making with patients who have co-morbid conditions or limited life expectancy^[6]. This review will focus on the association between specific adenoma features and future colonic neoplasia.

MATERIALS AND METHODS

We searched the National Library of Medicine through PubMed for articles from 1/1/2003 to 5/30/2015. We did not search prior to 2003 because of technological advances in colonoscopy optics in 2002, which dramatically improved the diagnostic accuracy of colonoscopy; data prior to 2003 were not considered relevant to the current risk estimates of CRC after colonoscopy. We used the following filters: English language, human, age > 18, clinical trial, multicenter, prospective observational, meta-analysis. Specific MESH terms were used: Colon, colon polyps, adenomatous polyps, epidemiology, natural history, growth, cancer screening, colonoscopy, colorectal cancer. The MESH terms were used in conjunction with subject headings/key words: Surveillance, adenoma surveillance, polypectomy surveillance, and serrated adenoma. We excluded reviews, guidelines, editorials, case-control, cross-sectional and case series or reports.

We excluded studies of patients with inflammatory bowel disease, personal history of CRC, or family history of genetic CRC syndromes. We reviewed all abstracts for relevance. Full articles of the relevant abstracts were then reviewed with the quality of evidence graded by all three authors using the American Heart Association Evidence-Based Scoring System for Level of Evidence as follows: A: Data derived from multiple randomized clinical trials (RCTs); B: Data derived from a single randomized trial or nonrandomized studies; C: Consensus opinion of experts. The bibliographies of all included articles were also evaluated for additional articles by a single author [histology and size (AHC), multiple adenomas and serrated polyps (HKR)] then

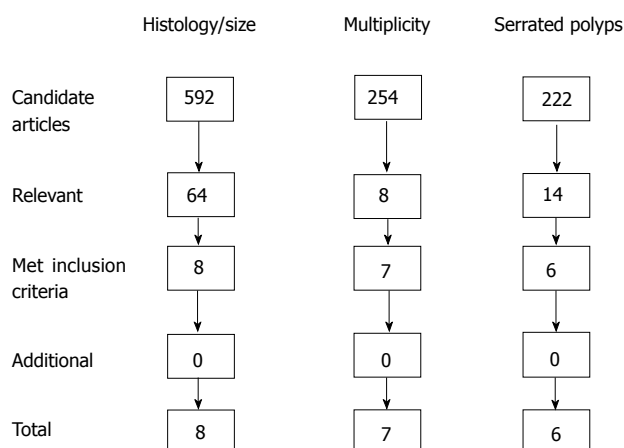

Figure 1 Results of the literature search. Literature search results evaluating the impact of histology and size of adenomas, number of adenomas, and serrated polyps on the risk of future advanced adenomas and colorectal cancer.

reviewed by all three authors for consensus.

We defined non-advanced adenomas as 1-2 adenomas each less than 10 mm in size^[5]. We defined advanced adenomas as any adenoma ≥ 10 mm size or with $> 25\%$ villous histology or high-grade dysplasia^[5]. A combined endpoint of advanced neoplasia included advanced adenomas and invasive CRC.

RESULTS

Histology (low grade vs high grade dysplasia, villous features)

Our search strategy identified 592 candidate articles (Figure 1), of which 64 were relevant. We excluded 56 based on study design or absence of relevant primary outcome or predictors, leaving 8 studies (Table 1). Six of these studies met the accepted quality indicator threshold for overall adenoma detection rate (ADR) $> 25\%$ among study patients^[7], including one study that explicitly described that ADR was $> 25\%$ for each individual endoscopist in study^[8]. ADR was only 22% in the study by Bonithon-Kopp *et al.*^[9] and the meta-analysis by Saini *et al.*^[10] did not present information on ADR.

A small to moderate association between adenoma histology and risk of future advanced adenomas and CRC with variable significance was found among the 8 studies. Four studies^[11-14], including a pooling project of 8 prospective RCTs (evidence level A), found that villous histology was a significant risk factor for future advanced neoplasia (adjusted OR = 1.3; 95%CI: 1.1-1.5)^[14]. Of note, the relative risk (RR) in Lieberman's study (6.1; 95%CI: 2.5-14.7) is higher compared to the other studies because the comparator was subjects without any neoplasia, in contrast to subjects with adenomas without villous histology used in the other studies. In addition, Lieberman studied a Veteran's Affairs (VA) population who are known to have higher rate of baseline adenomas compared to non-VA patients^[12]. A

prospective cohort study of 1086 patients with a median of 10.5 years of follow-up found that villous histology within an adenoma increased the relative risk of any future adenoma (1.8; 95%CI: 1.2-2.6) (evidence level B)^[15]. A primary RCT^[9], a meta-analysis of 5 studies^[10], and a prospective cohort study^[8] found no association of villous histology with future neoplasia (evidence level B).

Similarly, histological findings of high-grade dysplasia had a small and variable association with risk of advanced neoplasia. The meta-analysis by Saini *et al.*^[10] found an increased RR of 1.8 (95%CI: 1.1-3.2)^[10], whereas the primary RCT^[9], pooling project^[14], and prospective registry study^[13] found no association (evidence level A). A prospective cohort study found that compared to an external control population, patients with high-grade dysplasia at baseline had an elevated SIR for CRC of 2.8 (95%CI: 0.3-10.2) compared to the reference group without high grade dysplasia (SIR 0.52; 95%CI: 0.3-0.95)^[15]. In Lieberman's prospective study of 1193 VA patients, he found a RR of advanced neoplasia of 6.8 (95%CI: 2.6-18.1) compared to those with no neoplasia at baseline^[12].

In summary, villous histology within an adenoma may have a small association with future advanced neoplasia, however this was not seen uniformly across all studies. Compared to having no adenomas at baseline, adenomas with high-grade dysplasia are associated with an increased risk of future advanced neoplasia; however, compared to having adenomas that do not contain high-grade dysplasia, the association with future advanced neoplasia is small and variable depending on the study.

Size

We used the same search strategy for histology to evaluate the impact of adenoma size on risk of future colonic neoplasia, finding the same 8 studies (Table 2)^[8-15]. Larger adenoma size at baseline increased the risk of future advanced neoplasia. In Martinez's pooling project of 8 prospective RCTs, the risk of advanced neoplasia increased for each increase in size category (evidence level A). When adenomas < 5 mm were considered the reference group, those with adenomas 10-19 mm and adenomas ≥ 20 mm had a RR of 2.3 (95%CI: 1.8-2.8) and 3.0 (95%CI: 2.2-4.0), respectively^[14]. Similarly, four other prospective studies found that adenomas ≥ 10 mm imparted an increased RR of future advanced neoplasia ranging from 1.7 (95%CI: 1.2-2.3) to 3.0 (95%CI: 1.8-5.1) and 6.4 (95%CI: 2.7-14.9) (level of evidence B)^[8,12,13]. On the other hand, Saini's meta-analysis of 5 studies and a primary RCT, the European Fiber-Calcium Intervention trial (in which 552 patients with resected adenomas randomized to calcium and soluble fiber underwent surveillance colonoscopy at 3 years) failed to show any association between adenoma size and future advanced neoplasia (evidence level B)^[9,10]. A prospective study by Bertario of 1086 patients did not show an association between polyp size ≥ 10 mm and SIR of advanced

neoplasia (evidence level B)^[15].

In summary, adenoma size ≥ 10 mm appears to be associated with future advanced neoplasia and the magnitude of risk increases for larger adenomas ≥ 20 mm in size.

Multiple adenomas

Our search strategy revealed 254 articles of which 7 met inclusion criteria (Figure 1). Van Heijningen *et al*^[13] noted that among 2990 consecutive colonoscopies in the Netherlands, there was an increased risk of

advanced adenomas on surveillance exams depending on number of adenomas at initial screening colonoscopy (Table 3)^[13]. Using participants with one adenoma as the reference group, those with 2, 3, 4 and ≥ 5 adenomas at baseline colonoscopy had 1.6 (95%CI: 1.1-2.4), 2.1 (95%CI: 1.3-3.4), 2.0 (95%CI: 0.9-4.6) and 3.3 (95%CI: 1.7-6.6) times the relative risk of future advanced adenomas, respectively (evidence level B)^[13]. Lieberman *et al*^[12] evaluated 1193 Veterans undergoing surveillance colonoscopy 5 years after baseline colonoscopy. Compared to those who were neoplasia-free at baseline, patients with 1-2 small adenomas and ≥ 3 adenomas had a RR of advanced adenoma at follow-up of 1.9 (95%CI: 0.83-4.4) and 5.0 (95%CI: 2.1-12.0), respectively, the latter of which was comparable to the risk of having a single advanced adenoma at baseline (evidence level A).

Bonithon-Kopp *et al*^[9] found that in the European Fiber-Calcium Intervention trial, patients with ≥ 3 adenomas had a HR of 5.5 (95%CI: 2.4-12.6) of developing advanced adenomas at three year colonoscopy but only if one of the adenomas was proximal - if all the adenomas were distal, there was no increase in risk of advanced adenomas (0.83; 95%CI: 0.18-3.9) (evidence level A)^[9]. Analysis of 4 year surveillance colonoscopy data from the Polyp Prevention Trial (*n* = 1905) found that compared to having one non-advanced adenoma, individuals with 2 or ≥ 3 adenomas had a RR for advanced neoplasia of 1.38 (95%CI: 0.92-2.1) and 1.84 (95%CI: 1.2-2.8), respectively^[11]. Finally, a meta-analysis of older literature found that those with ≥ 3 adenomas at index colonoscopy were more likely to have recurrent advanced adenomas than were patients with 1 to 2 adenomas (RR = 2.5; 95%CI: 1.1-6.0) (evidence

level B)^[10]. In summary, these data suggest that adenoma number may confer a risk of future neoplasia comparable to adenoma size and as discussed below may be further influenced by the quality of the performance of colonoscopy.

Serrated polyps

Our search revealed 222 candidate articles of which 6 met inclusion criteria (Figure 1). Four were mainly cross-sectional studies, which evaluated the presence of concurrent adenomas and two evaluated the correlation with future neoplasia (Table 4). In a study of 10199 subjects, having a large serrated polyp ≥ 1 cm (LSP) was associated with an increased odds of concurrent advanced neoplasia (adjusted OR = 4.0; 95%CI: 2.8-5.7) and CRC (adjusted OR = 3.3; 95%CI: 2.2-5.0) compared to those who were neoplasia-free (evidence level B)^[16]. Álvarez *et al*^[17] reported that in 5059 patients randomized to undergo screening colonoscopy vs stool test, LSPs were associated with concurrent proximal (OR = 4.2; 95%CI: 1.7-10.2) and distal (OR = 2.6; 95%CI: 1.5-4.6) advanced neoplasia. Several other studies corroborate the relationship between proximal LSPs and concurrent advanced adenomas^[18,19].

With regard to future lesions, a secondary analysis of a large randomized flexible sigmoidoscopy study from Norway that included a median follow-up of 10.9 years provides some insights (evidence level A)^[20]. Having a LSP was associated with an increased risk of future CRC (adjusted OR = 3.3; 95%CI: 1.3-8.6), comparable to having a baseline advanced adenoma. Interestingly, none of the other serrated polyps left *in situ* developed CRC in that tumor, suggesting the serrated polyps might be a marker of field carcinogenesis rather than a precursor lesion^[20]. Schreiner *et al*^[21] found that

patients with proximal non-dysplastic serrated polyps followed for median of 5.5 years had an increased odds for future adenomas of 3.1 (95%CI: 1.6-6.2) compared to those who were polyp free at baseline (evidence level B). Thus, while it is clear that certain serrated polyps can progress to CRC, those that are right sided and/or ≥ 1 cm are associated with future neoplasia and are a marker for concurrent adenomas and need to be considered as equivalent to an adenoma from a surveillance perspective.

DISCUSSION

Our review found that specific histologic features of adenomas (*i.e.*, high grade dysplasia and villous features) are associated with a small risk of future advanced adenomas though data was inconsistent across studies (level B evidence). In particular, villous features did not confer a consistent or significant association, suggesting it may not be an important risk factor for future advanced adenomas. Data was even more inconsistent for adenoma size, although the linear association between size and risk is compelling (level B evidence). Size itself is challenging to determine reliably because of the lack of a standardized method for estimating adenoma size and the inter-observer variability among size estimation endoscopically as well

as differences in estimations between endoscopic and pathology measurements^[22,23]. Use of an open biopsy forceps as a reference standard for measurement during colonoscopy was accurate to the millimeter only 37% of the time^[24]. The variability in estimating size of adenomas is concerning given that a 1 mm difference in size can change surveillance by 2 years. In a prospective study using size on pathology as gold standard, endoscopists mis-sized polyps 63% of the time, leading to inappropriate surveillance intervals 35% of the time^[25]. Relying on pathology reports for size estimates is challenging, given that polyps are often removed piecemeal and can be fragmented during retrieval. Thus, the accuracy of size estimates for determining surveillance intervals should be viewed cautiously.

Having ≥ 3 adenomas at baseline is associated with an increased risk of future colonic neoplasia (level B evidence), particularly if at least one adenoma is located in the proximal colon, although more supporting data is needed. The findings of our study echo those of the seminal prospective randomized National Polyp Study^[26], in which multiple adenomas (≥ 3; OR = 6.9; 95%CI: 2.6-18.3) and large adenomas (OR = 2.2; 95%CI: 0.6-7.8) were associated with future advanced adenomas at surveillance. In that study, however only multiplicity was a significant risk factor ($P < 0.001$). The risk conferred by villous features or high grade dysplasia

at baseline was not included.

Current United States and European guidelines recommend repeat colonoscopy in 3 years for patients with ≥ 3 adenomas or any adenoma ≥ 10 mm size or with high grade dysplasia or villous features compared to 5-10 years for those with 1-2 small adenomas (Table 5)^[5,27]. The British guidelines do not take into account advanced histology and recommend earlier follow-up at 1 year for those with at least 5 small adenomas or 3 adenomas if one is ≥ 10 mm in size^[28]. Current level B evidence demonstrates a higher risk of future colonic neoplasia based on having a large serrated polyp (OR ranging from 3.3-4.2) and supports earlier surveillance at 3 years as recommended by guidelines in this group^[5,28]. The recommendations for surveillance of serrated polyps are identical to adenomas^[5]. While surveillance guidelines may be based primarily on adenoma features and risk of future neoplasia, they may also be influenced by national economics and local culture around population-based screening and surveillance, which can vary by country and continent.

The way in which very small differences in adenoma size and number (e.g., 2 vs 3 adenomas) can affect timing of recommended surveillance (from 3 to 5 years) emphasizes the importance of the quality of the colonoscopy performed. Adenoma detection rate (ADR) is considered the most important quality metric

in the performance of colonoscopy because it is a close surrogate measure for interval CRC rates and can be measured feasibly^[7,29]. Other important quality metrics include cecal intubation rates and bowel preparation quality, both of which impact ADR^[7]. A recent simulation study demonstrated that ADR correlates with a lower lifetime risk of CRC without an increase in cost, thus further underscoring the importance of colonoscopy quality^[30]. As ADR improves overall whether from improved endoscope optics or adjunctive techniques (e.g., narrow band imaging, caps, rings)^[31], the association between baseline colonic neoplasia findings and risk of future neoplasia may need to be reassessed.

Our review has certain limitations. We do not address the impact of other factors besides adenoma features on risk for CRC, which are beyond the scope of this article. However, since CRC involves the interactions of genes and the environment, other factors such as family history, age, smoking, diabetes, and obesity have the potential to impact the risk of recurrent neoplasia. Indeed, the NIH risk score looks at a variety of these factors, although its predictive ability has been modest^[32]. We also did not consider the location (proximal vs distal) of adenomas in this review. Location may impart a differential neoplastic risk, with proximal lesions portending a higher risk for recurrence, and merits further clarification in terms of biological underpinnings and clinical strategies. The duration of follow-up for most of the studies ranged from 2 to 5.5 years, which does not allow for the assessment of long-term outcomes. However, this time frame is in line with current surveillance guideline recommendations and provides an adequate follow-up period for the evaluation of the risk of recurrent neoplasia. Lastly, the existing data do not explicitly compare the risk of future advanced adenomas at surveillance based on having multiple different risk factors simultaneously, likely due to limitations of sample size and loss of power with subgroup comparisons. However, if multiple independent risk factors were identified (e.g., multiplicity and size), then having those simultaneously would increase the individual's overall risk of future advanced adenomas.

Future research should continue to evaluate the risk of CRC based on multiple factors incorporating serial colonoscopy information. A few studies have attempted to predict the risk of future neoplasia based on 2 or more examinations^[11,33]. In addition, other biomarkers of the risk of CRC are needed. Since colorectal carcinogenesis involves both genetic and exogenous risk factors of which approximately half are modifiable (i.e., obesity and smoking)^[34], assessment of risk at the level of the colonic mucosa where the interaction between genetics and environment plays out locally may provide a novel approach. While there are a plethora of candidate biomarkers of field carcinogenesis (e.g., molecular alterations such as methylation, gene expression, microRNA in the normal rectal epithelium), the adenoma is currently the only predictor of risk that is robust enough and practical for use in clinical

practice. Future research should also explore the impact of life expectancy on surveillance colonoscopy to guide clinicians who must weigh the risks and benefits for individual patients.

In conclusion, current United States Multi-Society Task Force on CRC recommendations to perform colonoscopy surveillance at 3-5 years after baseline adenomas and serrated polyps appear appropriately tailored to the risk of future neoplasia. The data on adenoma size, adenoma multiplicity and serrated polyps in terms of risk for future adenomas and CRC are compelling, however, the absolute effect size is relatively modest. Future research should identify methods of stratifying a patient's risk for CRC based on serial colonoscopy exams and could include composite risk scores and biomarkers.

COMMENTS

Background

Patients with adenomas of the colon undergo routine surveillance colonoscopy to survey for new adenomas. It is important to understand the existing evidence upon which surveillance colonoscopy recommendations are made.

Research frontiers

This review focuses on the association between specific adenoma features and the risk of future colonic neoplasia.

Innovations and breakthrough

This comprehensive review of the literature shows that adenoma size, adenoma multiplicity and serrated polyps increase the risk for future adenomas and colorectal cancer (CRC), however, the absolute effect size is relatively modest.

Applications

Current United States Multi-Society Task Force on CRC recommendations to perform colonoscopy surveillance at 3-5 years after baseline adenomas and serrated polyps appear appropriately tailored to the risk of future neoplasia.

Terminology

"Surveillance colonoscopy" refers to colonoscopy performed at set intervals (usually 3-5 years) in patients with a history of adenomas to survey for new adenomas.

Peer-review

This is a well-written comprehensive review of current literature on colon adenoma features and CRC risk. To add value to the manuscript, summarising guidelines round the world to provide the readers a more comprehensive review of suggested evidence and protocols would be proposed.

Abstract

Rhabdomyomatous well-differentiated esophageal liposarcomas are extremely rare. As of August 2016, only one other such case has been reported in the English-language medical literature. Liposarcomas in general are one of the most common soft tissue neoplasms in adults, but the incidence of primary esophageal liposarcomas is exceptionally low. There have been only 42 reported cases of primary liposarcoma of the esophagus worldwide thus far. These malignancies are harbored within giant fibrovascular polyps, which slowly grow within the esophageal lumen causing obstructing symptoms. We hereby present the case of a 68-year-old male patient who came in with a 2-mo history of worsening intermittent dysphagia, persistent cough, and postprandial retrosternal pain. After an esophagogastroduodenoscopy, a computed tomographic scan, and a diagnostic endoscopy, complete endoscopic resection was performed of the 13 cm × 6 cm × 2.6 cm fibrovascular polyp. A literature review was done and results are presented herein.

Core tip: This is only the second case of a rhabdomyomatous well-differentiated esophageal liposarcoma to be reported in the literature. Both cases clinically presented as standard esophageal liposarcomas housed in a giant fibrovascular polyp until histological examination by pathology. Given the rarity of the disease, there are only a few studies outlining its optimal management, nevertheless, diagnosis and treatment of this pathology can be approached by customary means, bearing extremely favorable prognosis.

Esophageal liposarcoma: Well-differentiated rhabdomyomatous type. *World J Gastrointest Oncol* 2016; 8(12): 835-839 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i12/835.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i12.835>

INTRODUCTION

Primary esophageal liposarcomas are rare, with only 42 cases being reported in English-language literature as of August 2016^[1]. Histologically, liposarcomas can be further classified into 4 subtypes based on their degree of differentiation: Dedifferentiated, well-differentiated, myxoid, or pleomorphic^[2]. We present the case of a patient who had an esophageal well-differentiated liposarcoma containing rhabdomyomatous cells, of which, only one other case - to the best of our knowledge - has ever been reported^[3].

CASE REPORT

A 68-year-old Caucasian male presented with a 2-mo history of worsening intermittent dysphagia, persistent cough, and postprandial retrosternal pain. He also complained of persistent dull pain on the left side of his neck, radiating to his left ear, which was not related to meals.

Suspecting gastroesophageal reflux disease, the patient was started on proton pump inhibitor pharmacotherapy. Upon no relief of symptoms, the patient was referred to an otolaryngologist to evaluate the pharynx with a laryngoscopy; no abnormalities were seen, and therefore the patient was referred to a gastroenterologist. An esophagram was first performed, which showed a voluminous intraluminal lesion within the thoracic esophagus, possibly being a neoplastic process such as a leiomyoma (Figure 1). An esophagogastroduodenoscopy was then performed, identifying a polypoid mass, which started at the level of the upper esophageal sphincter with a single stalk and extended all the way down to the esophagogastric junction. The polyp occupied about a third of the esophageal lumen, was heterogeneous in surface appearance, and consistent with a giant fibrovascular polyp; concurrently a small hiatal hernia was also seen. Biopsies from the head of the polyp

Figure 1 Barium esophagram showing an (A) obstructing intraluminal mass in the thoracic esophagus.

exhibited benign squamous mucosa with mild acute and chronic inflammation. A computed tomographic (CT) scan of the chest showed a large mass along the entire course of the esophagus (Figure 2). After an endoscopic ultrasound excluded the presence of major vessels within the main stalk, endoscopic resection was pursued. While using a flexible esophagoscope to visualize the mass, a snare was passed around the distal end of the polyp on retroflexion and then pulled up around the stalk, which was located on the left side of the esophagus just at the level of the upper esophageal sphincter. The proximal stalk was cauterized and divided with the snare, causing the polyp to drop into the distal esophagus. The polyp was then retrieved transorally using the endoscope and the snare to bring the mass to the level of the upper esophageal sphincter, followed by a laryngoscope and a clamp to extract it from the hypopharynx.

Pathology identified the 13.0 cm × 6.0 cm × 2.6 cm specimen as a well-differentiated liposarcoma arising in a giant fibrovascular polyp. Grossly the polyp had tan uniform surface without stigma of hemorrhage or necrosis (Figure 3). Histologically the polyp showed a central core of adipose and fibrovascular tissue surrounded by overlying squamous mucosa (Figure 4). An immunohistochemical stain for MDM-2 supported the diagnosis of liposarcoma (Figure 5). Focal areas of ossification were noted. In addition, there were scattered atypical cells with abundant eosinophilic cytoplasm, positive for desmin and also focally myogenin positive (Figure 6). The rhabdomyomatous differentiation is considered a low grade lesion (Figure 7). The final resection margin was uninvolved by the tumor. Patient recovered uneventfully and was discharged from the hospital on postoperative day 1. On follow up visit at 4 years, patient still has complete resolution of dysphagia, cough, neck and chest pain. He has been eating well and gained 15 pounds to date. Annual endoscopies and CT scans confirm no recurrence thus far.

DISCUSSION

Esophageal liposarcomas reside in giant fibrovascular

Figure 2 Computed tomographic scan of the chest (A) (B) showing a (arrowhead) large mass traversing the length of the esophagus.

Figure 3 A macroscopic view of the resected giant fibrovascular polyp (13 cm × 6 cm × 2.6 cm) with uniform surface and a large single stalk.

Figure 4 Histologically the polyp showed a central core of adipose and fibrovascular tissue surrounded by overlying squamous mucosa. A: Hematoxylin and eosin stain × 40 identifying (arrowhead) striated muscle cells and adipose tissue within the core of the esophageal liposarcoma; B: The giant polyp is characterized by a central core of adipose and fibrovascular tissue surrounded by overlying squamous mucosa.

polyps and are rare, consisting of 0.5% of all esophageal neoplasms^[4]. Of the histologic sub classifications, well-differentiated type are the most common, with a prevalence of approximately 68%; myxoid being 20%; dedifferentiated and pleomorphic at 6% each^[5]. The pathophysiology of esophageal giant fibrovascular polyps is unknown. The only theory with consensus is that an erroneous out-pouching of loose submucosal tissue undergoes traction and peristaltic forces causing it to insidiously grow and elongate into the lumen^[3].

The average size of a giant fibrovascular polyp is approximately 13 cm in length, and 3.5 cm in width^[3,5]. Liposarcomas are believed to originate from primitive mesenchymal cells rather than mature adipocytes^[2]. The average age of onset of symptoms is 58.4 years, ranged from 38 to 73 years^[4,5]. There has been a 72% male predominance of reported cases^[5]. Almost all lesions were polypoid, except for a couple that were transmural^[5,6]. Eighty percent of the liposarcomas described have been from the cervical portion of the

Figure 5 Immunohistology showed positive nuclear staining of lipoblasts with MDM2 confirming the diagnosis of liposarcoma.

Figure 6 Cell with rhabdomyomatous differentiation were focally positive for myogenin.

esophagus, with the rest originating more distally^[5].

Clinically, patients can present with dysphagia for solids and/or liquids, weight loss, intermittent odynophagia, nausea, globus sensation, cough, emesis and retrosternal pain^[2]. If proper diagnosis and treatment is not administered, there can be drastic complications such as anemia, vomiting of tumor fragments, oral regurgitation of polyp upon emesis, respiratory compromise and fatal asphyxiation^[2,3]. Objective diagnosis can be conducted with barium swallow, esophagogastroduodenoscopy, CT scans, and magnetic resonance imaging (MRI). However, making the diagnosis can require some scrutiny. More specifically, Jakowski and Wakely^[3] described a particular case in which the imaging investigations lead to a differential of achalasia initially, later corrected to a giant pedunculated mass. At best, an accurate esophagram can only identify the presence of a mass; often, other examinations must be used in combination to differentiate, evaluate, and grade the tumor. MRI and CT scans are of great help, not only in recognizing the tumor, but also by calculating the fat component of the tumor, hence providing better characterization of the mass: A 100% fat content is in fact consistent with a lipoma, whereas < 75% signifies atypical lipomas or low grade sarcoma^[2,7].

Figure 7 Rhabdomyomatous differentiation is characterized by single and loose aggregates of large round cells with abundant eosinophilic cytoplasm.

The standard of care for giant esophageal polyps is surgical resection, which can be directed by different techniques; including an aggressive open cervical approach, radical three-hole esophagectomy, or local endoscopic resection^[8,9]. Since in our case the endoscopic ultrasound identified a single proximal stalk without a significant feeding vessel, trans oral endoscopic resection was pursued; making sure completeness was achieved by examining margins of specimen to be uninvolved, as cases of reoccurrence after inadequate resection have been reported^[2,5]. Alternatively, resection can also be done through a cervical incision with excision of the polyp from the esophageal lumen, which is in fact the traditional approach, and would have been pursued in presence of a large feeding vessel. Lastly, if the polyps were to have had multiple stalks throughout the entire esophagus, making complete removal through cervical approach unfeasible, an esophagectomy would then be indicated.

In conclusion, given the rarity of the disease, there are only a few studies outlining its optimal management, nevertheless, diagnosis and treatment of this pathology can be approached by customary means, bearing extremely favorable prognosis.

COMMENTS

Case characteristics

A 68-year-old Caucasian male presented with a 2-mo history of worsening intermittent dysphagia, persistent cough, post-prandial retrosternal pain and dull pain on the left side of his neck radiating to his left hear.

Clinical diagnosis

Polypoid mass starting at the level of the upper esophageal sphincter and extending down to the esophagogastric junction, occupying a third of the esophageal lumen.

Differential diagnosis

Neoplastic lesion such as a leiomyoma.

Imaging diagnosis

Esophagogram and computed tomography scan showed a large mass along the

entire course of the thoracic esophagus and an esophagogastroduodenoscopy identified a polypoid mass.

Pathological diagnosis

A 13.0 cm × 6.0 cm × 2.6 cm specimen is identified as a well-differentiated liposarcoma with rhabdomyomatous differentiation arising in a giant fibrovascular polyp and an immunohistochemical stain for MDM-2 supported the diagnosis of liposarcoma.

Treatment

Complete endoscopic resection of the polyp.

Related reports

Esophageal liposarcomas reside in giant fibrovascular polyps and are rare consisting of 0.5% of all esophageal neoplasms. The pathophysiology of esophageal giant fibrovascular polyps is unknown. The only theory with consensus is that an erroneous out-pouching of loose submucosal tissue undergoes traction and peristaltic forces causing it to insidiously grow and elongate into the lumen.

Term explanation

Liposarcoma is a soft tissue neoplasm and is believed to originate from primitive mesenchymal cells rather than mature adipocytes.

Experience and lessons

The standard of care for giant esophageal polyps is surgical resection, which can be directed by different techniques, including a transoral endoscopic resection. A complete resection should be achieved to avoid reoccurrence.

Peer-review

This is only the second case of a rhabdomyomatous well-differentiated esophageal liposarcoma to be reported in literature.
