Editorial Board

2016-2019

The *World Journal of Gastrointestinal Oncology* Editorial Board consists of 420 members, representing a team of worldwide experts in gastrointestinal oncology. They are from 42 countries, including Argentina (2), Australia (11), Austria (1), Belgium (5), Brazil (2), Canada (5), Chile (2), China (55), Czech Republic (1), Denmark (1), Finland (2), France (8), Germany (23), Greece (13), Hungary (2), India (9), Iran (3), Ireland (2), Israel (4), Italy (39), Japan (44), Kuwait (2), Mexico (1), Netherlands (8), New Zealand (2), Norway (1), Poland (3), Portugal (4), Romania (1), Saudi Arabia (1), Serbia (2), Singapore (4), South Korea (29), Spain (10), Sweden (5), Switzerland (2), Syria (1), Thailand (1), Turkey (6), United Arab Emirates (1), United Kingdom (12), and United States (90).

World Journal of Gastrointestinal Oncology
Volume 8 Number 1 January 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Keishiro Aoyagi, MD, Assistant Professor, Department of Surgery, Kurume University, Kurume City 830-0011, Japan

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Colorectal cancer (CRC) ranked third in cancer related death and its incidence has been increasing worldwide. In recent decades important therapeutic advances have

been developed in treatment of metastatic CRC (mCRC), such as monoclonal antibodies against epidermal growth factor receptor (anti-EGFR), which provided additional clinical benefits in mCRC. However, anti-EGFR therapies have limited usage due to approximately 95% of patients with *KRAS* mutated mCRC do not response to anti-EGFR treatment. Thus, *KRAS* mutation is predictive of nonresponse to anti-EGFR therapies but it alone is not a sufficient basis to decide who should not be received such therapies because; approximately fifty percent (40%-60%) of CRC patients with wild-type *KRAS* mutation also have poor response to anti-EGFR based treatment. This fact leads us to suspect that there must be other molecular determinants of response to anti-EGFR therapies which have not been identified yet. Current article summarizes the clinical efficacy of anti-EGFR therapies and also evaluates its resistance mechanisms.

Key words: Colorectal cancer; Epidermal growth factor receptor; *KRAS* mutation; Anti-epidermal growth factor receptor antibody; Drug resistance

Core tip: Molecular targeting agents, such as monoclonal antibodies against epidermal growth factor receptor (anti-EGFR), provide additional clinical benefits in metastatic colorectal cancer (CRC). However, anti-EGFR therapies have limited usage due to approximately 95% of patients with *KRAS* mutated metastatic CRC do not response to anti-EGFR treatment. Thus, *KRAS* mutation is predictive of nonresponse to anti-EGFR therapies but it alone is not a sufficient basis to decide who should not be received such therapies because approximately fifty percent (40%-60%) of CRC patients with wild-type *KRAS* mutation also have poor response to anti-EGFR based treatment. This fact leads us to suspect that there must be other molecular determinants of response to anti-EGFR therapies which have not been identified yet. Current article summarizes the clinical efficacy of

anti-EGFR therapies and also evaluates its resistance mechanisms.

Kocoglu H, Velibeyoglu FM, Karaca M, Tural D. Clinical efficacy and drug resistance of anti-epidermal growth factor receptor therapy in colorectal cancer. *World J Gastrointest Oncol* 2016; 8(1): 1-7 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/1.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.1>

INTRODUCTION

Colorectal cancer (CRC) is one of the most commonly diagnosed cancers in both genders (second in females and third in males)^[1]; and it is also ranked third in cancer related death in both genders with approximately 15.1 deaths per 100000^[2,3]. While the mortality rate of CRC has been decreasing in Western countries, its incidence has been increasing worldwide, except United States^[4]. Despite of decreasing death rates, approximately fifty percent of patients with CRC are diagnosed with metastatic disease in their initial assessments^[5].

Several chemotherapeutic agents [*e.g.*, pyrimidine analogs (*e.g.*, 5-fluorouracil), platinum-based antineoplastic agents, and topoisomerase inhibitors] have become available in the past and thus survival rate of CRC patients significantly increased. Also, recently developed molecular targeting agents, such as monoclonal antibodies against epidermal growth factor receptor (EGFR) (*e.g.*, cetuximab and panitumumab)^[6,7], provided additional clinical benefits in metastatic CRC (mCRC)^[8-10].

In several types of cancer, including CRC, EGFR is overexpressed or amplified. Monoclonal antibodies keep EGFR in an inactive state by binding to and occluding the ligand-binding site of EGFR when the ligand is unbound (acting as competitive antagonists). This leads an inhibition of intracellular signaling pathways of EGFR (RAS/RAF/MAPK and PI3K/PTEN/AKT) that involved in several cellular activities including cell proliferation, motility, invasion, and survival^[11].

KRAS, a signal transduction molecule, transduces the signal from ligand-bound EGFR to the nucleus. Prospective randomized trials elucidated that presence of mutation in *KRAS* gene leads to non-response to anti-EGFR based treatment^[6-10,12-14]. Therefore, it is highly recommended that *KRAS* mutation status should be known before initiating anti-EGFR based treatment in mCRC patients. Thus, *KRAS* mutation is predictive of nonresponse to anti-EGFR therapies but it alone is not a sufficient basis to decide who should not be received such therapies because almost 60% of CRC patients with wild-type (WT) *KRAS* mutation also have poor response to anti-EGFR based treatment^[15]. This fact leads us to suspect that there must be other molecular determinants of response to anti-EGFR therapies which have not been identified yet. Current article summarizes

the clinical efficacy of anti-EGFR therapies and also evaluates its resistance mechanisms.

CLINICAL EFFICACY OF ANTI-EGFR ANTIBODY IN MCRC

Both Cetuximab, an IgG1 type chimeric monoclonal antibody, and panitumumab, an IgG2 type fully human monoclonal antibody, induce apoptosis by inhibiting downstream signaling pathways of EGFR (RAS/RAF/MAPK and PI3K/PTEN/AKT). Also, these molecules, especially cetuximab, activate antibody-dependent cellular cytotoxicity which consequently improves their cytotoxic actions and therapeutic effectiveness^[16].

The recent published randomized non-inferiority phase III study showed median overall survival (OS) was similar in patients with mCRC who treated with panitumumab alone and with cetuximab alone^[17]. The incidences of any grade and grade 3-4 adverse events were similar in both treatment groups, however, the incidence of grade 3-4 infusion reaction was lower and grade 3-4 hypomagnesaemia was higher in panitumumab group than in cetuximab group^[18]. In some studies, cetuximab and panitumumab have been investigated in combination with FOLFIRI (folinic acid, fluorouracil, and irinotecan) and FOLFOX (folinic acid, fluorouracil, and oxaliplatin) as initial therapy option for treatment of mCRC. And a meta-analysis of these 14 randomized studies concluded that there is a clear benefit to the use EGFR inhibitors in patients with WT *KRAS* mCRC^[18]. An updated analysis (CRYSTAL trial) demonstrated that adding cetuximab to FOLFIRI as first-line therapy improves survival in patients with WT *KRAS* mCRC^[19]. Also another randomized phase III study showed that the combination of panitumumab and FOLFIRI significantly improves progression-free survival (PFS), but not OS, in mCRC patients with WT *KRAS*^[9]. Three other trials have evaluated the addition of cetuximab to FOLFOX in first line treatment of patients WT *KRAS* mCRC. In randomized phase II OPUS study, combination of FOLFOX and cetuximab was associated with increased response rate and PFS. However, this treatment had no benefit in median OS^[12]. In the Medical Research Council (MRC) COIN study, adding cetuximab to oxaliplatin-based chemotherapy in patients with WT *KRAS* mCRC increased response rate with no benefit in PFS or OS^[20]. Similarly, another phase III study (NORDIC-VII) showed that cetuximab did not add significant benefit when combined with FOLFOX in treatment of patients with WT *KRAS* mCRC^[21]. In contrast to earlier studies, the recent published randomized phase III CALGB/SWOG 80405 trial demonstrated that addition of cetuximab to FOLFOX or FOLFIRI chemotherapy was significantly increased PFS and OS in treatment of patients with all RAS-WT mCRC^[22]. In the study by Douillard *et al.*^[23] (the PRIME study), which compared panitumumab plus FOLFOX and FOLFOX alone in mCRC patients with WT *KRAS*/NRAS,

panitumumab plus FOLFOX group showed a statistically significant improvement in PFS and OS.

Based on this knowledge, all patients with newly diagnosed mCRC should be tested for *KRAS* mutation. Also screening of *KRAS* mutations seems essential in mCRC patients to initiate anti-EGFR based treatment. But *KRAS* mutation alone is not a sufficient basis to decide who should not be received such therapies because almost 60% of CRC patients with WT *KRAS* mutation also have poor response to anti-EGFR based treatment^[15]. Also 5%-9% of CRC patients have a specific mutation in *BRAF* gene (V600E)^[24,25]. But the use of *BRAF* as a predictive marker for response to anti-EGFR based treatment is unclear. This fact leads us to suspect that there must be other molecular determinants of response to anti-EGFR therapies which have not been identified yet.

MECHANISMS OF RESISTANCE TO ANTI-EGFR TREATMENT

KRAS/NRAS/BRAF mutations

Approximately 40% of CRC patients have mutation in exon 2 of the coding of the *KRAS* gene^[26,27]. Prospective randomized studies showed that *KRAS* mutations are predictive of non-response to anti-EGFR based treatment^[6-10,12-14]. These studies showed that tumors with a mutation in codon 12 or 13 of exon 2 of the *KRAS* gene are essentially unresponsive to anti-EGFR based treatment. Recent studies demonstrated that mutation in *KRAS* outside of exon 2 and mutation in *NRAS* are also predictive for unresponsiveness to anti-EGFR treatment^[23,28]. Recently, a study assessed the superiority of FOLFOX plus panitumumab to FOLFOX alone according to *RAS* (*KRAS* or *NRAS*) or *BRAF* (B-type Raf kinase) mutation status. In that study, 17% of patients with non-mutated *KRAS* exon 2 had other *RAS* mutation which has been shown to be associated with inferior survival with panitumumab plus FOLFOX treatment^[23]. Cetuximab or panitumumab treatments seem to be eligible for selected patients with WT *KRAS* tumors who also have *BRAF*-WT mutations^[29].

BRAF oncogene encodes *BRAF* protein which is a member of *RAS/RAF/MAPK* (mitogen-activated protein kinase) pathway^[27]. Mutations in *BRAF* and *KRAS* genes are mutually exclusive^[30]. Approximately 9% (5%-9%) of patients with CRC have a mutation in *BRAF* gene (V600E)^[24,25]. CRYSTAL and PETACC-3 studies demonstrated that patients with *BRAF* mutation have a worse prognosis than those with the WT tumors^[19,31]. However, the use of *BRAF* as a predictive marker is unclear. CRYSTAL study elucidated that *BRAF* mutation does not seem to be strong predictive biomarker for the addition cetuximab to FOLFIRI in the first line treatment of WT mCRC^[19]. Also, subset analysis of the PRIME study found that *BRAF* mutation indicates poor prognosis but it may not be predictive of the benefit of adding panitumumab to FOLFOX in the first line treatment of

mCRC^[8]. Tol *et al*^[25] demonstrated that *BRAF* mutation is a negative indicator for prognosis in mCRC patients and in contrast to *KRAS* mutation, this feature is not restricted to the outcome of the cetuximab. In subsequent lines of therapy elucidated that *BRAF* mutation is a marker of resistance to anti-EGFR treatment in the non-first line setting of mCRC^[29,32,33].

Vemurafenib is orally administered selective inhibitor of *BRAF* V600 kinase but using it alone in *BRAF*-mutated CRC patients results insufficient activity^[34]. Studies suggested that feedback activation of EGFR signaling might be responsible of the resistance to Vemurafenib in CRC^[35,36]. In a cohort study by Hyman *et al*^[37], median PFS and OS did not change with vemurafenib monotherapy or vemurafenib and cetuximab combination therapy in patients with CRC (Table 1).

HYPERACTIVATION OF PI3K-PTEN AXIS

Interestingly, 41% of patients do not have *KRAS* or *BRAF* mutation, and they do not respond to anti-EGFR treatment^[29]. Some studies suggested that anti-EGFR downstream pathways other than *RAS/RAF/MAPK* [e.g., phosphoinositide 3-kinase/phosphatase and tensin homolog pathway (PI3K/PTEN)], might be responsible for the resistance to anti-EGFR based therapy. It was shown that mutation in *PI3KCA* (phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha) or loss of *PTEN* is associated with resistance to anti-EGFR based treatment^[38-40]. Tural *et al*^[41] investigated the effect of oncogenic activation of the members of EGFR downstream pathways (e.g., *PI3K*, *PTEN* and *BRAF*) on response to anti-EGFR therapy. They have showed that *PI3K* expression and *PTEN* loss might be used as predictive to the response to anti-EGFR treatment in mCRC patients with WT *KRAS*. According to this study, *BRAF* negative, *PTEN* expressing and *PI3K* non-expressing CRCs have higher response rate and longer PFS and OS than all others. Most studies evaluated *PI3K* mutation in response to cetuximab based treatments in CRC patients^[38,42-45]. In these studies, *PI3K* mutation has been suggested as predictive of resistance to anti-EGFR-based therapies. On the other hand, the role of *PI3K* mutation in response is conflict. Perrone *et al*^[38] has investigated *PI3KCA* gene mutations in CRC patients and they suggested that mutation in *PI3KCA* causes resistance to anti-EGFR therapies. Also Prenen *et al*^[45] analyzed *PI3KCA* and *KRAS* mutations status in chemo-refractory mCRC patients who treated with anti-EGFR based treatment and they did not determine any correlation between *PI3KCA* mutation and response to anti-EGFR treatment. Nevertheless, most of studies have suggested that *PTEN* inactivation is a negative predictor of response to anti-EGFR therapy^[38-40]. Bardellie *et al*^[46] stated that *PI3K* expression and *PTEN* loss are correlated with decreased survival and are predictors of poor response to anti-EGFR therapy. Based on these studies, it is well known that activating mutation in *PI3KCA* or inactivation of *PTEN* phosphates

can deregulate PI3K signaling pathway^[46]. Two studies demonstrated that PI3KCA mutation and PTEN loss which cause PI3K pathway activation are significant predictors of response to anti-EGFR treatment^[38,42]. Also, Tural *et al*^[41] indicated that PI3K expression and PTEN loss together are correlated with significantly worse outcome.

HYPEREXPRESSION OR HYPERACTIVATION OF TYPE 1 INSULIN LIKE GROWTH FACTOR RECEPTOR

The type 1 insulin like growth factor receptor (IGF-

1R) belongs to the class of tyrosine kinase receptors. IGF-1R functions by activating downstream signaling pathways which include MAPK and PI3K/AKT. Previous studies showed that IGF-1R overexpression results neoplastic transformation of cultured cells^[47]. Also IGF-1R overexpression was seen in several types of human tumors^[48] and its downregulation has been shown to be able to inhibit the growth of these cells^[49]. These findings make IGF-1R an attractive candidate as therapeutic target in anti-tumor therapies. A previous study showed that combination therapy of antibodies against to IGF-1R and anti-EGFR results in further inhibition of CRC cell line growth^[50]. A phase II study evaluated the safety and the efficacy of human anti-IGF-1R monoclonal antibody

(either alone or in combination with cetuximab) in mCRC patients, and both treatment modalities was reported as insufficient in chemorefractory mCRC patients^[51] (Table 1).

Abstract

Minimally invasive surgery for gastric cancer is a relatively new research field, with convincing results mostly stemming from Asian countries. The use of the robotic surgery platform, thus far assessed as a safe procedure, which is also easier to learn, sets the background for a wider spread of minimally invasive technique in the treatment of gastric cancer. This review will cover the literature published so far, analyzing the pros and cons of robotic surgery and highlighting the remaining study questions.

Key words: Gastric cancer survival; Robotic surgery; Gastric cancer surgery; Lymphadenectomy; Minimally invasive surgery

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: An important problem remains regarding the selection of the appropriate technique for a given gastric cancer case. Encouraging results are being published using the robotic technique, but the lack of homogenous study groups in terms of staging, comorbidities and adjuvant and neoadjuvant therapies makes it hard to establish a clear indication for the robotic gastrectomy in gastric cancer. Carefully weighing the treatment options is especially important since there are more and more groups publishing acceptable results with the robotic technique.

INTRODUCTION

Surgery is unanimously considered the mainstay curative treatment in gastric cancer. Technically, the possibilities range from open surgery to minimally invasive methods like laparoscopy or robotic surgery. However, the newer laparoscopic techniques have only proven their effectiveness in early gastric cancer^[1]. The current challenge for robotic surgery in gastric cancer is to prove its benefit as a treatment option, ideally in the form of a survival advantage. Up until now studies only proved its non-inferiority compared with existent techniques.

Technologic progress has clearly had an impact in medicine and surgery, in particular. However the newest developments in the field of technology are not always the best ones and examples can easily be found in the last decades. Rejecting a new technique altogether is, however, not an option in the field of surgery. It would possibly mean closing the roads to a new development that could allow for patients to benefit from procedures which are not easily or not at all undertaken at the moment.

MINIMALLY INVASIVE SURGERY FOR GASTRIC CANCER

The existence of so many treatment options for gastric cancer suggests that currently there is no consensus regarding the adequate therapeutic conduct. Thus far, the following objectives for gastric cancer surgery have been made clear and should be pursued in any case: (1) If surgery can be performed, it must proceed, usually as a part of multimodal cancer treatment^[1]. The surgical approach is based on the Virchow-Halsted theory of centrifugal dissemination of carcinomas. This mechanistic theory dating from the end of the 19th century is based on the fact that cancer was believed to begin in the target organ and then spread in an orderly fashion through lymphatic drainage routes invading lymph nodes along the way^[2,3]; (2) The tumor must be resected according to oncological safety limits^[1]; and (3) An adequate lymphadenectomy must be performed. Its extent varies depending on the location and stage of the tumor^[1]. Reaching these objectives correlates with a higher survival rate and a lower rate of recurrence^[4,5].

Modern day gastric cancer treatment was definitely impacted by technological progress. The laparoscopy revolution was quickly introduced in this field, with the first laparoscopic gastrectomy performed by Kitano *et al.*^[6]. Experience accumulated with bariatric surgery must not be neglected either, as it led to an improvement

in the technique required to perform intracorporeal anastomoses. The consequence was a rapid development of laparoscopic surgery for gastric cancer beginning, of course, with the early stages. On the other hand, the treatment options for gastric cancer were also enriched by the development of endoscopy, which limited the indications for video-assisted surgery.

Nonetheless, minimally invasive surgery failed to disseminate with great speed worldwide owing mostly to the fact that it is a technically demanding procedure. It is currently particularly favored in Asian countries^[7,8] where it is gaining terrain as a treatment for early gastric cancer, but it is interesting to note that laparoscopic surgery for gastric cancer is still an investigational procedure even in countries like Japan^[1]. To advance this type of surgery into the category of standard procedures, results of large randomized controlled studies like KLASS-01^[9], KLASS-02^[10] and JCOG 0912^[11] comparing the results of open and laparoscopic surgery are still awaited.

At the moment, the benefits of laparoscopy are still being debated, despite all the published studies which seemingly accrue "pro" arguments at a constant rate. In our opinion, the main objection is that these studies presenting good postoperative as well as oncological outcomes, mostly come from highly experienced large-volume surgical centers, which offer a standard of care that is not easily reproducible everywhere in the world.

ROBOTIC SURGERY

The robotic technologies were brought about to circumvent some of the difficulties of laparoscopic surgery. The laparoscopic procedures for gastric cancer have indeed been associated with improved postoperative outcomes and oncological results^[12-15], but the platform itself imposes a series of technical shortcomings. The two-dimensional views coupled with the fulcrum effect and the inherent tremor reduce the surgical range of motion and prolong the learning curve especially for large scale procedures such as gastrectomy. The robotic system comes with a three-dimensional view enabling depth perception, the EndoWrist[®] technology which allows for seven degrees of freedom and tremor filtration. Additionally, images can be enlarged enabling the performance of delicate steps such as lymph node dissection along great vessels which are essential in achieving a D2 dissection, suturing or knotting. These features could enable the performance of relatively complicated procedures such as function-preserving gastrectomy or extended resections for advanced gastric cancer using a minimally invasive method. Nonetheless this technique also has its disadvantages: Costs, duration of the procedures, the necessary trainings.

The use of the robotic platforms in general surgery did not enjoy the same success as it did in urologic surgery, and the field of gastric cancer is no exception. There are a series of shortcomings of the robotic platform explaining this situation. First of all the lack of robotic staplers and robotic seal and cut devices like

LigaSure™ is a considerable inconvenience. Second, due to the costs, the robotic platform cannot be used to cover the whole spectrum of procedures normally performed by a general surgeon^[12].

Current status of robotic surgery in early gastric cancer

Studies evaluating robotic surgery for early gastric cancer alone are scarce and stem mostly from Asian countries. The higher incidence of gastric cancer in these countries, together with the wide extent and increased efficacy of the national gastric cancer screening programs fueled the search for minimally invasive treatment modalities for the early stages of the disease. This led not only to the development of endoscopic resection, but also to a large pool of surgeons well versed in minimally invasive gastrectomies. The encouraging results published in small non-randomized comparative studies of laparoscopic vs open surgery for early gastric cancer^[13-15] were followed by the increased use of laparoscopy in clinical practice. Japan reports that at least 20% of the gastrectomies for early gastric cancer in its hospitals are now being performed laparoscopically^[1]. The need for better statistical evidence supporting the minimally invasive treatment of early gastric cancer was answered by starting two major randomized controlled trials which are now underway in Japan and South Korea comparing laparoscopy and open surgery^[9,11].

Following the foot-steps of laparoscopic surgery, robotics was first introduced in the treatment of early stage patients by the same surgeons who had acquired experience in the field of laparoscopic gastrectomies. After the first robotic gastrectomy reported in 2003 by Hashizume *et al*^[16], a series of encouraging reports on robotic surgery for gastric carcinomas began to appear in literature (Table 1).

In keeping with the trends of gastric cancer incidence in the eastern and western continents, Asian studies focus on mixed cohorts of gastric cancer patients with a high prevalence of the early stages or on early gastric cancer patients alone (Table 1). The largest cohort of early-stage gastric cancer to date was published by Woo *et al*^[17]. A total of 827 patients were included in this nonrandomized comparative study of robotic (236 patients) and laparoscopic surgery (591 patients) for stage Ia and Ib gastric carcinomas. The total operative time was significantly increased for the robotic procedures compared with laparoscopy (219.5 min vs 170.7 min, $P < 0.001$), but the robotic group also showed a lower estimated blood loss (91.6 mL vs 147.8 mL, $P = 0.02$). The length of hospital stay was slightly in favor of the laparoscopic group (7 d vs 7.7 d, $P = 0.004$) and there were no differences regarding morbidity and mortality. In terms of oncological principles, the number of retrieved lymph nodes was not different and all the patients in the robotic group had negative resection margins^[17].

Other studies comparing robotic surgery to laparoscopy in the treatment of gastric cancer show the same operative outcomes. The operative times are always

significantly longer for the robotic group (Table 2). This has been attributed to longer docking times necessary for the robot. However, a learning curve effect can be derived from the two studies separating the laparoscopic surgery group into an initial and a recent subgroup^[18,19]. The operating times reported for the initial laparoscopic technique subgroup are even longer than those of the robotic subgroup. That is no longer the case for the recent laparoscopy subgroup which yields the shortest operating time between the three subgroups (Table 2). In the study of Song *et al*^[19] the difference between these mean operative times were 289.5, 230 and 134 min, respectively with a statistically significant difference. The decrease of the mean operative times between the initial and the latter robotic cases (231 min vs 208 min) in the large cohort published by Woo *et al*^[17] indicates that shortening the operating times is also a matter of exercise, as was the case when the laparoscopic gastrectomies were introduced.

Regarding the estimated blood loss and the number of retrieved lymph nodes, there are conflicting results stemming from most of the cohorts comparing laparoscopy to robotic surgery (Table 2). A meta-analysis performed by Shen *et al*^[20] including the studies which also appear in our retrospective tables (Tables 1-3) comparing robotics and laparoscopy also found no statistically significant difference on the number of retrieved lymph nodes. However, a significantly lower blood loss was found in favor of the robotic group.

Current status of robotic surgery in advanced gastric cancer

Papers stemming from Europe, on the other hand, have a large prevalence of advanced gastric cancer cases in their study groups. In the largest study up to date (5839 patients) comparing robotic (436 patients), laparoscopic (861 patients) and open surgery (4542 patients) performed for stage I, II and III gastric cancer by Kim KM *et al*^[47], overall safety of these three types of surgery was the main focus. The overall complication rate was the same between the three groups (OG 10.7% LG 9.4% and RG 10.1%, $P = 0.494$) and so was their severity ($P = 0.424$). However, robotic surgery was prone to complications related to leaks ($P = 0.017$), whereas ileus and abscesses were more prevalent in open surgery ($P = 0.001$, $P = 0.013$ respectively). The authors explain that stapling lines were not reinforced with sutures in minimally invasive surgery, as opposed to open surgery and that the patients included in the open surgery group were mainly patients with more advanced disease for whom the complexity of the resections was higher. The robotic group showed a faster recovery with a shorter time to starting the soft diet and a shorter postoperative stay ($P < 0.001$ for both parameters) (Table 3). This study also showed an increased duration of the procedure compared to laparoscopic and open surgery (224 min vs 176 min vs 158 min, $P < 0.001$) combined with a lower estimated blood loss for the robotic group ($P < 0.001$). The

number of harvested lymph nodes was no different between open and robotic surgery.

In the experience of our group, the robotic platform is a versatile tool in the surgical approach of advanced gastric cancer. Our study^[50] enrolled 47 patients who were exclusively advanced gastric cancer patients and went on to receive either open ($n = 29$) or robotic ($n = 18$) surgery. Significantly longer mean operating times (320.83 min vs 243.36 min), but significantly lower blood loss (208.26 mL vs 546.62 mL) and shorter hospital stay (11.04 d vs 8.1 d) were obtained for the robotic group (Table 3). We found no difference in the number of retrieved lymph nodes or the rate of complications. After a mean follow up time of 31.66 mo for the open surgery group and a 24.72 for the robotic surgery group, the Kaplan-Meier analysis of the survival data revealed no statistically significant difference between the two cohorts ($P = 0.177$).

The authors consider that special emphasis needs to be placed on the long-term results of robotic surgery in advanced gastric cancer. The MAGIC trial^[51] published

in 2006 showed a survival benefit for gastric cancer patients receiving epirubicin, cisplatin and fluorouracil perioperatively when compared with patients treated with surgery alone. But the study also reported that 34% of the patients enrolled in the perioperative chemotherapy group, were unable to receive the regimen after surgery owing, among others, to postoperative complications. This creates a need for less invasive surgery like robotic surgery even in the treatment of the advanced gastric cancer patients. Patients would be thus enabled to receive the complete chemotherapy regimen, which would positively impact their survival prognosis^[51].

Another reason to investigate robotic surgery in the treatment of advanced gastric cancer would be the imperfect staging systems currently available. Studies report a considerable amount of patients staged as EGC perioperatively who turn out intraoperatively to suffer from advanced gastric cancer^[52,53]. Given these numbers Pugliese *et al*^[35] even proposed that all gastrectomies be performed including a D2 lymphadenectomy regardless

of the initial tumoral staging.

TECHNICAL ASPECTS

Combined resections

There has been a lack of studies specifically focused on the possible benefits of robotic multivisceral resections for advanced gastric cancer. Previous research by surgeons experienced in minimally invasive surgery suggests that the precision offered by the robotic platform might be of more use in large, technically-challenging procedures like multivisceral resections, rather than in cases requiring less complex surgery^[54,55].

Lymphadenectomy

To put forth robotic surgery as a viable surgical tech-

nique in gastric cancer treatment, its contribution to performing an extended lymphadenectomy needs to be made clear.

In laparoscopy, one of the major sources of intraoperative bleeding was shown to be lymph node dissection, especially when occurring around the large vessels^[56,57]. In our experience with the robotic platform owing to the elimination of physiologic tremor, the 3D steady view, and the 7 degrees of freedom of the EndoWrist® instruments lymph node dissection along the celiac trunk, the left gastric artery and the hepatic pedicle which are usually associated with increased bleeding, are now performed in a more precise and safe environment^[50].

The cohorts of Hyung^[18] and Song *et al*^[30] both included an initial and a recent laparoscopy group thus

allowing the assessment of the evolution of surgery parameters along the learning curve for this type of surgery and their comparison to the initial experience in robotic surgery. Although not statistically significant, recent laparoscopy showed the highest number of retrieved lymph nodes, with initial robotic cases coming second, in front of the initial laparoscopic cases. This comes to support the view that laparoscopy has a steeper learning curve than robotic surgery and that even inexperienced surgeons may obtain easily reproducible, high quality results faster with the robotic platform. This difference between the two techniques may not be important in the east, where experienced laparoscopic surgeons show no difficulties in quickly adjusting to the robotic platform, but it could bring a significant advantage to the western surgeons who simply cannot benefit from the same training in laparoscopy for gastric cancer due to the particular epidemiology of this disease.

The majority of the studies listed in Tables 1-3 show a higher number of retrieved lymph nodes for robotic procedures, which is an encouraging result given the extent of the preoperative under staging reported until now and the probable need to perform D2 lymphadenectomies for all patients until a reliable method for precise preoperative staging is introduced.

Digestive tract reconstruction

Key moments for the anastomosis are as follows: (1) closure of the duodenal stump; (2) closure of the stomach stump in subtotal gastrectomy or that of the esophageal stump in total gastrectomy; and (3) preparing the jejunum for the gastro-jejuno anastomosis or the eso-jejunoanastomosis. We generally opt for a Roux-en-Y anastomosis^[58].

The reconstruction solutions after total or subtotal gastrectomy can be grouped into two large categories. First, the extracorporeal anastomoses by the robot-assisted surgery require the performance of a minilaparotomy (smaller than 6 cm) through which the ends that need to be anastomosed are brought out and continuity of the digestive tract is reestablished, usually using circular stapler. This technique is not suitable for obese patients for whom the incision may need to be larger than 6 cm to perform the proximal resection and the purse-string suture on the esophageal stump.

To fully take advantage of the minimal invasiveness provided by the robotic platform, several techniques for intracorporeal anastomoses have been developed. They avoid the laparotomy and imply sectioning the esophagus under video control and then performing the anastomosis with a specific technique not requiring an abdominal incision. One option is using the OrViI™ device (Covidien, Mansfield, MA, United States). This consists of a foldable stapler anvil forming a 170° angle with the adjoining PVC tube. The OrViI™ device is introduced through the mouth and into the esophageal stump at which point the anvil is unfolded and connected to the circular stapler introduced abdominally. For this technique our team uses a 21 mm anvil followed by

a Roux-en-Y reconstruction with good postoperative results^[58]. Similar to this is the technique described by Hiki *et al.*^[59] in which the anvil of a circular stapler is attached to a nasogastric tube using sutures and then introduced trans-orally. Another technique was described by Inaba *et al.*^[60] and involves the creation of a side-to-side anastomosis using a linear stapler. Yet another option would be the manual sewing of the anastomosis, which we do not recommend, since it would prolong operating times unnecessarily, given the fact that the available mechanical devices are reliable alternatives.

The role of the assistant surgeon

In a study published by our team^[61], we assessed the role of the patient-side surgeon in robotic surgery. We found obvious benefits for the team when highly-trained assistants were involved in the procedure. Remarkable improvements were seen in handling the robot (docking and undocking times), the speed and precision in manipulating laparoscopic devices like the LigaSure or clip applier devices. Our data show that maintaining the same members of the team throughout more procedures and including assistants who undertook a structured, formal training program are more likely to warrant for fast and safe interventions.

OPEN QUESTIONS OF RESEARCH

An important problem remains regarding the selection of the appropriate technique for a given gastric cancer case. Thus far indications for robotic gastrectomy were: (1) a diagnosis of early gastric cancer without evidence of lymph node involvement; (2) T1 cancer with perigastric lymph node involvement; and (3) serosa-negative gastric cancer without lymph node metastasis. However, many of the patients were understaged preoperatively. This raises the need to study the outcomes of robotic surgery on large patient cohorts in randomized prospective studies not only for early gastric cancer, but also for tumors possibly requiring the D2 lymphadenectomy.

A recently published study surveying gastric cancer surgery techniques in United States academic medical centers^[62] shows that the number of robotic gastrectomies for gastric cancer has remained constant in 2011, 2012 and 2013. The study also mentioned that the robotic technique was utilized in the patients with the highest risk of mortality and severity of illness, in keeping with the fact that minimally invasive surgery has a lower impact on patient performance status and immune response mechanisms postoperatively^[62-64]. Therefore, extending the indications of robotic surgery to advanced gastric cancer is also a valid study point, especially in the West.

The option between endoscopic, laparoscopic, robotic or open surgery must be made based on well-established diagnostic criteria. This is not easy and one must take into account the caveats of evidence based

medicine and randomized controlled trials. The case of the results published by Bonenkamp *et al.*^[65] and Cuschieri *et al.*^[66,67] regarding the survival benefit of the D2 lymphadenectomy and the controversies thereafter have marked a decade of debate regarding the strategies for gastric cancer treatment. Carefully weighing the treatment options is especially important since there are more and more groups publishing acceptable results with the robotic technique.

CONCLUSION

Encouraging results are being published using the robotic technique, but the lack of homogenous study groups in terms of staging, comorbidities and adjuvant and neo-adjuvant therapies makes it hard to establish a clear indication for the robotic gastrectomy in gastric cancer.

Robotic surgery has proven to be safe and feasible thus far, but more convincing large volume prospective studies are needed to put it on the treatment list of early and advanced gastric cancer.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is the 4th

deadliest cancer in the United States, due to its aggressive nature, late detection, and resistance to chemotherapy. The majority of PDAC develops from 3 precursor lesions, pancreatic intraepithelial lesions (PanIN), intraductal papillary mucinous neoplasm (IPMN), and mucinous cystic neoplasm. Early detection and surgical resection can increase PDAC 5-year survival rate from 6% for Stage IV to 50% for Stage I. To date, there are no reliable biomarkers that can detect PDAC. MicroRNAs (miRNA) are small noncoding RNAs (18-25 nucleotides) that regulate gene expression by affecting translation of messenger RNA (mRNA). A large body of evidence suggests that miRNAs are dysregulated in various types of cancers. MiRNA has been profiled as a potential biomarker in pancreatic tumor tissue, blood, cyst fluid, stool, and saliva. Four miRNA biomarkers (miR-21, miR-155, miR-196, and miR-210) have been consistently dysregulated in PDAC. MiR-21, miR-155, and miR-196 have also been dysregulated in IPMN and PanIN lesions suggesting their use as early biomarkers of this disease. In this review, we explore current knowledge of miRNA sampling, miRNA dysregulation in PDAC and its precursor lesions, and advances that have been made in using miRNA as a biomarker for PDAC and its precursor lesions.

Key words: Pancreatic cancer; MicroRNA; Biomarkers; Pancreatic intraepithelial lesions; Intraductal papillary mucinous neoplasm

Core tip: Reliable biomarkers are needed to detect pancreatic ductal adenocarcinoma (PDAC) early in order to decrease mortality. In this review, we discuss what the current knowledge is on microRNA (miRNA) in PDAC and its precursor lesions. MiR-21, miR-155, miR-196, miR-210 are dysregulated in tissue, serum, cyst fluid, and stool of PDAC patients. MiR-21, miR-155, and miR-196 are dysregulated in intraductal papillary

mucinous neoplasm and pancreatic intraepithelial lesions demonstrating that these miRNAs may serve as potential biomarkers for early stage lesions and cancer.

Hernandez YG, Lucas AL. MicroRNA in pancreatic ductal adenocarcinoma and its precursor lesions. *World J Gastrointest Oncol* 2016; 8(1): 18-29 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/18.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.18>

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is the 4th deadliest cancer in the United States, due to its aggressive nature, late detection, and resistance to chemotherapy^[1,2]. The majority of PDAC develops from 3 precursor lesions, pancreatic intraepithelial lesions (PanIN), intraductal papillary mucinous neoplasm (IPMN), and mucinous cystic neoplasm (MCN)^[3]. The cystic precursor lesions of the pancreas are detectable by certain imaging modalities such as Endoscopic ultrasound (EUS)^[4-6], Magnetic Resonance Imaging of the Abdomen with Cholangiopancreatography^[7], and computerized tomography scan^[8,9]. To date, there is no modality that clearly detects PanIN lesions, although studies have suggested a correlation between multifocal PanIN and lobular atrophy of the pancreas on EUS^[10].

Early detection and surgical resection can increase PDAC 5-year survival rate from 6% for Stage IV to 50% for Stage I^[11,12]. Detection and surgical removal of precursor lesions has the potential to be curative. Because of this, there has been much research focused on identification of individuals at high-risk of PDAC, detection of early stage lesions, and on the discovery of reliable biomarkers of this deadly disease. Carbohydrate antigen (CA) 19-9 is a poor biomarker of PDAC, as it is elevated in 30%-40% of benign diseases of the pancreas^[13,14] with a sensitivity of 79% (70%-90%) and specificity of 82% (68%-91%)^[15] for PDAC.

MicroRNA (miRNA) expression has been studied in tumor detection, cancer development and progression, and prognosis^[16]. MiRNAs are small noncoding RNAs (18-25 nucleotides) that regulate gene expression by affecting translation of messenger RNA (mRNA)^[16-18]. MiRNA function to stabilize mRNA transcripts *via* post-transcriptional gene silencing *via* inhibition of the translation process or cleavage of their target mRNAs^[16,19]. Over the last decade, the role of miRNA in cancer development and detection has evolved. MiRNA is very stable in tissue, plasma, stool, and other fluids and can be quantified in very small sample sizes, making it an excellent potential biomarker for the detection of PDAC. Current priorities include: (1) identification of miRNAs that are reliably dysregulated in PDAC; (2) determining which sample source(s) are easily accessible and have the highest yield for detecting these biomarkers; and (3) development of novel ways in which to use this

information to detect early onset PDAC and precursor lesions. Array-based analysis is used to evaluate the expression levels of thousands of miRNAs in various tissue types. Subsequent trials have validated these findings by performing quantitative real time PCR (QRT-PCR) and performed receiver operating characteristics (ROC) analysis to determine the sensitivity and specificity of these miRNAs as potential biomarkers for early or advanced disease. Some miRNAs, such as miR-21, miR-155, miR-196a, and miR-210 have stood out as potential biomarkers of this highly fatal disease^[20-24]. Our review is aimed at exploring current knowledge of miRNA sampling, miRNA dysregulation in PDAC and its precursor lesions, and advances that have been made in using miRNA as a biomarker for PDAC and its precursor lesions.

ROLE OF MIRNA IN PDAC DETECTION: SAMPLES FROM TISSUE, SERUM, PANCREATIC JUICE, STOOL AND SALIVA

Attention has been paid to circulating serological signatures, autoantibodies, epigenetic markers, circulating tumor cells (TCs), and miRNAs in order to detect PDAC at an earlier stage of disease^[25,26]. The use of miRNA for diagnosis and screening is still an evolving field; in the right patient population, an ideal miRNA test would be highly sensitive and specific, minimally-invasive and cost-effective. MiRNA expression in PDAC was first examined in PDAC tissue cells^[27]. Now miRNA has been found in serum, blood, whole plasma, stool, saliva, and cyst fluid (Table 1). Current knowledge is described below.

MiRNA in whole pancreas tissue or PDAC biopsies

Szafranska *et al.*^[27] performed the first analysis comparing miRNA expression in normal pancreas tissue, chronic pancreatitis (CP) tissue and PDAC tissue. On imaging, it can be challenging to distinguish CP from PDAC given the thick stroma and inflammation that may be found in both of these conditions. Furthermore, it is unclear if the aberrant expression of particular miRNAs is secondary to the desmoplastic reaction in CP and PDAC, and not related to tumorigenesis itself. They and others have found that miRNA-216 and miRNA-217 are significantly down-regulated in PDAC and miRNA-143, miR-145, miR-146a, miR-148a, miR-150, miR-155, miR-196a, miR-196b, miR-210, miR-222, miR-223, miR-31 are up-regulated in PDAC^[24,27-29]. However, this study also demonstrated that dysregulation of miRNA-196a, miR-196b, miR-203, miR-210, miR-222, miR-217, and miR-375 were found only in PDAC, whereas miRNA-29c, miR-96, miR-143, miR-145, miR-148b, and miR-150 were abnormally expressed in both CP and PDAC. This may suggest that the latter are responsible for causing the desmoplastic reaction as opposed to tumorigenesis.

Table 1 MiRNA in pancreatic ductal adenocarcinoma

MiRNA	Whole pancreas	Serum and plasma	Saliva	Stool	Pancreatic juice
miR-10b		↑[54]			
miR-16		↑[52]			
miR-18a		↑[29,56,57]			
miR-20a		↑[55,134]			↓[62]

miR-3679-5p			↓[74]	↓[72,74]	

miR: MicroRNA; ↑: Up-regulated; ↓: Down-regulated; ↔: Unchanged.

MiR-1290 is elevated in early stage PDAC compared to normal controls^[30]. Additionally, miR-135b has been shown to be an effective biomarker for distinguishing PDAC from CP with high sensitivity and specificity^[31].

MiR-21, MiR-155, and miR-196 have been demonstrated by multiple groups to differentiate PDAC from non-cancerous lesions of the pancreas^[20-24,27,32]. Special attention has been placed on the role of miR-21 in

PDAC, as it has been implicated in tumorigenesis, TC invasion, the desmoplastic reaction, and metastasis of TC^[33-36]. Further studies did not demonstrate that miR-21 expression in stromal cells correlated with tumor stage.

MiR-192 has also been found to be present in pancreatic TC, but is seldom seen in stromal cells and not found in adjacent normal pancreas tissue^[37]. In this same study, miR-194 expression was detected in PDAC tissue, but not found in the surrounding normal pancreatic tissue. Unfortunately, despite these findings, no significant difference was found between the serum levels of miR-194 in patients with PDAC and healthy controls.

One proposed mechanism for PDAC development includes signaling between the molecular markers of the desmoplastic reaction and TCs^[38-41]. Liffers *et al.*^[29] demonstrated that miR-148a is down-regulated in microdissected PDAC tissue and when over-expressed prevents tumor growth. This suggests that miR-148a may have a crucial role in the molecular signaling by which tumorigenesis occurs. While it is important to find biomarkers that are deregulated in PDAC, it is also important to understand which miRNAs are involved in these aberrant signaling pathways.

MiRNA in serum and plasma of PDAC patients

MiRNAs are known to have organ-specific expression in many human cancers^[42,43]. Less than a decade ago, studies found that miRNA could reliably be detected in the serum in both animal models and humans^[44,45], and since that time, there has been much research dedicated to identifying which miRNAs have differential expression and the implications of these findings in the detection, staging, treatment, and prognosis of cancers^[46-50].

Attempts to use miRNA biomarkers in conjunction with CA19-9 have yielded mixed results. A study examining 847 different miRNAs in patients with PDAC found increased expression of miR-375 in PDAC as opposed to controls. MiR-375 did not improve detection nor predict prognosis in patients with PDAC when compared to CA19-9 alone^[51]. Liu *et al.*^[52] found that using serum miR-16 and miR-196a in combination with CA19-9 increased detection of PDAC and Stage I lesions when compared to either modality alone, which suggests that miR-16 and miR-196a may be deregulated early in PDAC. These biomarkers were also up-regulated in studies performed on pancreas tissue, demonstrating that miR-16 and miR-196a can be used as peripheral biomarkers of PDAC. Gao, *et al.*^[53] also demonstrated that miR-16, when combined with CA19-9, served as a potential biomarker for detection of PDAC when compared to patients with CP.

One limitation of CA19-9 as a biomarker is that it is elevated in a large portion of patients with benign pancreatic diseases. Because of this limitation, studies have evaluated the miRNA expression of patients with PDAC compared to those with benign diseases such as CP or choledocolithiasis. They found that miR-10b,

miR-155, and miR-106b were consistently elevated in the serum of patients with PDAC but not in those with benign pancreatic disease^[54]. Liu *et al.*^[55] have demonstrated that up-regulation of miR-20a, miR-21, miR-24, miR-25, miR-99a, miR-185, and miR-191 can be used to distinguish PDAC from healthy controls and CP. Additionally, miR-135b has been shown to be an effective biomarker for distinguishing PDAC from CP with high sensitivity and specificity^[31]. MiR-18a levels have also been shown to have increased expression in patients with PDAC and interestingly decrease after surgical resection suggesting that miR-18a levels may be a good marker to not only detect disease but also to monitor disease recurrence^[29,56,57]. Zhang *et al.*^[37] also demonstrated that miR-194, miR-192, miR-602, miR-801, miR-212, miR-34a are up-regulated in PDAC, while miR-923, miR-139-3p, miR-513a-5p, miR-630, miR-30c-1, miR-887, miR-508-5p, and miR-139a-5p were down-regulated in PDAC specimens^[37,58]. From these data, they demonstrated that miR-192 is neither present in the stromal cells of the pancreas nor the serum, but it is up-regulated in PDAC TCs and is involved in cell proliferation of PANC-1 TC lines *in vitro*^[58]. Lin *et al.*^[59] performed microarray on 1711 serum miRNAs and found that 23 were down-regulated and 22 were up-regulated in the serum of PDAC patients when compared to normal controls. Of these, miR-492 and miR-663a were found to have decreased expression that was statistically significant in PDAC; however, only miR-663a was found to have a positive correlation with stage of disease^[59]. Further studies are needed to determine which miRNAs will be clinically relevant.

Pancreatic juice miRNA

Pancreatic juice sampling requires an invasive endoscopic procedure, but studying the miRNA concentrations of patients with PDAC, benign pancreatic lesions, and healthy controls can shed light on potential biomarkers for detecting disease as they are found in high concentration in cyst fluid. As EUS and endoscopic retrograde cholangiopancreatogram (ERCP) are two methods by which pancreatic masses are frequently detected and sampled, these specimens could be sent for miRNA analysis in order to determine the malignant potential of these lesions. Wang *et al.*^[60] performed microarray of 49 miRNAs on secretin-stimulated pancreatic juice of a group of patients with PDAC, CP, and normal controls. They demonstrated that miR-205, miR-210, miR-492, and miR-1427 are all significantly elevated in PDAC when compared to controls; however, this statistical significance does not exist when compared to patients with CP^[60]. Additionally, by using ROC curves, they determined that combining these 4 miRNAs with serum CA19-9 the sensitivity and specificity of PDAC detection is 91% and 100% respectively, though this analysis was limited by a sample size of 6. Other groups have evaluated the pancreatic juice of patients with PDAC pre-operatively *via* ERCP and from post-operative specimens^[61,62]. Sadakari *et al.*^[61] analyzed the expression

of miR-155 and miR-21 in pancreatic juice sampled *via* ERCP and found that these miRNAs were significantly elevated when compared to patients with CP and healthy controls, though the levels did not correlate with pancreatic juice cytology^[61]. Again these findings are consistent with those from pancreatic tissue and serum. Hong *et al.*^[62] evaluated 158 miRNAs in post-operative fine needle aspiration specimens and found by qRT-PCR that miR-21, miR-27a, miR-146a, and miR-186a were significantly over-expressed in PDAC tissue and miR-217, miR-20a, and miR-96 were significantly down-regulated in PDAC tissue when compared to normal controls^[62]. These two studies have demonstrated the feasibility of detecting miRNA from pancreatic juice, thus indicating the potential for using pancreatic juice biomarkers to detect early lesions given the higher concentration of miRNA in this fluid sample.

miRNA in stool specimens

Frozen stool specimens may serve as potential non-invasive biomarker samples for PDAC. Over-expressed miRNAs from gastrointestinal cancers are shed from the exfoliative cells of the gastrointestinal tract. Intraluminal release of pancreatic juice also allows for detection of miRNAs in the stool^[63-69]. Previous studies have largely focused on genetic markers of tumorigenesis and not miRNA^[70]. Yang *et al.*^[63] performed a feasibility study of using stool miRNAs as a potential screening tool for detection of PDAC. They evaluated expression of 5 miRNAs that had been previously shown to be over-expressed in PDAC and found that miRNA-21 and miR-155 were over-expressed and miR-216 was under-expressed in all PDAC stool specimens when compared to normal controls and CP patients. These findings are consistent with what has been found in whole pancreas, pancreatic cyst fluid, and serum specimens. Additionally, with ROC analysis they demonstrated that combining miR-21 and miR-155 in stool samples there was a sensitivity of 93.33% and specificity of 66.67%. When they combined all 3 miRNAs (miR-21, miR-155, and miR-216), the sensitivity and specificity were 83.33% each. Link *et al.*^[71] selected 7 miRNAs (miR-21, miR-210, miR-143, miR-155, miR-196a, miR-216a, miR-375) and determined that like Yang's group miR-216a was found in lower concentrations in the stool of patients with PDAC. However, unlike Yang's group, they found that miR-155 was down-regulated in this population and miR-21 was unchanged in the stool of controls compared to CP or PDAC^[71].

Ren *et al.*^[72] also evaluated the expression of miR-21, miR-155, miR-181a, miR-196a, and miR-210 and found that miR-181b, miR-196a, and miR-210 were significantly over-expressed in PDAC patients when compared to controls, but only miR-181b and miR-210 were elevated in CP patients, though these elevations were not significant. Ren *et al.*^[72] established a positive correlation between miR-196a levels and tumor size, which had not been previously described in studies of

the serum or stool. Overall, while studies of fecal miRNA have demonstrated feasibility, conflicting data have emerged on which miRNAs are differentially expressed in the stool of PDAC, benign pancreatic disease, and normal controls.

Salivary miRNA

The field of salivonomics has been developing since blood molecules have been found in saliva^[73]. As with stool miRNA, salivary miRNA may serve as a non-invasive biomarker for PDAC. Xie *et al.*^[74] is the only group to have evaluated salivary miRNA in PDAC. They conducted a microarray of 2006 miRNAs and noted that 10, including miR-4433-5p, miR-4665-3p, miR-940, miR-1273g-3p, miR-3676-5p, miR-3679-5p, miR-3940-5p, miR-4327, miR-4442, and miR-5100, were up-regulated or down-regulated in salivary samples. Of these, only miR-940 was significantly up-regulated and miR-3679-5p was significantly down-regulated in the PDAC specimens during the validation phase of the study. Until now, neither has been implicated in PDAC in the serum, stool, whole pancreas, or pancreatic juice. More studies are needed in this area.

ROLE OF MIRNA IN DETECTION OF PRECURSOR LESIONS

The absence of symptoms in early disease makes PDAC a cancer that is detected at very late stages when mortality approaches 100%. Much research has been dedicated to detecting miRNA in patients with PDAC as a novel biomarker for the presence of disease. Given the aggressive nature of PDAC, detection of precursor lesions with malignant potential would be critical to increasing the survival of these patients. PanIN lesions are microscopic PDAC precursor lesions that are graded 1-3 and are categorized based on the level of architectural and cytological atypia that is present^[75,76]. Grade 1a is early intraepithelial proliferative lesions that have flat architecture, while grade 1b lesions have papillary architecture. PanIN-2 lesions have moderate abnormalities and PanIN-3 lesions have severe abnormalities, though none of these lesions invade the basement membrane^[75,76]. IPMN lesions are mucin-producing cystic tumors, which arise from the epithelium of the pancreatic ducts and have the potential for malignant transformation^[77,78]. They are categorized by main duct type (MD) or branch duct type (BD) and histologically are classified as having low-, intermediate-, and high-grade dysplasia^[3]. Their malignant potential differs based on their location within the pancreatic ducts, and MD-IPMN carry a 44%-48% risk compared to BD-IPMNs, which only carry a 11%-17% risk of malignant transformation^[79-82]. MCN are also mucin-producing epithelial neoplasms with ovarian-type stroma occur primarily in middle-aged females and are located in the body and tail of the pancreas and carry a 12% chance of tumor progression^[83-86]. Cystic fluid is analyzed

Table 2 MiRNA in precursor lesions

MiRNA	IPMN	PanIN-1	PanIN-2	PanIN-3

miR: MicroRNA; ↑: Up-regulated; ↓: Down-regulated; PanIN: Pancreatic intraepithelial lesions; IPMN: Intraductal papillary mucinous neoplasm.

for CEA and amylase as other tumor markers have not demonstrated reliability in detecting malignant lesions.

As cystic neoplasms of the pancreas carry the risk of malignant transformation, determining a way to accurately predict which will progress to invasive carcinomas may guide surgical management and treatment decisions. MiRNA has been examined in PanIN lesions and IPMN as a potential candidate for early detection and the likelihood of progression to cancer. Understanding which miRNAs become deregulated early in the disease process may lead to advances for treatment decisions (Table 2).

MiRNA in IPMN lesions

Given the increased use of abdominal imaging, more pancreatic cystic lesions are being detected. There are guidelines in place to help guide management based on cystic characteristics that are consistent with malignancy^[77]. The first study looking at miRNA expression levels in precursor lesions of the pancreas was performed by Habbe *et al.*^[23] who determined that miR-155 and miR-21 were over-expressed in the IPMN neoplastic epithelium, specifically those with carcinoma-in-situ^[23,87]. MiR-155 was also significantly elevated in the pancreatic juice of these patients. While the levels of up-regulation of miRNA-21 and miR-155 correlated with the degree of cellular atypia found in the IPMN lesions, the study lacked long-term outcome data, highlighting the need for large and more longitudinal studies. Caponi *et al.*^[32] established a relationship between expression of miR-21 in invasive IPMNs and

clinical outcome and observed that higher levels of miR-21 were correlated with worse overall and disease-free survival. Furthermore, they demonstrated that miR-155 and miR-21 had higher expression levels in invasive IPMN lesions when compared to non-invasive lesions, suggesting that these miRNAs may serve as early markers of malignant transformation^[32,88]. MiR-101 has been shown to be down-regulated in invasive IPMNs when compared to non-invasive IPMNs and normal tissue. This deregulation of MiR-101 has not been described in PDAC samples, which may indicate that miR-101 plays a role in tumor invasion^[32,89]. As with studies of miRNA in the serum and tissue of PDAC patients, miR-196a was found to be up-regulated in the pancreatic juice of intestinal-type IPMN^[90]. In a recent study miR-100, miR-99b, miR-99a, miR-342-3p, miR-126, miR-130a were found to be down-regulated were up-regulated in high-risk vs low-risk IPMN lesions^[91]. Furthermore, low miR-99b in IPMN fluid was associated with MD involvement, which is associated with a greater risk for transformation into a malignant neoplasm. Abue *et al.*^[88] found that miR-483-3p was up-regulated in PDAC cells and plasma when compared to IPMN lesions and may also serve as a useful biomarker in differentiating IPMN lesions with malignant potential from normal tissue and PDAC. The down-regulated miRNAs correlated with high-risk IPMNs and may be involved in cyst invasion and progression. Lee *et al.*^[92] found that miRNA expression varied amongst pancreatic cystic neoplasm. Specifically, miR-31-5p, miR-4830-5p, miR-99a-5p, and miR-375 were characteristic of serous cyst adenomas (SCA), whereas miR-10-5p, miR-202-3p, miR-210, and miR-375 differentiated MCN from SCA, IPMN, and PDAC^[92]. It is unclear why this overlap in miR-375 occurs^[92]. Henry *et al.*^[93] found that miR-92a, miR-99a, miR-100, miR-125b, miR-145, miR-212 and miR-483 were differentially expressed between benign and pre-malignant and malignant lesions of the pancreas and they suggested that a high amount of RNA present in the cystic fluid may suggest the presence of malignant transformation^[93]. As previously described miR-21, miR-155, miR-196a have been implicated in both PDAC and IPMN and given these widely replicated results, studies aimed at detecting these biomarkers in serum, saliva, and stool could help to determine, in a non-invasive way, if they are increased in pre-malignant lesions.

MiRNA in panin lesions

Currently, PanIN lesions are found in the neighboring pancreatic tissue of patients with PDAC; however, there is no consistent way to detect the presence of these lesions^[10,94-96]. Identifying a biomarker to detect PanIN lesions may be critical in early detection of PDAC. Slater *et al.*^[97] demonstrated that miRNA-196a and miR-196b were elevated in PDAC and PanIN-2/3 lesions in both animal models of PDAC and humans with PDAC. Ryu *et al.*^[98] demonstrated that miR-155

is up-regulated in PanIN-2 and PanIN-3 lesions when compared to neighboring healthy pancreatic tissue, but not in PanIN-1 lesions. Furthermore, miR-21 has been shown to be over-expressed in PanIN-2^[98,99] and PanIN-3^[98,99], but not PanIN-1 lesions suggesting that this is a marker for later disease. These are significant findings as miR-155 and miR-21 have been shown to be up-regulated in IPMN lesions and PDAC suggesting that they are early markers for cells with malignant potential. Yu *et al.*^[100] found that miR-196b was up-regulated in PanIN-3 lesions, which correlates with previous studies that have found that miR-196b is up-regulated in PDAC lesions^[100,101]. Importantly, miR-21, miR-155, miR200a, miR-200b, miR-182, and miR-296-5p were deregulated as early as PanIN-1 lesions and remained deregulated until progression to PDAC, with the exception of miR-200c that normalized in PanIN-3 lesions. A recent publication describing miRNA expression in PanIN lesions found that miRNA-148a and miR-217 were down-regulated while miR-10b was up-regulated in PanIN-2 and PanIN-3 lesions^[101]. While miR-21 has been shown repeatedly to be over-expressed in PDAC, there are conflicting studies on its deregulation in early PanIN lesions suggesting that it may represent a later and more aggressive dysregulation in the progression to PDAC. A non-invasive method to detect advanced PanIN lesions would represent a significant advance in the field.

DISCUSSION

While PDAC is the fourth most common cause of cancer-related deaths, there is still no reliable way to detect early disease and patients present with late-stage disease with a nearly 100% mortality. Research in the field of biomarkers shows a great deal of promise as current research aims to understand the molecular mechanisms and stromal microenvironment of this deadly tumor. MiRNA are small nucleotides that control the genetic expression in all cells and importantly in an organ-specific manner. Abberant miRNA expression has been identified in various cancers^[102-106], and factors such as transcriptional deregulation, epigenetic alterations, mutations, DNA copy number abnormalities, and defects in the miRNA biogenesis pathway may account for these differences in expression^[107,108]. C-myc and p53 are two transcriptional factors that have been associated transcriptional deregulation of miRNA^[109-111]. Epigenetic regulation of miRNAs by DNA methylation and histone tail modification play a role in miRNA expression through chromatin remodeling^[105,112-114]. Both germ-line and somatic mutations are responsible for miRNA expression levels in various types of cancers^[115-117]. It has been described by Calin *et al.*^[118], that miRNAs are located a fragile sites on the chromosome, minimal regions of loss of heterozygosity, minimal regions of amplifications, and common breakpoints, thus increasing the risk for DNA copy abnormalities. DNA copy abnormalities have been found in melanoma, breast cancer, ovarian cancer,

leukemia, colorectal cancer^[119-122]. Lastly, defects in miRNA biogenesis pathway may contribute to varying expression levels and cancer phenotype as miRNA undergoes complex processing intracellularly prior to reaching its mature form^[123-127]. In addition to the aforementioned mechanisms, dietary components, such as folate, retinoids, curcumin, and Vitamin D have been implicated in the modulation of miRNA expression^[128-130]. Some miRNAs have been shown to increase muscle loss in cancer cachexia and specifically, increased miR-21 levels have been shown to increase muscle breakdown in pancreatic cancer^[131,132]. Deeper understanding of the regulatory mechanisms of miRNA expression will hopefully give new insight to the factors responsible for miRNA deregulation and lead to miRNA-based diagnostic testing and miRNA-directed therapy for PDAC.

Some limitations that exist with the current miRNA research at this time include standardization of extraction, reproducibility of testing, diagnostic yield in the various sample methods, and small sample sizes. Additionally, despite finding biomarkers for this disease, there is limited evidence that miRNA will impact PDAC-related mortality. Dysregulation of miRNA affects the cell cycle, proliferation, apoptosis, epigenetics, oncogenesis, tumor differentiation, tumor invasion, tumor metastasis and migration, prognosis, and chemoresistance in numerous cancers^[133]. Increased efforts to understand the biological function of miRNA expression and its effects on cancer development are needed.

Despite these limitations, great advances have been made in this field and now miRNA expression is being analyzed not just in pancreatic tissue and cystic fluid, but also in stool, saliva, and serum; which would lead to non-invasive ways by which to analyze the expression levels of miRNA in patients at high risk. There have been great efforts to identify which of the greater than 2000 miRNAs are deregulated in PDAC and its precursor lesions and miRNA-21, miR-155, and miR-196b seem to be dysregulated in both early lesions and advanced cancer and show promise as potential screening tools in the future.

Abstract

Historically, natural products have represented a significant source of anticancer agents, with plant-derived drugs becoming increasingly explored. In particular, sanguinarine is a benzophenanthridine alkaloid obtained

from the root of *Sanguinaria canadensis*, and from other poppy *Fumaria* species, with recognized anti-microbial, anti-oxidant and anti-inflammatory properties. Recently, increasing evidence that sanguinarine exhibits anticancer potential through its capability of inducing apoptosis and/or antiproliferative effects on tumor cells, has been proved. Moreover, its antitumor seems to be due not only to its pro-apoptotic and inhibitory effects on tumor growth, but also to its antiangiogenic and anti-invasive properties. Although the precise mechanisms underlying the antitumor activity of this compound remain not fully understood, in this review we will focus on the most recent findings about the cellular and molecular pathways affected by sanguinarine, together with the rationale of its potential application in clinic. The complex of data currently available suggest the potential application of sanguinarine as an adjuvant in the therapy of cancer, but further pre-clinical studies are needed before such an antitumor strategy can be effectively translated in the clinical practice.

Core tip: Sanguinarine is a benzophenanthridine alkaloid isolated from the root of *Sanguinaria canadensis*, and other poppy *Fumaria* species, which exhibits a clear-cut anticancer potential by inducing apoptosis and/or antiproliferative effects on tumor cells. Sanguinarine also shows antiangiogenic and anti-invasive properties, as demonstrated *in vitro* and *in vivo*. In consideration of the multiple biological effects of sanguinarine, which suggest its possible use in cancer therapy, further detailed pharmacokinetic and toxicologic studies are required to assess both the efficacy and safety of the compound before proposing a possible translation into the clinic.

INTRODUCTION

Tumor initiation is the result of multiple genetic and epigenetic events. Transformed cells are characterized by indefinite proliferation, apoptosis-resistance and the capability to metastasize and support angiogenesis^[1].

Chemotherapy, irradiation and/or immunotherapy represent the gold standard approach for the treatment of cancer worldwide. The increased frequency of tumor relapse and the toxicity of the anticancer drugs, however, often reduce the therapeutical effectiveness of several antitumor therapy protocols. Therefore, the identification of more effective therapeutic protocols is needed and, in this direction, phytochemicals may represent an attractive alternative because of their low toxicity and low cost^[2]. In this scenario, sanguinarine (Figure 1) and chelerythrine are the principal members of quaternary benzo[c]phenanthridine alkaloids (QBAs)^[3] obtained from *Sanguinaria canadensis*, *Chelidonium majus*, and *Macleaya cordata*. Alkaloids include a large group of secondary metabolites (SMs) that differ in relation to structure, function and biodistribution^[4]. In the past, QBAs have attracted the attention of many pharmacologists because of their own low toxicity^[5,6] and their multiple biological activities, such as the antitumor^[7], antimicrobial^[8,9], anti-inflammatory^[10], anti-HIV^[11], anti-platelet^[12], anti-angiogenesis^[13], and antiparasitic activities^[14-16]. The influence of QBAs on the activity of various important biological enzymatic pathways has been also demonstrated^[7]. For long times, sanguinarine-containing herbs were believed to possess anticancer activity but only recently evidence that sanguinarine possesses a strong anti-neoplastic activity, which is mediated mainly by the induction of tumor cell apoptosis has been proved.

This review summarizes the most recent findings on the molecular mechanisms underlying the antitumor activity of sanguinarine both *in vitro*, in a variety of human tumor cells, and *in vivo* in selected experimental tumor models, together with the rationale of its potential application in clinical practice.

SANGUINARINE INDUCES APOPTOSIS IN TUMOR CELLS

Physiologically, the human body controls homeostasis by eliminating damaged and aged cells by means of a genetically programmed process named apoptosis^[17,18]. Tumor cells evade apoptosis and grow indefinitely. Several proteins, among which are caspases, pro-

apoptotic Bax and anti-apoptotic B cell lymphoma (Bcl)-2, cytochrome c, and apoptotic protease activating factor -1, carry out the apoptotic programme either by intrinsic or extrinsic pathways. The first one is dependent on mitochondria, whereas the second one is initiated by the so-called death receptors (DRs). Selected anti-apoptotic proteins, among which Bcl-2, have been found over-expressed in different types of cancers. The down-regulation of anti-apoptotic proteins in cancer cells represents a promising therapeutic strategy of intervention in cancer therapy.

A number of plant-derived agents, have been shown to be capable of hampering disease progression by inducing cell apoptosis in multiple types of human and experimental cancers. Recently QBAs, and particularly sanguinarine, have been indicated as potential anti-cancer compounds. In detail, it has been reported that micromolar concentrations of sanguinarine are capable of inhibiting tumor cell growth, and this inhibitory effect is associated with cell cycle arrest and induction of apoptosis^[19-22]. The anti-proliferative and/or pro-apoptotic activities of sanguinarine have been demonstrated in *in vitro* studies on several cancer cell types including epidermal^[23], keratinocyte^[24,25], prostate^[26-28], cervical^[29], breast^[20,30-33], leukaemia^[34,35], lymphoma^[36], melanoma^[37-39], colon^[40,41], colorectal^[21], gastric^[42], pancreatic^[19], lung^[22], neuroendocrine^[43], osteosarcoma^[44], and human neuroblastoma cells^[45]. By contrast, there are few studies on the *in vivo* effectiveness of sanguinarine administration *per os*^[46,47] in animal tumor models^[33,48].

It has been reported that sanguinarine exerts an antiproliferative activity on murine melanoma cells both *in vitro* and *in vivo* (B16 melanoma 4AS in the syngeneic host C57BL/mice), as well as in A375 human melanoma xenografts in athymic nude mice^[48]. We also have conducted a study aimed at evaluating the anti-tumor effect of sanguinarine both *in vitro* and *in vivo* in a rat colorectal cancer model (DHD/K12/TRb cell line)^[49]. We found that the *in vitro* addition of sanguinarine has a dose-dependent inhibitory effect on the proliferation of DHD/K12/TRb cells and induces tumor cell apoptosis. Sanguinarine also showed a clear-cut *in vivo* anti-tumor activity, leading to an inhibition of tumor growth higher than 70%^[49]. The sanguinarine-induced inhibition of tumor growth was associated with its pro-apoptotic effect on tumor cells, as confirmed by the *ex-vivo* histopathological examinations performed on experimental tumor sections and by TUNEL assay^[49].

It is known that sanguinarine-induced apoptosis occurs through multiple pathways, including the activation of nuclear factor- κ B (NF- κ B)^[50], the mitochondrial damage resulting in activation of the caspase machinery^[24] and the cell cycle arrest^[27]. In detail, the sanguinarine-induced apoptosis occur either *via* a mitochondrial pathway dependent on caspase-9 or by the DR pathways, with the activation of caspase 8. The activation of caspase 3, which represents a key factor for apoptosis execution in both pathways, and the following

Figure 1 Chemical structure of sanguinarine.

cleavage of PARP together with the down-regulation of Bcl-2 and c-FLIP, may play a very important role in the apoptosis induced by sanguinarine^[26,51,52]. Studies performed in human neuroblastoma cells SH-SY5Y have shown that sanguinarine reduces the expression of anti-apoptotic genes, particularly of NOL3, BCL2, and HRK genes^[45]. A down-regulation of pro-caspase 3, Bcl-2, cIAP2, XIAP, and c-FLIPs^[20,52] has been also observed in basal cell-like MDA-MB-231 human breast carcinoma cells treated with sanguinarine. The effect of sanguinarine treatment has been evaluated also on the expression levels of Bax and Bcl-2 proteins in immortalized human keratinocytes (HaCaT)^[24,25], human leukaemia JM1 and K562 cells^[35] and in HeLa and SiHa human cervical tumor cells^[53]. These findings indicate that sanguinarine, depending on the dose employed, down-regulates the expression levels of Bcl-2 protein while increasing those of Bax protein, which is a key regulator of mitochondrial damage. Notably, Bax expression has been associated with an increased sensitivity of cancer cells to chemotherapy^[54], whereas an increase of Bcl-2 has been associated with the occurrence of drug-resistance phenomena^[55].

It has been proved that sanguinarine is capable of inducing DNA damage, acting as an intercalating agent^[56,57], and also a very rapid cell apoptosis which does not seem to be mediated by a p53-dependent DNA damage signalling in human colon cancer^[41] and in malignant melanoma cells^[38].

The concentration of sanguinarine plays a key role in the induction of cell death. Consistently, both apoptotic and non-apoptotic cell death pathways have been observed in response to sanguinarine. Thus, a sanguinarine-related and bimodal cell death effect, which consists of two different types of cell death, *i.e.*, by apoptosis (induced by low SA concentration; characterized by caspase 3 and PARP positivity) and oncosis (induced by high SA concentration; characterized by caspase 3 and PARP negativity), has been demonstrated in various cancer cells types^[52].

SANGUINARINE INDUCES ALTERATIONS IN CELL CYCLE

Tumor cells are characterized by deregulated proliferation. Conversely, normal cells proliferation is the

results of the action of selected growth signals [cyclins and cyclin-dependent kinases (CDKs)] and anti-growth signals (p21 and p27 proteins). Cyclins and CDKs cooperate in G1 for the initiation of the S phase and in G2 for inducing mitosis, whereas p21 and p27 selectively block the catalytic activity of CDK. Following addition of anti-mitogenic compounds or DNA injury, p21 and p27 bind to cyclin-CDK complex blocking their catalytic activity and consequently the cell cycle progression.

Actually a number of inhibitors and/or regulators of the cell cycle, among which sanguinarine, are suggested as potential antitumor agents. Sanguinarine treatment (0.2-2 mol/L for 24 h) blocks cell cycle by enhancing the expression of CDK inhibitors and by reducing not only cyclin D1, D2 and E, but also CDK2, 4 and 6 in human prostate cancer cells^[27]. This alkaloid also up-regulates p27 and down-regulates cyclin D1, while inhibiting the activation of STAT3, as demonstrated *in vitro* in basal cell-like MDA-MB-231 human breast cancer cells and *in vivo* in a murine breast cancer model^[33]. Holy *et al.*^[31] studied the effects of sanguinarine (5-10 µmol/L) on the cell cycle regulatory molecules, by immunocytochemistry, that visualized the cyclin D1 and topoisomerase II in MCF-7 breast cancer cells. They reported that sanguinarine-mediated cellular events induce cell cycle arrest in G0/G1 and inhibit cell proliferation, which is associated with a striking re-localization of cyclin D1 and topoisomerase II from the nucleus to the cytoplasm.

SANGUINARINE-INDUCED APOPTOSIS THROUGH THE GENERATION OF REACTIVE OXYGEN SPECIES

Apoptosis induced by sanguinarine has been associated also with the production of reactive oxygen species (ROS)^[20,36,52,58]. ROS are a group of highly reactive molecules, among which are superoxide anion radical, hydrogen peroxide, singlet oxygen, and hydroxyl radical. ROS are the products of the oxygen metabolism within the cell. ROS are known as key regulators of normal cell proliferation and differentiation, however, high levels of ROS have also been associated with damage of DNA and proteins and thus with the occurrence of apoptosis^[59,60]. Moreover, an overdone oxidative stress has been shown capable of inducing a reduction of the normal mitochondrial membrane potential, which in turn leads to apoptosis^[21,61-63]. It has been shown that ROS generation, is crucial for the apoptosis induced by sanguinarine in human breast cancer^[52], SK-Mel-2 human melanoma^[37], human prostate cancer^[25] and in both HCT-116^[21] and HT-29 human colon cancer cells^[40]. Consistently, pre-treatment of tumor cells with antioxidants such as *N-acetylcysteine* or glutathione counteracts the apoptosis induced by sanguinarine^[21,32,37,52]. Moreover, the over-expression of cyclooxygenase-2 (COX-2) also rescues prostate cancer cells from sanguinarine-induced apoptosis by

inhibiting the activity of NO synthase, thus suggesting the possibility to use a combination of COX-2 inhibitors and sanguinarine in the treatment of human prostate cancer^[28].

SANGUINARINE-MEDIATED INHIBITION OF NF- κ B

The molecular pathways associated with carcinogenesis are linked also with chronic inflammation, which emerges as an important co-factor in tumor development. The NF- κ B controls the inflammatory gene expression and recently it has been suspected to be involved also in the control of tumor development^[64]. Resting NF- κ B localizes within the cell cytoplasm in the form of a heterodimer composed by p50, p65, and the inhibitory subunit I κ B α ^[65]. Following activation, the I κ B α protein is phosphorylated, ubiquitinated and finally degraded. Then, the p50 and p65 reach the nucleus of cell, where they interact with selected DNA sequences localized in the promoter region of various genes, leading to their transcription. Consistently, the NF- κ B signalling pathway has been indicated as a key-target for the development of new chemotherapeutic approaches in cancer.

Sanguinarine has been suggested as a potential actor in the control of NF- κ B-dependent pathological responses by blocking phosphorylation and degradation of I κ B α . Studies by Chaturvedi *et al.*^[50] showed that in human myeloid ML-1a cells, the treatment with sanguinarine is capable of abrogating, dose- and time-dependently, the activation of NF- κ B induced by tumor necrosis factor.

INHIBITION OF TUMOR ANGIOGENESIS BY SANGUINARINE

Many reports indicate that sanguinarine exerts antitumor activity not only by inhibiting tumor cells migration and/or invasion, but also by repressing angiogenesis^[22,66]. Since solid tumors require active angiogenesis, the inhibition of endothelial cell proliferation result in the inhibition of tumor growth and progression. The best known angiogenic growth factor is represented by VEGF. Several studies have explored the relationship existing among sanguinarine, angiogenesis and metastatization. In particular, Eun and Koh^[13] showed that sanguinarine inhibits the VEGF-induced endothelial cell migration, sprouting and survival *in vitro*, and blocks blood vessel formation *in vivo* in different experimental models. Furthermore, Basini *et al.*^[67] showed that sanguinarine is capable of blocking the VEGF-induced blood vessel growth. Depending on the concentration used, sanguinarine also inhibits VEGF secretion in human microvascular endothelial cells HMVEC as well as in A549 lung cancer cells^[68]. This inhibitory effect has been associated with the suppression of the phosphorylation of Akt, p38 and VE-cadherin, which are well known modulators of the VEGF signal transduction pathway^[67,69]. Moreover,

sanguinarine enhances apoptosis in human mammary adenocarcinoma MCF-7 through the inhibition of VEGF release, induced by generation of ROS^[32]. Sanguinarine also inhibits angiogenesis in preclinical experimental tumor models, such as mouse melanoma^[48] and rat colorectal cancer, as we reported previously^[49]. In both the experimental studies, the therapeutic efficacy of sanguinarine could not be attributed only to a direct anti-proliferative activity but also to the inhibition of tumor angiogenesis induced by this alkaloid.

The rationale of using VEGF-targeted therapies in the treatment of cancer lies in the possibility they offer to counteract the over-expression of VEGF provoked by chemotherapeutic drugs and radiation^[70]. Consistently, dacarbazine, which is used in the therapy of human melanoma, induces increased VEGF-A production^[71], and dacarbazine-resistant melanoma cells show an increased *in vivo* growth together with an increased microvessel density^[72]. These studies suggest the potential application of sanguinarine, alone or in association with other VEGF inhibitors, in the control of both angiogenesis and metastatization of solid tumors.

INHIBITION OF TUMOR CELL INVASION BY SANGUINARINE

In solid tumors, neoplastic cells can penetrate the basement membrane by proteolysis and initiate metastatization, which accounts for the majority of cancer deaths. Metastatization is the result of the cooperation between cancer cells and a sort of "inflamed" micro-environment^[73]. Consistently, inflammatory cells are an important source of proteases capable of causing a degradation of extracellular matrix, which represents a crucial event in the initiation of cancer cell invasion. Matrix metalloproteinases (MMPs) are an example of agents capable to degrade the extracellular matrix^[74,75] and an over-production of these enzymes has been detected in various metastatic cancers^[76-78]. Indeed, there is a strong evidence that increased expression and activation of MMP-2 and MMP-9 is present in tumor tissues but not in normal tissues in patients with breast cancer^[79] and that MMP-2 induces cancer cell migration by means of its interaction with collagen^[80].

Recent findings show that sanguinarine inhibits the tetradecanoylphorbolmyristate acetate (TPA)-induced breast cancer cell migration and invasion while inhibiting the expression of MMP-9, NF- κ B and AP-1 signaling pathways^[81]. Moreover, previous studies by Sun *et al.*^[66] have showed that sanguinarine reduces prostate cancer cell growth and invasion by the inhibition of STAT3 activation. STAT3 is constitutively active in human prostate cancer metastases and has a key role in the phenomena of tumor cell migration and invasion in different types of cancer^[82-84]. Since the invasivity and/or metastatic potential of a tumor parallel its malignancy, the above findings indicate that sanguinarine may play a crucial role as a therapeutic agent in anticancer therapy

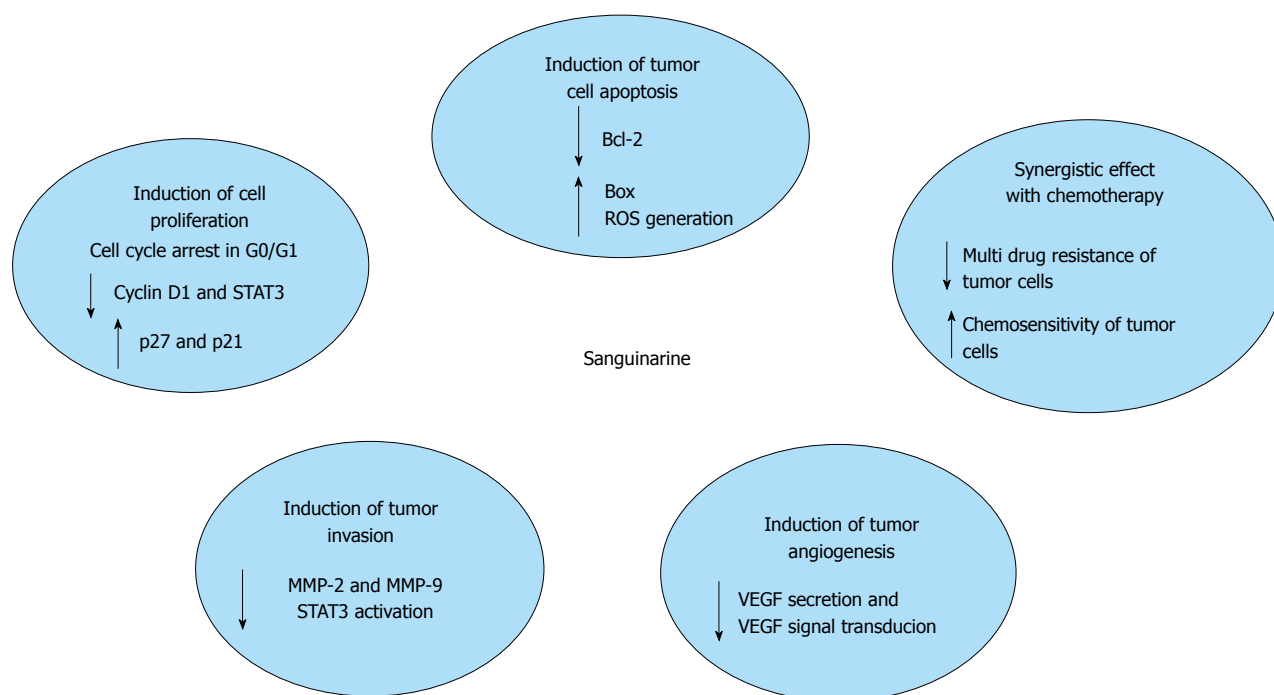

Figure 2 Cellular and molecular mechanisms underlying the antitumor activity of sanguinarine, as assessed by means of *in vitro* and *in vivo* experimental studies. ROS: Reactive oxygen species; Bcl: B cell lymphoma; VEGF: Vascular endothelial growth factor; MMP: Matrix metalloproteinase; STAT: Signal transducer and activator of transcription.

not only for its ability to induce apoptosis but also for its own “anti-invasive” properties.

SYNERGISTIC INTERACTION OF SANGUINARINE WITH CHEMOTHERAPEUTIC AGENTS

Several plant SMs are capable of influencing effectively the multidrug resistance phenomenon in tumor cells and are able also to “chemo-sensitize” them^[85-89]. Some clinical studies have explored the possible advantage of combining natural products with classical chemotherapeutic regimens^[90-92]. Phytotherapy, which employs plants extracts, is still used worldwide for the treatment of various human diseases. However, evidence has been proved that combinations of individual SM in an extract may exert synergistic effects. As an example, a recent study demonstrates that the combined use of non-toxic concentrations of sanguinarine and digitonin with doxorubicin, synergistically sensitizes Caco-2 (human colorectal adenocarcinoma) and CEM/ADR5000 adriamycin-resistant leukemia cells and increases the cytotoxicity of the chemotherapeutic agent doxorubicin^[93]. In this regard, it is worth mentioning that the main advantage of combination therapies is represented by the possibility of reducing the doses and thus the toxicity of chemotherapy, while retaining its own efficacy. Thus, because of its potential synergistic interaction with chemotherapeutic agents, the therapeutic use of sanguinarine as an adjuvant, in association with chemotherapy, might be considered as a theoretical option in cancer therapy.

CONCLUSION

A successful resolution to the design of antitumor drugs relies, at least in part, on the possibility to overcome the intrinsic resistance to undergo apoptosis detected in many transformed cells. Findings from the studies above mentioned show that sanguinarine is capable of inhibiting tumor growth through different molecular pathways (Figure 2). A summary of the results is shown in Table 1. In conclusion, despite sanguinarine has been extensively studied, the precise mechanisms responsible for its antitumor effects still have not been completely elucidated and are strictly dependent on the cell type studied. According to the results obtained so far, it can be said that the anti-tumor action of this alkaloid is the result of a combined effect both on proliferation and invasiveness of tumor cells, that on regulation of the complex phenomena of tumor angiogenesis. In particular, owing to its pro-apoptotic potential, sanguinarine is a good candidate for the development of new anticancer therapies either when used alone or in combination with other chemotherapeutic regimens. More extensive investigation and greater caution are needed, however, to clarify the following important issues. First of all, most of the studies above mentioned have been performed *in vitro* using cancer cell lines, whereas there are only a few *in vivo* studies validating the efficacy and safety of sanguinarine administration in animal tumor models. The results of our *in vivo* studies confirm the effectiveness and safety of using oral sanguinarine administration to control tumor growth in rats^[49]. Similar results had been previously reported in a murine melanoma model^[48]. In that study, and

Table 1 The antitumor activity of sanguinarine

Sanguinarine induces apoptosis in tumor cells through multiple pathways, including the activation of NF- κ B, the mitochondrial damage and cell cycle arrest
Sanguinarine-induced apoptosis is associated with the decrease of Bcl-2 and the increase of Bax proteins and the generation of reactive oxygen species
Sanguinarine causes cell cycle arrest by increasing the expression of p27 and decreasing cyclin D1, D2 and E, and CDK2, 4 and 6
Sanguinarine inhibits tumor progression associated with chronic inflammation <i>via</i> the inhibition of NF- κ B
Sanguinarine inhibits tumor angiogenesis through the inhibition of VEGF secretion and VEGF signal transduction (Akt, p38 and VE-cadherin)
Sanguinarine has an inhibitory effect on tumor cell migration by the inhibition of MMP-9 and STAT3 activation
Sanguinarine exerts a synergistic effect with chemotherapeutic agents and enhances the chemosensitivity of Caco 2 and CEM/ADR5000 adriamycin-resistant leukemia cells

NF- κ B: Nuclear factor- κ B; CDK: Cyclin-dependent kinase; Bcl: B cell lymphoma; VEGF: Vascular endothelial growth factor; STAT: Signal transducer and activator of transcription.

in agreement with our findings, the anti-proliferative and anti-angiogenic effects of the oral sanguinarine administration were observed at a dosage, *i.e.*, 5 mg/kg, devoid of apparent toxicity. On the other hand, an increase of serum levels of transaminases and LDH, hepatic vacuolization, lipid accumulation and peroxidation in the liver and a reduction of triglycerides, were observed in mice treated with high-dose sanguinarine (10 mg/kg), suggesting liver injury^[94]. Previous studies showed that sanguinarine can cause physiological dysfunction in skeletal, smooth and cardiac muscles^[95-97]. More recent studies clearly indicate that sanguinarine acts as a pro-apoptotic factor and alters mouse normal embryonic development at a physiological dosage, *i.e.*, 0.5-2 μ mol/L, which are obtained *via* dietary intake^[98]. These experimental results need further confirmation in view of the possible administration of the compound in pregnancy, although at present no teratogenic effects have been reported in humans.

Most of the studies actually known have reported that sanguinarine exerts cytotoxic activity selectively on cancer cells. Consistently, sanguinarine is a negative regulator of human epidermoid carcinoma cells (A431) but not of normal epidermal keratinocytes^[23]. Evidence of this differential activity have been reported recently, showing that mouse lymphocytic leukemic cells are more sensitive to sanguinarine than normal splenocytes^[99].

It is a matter of fact, however, that sanguinarine has been listed as responsible for the toxicity of *Argemone mexicana* seed oil^[100-102]. Das *et al.*^[103] reported that topical use of argemone oil (0.15-0.3 mL) or sanguinarine (4.5-18 μ mol/L) followed by application of TPA induces tumor development in a murine experimental model. Ansari *et al.*^[104] also reported that intraperitoneal administration of sanguinarine induces DNA damage in Swiss albino mice. Sanguinarine in argemone oil, is suspected to cause glaucoma^[101,102]. Argemone oil increases incidence of bladder cancer in animal models^[103] and of gall bladder cancer in humans^[104]. Furthermore, sanguinarine extract from bloodroot (*Sanguinaria canadensis*), previously used in oral hygiene products, was discontinued until a link between product administration and occurrence of leukoplakia was established^[105,106]. Hepatic microsomes transform sanguinarine in a mutagenic epoxide and the same sanguinarine is capable of activating polycyclic aromatic

hydrocarbon signaling^[107]. However, related to this topic, the results available in literature are not univocal^[3]. So that is still not clear if sanguinarine may act as a carcinogenic without the cooperation of other risk factors or it is capable of acting in concert with various co-carcinogens. In light of the above facts, the possibility of obtaining beneficial effects in humans by using sanguinarine remains largely unpredictable.

Finally, since at present there is increasing interest in nanotechnology application in cancer therapy and in order to prevent the potential toxic and/or side effects induced by sanguinarine administration, *in vivo* studies might be performed in experimental tumor models by encapsulating the alkaloid in tumor-targeted nanoparticles^[108], which accumulate preferentially in tumors recognizing single cancer cells for diagnosis and treatment. Actually, the administration of sanguinarine (10 mg/kg) *per os* and encapsulated by lipid nanoparticles (SG-SLNs), has been shown to induce an anti-inflammatory effect in an LPS-induced endotoxin shock murine model, and the pharmacokinetic studies have proved that the AUC₀₋₂₄ and C_{max} of SG-SLNs were significantly increased when compared to those of sanguinarine alone^[109].

In conclusion, several studies indicate the potential application of sanguinarine as an adjuvant in the therapy of cancer, but further detailed pharmacokinetic and toxicology studies, which have to be conducted in appropriate experimental tumor models, are absolutely required to assess the efficacy and safety of this compound before such an antitumor strategy can be translated in clinical trials.

Abstract

Gastric carcinoma (GC) develops in only 1%-3% of *Helicobacter pylori* (*H. pylori*) infected people. The role in GC formation of the bacterial genotypes, gene polymorphisms and host's factors may therefore be important. The risk of GC is enhanced when individuals are infected by strains expressing the oncoprotein CagA, in particular if CagA has a high number of repeats containing the EPIYA sequence in its C-terminal variable region or particular amino acid sequences flank the EPIYA motifs. *H. pylori* infection triggers an inflammatory response characterised by an increased secretion of some chemokines by immunocytes and colonised gastric epithelial cells; these molecules are especially constituted by proteins composing the interleukin-1beta (IL-1 β) group and tumour necrosis factor-alpha (TNF- α). Polymorphisms in the promoter regions of genes encoding these molecules, could account for high concentrations of IL-1 β and TNF- α in the gastric mucosa, which may cause hypochlorhydria and eventually GC. Inconsistent results have been attained with other haplotypes of inflammatory and anti-inflammatory cytokines. Genomic mechanisms of GC development are mainly based on chromosomal or microsatellite instability (MSI) and deregulation of signalling transduction pathways. *H. pylori* infection may induce DNA instability and breaks of double-strand DNA in gastric mucocytes. Different *H. pylori* strains seem to differently increase the risk of cancer development run by the host. Certain *H. pylori* genotypes (such as the *cagA* positive) induce high degrees of chronic inflammation and determine an increase of mutagenesis rate, oxidative-stress, mismatch repair mechanisms, down-regulation of base excision and genetic instability, as well as generation of reactive oxygen species that modulate apoptosis; these phenomena may end to trigger or concur to GC development.

Key words: *Helicobacter pylori* infection; CagA; CagA gene polymorphism; Haplotype; Human gene mutation;

Gene methylation; Gastric carcinoma; Inflammatory cytokine

Core tip: CagA and the *cagA* types may play different roles in the intestinal and diffuse histotypes of gastric carcinoma (GC); The current criteria of *Helicobacter pylori* (*H. pylori*) strain classification based on their carcinogenic potential gave rise to confusion and should be unified. The possible role of inflammatory cytokine haplotypes in GC development should be reassessed taking into account some host's factors, the most important being different ethnic origin. Infection by the *cagA* positive *H. pylori* genotype may determine an increased inflammatory response and a consequent enhancement of mutagenesis rate, oxidative-stress, reactive oxygen species generation, dysfunction of DNA repair mechanisms, genetic instability and resultant high risk of GC development.

INTRODUCTION

Gastric carcinoma (GC) is the second most frequent cause of death from cancer worldwide and the most common example of a neoplasia developing on a ground of a chronically inflamed mucosa. GC has also another record: It is the only known malignant tumour that can develop as a consequence of a chronic bacterial infection^[1]. In 1994, the International Agency for Research on Cancer classified the organism responsible for the infection, *Helicobacter pylori* (*H. pylori*) - a Gram negative, microaerophilic and spiral-shaped species that finds its *habitat* in human stomachs - as a definite carcinogen to humans (Group 1): The connection of *H. pylori* with gastric cancer was considered similar to that existing between the cigarette smoke and lung cancer^[2].

The bacterium *H. pylori*: Not all the strains are alike

It soon became clear, however, that such comparison was reductive and too simplistic, especially because the ability of these bacteria to trigger a neoplasm is not limited to the inflammatory and immune response to the infection that they cause, but it also resides in a series of bacterial factors capable of prompting and modulating the carcinogenic process^[3].

As is the case for all diseases, also GC develops from the concomitance of three factors: The etiological agent, the host and the environment. Of course, many other factors may occur; for example, the cancer histological

variant, the degree of differentiation of the neoplasia *etc.*^[4]. Regarding the etiological agent, *H. pylori*, there are many indications that not all strains are equivalent in their carcinogenic potential and that those expressing an immunodominant peptide determinant called CagA (cytotoxin associated gene A), are endowed with an increased inflammatory and carcinogenic potential^[5-9]. A first point has therefore been established: Strain genomic diversity corresponds to different ability to promote cancer. The possibility that a bacterial factor (CagA) could trigger or concur to the development of GC is one of the most important scientific achievements following the isolation of *H. pylori*.

The importance of being called CagA positive

It is worthwhile mentioning the steps that paved the way to the discovery of CagA. At the end of the 80ies, Leunk *et al.*^[10] first proposed that *H. pylori* should not be considered a clonal pathogen, as a relevant proportion of isolates produce a vacuolating toxin, which could account in part for the gastric mucosa damage observed in infected individuals. Afterward, our group suggested that infection by cytotoxic strains increased the risk of developing peptic ulceration^[11] and that virtually all cytotoxic isolates also secreted a 120 kDa highly immunogenic protein, later called CagA^[12]. In 1992, Crabtree *et al.*^[13] demonstrated, through *ex vivo* experiments, that such a protein was produced either by the bacteria isolated in culture and also by the organisms colonizing the gastric epithelium: Gastric antral explants of patients with GC and other pathologies were cultured *in vitro* for a few days; the bacteria that colonized the mucosa kept on secreting this peptide, which could lastly be detected in the culture medium by using immunological methods^[13]. In 1993, the same team established, for the first time, the existence of a relationship between infection by strains expressing the 120 kDa protein and GC development^[14]. Their observations were important also because these researchers found anti-120 kDa protein mucosal IgA antibodies even in the absence of systemic IgG to this protein and, in some patients, also in cases with urease negative biopsies (false negatives). In the same year (1993), the gene encoding for the 120 kDa protein was cloned, sequenced and called *cagA* due to the strict association of protein expression with cytotoxin production^[5]. As a result of these findings, the number of studies dealing with the characterisation of CagA and its potential carcinogenicity increased exponentially and results lead to the common conclusion that such peptide is a major factor in gastric carcinogenesis.

CagA is the product of the homonymous gene placed at the end of the so-called pathogenicity island (PAI) *cag*, a fragment of DNA encompassing an approximately 40 kb cluster of genes involved in virulence. In the field of bacteriology there are numerous examples of PAIs harboured by diverse bacterial species or their virulent variants, whether they are human (*Bordetella*

pertussis, *Escherichia coli*, *Salmonella enterica*, etc.) or plant pathogens (*Agrobacterium tumefaciens*). In some species, PAI genes cooperate to translate effectors (mainly proteins) endowed with carcinogenic potential inside colonised cells. In *H. pylori*, such determinant is CagA. Similarly, *A. tumefaciens* exploits the Type IV secretion system *vir* to translate a single-stranded form of T-region (T-strand) coated by the ssDNA-binding protein VirE2 (T-Complex) into the host's vegetal cell nuclei. Once inside the nucleus, the T-strand can be converted in a double-stranded form (T-DNA), whose expression causes an uncontrolled host cell proliferation and tumour development^[15].

Epidemiological and genomic studies suggest that the development of GC is a possible consequence of infection by strains expressing CagA^[1,8,9,14,16]. In effects, using Mongolian gerbils infected experimentally, it was shown that only CagA positive (CagA+) *H. pylori* strains were able to induce stomach tumours^[17]. In addition, a study of our group revealed that, while virtually all patients with intestinal histotype of GC had serum antibodies to CagA, the prevalence of anti-CagA antibodies in patients with the diffuse GC variety was similar to that observed in infected controls without neoplasia^[16]. These data were confirmed by the results of an epidemiological study: The overall GC risk in infected people lacking anti-CagA antibodies (CagA-) was increased, but in non-significant way; in any case, CagA- *H. pylori* infection was associated with the growth of the diffuse variety of GC (with an OR of 9.0)^[8].

It therefore seems that infections by CagA+ strains expose people to an increased risk of GC respect to infections by CagA- *H. pylori* strains, which can only be associated with the diffuse histotype. In effect, things work slightly differently. In a recent study, we examined for the presence of *cagA* up to 25 distinct, well separated colonies per patient with GC; even though only individuals with diffuse histotype GC harboured *cagA* negative (*cagA*-) organisms, in all cases patients were also infected by at least one *cagA* positive (*cagA*+) strain^[18]. These observations do not corroborate the supposed propensity of strains lacking *cag* PAI to concur to diffuse GC development and suggest that, for a better comprehension of the role played by *cagA* in the histological variety of GC, many colonies per patient should be examined genomically.

CagA phosphorylation by mucocytes: Like shooting oneself in the foot

H. pylori organisms expressing CagA differ in their carcinogenic potential. Let us have a look at the mechanisms that may influence the ability of such a protein to trigger and/or concur to GC formation. CagA, following colonisation, is translated into the gastric epithelial cells through a conjugative apparatus encoded by the *cag* PAI genes upstream *cagA*; then, a portion of intracellular CagA is phosphorylated by numerous kinases, members of the host cell Src family (such as Yes, Lyn, Fyn and

c-Src,) at the EPIYA C'-terminal site (Glu-Pro-Ile-Tyr-Ala) motif of tyrosine^[19]. Phosphorylated CagA physically interacts with the oncogenic tyrosine phosphatase SHP-2 (Src homology phosphatase 2), modifying cellular functions and altering mammalian signal transduction machineries. SHP-2, in fact, is implicated in the regulation of cell adhesion, spreading and migration. In this manner, phosphorylated CagA causes deregulation of SHP-2 and induces abnormal proliferation, as well as movement of cells of the gastric epithelial layer, activates mitogenic signalling and disturbs host-signalling routes^[20]. All these events may also predispose cells to accumulate multiple genetic and epigenetic alterations involved in gastric tumorigenesis^[21].

Unphosphorylated CagA, on the other hand, interacts with the tumour suppressor protein of p53 (ASPP2), which also exert an apoptosis-stimulating activity^[22]. In normal conditions, following genotoxic and oncogenic stimuli, ASPP2 associates with tumour suppressor p53, activates it and induces apoptosis. After interaction with CagA, cytosolic p53 is recruited by ASPP2 and subsequently is degraded by an enzyme complex that control cell-cycle and apoptosis, the proteasome. As a consequence, the apoptotic response of host cells is inhibited. In other words, unphosphorylated CagA takes control of ASPP2 and subverts the tumour suppressor pathway of apoptosis-stimulating protein p53 with consequent promotion of cell survival and cell transformation^[20-22]. The resultant abnormal proliferation of gastric epithelial cells may contribute to GC development.

Individual CagA proteins have different biological activity and tumorigenic potential: When size matters

H. pylori strains secreting CagA protein endowed with increased biological activity can be considered more virulent and even more closely associated with gastric cancer. At the end of 90's, the group of Graham discovered the ability of distinct CagA proteins to perturb cellular functions might vary in different isolates^[23]. The CagA C'-terminal region contains one or more repeats of the same amino acids in sequence (Glu-Pro-Ile-Tyr-Ala, or EPIYA)^[5]; the teleonomic significance of such phenomenon reflects the bacterial strategy to generate antigenic diversity, which may protect the organisms from the immune response. The number of EPIYA motifs correlates with the size of the *cagA* variable region. Yamaoka *et al.*^[23] basing of the amplicon sizes obtained with primers encompassing the entire *cagA* variable region, classified *H. pylori* isolates in *cagA* structural types A, B, C and D (amplicons characterising types B and D have the same size and can be differentiated by sequencing). Strains with the *cagA* structural type C have the highest number of EPIYA phosphorylation motifs and were isolated significantly more often from patients with GC^[23], confirming a previous observation that individuals with GC are infected by strains expressing CagA proteins with higher mass^[24]. The incr-

eased carcinogenic potential of the *cagA* structural type C was also confirmed by another study of the same group, which showed that patients infected by *H. pylori* with this *cagA* genotype run a higher risk of developing gastric mucosa atrophy, a precancerous condition^[25].

Now, it should be highlighted that the primers used in these studies to amplify the *cagA* variable region were designed on oriental (Japanese) strains, which may differ from western strains in the nucleotide sequence encoding the C'-terminal variable region^[26]. Probably for this reason not all surveys on the same subject have confirmed the Yamaoka *et al.*^[23,25]'s findings. In an initial study of our group, in which we used the Yamaoka's primers to amplify the *cagA* variable region of Italian strains^[27], we sometime obtained amplicons shorter than the PCR product that characterises the *cagA* structural type A; strains producing such amplicons, which presented a deletion of about 100 bp respect to *cagA* type A, were named type A(I), with (I) standing for Italy, because, as far as we know, similar *cagA* structural variety had not previously been described. In a more recent investigation, we observed similar proportions of the various *cagA* structural types in Italian *H. pylori* organisms isolated from GC cases and from controls (patients without neoplasia, with chronic gastritis only)^[28]. In addition, in the control subjects, we frequently detected strains with the *cagA* structural type A(I). The increased prevalence of such a *cagA* type in individuals without GC prompted us to hypothesise that the reduced dimensions of the encoded CagA may decrease the ability of these bacteria to trigger a neoplastic process. As a matter of fact, the capability of CagA of binding SHP-2, and therefore of disturbing the various cellular functions, is regulated by the amounts of tyrosine phosphorylation site sequences, *i.e.*, the CagA size^[20]; therefore, the shorter the protein, the less numerous are the EPIYA repeats that undergo phosphorylation and the lower is the carcinogenic potential of strains.

The employment of primers proposed by Yamaoka *et al.*^[23] to amplify the *cagA* variable region of western strains has sometimes led to results similar to those of the Japanese researchers: South African researchers, for instance, have confirmed that patients with GC have an increased prevalence of strains with type C CagA^[29]. Investigations dealing with this important subject, however, are not numerous; in addition, sometimes they attained different conclusions and have even contributed to create confusion in this subject. Malaysian authors, for instance, using the primers designed by Yamaoka *et al.*^[23], determined the presence and distribution of *cagA* variants among different ethnic groups and various gastroduodenal diseases^[30]. They obtained three types of amplicons and named the *cagA* subtypes with capital letters, A, B and C (like did Yamaoka *et al.*^[23]), but, just to complicate this topic further, they used a different criterion (respect to that of the previous study) and called subtype C the strains with the smallest amplicon

size and subtype B those with the greatest one. Specific *cagA* subtype A strains (those yielding amplicons of intermediate size) were predominantly isolated from Chinese compared to Malays and Indians patients. Since Chinese patients have the highest risk of GC disease respect to the other ethnic groups, these investigators concluded that *cagA* subtyping could be used as a clinical biomarker for severe outcome of infection. Such statement, however, was based on indirect observations because they did not examine strains from GC cases^[30].

In 2002, Higashi *et al.*^[20] observed that the ability of CagA secreted by different strains to disturb host-cell functions can be influenced by the strength of SHP-2 binding activity, which was increased in *H. pylori* strains obtained from patients living in East Asian areas (Japan, Chorea and China) respect to those isolated from patients of Western countries (Europe, America, and Australia). In addition to the number of EPIYA repeats, it was also found that polymorphism in the nucleotide sequence flanking the regions that encode EPIYA could affect the potential of different *H. pylori* strains to promote gastric carcinogenesis^[31]. According to the geographic regions in which strains are isolated, it is possible to characterise the *cagA* variable region on the basis of the number and the type of sequences. The Western *H. pylori* CagA has two segments of 32 and 40 amino acids flanking EPIYA (EPIYA-A and EPIYA-B types) and one to three 34 amino acid EPIYA-C segments (A-B-C type CagA)^[21]. Eastern CagA presents EPIYA-A and EPIYA-B segments, but none of the EPIYA-C fragment; it has instead one copy alone of a segment called EPIYA-D, which represents the main tyrosine phosphorylation site^[20,21]. In western strains, the major site of tyrosine phosphorylation of CagA is EPIYA-C; the tyrosine residues that characterize EPIYA-A and EPIYA-B segments are phosphorylated only very weakly. Such a difference in phosphorylation degrees resides in the diverse consensus high-affinity binding sequence for the SH2 domains of SHP-2. Unlike what happens for EPIYA-D type, the western EPIYA-C type of CagA differs by a single amino acid from the consensus SHP-2 binding sequence^[21].

In conclusion, the carcinogenic potential of *H. pylori* varies according to the number and the *cagA* structural types of the EPIYA flanking regions. East Asian CagA has an increased virulence and a strong ability to trigger GC, while, among western isolates, more carcinogenic are the helicobacters with two or three CagA EPIYA-C sites. This was also demonstrated by a study in which it was observed that 83.3% of GC strains possessed multiple EPIYA-C sites, vs only 5.2% of strains isolated from patients with chronic gastritis only (controls)^[32].

Often, *cagA*+ strains are also isolated from patients with duodenal ulcer (NF personal observation). This finding may create confusion, because is common knowledge that patients with duodenal ulcer are like protected from GC development; however, the results of a recent study^[33] showed that the increased virulence

of strains with CagA EPIYA-C type augmented the risk of gastric cancer and not peptic ulceration. Some studies diverge from these conclusions: Findings of an investigation carried out in Colombia suggest that polymorphic CagA proteins, based on sequences flanking the EPIYA motifs, are not clearly associated with the outcome of the infection^[34]. The absence of association between the CagA polymorphisms and pathogenesis of gastroduodenal diseases could be due to geographic factors and/or the host's genetic features and environmental determinants.

In conclusion, the results of this kind of investigations are potentially useful, but the confusion existing in this field ought to be rectified and the different researchers should use the same criteria for classification. The various groups, however, have reached a common conclusion: Not all the strains are alike in their carcinogenic potential.

NOT ALL PATIENTS ARE ALIKE: THE ROLE OF THE HOST'S INFLAMMATORY CYTOKINE HAPLOTYPES IN GC DEVELOPMENT

Background

The hypothesis that human genetic polymorphisms may affect predisposition to GC has recently been explored. GC develops in only 1%-3% of *H. pylori* infected individuals, which suggests that the host background matters in this neoplasia. Several pro-inflammatory cytokines are produced by the immune system against *H. pylori*; among them, IL-1 β is of paramount importance; a second one is tumor necrosis factor-alpha (TNF- α); both of them are closely related to epithelial injury and gastric hypochlorhydria^[35,36]. At low concentrations, TNF- α enhances the protective inflammatory response; at high concentrations, it can injure the gastric mucosa and cause severe pathology^[37]. IL-1 β increases the surface molecule expression on endothelial cells, causing leukocytes to adhere; IL-1 β also induces the production of macrophage chemokines leading to neutrophil activation. Recent investigations have revealed that there is a genetic regulation of the host cytokine response to inflammatory stimuli. Genomic variants of *IL-1 β* and *TNF- α* were shown to correlate with the clinical outcomes of tumors, including GC^[38,39]. The *IL-1 β* gene cluster is polymorphic, with some alleles present at relatively high frequencies. Particular *IL-1 β* haplotypes enhance the risk of GC because they induce an over expression of its product in the stomach, causing chronic hypochlorhydria, which in turn may produce gastric atrophy and, eventually and in the presence of other risk factors, GC^[40]. In addition, patients with a particular haplotype of the gene that encodes IL-1RA (receptor antagonist) have an elevated risk of developing GC. IL-1RA is an anti-inflammatory cytokine, which is a competitor for IL-1 β receptors, thus regulating the possible

harmful effects of IL-1 β receptors.

The role of the host in GC development could be important because the inflammatory response to infections varies from patient to patient due to the gene polymorphism of inflammatory and anti-inflammatory cytokines. Many studies have been performed in the last 15 years, with the scope of identifying a genetic marker that can determine whether or not people carrying the infection might be at risk of developing GC in *H. pylori* infected patients^[41-59]. Such a marker is still lacking, and we shall try to explain some of the reasons underlying this problem.

The association between chronic inflammation and cancer has been known since Virchow, in 1864, wrote that cancer would arise from sites of inflammation: "Chronic irritation which is manifested by a chronic inflammation is a key promoter of cancer" (Quoted by Balkwill and Mantovani^[60]). Individual cytokines were specifically examined, in particular the proinflammatory ones. The most well known cytokine is IL-1, along with its receptor (IL-1R) and the antagonist of this receptor (IL-1RA); all of them share the chromosomal location of the *IL-1* gene family (namely 2q13-14). IL-1 β has thus been established as an important regulator of carcinogenesis, characteristic of interactions between the host and environment^[54].

IL-1 β haplotypes

The *IL-1 β* gene displays considerable polymorphism^[54]; the presence of C to T transition was frequently found either in the promoter region at positions -511 (CT; dbSNP: rs16944), at position -31 (TC; dbSNP: rs1143627) or in the coding region at position +3954 (CT; dbSNP: rs1143634) base pairs from the origin of transcription. The two single nucleotide polymorphisms (SNPs) within promoter region are in linkage disequilibrium. The *IL-1 β* -31 TC substitution disrupts a TATA-box motif; this leads to several transcription factors having altered binding affinities, resulting in modified IL-1 β transcription. The *IL-1 β* +3954 CT substitution is a synonymous SNP. It was demonstrated *in vitro* that the C to T transition at positions -511 and +3954 correlated with elevated IL-1 β levels as a result of lipopolysaccharide (LPS)-stimulated IL-1 β protein secretion^[54].

The paradigm of all subsequent studies regarding GC with respect to different haplotypes in cytokines was the focus of the paper by El-Omar *et al.*^[38], who noted for the first time that the presence of two polymorphisms (rs16944 and rs1143627) in the promoter region of the *IL-1 β* gene, identified an increased risk of hypochlorhydria, as a result of *H. pylori* infection and GC^[38]. These polymorphisms determine an increased secretion of IL-1 β ^[61], a conclusion confirmed and generalized by later reports^[62]. The discrepancy of results reached in different papers was clarified only after several years, once taking into account the origin of the population and the type of GC. Overall, more than 90 publications dealt with this issue, over half of them from Asia, and a single one

from North America, a clear indication of the perceived relevance of this neoplasia in the different populations.

Since the single studies are extremely inconsistent and, if taken alone, contribute little to the general overview, we opted for reporting from selected meta-analyses in this paper. Meta-analyses accrued from time to time in a number of studies originating from different countries, which is one of the main causes of contradictory results, as well as from different histological variety of stomach malignancies, another cause of strong difference in results^[41-59].

The overall findings from the large amount of efforts can be summarized as follows:

(1) *IL-1 β receptor antagonist (IL-1 β RA)* polymorphism: The most credible and consistent association of peculiar genetic variation with GC was found for *IL-1 β RA* haplotypes. Four alleles, numbered 1 to 4, are widely present in the general populations. People carrying the homozygous allele 2/2 (*IL-1 β RN2*) were found to be at higher risk of developing cancer among non-Asian populations. Moreover, the analysis of GC patients altogether, without stratifying according to histological type, anatomic site or country of origin, showed that patients carrying homozygous allele 2, or *IL-1 RN2* had an increased risk of developing cancer, which was statistically significant. The risk was found both in cardia and non-cardia types of neoplasia. A possible explanation for the risk stems from the high *IL-1 β* levels circulating among *IL-RA* allele 2/2 carriers^[63].

(2) *IL-1 β -31 CT* polymorphism: A second plausible association was the decreased risk of GC in Asians carrying the haplotypes in the *IL-1 β -31 CC* promoter region. A decreased risk of GC among *IL-1 β -31C* carriers was confirmed, but solely for Asian patients.

(3) *IL-1 β -511 CT* polymorphism in populations of different ethnic origin: Sub-analysis of various populations revealed a statistically significant association of stomach cancer with the *IL-1 β* polymorphism at promoter region -511 CT in case-control studies based on populations (OR = 1.20, 95%CI: 1.00-1.43)^[54]. The association is more consistent if only Caucasian populations are analyzed. Nevertheless, if taken together, the studies failed to show the association when stratified by ethnicities; *IL-1 β -511 CT* polymorphism according to tumor site: A significant association of *IL-1 β -511 CT* promoter region polymorphism was observed for stomach cancers when the tumor site (cardia vs non-cardia) was taken into account, as well as for histology subtypes (intestinal or diffuse/mixed). The association was present both in the case of non-cardia GC (OR = 1.57, 95%CI: 1.06-2.31) as well as intestinal GC (respectively OR = 1.57, 95%CI: 1.06-2.31 and OR = 1.24, 95%CI: 1.04-1.49)^[54]; *IL-1 β +3954 CT* polymorphism: Recently, Xu *et al*^[54] performed a meta-analysis that was confirmed by that one by Xue *et al*^[49]: There is a lack of association between *IL-1 β +3954 CT* and GC risk.

(4) *IL-10* haplotypes: *IL-10* - regarded as the ma-

jor anti-inflammatory cytokine - will bind in form of homodimer its complex receptor, comprising four *IL-10* receptor molecules, namely 2 *IL-10 R1* and 2 *IL-10 R2*. The binding induces *STAT3* signaling *via* the phosphorylation of the cytoplasmic tails of *IL-10* receptor 1. *IL-10* can inhibit the synthesis of pro-inflammatory cytokines; moreover it can block the function of nuclear factor-kappa B (*NF- κ B*), and has other regulatory properties, *e.g.*, *JAK-STAT* signaling^[64]. The *IL-10* gene is known to possess several SNPs, some in the distal region upstream of the coding gene (-1082 A/G, -819 T/C) and a proximal one (the -592 A/C). Again, the complex signaling and polymorphism of *IL-10* can explain the contradictory results of the investigations.

(5) *IL-10 -1082 AG* polymorphism: A clear and curious dichotomy is evident, that is, when the studies were stratified according to Asian and non-Asian populations the observations reached opposite results. The Asian populations had greater risk of GC among *IL-10 -1082 G* carriers; conversely, there was a decreased risk among the non-Asian populations. Meta-analysis specific for *IL-10* confirmed for Asian population the increased risk for intestinal type of gastric neoplasia in *IL-10 -1082 GG* or *GA* haplotypes^[53]; *IL-10 -592 AC* polymorphism: The -592 AC polymorphism failed to show any association, as the odd ratios for GC were 0.93 and 0.94 for homozygous and heterozygous population^[55,65]; *IL-10 -819 TC* polymorphism: Little data is available for this polymorphism, confirming a protective effect in Asian populations. Nevertheless, it was not found to be associated with the reduced susceptibility to GC in individuals infected with *H. pylori* compared to uninfected controls. The *IL-10 -819 TT* genotype was found to be inversely correlated with the risk of the diffuse subtype, but not the intestinal subtype GC^[51].

(6) *IL-8 - 251* polymorphisms: Continuous expression of human *IL-8* in transgenic mice (whereby *IL-8* is under the control of its own regulatory elements) increased tumorigenesis. Therefore, *IL-8* may play an important role in gastrointestinal cancers. Elevated *IL-8* levels could be linked to a poor prognosis of neoplasia, henceforth its levels may be indicative of more aggressive GCs.

Early data seemed to provide a possible association in GC as well^[66]. A recent meta-analysis showed that the *IL-8 -251 AA* genotype in the Han population correlates with augmented risk of developing GC and *AA* genotype carriers appear to be more likely to develop GC in Asian populations. In addition, the *IL-8 -251 AA* genotype tended to be related to intestinal GC, but not with *H. pylori* infectious status^[52]. There was no link between *IL-8* polymorphisms and *H. pylori*-related gastric malignancies in non-Asian populations in all the meta-analyses examined^[48,67].

(7) *TNF- α* polymorphism: Experimental studies have implicated *TNF- α* in processes that are involved in cancer progression, including promotion of metastatic behaviour and cancer associated cachexia^[68,69]. The lack of *TNF- α*

in mice makes them resistant to carcinogenesis^[70]. Clearly, such observation highlighted the link between genetic haplotypes for *TNF-α* and GC.

***TNF-α* -308 AG polymorphism:** It was surprising to find a lack of association of this polymorphism with increased risk of GC, with only one exception: Non-Asian patients with distal cancer and homozygous for -308 AA alleles; the association, moreover, appeared to exist for cancer of diffuse type only. However, this association was not confirmed when only good quality studies were taken into account, according to Persson *et al.*^[48]. Opposite conclusions were obtained by Zhu *et al.*^[59]; they recently analyzed all studies and concluded that, in the Caucasian populations, *TNF-α* rs1800629 (-308 AG) polymorphism indeed posed increased risk of GC. They used several genetic comparison models, *i.e.*, A vs G, AA vs GG and AA vs GG/GA that gave OR respectively of 1.32, 1.76 and 1.62, all highly significant (A vs G: OR = 1.32, 95%CI: 1.12-1.56, *P* = 0.001; AA vs GG: OR = 1.76, 95%CI: 1.37-2.26, *P* < 0.001; AA vs GG/GA: OR = 1.62, 95%CI: 1.27-2.07, *P* < 0.001)^[59].

***TNF-α* -238 polymorphism** did not correlate with an increased cancer risk^[48,58].

***TNF-α* 857 CT polymorphism:** Reports on this topic are quite controversial. Cen *et al.*^[57] recently published his analysis of nine studies (all the reported ones); overall, they confirm that the *TNF-α* 857 CT polymorphism posed an elevated risk of GC solely among Asians; all four genetic models considered T vs C, TT vs CC, CT vs CC and TT vs CT gave consistent data, respectively with OR of 1.19, 1.44, 1.19 and 1.21 (their statistical significance being *P* = 0.002, *P* = 0.032, *P* = 0.008, *P* = 0.003 respectively).

***TNF-β* 252 AG polymorphism:** A weak association with stomach malignancy was present in Asian populations, according to Xu *et al.*^[71]. Analysis by ethnicity revealed that the *TNF-β* 252 AG polymorphism correlated with a minor risk of GC (G vs A: OR = 1.10, 95%CI: 1.02-1.19, *P* = 0.015) exclusively in Asians, not in Caucasians.

Dutch patients were analyzed for their polymorphism of IL-1β; they were found to carry lower risk of GC when heterozygous for either the IL-1B -511 and for the IL1β -31 TATA-box (genotype T/C)^[72]. The EBV status of the patients did not affect this correlation and there could therefore be an early shared molecular mechanism in the progression of EBV-positive and negative GCs^[72].

IL-6 polymorphism was not studied in relation to GC.

IL-6 knockout mice develop cancer less frequently^[73]. It is therefore plausible that high IL-6 levels will promote tumorigenesis. Today, IL-6 is considered to be a relevant tumor-promoting factor also in humans. Indeed, it was correlated with glioma, lymphoma and melanoma at first, then with solid cancers such as breast and colorectal neoplasia (also ovarian and pancreatic), prostate, renal and colorectal cancers.

IL-6 is a critical factor during chronic inflammation, since it is required for the induction of effector Th17

cells and inhibits the differentiation of regulatory T cells.

Stomach cells, however, lack IL-6 receptors; hence it cannot dimerize with the second receptor (gp 130) and the "classic signaling" is restricted to cells bearing both mIL-6R and gp130 on their surface. The latter is widely expressed, whilst mIL-6R expression is limited to some leukocytes, hepatocytes and cancer cells. It is therefore quite understandable that, as recently reported, a large meta-analysis on 105000 people established the lack of association of cancer risk with *IL-6* polymorphism in Caucasians^[74], despite the association which holds true for Africans.

Other cytokines

Gene polymorphism concerning cytokine different from those we have dealt with was recently considered in relation to the risk of developing GC. The studies are not sufficiently large so far; however it is worth reporting that a haplotypes of *IL-17*, *IL-17F* rs763780 TC, was significantly associated with GC development in Asian population^[75].

IL-11 was taken into consideration in a single study^[76]. A reduced risk for developing cancer at the gastric site was found for a polymorphism in the *IL-4* -590 CT gene in Caucasian but not in Asian populations. *H. pylori* status was not taken into consideration in these studies^[77].

Different results in different studies: The origin of the problem

IL-1β, *TNF-α* and the remaining dozens of cytokines are not the final executor of immune signaling or the resulting consequences in cancer promotion and spread. IL-1, *TNF-α*, together with bacterial antigens, LPS and several other signaling molecules bind their respective receptors on the cell membrane; a cascade of signals ensues upon receptor activation, which depends on the levels of Mg-ATP availability (in turn on Mg²⁺ concentration in cells). Numerous different proteins are involved and regulate the signaling pathway, which finally results in the activation of a large family of DNA-binding proteins, the NF-κB family^[78], which is a complex that regulates DNA transcription. NF-κB dimers are formed upon activation, stimulating the transcription of genes that encode cytokines, growth factors, chemokines, and anti-apoptotic factors^[79]. However, some NF-κB dimers act by repressing, whilst others activate specific genes.

Cytokine polymorphism and Epstein-Barr virus-associated GC

Worldwide, it was noted that Epstein-Barr virus (EBV) is present in a relevant proportion of malignant tumors of the stomach, with an incidence that is inversely proportional to that of GC. In the USA 16% to 18% of all stomach tumors were found EBV-associated (EBVaGC), in Southern China only 4.3%^[80]; a survey of 101 published papers reported that EBVaGC was evident in 7.08% of intestinal type GC, while diffuse type GC had

an incidence of 9.82%^[80]. Western and Central Asian countries had significantly more EBV positive cases than South-Eastern countries; in Europe, the frequency of EBV infection ranged from 1.7% in the United Kingdom to 40% in Poland^[80].

An *in vitro* model of EBVaGC was used to demonstrate that gastric cells, following EBV infection, have a high IL-1 β expression, compared to EBV-negative gastric tumour cells. EBV-positive clones rapidly proliferated and were shown to be anchorage-independent in colony-forming assays^[81].

Since EBV infection is highly prevalent in all populations, whilst EBVaGC is quite rare, there were attempts to identify people who run an increased risk of developing GC. Polymorphisms of proinflammatory, as well as anti-inflammatory cytokines were studied, in particular in the promoter regions of *IL-10* and *TNF- α* . For the latter, the allele -308 A (linked to high levels of *TNF- α*) had significantly higher frequency among EBVaGC individuals (23.3%) when compared to control subjects (12.0%, $P < 0.05$). The opposite was found in the case of the anti-inflammatory *IL-10*: The high-producer allele (-1082 G) was found to be less frequent in EBVaGC patients in comparison to controls (6.3% vs 3.0%, $P < 0.05$)^[39,72].

The extreme complexities of all these interactions can explain the great variability in data when investigating the possible correlation between cytokine haplotypes and GC.

Gleanings on the usefulness of characterising *H. pylori* infected individuals for inflammatory haplotype

In addition to the complexity of this subject, the expectations created by the assertion that the host's factors could contribute to the development of GC are disappointing, at least as far as the host's inflammatory response to *H. pylori* infection is concerned. Once we get into details, we realize that in fact, the only determinant that really matters is the infection. The examination of the scientific literature on the cytokine subject has led to contradictory results: For each cytokine, the observations made by studying Caucasian people cannot be applied tout course to Asians; in certain cases, we get opposite results. In the different surveys, one can find association of determined haplotypes of inflammatory cytokines with an increased risk of GC, the opposite, or nil. Even the results of meta-analyses do not agree one another, according to whether studies are carried out by Chines or researchers from other nations. What does it mean? Is it because cytokines are not the final effectors, as they principally work on the long and winding road paved by the broad NF- κ B family, which leads to GC (which means that the final response to inflammatory stimuli is far from hitting its target)? And what about the observations that people suffering from diseases far more inflammatory than chronic gastritis, such as rheumatoid arthritis, are likely protected from developing GC^[82].

These observations may suggest that, if host factors are important in GC development, they probably have to be sought outside of the genes encoding the inflammatory cytokines.

NOT ALL PATIENTS ARE ALIKE:

MOLECULAR BIOLOGY

The recent advances of molecular biological techniques allowed researchers to reach important insights into the oncogenesis mechanisms in gastric cancer. Besides the well-known pathogenic factor, *H. pylori*, several oncogenes and tumour suppressor genes, including cell cycle regulation genes involved in the growth and signal transduction pathways, have been identified^[83-85]. In particular, alterations of genes involved in signalling pathways deregulation, patterns of aberrant DNA methylation, and chromosomal imbalances have been evidenced^[86,87].

CHROMOSOMAL INSTABILITY

Chromosomal instability (CIN) represents one of the main type of genomic instability observed in several neoplasms and it has been observed in a large cohort of patients with gastric cancer^[88]. In particular, it is commonly detected in gastric malignant tumours and has been shown in up to 84% of gastrointestinal cancers^[89].

CIN is characterized by chromosomal anomalies, including gain or loss of the complete chromosome (aneuploidy) and segments of chromosomes (loss of heterozygosity, amplifications and translocations)^[90]. These abnormalities can impact on the oncogenes expression, tumour suppressor genes and other genes, as well as those involved in digestion, DNA repair, growth regulation, and control of cell cycle checkpoint^[91-93]. The genetic mechanisms leading to CIN are not entirely known; *H. pylori* infection, smoking habit and some chemical substances such as nitrates and nitrites probably have an effect on inducing CIN; anyway their influence is actually uncertain^[94]. On the other side, defects of chromosome segregation (CS), imperfect DNA damage response (DDR), anomalies in cell cycle regulators and telomere dysfunction have been identified as factors leading to numerical and structural chromosome alterations^[95,96]. These carcinogens may alter chromosomes and the cytoskeleton promoting malignant modification^[97].

CS alterations

CS represents an important cellular process inducing the gastric epithelial cells division. Alterations of CS regulating mechanisms can cause DNA alterations or mitotic failures, leading to unfixable mutations as well as chromosomal number alterations^[98]. In particular, the three recently proposed ways producing CIN are: Altered expression, polymorphisms and/or mutations of mitotic genes implicated in CS and the carcinogen activity upon

susceptible genetic background of individuals^[99,100]. Many authors showed an aberrant expression of mitotic genes in CS. Moreover, the altered expression of BUB1 protein (involved in controlling the spindle assembly checkpoint), was significantly increased in patients with diffuse type gastric adenocarcinoma, but not related to DNA ploidy^[89]. Furthermore, in another study, BubR1 and AURKB (proteins involved in the mitotic spindle assembly) expression resulted in association with a low risk of GC progression^[101-103]. Aurora kinase A (AURKA/STK15), a cell-cycle-regulated kinase with important role in microtubule formation and stabilization during CS, is often overexpressed in adenocarcinomas of the stomach, showing a suggestive new oncogenic pathway in GC^[104].

Defective DDR

The mucosa of the stomach is continually subject to several environmental and intracellular mutagens, like ROS, *H. pylori* infection, nitrates, sodium, nitrites, and other water and food contaminants, able to induce DNA damage through different mechanisms^[105,106]. Failure of the most important mechanisms of repair [nucleotide excision repair, base excision repair, mismatch repair (MMR) and recombination and/or DDR] may conduce to CIN and genetic aberrations, favouring carcinogenic process^[107,108]. Several studies revealed differential mRNA expression of genes implicated in DNA repair process: *ATM* and *HMGB1* (implicated in base excision repair), *RAD23B* (involved in nucleotide excision repair), *UBE2V2*, *MUS81* [involved in resolving Holliday junctions (a branched DNA structure that contains four double-stranded arms joined together, considered the central intermediate in homologous recombination)], *REV3L* (involved in replication post-DNA damage), *TP53*, *hHR23A* and *DDB1* (implicated in nucleotide excision repair), and *XRCC1* (implicated in single-strand breaks repair) and *MUTYH* (implicated in base excision repair)^[109-113].

H. pylori

H. pylori has been shown to be able to induce DDR and double-strand breaks in gastric cancer with a mechanism of adhesion of bacteria that takes place between Lewis epitopes of the host and BabA adhesin^[114]. Anyway, gastric mucosa cells can repair the DNA lesions induced by short-term infections. On the other side, prolonged infections induce saturation of repair mechanisms with a consequent ineffective DNA repair and malignant process begin. Moreover, continued infections lead to chronic inflammation, with resulting increase of mutagenesis rate, oxidative-stress, down-regulation of MMR mechanisms, instability of genes and modulation of apoptosis by means of ROS formation^[115-119]. Gastric inflammation represents an important host response able to induce *H. pylori*-related carcinogenesis^[120]. In fact, in infected patients with *IL-1 β* , *TNF- α* , *IL-10* and *IL-8* polymorphisms, has been observed an in-

creased risk of distal gastric cancer progression^[120,121]. Furthermore, different *H. pylori* strains seem to differently increase cancer risk by means of host genotypes^[122] as these bacteria are able to communicate with their hosts. The equilibrium is determined both by host and bacterial features and may explain the reason why some *H. pylori* strains augment the carcinogenesis risk. For example, CagA positive strains promote severe gastritis and increase the pro-inflammatory cytokines' level. This may lead to an environment favourable to the growth of other bacteria that can support inflammation and continually induce oxidative stress, increasing the risk for GC^[1].

MICROSATELLITE INSTABILITY

Microsatellite instability (MSI) represents a genomic instability commonly detected in almost half of patients with GC. It is often observed in the Lynch syndrome (hereditary non-polyposis colorectal cancer) and in several sporadic cancers^[123]. MSI phenotype is characterized by a high replication mistake rate leading to insertions and/or deletions of nucleotides within microsatellite repeats in neoplastic areas^[123]. The MMR proteins are able to detect and repair these alterations, causing the dysfunction in MMR genes (*MLH1* and *MSH2*) a MSI phenotype's establishment, with a consequently power off of cancer suppressor genes' and loss of heterozygosity^[124,125]. To this address, genes that are frequently modified induce cell cycle regulation and apoptosis (*TGF β RII*, *RIZ*, *IGFIR*, *TCF4*, *BAX*, *FAS*, *CASPASE5*, *BCL10* and *APAF1*) or are involved in the maintenance of genomic integrity (*MSH6*, *MED1*, *MSH3*, *BLM*, *RAD50*, *ATR*, and *MRE11*)^[126].

DEREGULATION OF SIGNALLING TRASDUCTION PATHWAYS

The effects of genomic destabilization consist of aneuploidy and gain or loss of the chromosome tracts involved in mRNA transcription. Genomic alterations can modify the normal cellular biology with a consequent neoplastic switch^[127]. The clearly explored pathways that probably are involved in gastric pathogenesis are Wnt/betacatenin, extracellular signal-regulated MAPK, Hedgehog, Notch, NF- κ B, TGF- β /BMP pathways, COX2/PGE₂, and tyrosine kinase signalling^[128-143].

Finally, several studies evidenced that pathway deregulation involved in systemic inflammatory response, such as IL-11/STAT1/gp130/STAT3, can induce a carcinogenic transformation too^[144,145].

CONCLUSION

GC is a multifactorial disease. The main determinant, *H. pylori* infection, can be considered a *sine qua non* for GC development; however, despite almost all individuals who get GC are currently, or have been infected, it

is neither a necessary nor a sufficient condition. The intricacy of this topic resides in the proportion of infected people that will never get GC: 97% to 99%, according to the ethnic groups and geographic areas. Other remarks are unraveling the tangle: Almost all *H. pylori* strains from Japan and East Asia, the areas with the highest incidence of GC, are *cagA*+ and can be considered highly carcinogenic; in addition, the infection by certain *cagA* genotypes in western countries increases by far the risk of GC.

At this point, one may wonder why these strains keep on infecting people. Following along with the evolution, only the characteristics that provide a selective advantage continue to be transmitted; this is a basic rule in eukaryotic and prokaryotic worlds. What is the benefit of being infected by carcinogenic strains? Why do they not disappear? People infected by strains that multiply the risk of GC by many times over, cannot be considered advantaged. Possible answers could reside in the following observations: (1) 97% to 99% of people never acquire GC; (2) the development of the sequence gastritis-metaplasia-dysplasia-cancer takes 40 years, or more, after the infection; which means that all women, as well as men, are fertile before the age at which GC occurs (many men also in old age, but they are less important, statistically speaking); hence, fertility is not affected by cancer development; and (3) women, who develop GC far less frequently than men, are the necessary genetic traits holders. Could these answers satisfy the laws of evolution (or distract them)? And how can the occurrence of GC in younger and younger ages be explained?

Apart from the complexity of this subject, the prospect created by the assertion that the host's factors, such as the way the host reacts to infectious stimuli, may be important in the development of GC is discouraging. Despite cytokines involved in the inflammatory response to infection, there are more than 30, just over half a dozen that have been examined in the relationship of *H. pylori* infection with GC and only haplotypes of *IL-1* and *TNF- α* genes were found to possibly increase the GC risk, but only if the ethnicity of patients is not considered. Pursuing this line of inquiry makes us run the risk of sounding racist.

The hypothesis that the dissection of oncogenes and tumour suppressing genes could provide us with an answer to the question whether host factors are important in GC development has only been partly proved. However, the conclusions have led us to a starting point, that is, they ended to indirectly confirm the pathogenic role of strains expressing CagA. The local and systemic levels of substances endowed with an increased mutagenic potential, ROS, generated by immunocytes, and the consequent DNA damage are far higher when the infecting organisms harbour the *cag* PAI.

In conclusion, as regards the development of GC, not all the *H. pylori* strains and patients are alike and not all share the same responsibility, but the only deter-

minant that really matters is the infection.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal malignancies with a five-year survival rate of approximately 5%. Several target agents have been tested in PDAC, but almost all have failed to demonstrate efficacy in late phase clinical trials, despite the better understanding of PDAC molecular biology generated by large cancer sequencing initiatives in the past decade. Erlotinib (a small-molecule tyrosine-kinase inhibitor of epidermal growth factor receptor) plus gemcitabine is the only schedule with a biological agent approved for advanced pancreatic cancer, but it has resulted in a very modest survival benefit in unselected patients. In our work, we report a summary of the main clinical trials (closed and ongoing) that refer to biological therapy evaluation in pancreatic cancer treatment.

State of the art biological therapies in pancreatic cancer. *World J Gastrointest Oncol* 2016; 8(1): 55-66 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/55.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.55>

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal malignancies, representing the fourth leading cause of cancer death. The five-year survival rate is approximately 5%, and surgery remains the most effective treatment^[1].

Unfortunately, only 20% of patients are suitable for radical resection, and recurrence of disease occurs in 80% of patients who undergo resection^[2].

The most important improvement concerns the conventional chemotherapy, represented by FOLFIRINOX and gemcitabine plus nab-paclitaxel regimens, but it results in a modest outcome advantage^[3,4].

No significant progress has been made in the field of targeted therapy. Erlotinib [a small-molecule tyrosine-kinase inhibitor of epidermal growth factor receptor (EGFR)] plus gemcitabine is actually the only schedule with a biological agent approved for pancreatic cancer, but it results in a very modest survival benefit in unselected patients^[5].

In recent decades, several combinations of classic chemotherapy and novel biological agents have been studied, but they have not improved overall survival, and furthermore, those trials did not use biomarkers to select responder patients^[6].

Our study aims to give an overview of the progress made in molecularly targeted therapy for pancreatic cancer in recent years and the current status of clinical trials in the field, as summarized in Tables 1-3.

MOLECULAR CHARACTERIZATION OF PDAC: HAS A BETTER UNDERSTANDING OF THE TUMOUR'S MOLECULAR BIOLOGY REALLY IMPROVED TARGETED THERAPY APPLICATIONS?

Large cancer sequencing initiatives generated a large quantity of data in the past decades. Those findings showed a complex genomic landscape characterized particularly by inter-tumoural and intra-tumoural hetero-

geneity involving genomic aberration^[7].

With the exception of the well-known KRAS, TP53, CDKN2A and SMAD4 alterations occurring at respective frequencies of 71%, 49%, 22% and 20%, a large number of genomic rearrangements with mutational frequencies less than 2% were found^[8,9].

The majority of single gene mutations in pancreatic cancer can be grouped into common cellular pathways. Jones *et al.*^[10] identified 69 mutated gene sets in most of the 24 samples analysed in their pioneering sequencing study, of which 31 could be grouped into 12 core signalling pathways. These pathways included KRAS signalling, the transforming growth factor β (TGF- β) pathway, DNA damage control, apoptosis, regulation of G1/S cell cycle transition, Hedgehog signalling, the homophilic cell adhesion pathway, integrin signalling, TGF- β signalling, Wnt/Notch signalling, and the invasion pathway^[10].

Genomic heterogeneity, a characteristic of PDAC, implies genomic instability, which is due to the acquisition of telomere dysfunction and abnormal cell-cycle control occurring predominantly in early cancer stages, but it persists after cancer dissemination, resulting in parallel evolution among different metastases. Cell clones arranging metastasis may require other driver mutations compared with primary tumour cells implementing genetic variation in pancreatic cancer^[11,12].

Given this molecular complexity, it is very difficult to separate passenger from driver mutations, to identify molecular mutations with a crucial role in pancreatic carcinogenesis that can be developed into actionable molecular targets of novel biological agents or to identify patients potentially responsive to existing agents already approved for human use in other cancers (Figure 1), and currently no predictive or prognostic biological factors are employed in clinical practice.

TARGETED THERAPY IN PDAC

EGFR pathway inhibitors

EGFR is a transmembrane receptor member of the ErbB family with a tyrosine kinase domain that is activated by many ligands including epidermal growth factor (EGF), TGF- α , heparin-binding EGF, amphiregulin, epiregulin, betacellulin and neuregulin (an epidermal growth factor). EGFR is involved in cell cycle regulation, cell survival, adhesion and differentiation through activation of the Ras/MAP kinase, phosphatidylinositol 3'-kinase (PI3K)/Akt, Janus kinase/Stat and phospholipase C/protein kinase C pathways. Several trials showed that EGFR is overexpressed in up to 90% of pancreatic cancer samples. Therefore, inhibitors targeting EGFR have been considered a promising therapeutic agent^[13].

Erlotinib is a tyrosine kinase inhibitor (TKI) molecule that competes with ATP for binding to the kinase domain, thereby blocking downstream signal transduction. A possible therapeutic role was evaluated in a large phase III trial, enrolling 569 chemotherapy naïve patients with locally advanced or metastatic pancreatic

Table 1 Principal phase III clinical trials involving targeted therapy in pancreatic cancer

Agent	Target pathway	Treatment	Setting	n	mOS (mo)	PFS (mo)	FDA approval	Ref.

adenocarcinoma randomized to receive gemcitabine plus placebo or gemcitabine plus erlotinib 100-150 mg daily. The median overall survival (mOS) and progression free survival (PFS) were modestly, but statistically significantly, improved in the combination arm, 6.24 mo vs 5.91 mo (*P* = 0.038) and 3.75 mo vs 3.55 mo (*P* = 0.004), respectively^[5].

Neither EGFR status nor KRAS status analysed in the

subgroup of patients treated with erlotinib was shown to be predictive of a survival benefit in patients receiving the combination schedule^[14].

Erlotinib has been approved by the FDA in combination with gemcitabine as a first-line treatment for advanced pancreatic adenocarcinoma.

Cetuximab is a monoclonal antibody binding the extracellular domain of EGFR. After encouraging results

in a phase I trial, subsequent studies in association with gemcitabine-based chemotherapy have failed to demonstrate any survival benefit^[15,16].

A phase II study has evaluated the possible therapeutic role of gefitinib, a competitive inhibitor of ATP binding to the intracellular kinase domain of EGFR, in

combination with gemcitabine in inoperable or metastatic pancreatic cancer patients. The combination demonstrated promising activity with a mOS and PFS in the combination arm of 7.3 and 4.1 mo, respectively, but other evidence supporting a role of gefitinib in PDAC treatment is lacking^[17].

Another ErbB family of transmembrane tyrosine kinase receptors is HER-2, which is overexpressed in 11% of pancreatic adenocarcinoma cases. HER2-positive status has also been correlated with shorter survival^[18].

Trastuzumab plus gemcitabine was tested in 34 metastatic pancreatic cancer patients with HER-2 overexpression as determined by immunohistochemistry, and partial responses were observed in 6% of cases^[19]. Harder *et al.*^[20] in a multicentre phase II study, investigated the efficacy and toxicity of the HER2 antibody, trastuzumab, plus capecitabine in patients with pancreatic cancer and HER2 overexpression, but this treatment did not perform favourably with respect to either PFS or OS compared with standard chemotherapy.

After FDA approval of lapatinib, clinical trials have been initiated to test the effect of this HER-2 inhibitor combined with chemotherapy in pancreatic carcinoma. In particular, lapatinib was tested in combination with capecitabine as a second-line treatment in advanced pancreatic cancer with promising preliminary results. Further studies are needed to evaluate the real effectiveness and role of this molecule in the treatment of PADC^[21].

Nimotuzumab, another anti-EGFR monoclonal antibody, showed promising results^[22]. In a phase II trial where advanced pancreatic cancer patients were randomized to receive second-line monotherapy with nimotuzumab, Strumberg *et al.*^[23] showed PFS after 1 year of 10.3% and median overall survival of 18.1 wk with a tolerable toxicity profile.

Based on preclinical evidence, afatinib, an inhibitor of EGFR, HER2 and HER4, is under evaluation in an ongoing phase II trial^[24,25].

The KRAS pathway and downstream signalling cascade inhibitors

KRAS activating mutations are present in 70% to 90% of cases of pancreatic cancer. K-Ras is a GTPase protein belonging to the Ras protein family, which has oncogenic activity, and gain-of-function mutations resulting in constitutive activation promote proliferation and inhibit apoptosis through the RAF/MEK/ERK and PIK3/AKT pathways. K-Ras is very difficult to target, and no inhibitors are actually available to use in clinical practice^[26].

Preclinical study has shown that farnesylation is an important post-translational modification required for Ras activation, allowing the protein to be attached to the plasma membrane for signal transduction^[27].

After promising results in terms of anti-proliferative activity in pancreatic tumour cell lines, farnesyl-transferase inhibitors, particularly tipifarnib, failed to improve overall survival either as a single agent or in combination with gemcitabine in a phase III trial^[28,29].

Due to the difficulty of targeting Ras directly, a possible solution could be to block targets downstream of KRAS, such as the protein kinase MEK. Selumetinib is an oral small molecule that inhibits MEK1/2. In a phase II trial, patients were randomized to receive single-agent

capecitabine or selumetinib as a second-line treatment for advanced pancreatic cancer. The selumetinib arm showed a median overall survival of 5.4 mo vs 5.0 mo in the capecitabine arm, but this result was not statistically significant^[30].

Another MEK1/2 inhibitor, trametinib, was tested in pancreatic cancer in combination with gemcitabine against a regimen of gemcitabine plus placebo in a phase II randomized multicentre study. Nevertheless, no significant advantages were demonstrated in terms of overall survival or PFS^[31].

Rigosertib, a first-in-class Ras mimetic and small molecule inhibitor of multiple signalling pathways, including polo-like kinase 1 and phosphoinositide 3-kinase (PI3K), was assessed in combination with gemcitabine in patients with treatment-naïve metastatic pancreatic adenocarcinoma in a phase II/III randomized study, but the combination regimen did not improve survival or response, as recently presented at the 2015 ASCO Annual Meeting^[32].

Research in this field is in development, but the available trials have failed to show any survival benefit.

IGFR pathway inhibitors

Another possible target in ductal pancreatic cancer is represented by insulin like growth factor 1 receptor, which is highly expressed in pancreatic cells, and upon ligand binding activates several pathways involved in cell proliferation and cell survival such as the PIK3/AKT pathway^[33].

Monoclonal antibodies against IGFR (cixutumumab, ganitumab) were evaluated in PDAC treatment, but unfortunately, they failed to show a statically significant survival benefit^[34].

In particular, the phase III trial assessing ganitumab in combination with gemcitabine was closed early based on a pre-planned futility analysis: The median overall survival was 7.1 mo in the maximum dose ganitumab arm vs 7.2 mo in the placebo arm (HR, 0.97, $P = 0.397$)^[35].

Angiogenesis pathway inhibitors

Neoangiogenesis is essential for tumour progression and metastatization mechanisms. Vascular endothelial growth factor (VEGF) stimulates the proliferation of endothelial cells and is overexpressed in human pancreatic cancer. Nevertheless, neoangiogenesis inhibitors, particularly VEGF inhibitors, failed to improve overall survival in combination with gemcitabine in advanced pancreatic cancer. After encouraging results, phase III trials that tested the efficacy of bevacizumab in association with gemcitabine alone, or gemcitabine plus erlotinib, did not confirm previous findings^[36,37].

Aflibercept, a new recombinant fusion protein with extracellular portions of VEGFR-1 and VEGFR-2, which binds VEGF-A, VEGF-B and placental growth factors 1 and 2 thereby inhibiting VEGF-ligand-dependent signalling processes, suppresses tumour growth in pancreatic cell lines and xenografts. Nevertheless, a

phase III study aiming to investigate OS in metastatic pancreatic cancer patients receiving standard gemcitabine and either aflibercept or placebo demonstrated that adding aflibercept to gemcitabine did not improve OS in metastatic pancreatic cancer patients^[38].

Similarly sorafenib, an oral multikinase inhibitor of Raf-kinase, VEGF-R2/-R3 and PDGFR- β , tested alone or in combination with gemcitabine in small phase I and II trials, and axitinib, an anti-angiogenesis agent assessed in combination with gemcitabine, showed no statistically significant efficacy in a phase III trial in advanced PDAC^[39-41].

Phase II studies combining chemotherapy with promising new anti-angiogenic molecular agents, such as TL-118, a nonsteroidal anti-inflammatory oral medication, or necuparanib, which is re-engineered from heparin with possible anti-tumour activity, are underway^[42,43].

Embryonic pathway inhibitors

Hedgehog signalling has a critical role in cell proliferation and survival during embryonic development. Normal pancreatic cells silence this pathway, but pathological activation is observed in many solid tumours, particularly in PADC. Hedgehog binds to the extracellular receptor Patched, which, in the absence of Hedgehog, suppresses activation of the G-protein-coupled receptor Smoothened and upregulates glioma associated oncogene homolog1 transcriptional activity. Cancer cell lines show both Hedgehog ligand-dependent and -independent mechanisms of aberrant signalling^[44].

Bailey *et al.*^[45] showed how Sonic hedgehog (SHH) and other proteins downstream of the Hedgehog pathway, detected in precursor lesions and in PDAC primary tumour samples, contribute to the formation of the desmoplastic reaction, an important characteristic of pancreatic cancer that limits the effective delivery of anticancer agents to pancreatic cancer cells. Genetically engineered mouse models demonstrated a depletion of tumour matrix from SHH pathway inhibition, which could be a promising strategy in pancreatic cancer therapy^[46].

Vismodegib (GDC-0449), an oral small-molecule inhibitor targeting Smoothened^[47], is under assessment in open phase II trials in combination with gemcitabine in advanced cancer, in combination with gemcitabine and nab-paclitaxel in metastatic settings with promising preliminary data^[48], and as a single agent in neoadjuvant settings followed by surgery^[49-51].

The Smoothened inhibitor saridegib (IPI-926) was tested in association with gemcitabine against gemcitabine plus placebo in a randomized, double-blind, placebo-controlled phase II trial enrolling patients with metastatic disease. Unfortunately, this study was closed ahead of time due to evidence of decreased patient survival in the saridegib arm^[52].

Hedgehog inhibitors are an active research field, and several clinical trials are ongoing^[53]. Notch signalling is another embryonic pathway crucial for pancreatic organogenesis, but after pancreas development, it is

active only in a stem cell subgroup. This pathway is upregulated in PDAC and promotes tumourigenesis. Binding of Notch ligand to its receptor promotes a cascade of proteolytic cleavages, mediated by γ -secretase (presenilin). The activated form ICN (intra cellular notch) forms part of a transcription complex that, after translocating to the nucleus, regulates transcription of several genes involved in proliferation and differentiation of cells, interacting with other pathways such as Hedgehog, KRAS and NF- κ B signalling^[54,55].

RO4929097 is a selective inhibitor of the γ -secretase enzyme with anti-tumour activity in preclinical studies^[56].

A recent phase II single-arm trial assessed the possible role of RO4929097, enrolling 18 previously treated advanced PDAC patients. The treatment was well tolerated; the median survival was 4.1 mo, and the median progression-free survival was 1.5 mo^[57].

Encouraging clinical results were observed testing demcizumab, an anti- Delta-like ligand 4 antibody, plus gemcitabine and nab-paclitaxel in advanced PDAC in a phase I b trial. Further evidence is needed to confirm these preliminary data^[58].

PARP inhibitors

Mutations affecting BRCA pathway components, especially the tumour suppressor gene BRCA2, which is associated with hereditary predisposition to breast, ovarian and pancreatic cancer, promote deficiency in DNA damage repair mechanisms and genomic instability^[11].

Poly ADP-ribose polymerase (PARP) is a nuclear enzyme recruited to repair cell DNA damage, and as recent evidence showed, patients with defects in the homologous DNA recombination pathway may benefit from the use of PARP inhibitors as monotherapy or in combination with radiation or other chemotherapeutic agents. Clinical trials testing those new agents in selected patients are currently in the development phase^[59-61].

mTOR and PI3K/Akt pathway inhibitors

After activation, Ras can phosphorylate PI3K, which activates Akt, a serine/threonine kinase. Signal transduction by activated PI3K/Akt plays a role in tumour cell proliferation, survival and metabolism, usually through several downstream targets, including the mammalian target of rapamycin (mTOR)^[62].

Several trials testing PI3K/AKT axis inhibitors are currently ongoing in advanced pancreatic cancer patients after encouraging preclinical model results^[63]. These trials included the following PI3K/AKT axis inhibitors: BKM120, a PI3K inhibitor tested in combination with the mFOLFOX-6 schedule; RX-0201, an Akt antisense oligonucleotide tested in a phase II study plus gemcitabine; and BEZ235, a combined inhibitor of PI3K and mTOR assessed in a phase study in combination with the MEK inhibitor MEK162^[64-66].

Wolpin *et al.*^[67] evaluated a possible role of everolimus, an oral mTOR inhibitor, as monotherapy in 33

gemcitabine-refractory pancreatic cancer patients. The PFS and OS were 1.8 and 4.5 mo, respectively.

Recently, the results of a single arm phase II study where everolimus was tested in combination with capecitabine were published. The median OS was 8.9 mo and PFS was 3.6 mo^[68].

The results of a phase I / II study testing everolimus in combination with gemcitabine in advanced settings and the results of a phase II trial testing temsirolimus, another mTOR inhibitor, in locally advanced or metastatic settings are anticipated^[69,70].

Tumour stroma inhibitors

The stroma is a dynamic compartment of pancreatic tumours that is critically involved in tumour formation, progression and the metastasis process. Therefore, targeting stromal microenvironment elements could be an efficient therapeutic strategy in addition to previously described trials evaluating Hedgehog signalling inhibitors^[71].

After promising data derived from a preliminary clinical study on the possible role of PEGPH20, a pegylated formulation of recombinant hyaluronidase, a phase II trial is currently in the recruitment phase. The purpose of that study is to enrol untreated patients with metastatic disease to receive a combination of PEGPH20, nab-nab-paclitaxel and gemcitabine or a combination of nab-paclitaxel and gemcitabine^[72,73].

Additionally, inhibition of PDGFR, a receptor expressed in stromal cells with a critical role in recruiting pericytes and in interstitial fluid pressure in the tumour stroma, could be an interesting molecular target, as suggested by preclinical studies using an orthotopic pancreatic tumour mouse model^[74].

TKI258, a PDGFR inhibitor, is under evaluation in a phase I dose assessment for advanced pancreatic cancer patients^[75].

In the past, matrix metalloproteinase inhibitors such as marimastat were tested. Matrix metalloproteinases (MMPs) are a family of proteolytic enzymes responsible for the degradation of connective tissue proteins, and aberrant MMP expression is observed in PDAC. Nevertheless, the results of a phase III trial provided no evidence to support a combination of marimastat with gemcitabine in patients with advanced pancreatic cancer^[76].

CONCLUSION

Knowledge of the molecular biology of PDAC has important potential clinical relevance, but current efforts to improve understanding of the mutational profile of this tumour have not provided any significant advantage in the use of targeted therapy. Several agents have been tested in PDAC, but almost all have failed to demonstrate efficacy in late phase clinical trials. Only erlotinib has been approved by the FDA for advanced pancreatic cancer treatment, but the improvement of overall survival is barely 2 wk compared with gemcit-

abine alone^[5].

There could be many reasons for those unsatisfying results. First of all, the extreme genomic heterogeneity of PDAC is an important block to identifying new candidate actionable molecular targets or to testing existing biological therapies already approved for human use for other cancers. In addition, no significant results have been observed by matching targeted agents with patients harbouring the cognate molecular abnormality, such as, for example, the use of trastuzumab in HER2 overexpression cases. Due to poor results derived from targeting a single molecule, new strategies using multitargeted agents or molecular agent combinations are in the development phase in order to block more than one driving genomic aberration and to prevent or evade resistance.

Additionally, the type of chemotherapy used in combination could be a failure factor. Indeed, the majority of trials have combined target agents with gemcitabine, but actually, the first-line schedules are represented by FOLFIRINOX or gemcitabine plus Nab-paclitaxel. Therefore, greater efficacy may be obtained from the combination of target agents with those chemotherapeutic drugs.

Furthermore, most studies in which molecular or chemotherapeutic agents in pancreatic cancer were tested enrolled an unselected population of patients to treat. In the last 3 years, approximately 116 trials specific for PDAC systemic therapy were registered of which only about 8% applied criteria to select a patient subset based upon molecular biomarkers^[77].

FUTURE CHALLENGES

Most studies in which molecular or chemotherapeutic agents in pancreatic cancer were tested enrolled an unselected population of patients to treat. In the last 3 years, approximately 116 trials specific for PDAC systemic therapy were registered of which only about the 8% applied criteria to select a patient subset based upon molecular biomarkers^[77].

To stratify patients, the Australian Pancreatic Cancer Genome Initiative has started a pilot study to evaluate the feasibility of assessing a more stratified approach in the management of pancreatic cancer through predefined actionable molecular phenotypes. Patients are enrolled in this trial, called IMPaCT (Individualised Molecular Pancreatic Cancer Therapy), after a preliminary phenotype screening in order to compare the use of gemcitabine in an unselected population to a stratified approach. The aim of the study is to create a tailored approach to pancreatic cancer treatment, which seems to be one of the major challenges for the future^[78].

Finally, thanks to biotechnology advancement, biological agents can find application in cancer treatment by tumour-targeted delivery of cytotoxic drugs. Particularly, Ahn *et al.*^[79] developed antibody fragment-installed polymeric micelles *via* maleimide-thiol conjugation

for selective delivery of platinum drugs to pancreatic tumours. This antibody-drug conjugate significantly suppressed the growth of pancreatic tumour xenografts. This technology, with potential activity *in vitro* and in a mouse model, could be a promising future strategy in pancreatic cancer therapy^[79].

In conclusion, the lack of efficacy of targeted therapy in PDAC represents a challenge for the future, and more efforts are needed in order to make pancreatic cancer a curable disease.

Abstract

For a long time, treatment of peritoneal metastases (PM) was mostly palliative and thus, this status was link with "terminal status/despair". The current multimodal treatment strategy, consisting of cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC), has been strenuously achieved over time, but seems to be the best treatment option for PM patients. As we reviewed the literature data, we could emphasize some milestones and also, controversies in the history of proposed multimodal treatment and thus, outline the philosophy of this approach, which seems to be an unusual one indeed. Initially marked by nihilism and fear, but benefiting from a remarkable joint effort of human and material resources (multi-center and -institutional research), over a period of 30 years, CRS and HIPEC found their place in the treatment of PM. The next 4 years were dedicated to the refinement of the multimodal treatment, by launching research pathways. In selected patients, with requires training, it demonstrated a significant survival results (similar to the Hepatic Metastases treatment), with acceptable risks and costs. The main debates regarding CRS and HIPEC treatment were based on the oncologists' perspective and the small number of randomized clinical trials. It is important to statement the PM patient has the right to be informed of the existence of CRS and HIPEC, as a real treatment resource, the decision being made by multidisciplinary teams.

Key words: Hyperthermic intraperitoneal chemotherapy; Peritonectomy procedures; Systemic chemotherapy; Peritoneal metastases; Survival

Core tip: The multimodal treatment of peritoneal metastases (PM), involving cytoreductive surgery and hyperthermic intraperitoneal chemotherapy, has been strenuously achieved over time, but seems to be the best treatment option, for selected cases. This paper addresses data about the multimodal treatment strategy, focused to patient's survival, the key indicator for assessing results, in the case of PM. Also, it were highlighted the treatment key aspects and the controversies, high in the 35 years of treatment implementing. By understanding the philosophy of multimodal treatment, physicians will be able to offer an alternative to the routine systemic chemotherapy.

Multimodality treatment strategies have changed prognosis of peritoneal metastases. *World J Gastrointest Oncol* 2016; 8(1): 67-82 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/67.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.67>

INTRODUCTION

Peritoneal metastases (PM) were described by Sampson *et al.*^[1] (1931) in an ovarian cancer patient. For a long time since then, treatment was mostly palliative and thus, PM was linked to "terminal status/despair". The current multimodal treatment consisting of cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) has been strenuously achieved over time, but seems to be the best treatment option for selected PM cases.

As we reviewed the literature data, we could emphasize some milestones and also, controversies in the history of PM treatment and thus, outline the philosophy of proposed multimodal radical treatment, which seems to be an unusual one indeed. To understand this radical treatment, we start with the natural evolution of PM and "conventional" systemic chemotherapy approach, in fact the treatment of choice for stage IV cancer, regardless of the dissemination type and location. Four periods must be considered in the evolution of "dedicated" PM treatment: Before 1980; 1980-2000; 2000-2010 and 2010-present. The first time period, before 1980, was a period of palliative intraperitoneal treatment of ascites. In 1980-2000 were proposed the methods and define the foundation laying for a new multimodal approach of PM by intraperitoneal chemotherapy and CRS. The next periods, until 2010, were those of the progressive development of dedicated multimodal treatment strategy, concluding with the actual CRS-HIPEC. From 2010, the studies were focused about new research pathways. The PM treatment approach related survival was the main issue considered in this review.

NATURAL EVOLUTION OF PM

In the literature concerned with PM, the EVOCAPE I study^[2] is classical and it reflected the natural evolution of patients with non-gynecological PM. The mean survival (mS) was 6 mo, significantly correlated with the PM stage (Figure 1), according Gilly system^[3] (nodules/lumps < 5 mm: 9.8 mo; > 2 cm: 3.1 mo). PM of pancreatic origin had the lowest mS (2.9 mo), followed by PM of gastric origin (6.5 mo) and of colorectal origin (6.9 mo). The degree of differentiation had no influence on survival.

Several other "historical"^[4-6] studies confirmed the unfavorable prognosis of PM. Ascites is a negative prognostic factor: In pancreatic cancer, median survival (MS) was < 1 mo, with an important negative impact on the quality of life. Surgery was aimed at palliating gastrointestinal complications, as it was contraindicated in patients with gastric, pancreatic tumors or ascites^[4]. In colorectal cancer (marked by a favorable biological pattern), MS was significantly less for synchronous PM than that in metachronous (7 mo vs 28 mo, $P < 0.001$)^[6].

"CONVENTIONAL" SYSTEMIC CHEMOTHERAPY OF PM

Recent studies on colorectal cancer compared patients having only PM, as a distant metastatic location, with patients having other systemic dissemination. Franko *et al.*^[7] (2012) revealed a significantly lower ($P < 0.001$) global MS (12.7 mo vs 17.6 mo) and disease-free survival (5.8 mo vs 7.2 mo) for patients with PM vs other metastatic locations. Also, the poor global MS of PM metastasis patient was unchanged by various chemotherapy regimens (Figure 2).

Systemic chemotherapy carried MS significant benefit ($P = 0.026$) in colorectal PM patients only compared to those patients who did not receive chemotherapy (Figure 3): Increasing from 5 mo without chemotherapy (95%CI: 3-7 mo) to 11 mo with the fluorouracil-leucovorin protocol (95%CI: 6-9 mo), and to 12 mo with the oxaliplatin-irinotecan protocol (95%CI: 4-20 mo)^[8].

Despite the progressive development of systemic chemotherapy, in a population-based study, Lemmens *et al.*^[9] confirmed the poor MS in PM patients (1995-2001: 7 mo; 2002-2008: 8 mo), unlike that of patients with liver metastases, which underwent improvement (1995-2001: 8 mo; 2002-2008: 12 mo).

"DEDICATED" INTRAPERITONEAL TREATMENT OF PM

Palliative treatment (< 1980)

The first attempts for a treatment approach of peritoneal malignancies began in 1950, with the sporadic use of intraperitoneal chemotherapy for malignant ascites. For this intraperitoneal treatment, hemisulphur mustard^[10],

Figure 1 Kaplan-Meier survival curve of non-gynecological peritoneal carcinomatosis, stratified according to the Gilly staging system (Stage 0, 1 and 2 vs Stage 3 and 4)^[2] (with permission). Kaplan-Meier survival curve according to PM staging^[2]. Available from: URL: <http://click.info.copyright.com/?qs=e232cb87f594dcec17211f4d00b2929249713825e6b912c104538a1695c335dde91d3fd5f03fa97>. PM: Peritoneal metastases.

thiotepa^[11], nitrogen mustard^[12], quinacrine^[13] and bleomycin^[14] were used. Nitrogen mustard had a high digestive toxicity, so it was replaced by thiotepa (considered elective for ascites control in 1964), but even at that time it was foreseen that it would be replaced by 5-fluorouracil in digestive cancer palliation^[15]. Nevertheless, nitrogen mustard was the basis for developing further drugs: Cyclophosphamide, chlorambucil, uramustine, ifosfamide, melphalan, and bendamustine.

Multimodal treatment - methods and foundation-laying (1980-2000)

In 1978-1980, the first documented data became available, at first referring to the clearance of intraperitoneal cytostatic drugs^[16], then to circulating intraperitoneal cytostatic solutions, all thanks to the contributions of Speyer *et al*^[17] and Spratt *et al*^[18]. They were “the fathers” of regional intraperitoneal chemotherapy. Spratt augmented the cytostatic effect by hyperthermia using a specially designed device (Thermal Infusion Filtration System). Thus, the foundation was laid for a multimodal treatment of PM by normothermic and HIPEC.

The mechanism by which hyperthermia cytotoxic effects associating with and increasing the cytostatic drug effect is due to certain particularities of these drugs; studies regarding this aspect are exhaustive^[19-25].

The key merit in developing and implementing this multimodal treatment strategy belongs to Sugarbaker, who outlined and detailed the premises substantiating it. The starting model was that of PM in appendiceal cancer^[26]. The most important phase was the adjustment in the existing pathophysiological concept of PM, as a systemic disease and, consecutively, its treatment with systemic chemotherapy. In the new approach, the peritoneum was regarded as an organ (similar to the liver), the pathogeny of PM implying, first and foremost, peritoneal dissemination. Thus, it appears natural to use

a regional treatment in PM^[27-31]. Sugarbaker’s research was regarded mistrustfully, and 25 years had to pass before the “European contributions to the Sugarbaker protocol”^[32] appeared: One multicenter retrospective study^[33], two randomized prospective phase III studies^[34,35] and the use of oxaliplatin and irinotecan as new cytostatic drugs in the protocols for intraperitoneal chemotherapy^[36,37].

Sugarbaker also has the merit of being the first to have described and implemented the surgical procedures associated with regional chemotherapy, generically named “Peritonectomy”^[38]. So, the road lay open for the PM multimodal treatment by CRS and HIPEC.

He then brought in other special aspects regarding the surgical technique of Peritonectomy procedures: Required electrocautery, circumferential skin traction, dissection of subpyloric space and falciform ligament^[39-42]. He also described a method for staging PM and assessing the result of CRS, which were subsequently used in the majority of studies: The “Peritoneal Cancer Index” (PCI), based on the extension of peritoneal injury and the size of peritoneal deposits, respectively, the “Completeness of Cytoreduction Score” (CCRS), based on the size of the remaining peritoneal nodules/lumps^[43].

PM MULTIMODAL TREATMENT - CONFIRMATION, ASPECTS, PATIENT SELECTION, CONTROVERSIES (2000-2010)

“Confirmation”

Although the number of patients progressively and significantly increased and the so-called “long-term survivors” were identified, it took about 20 years before the “confirmations of a multimodal treatment option for PM” appeared. The initiator was Verwaal (2003)^[35], who carried out a randomized clinical trial for patients with colorectal PM. He showed that, during a mean follow-up of 21.6 mo, the MS of patients treated with CRS-HIPEC (22.3 mo) was significantly ($P < 0.032$) improved compared to patients treated with palliative surgery and systemic chemotherapy with fluorouracil-leucovorin (12.6 mo) (Figure 4A).

Verwaal’s research was confirmed by two other reference-worthy studies, which had the merit of comparing CRS-HIPEC with modern systemic chemotherapy treatment, in colorectal PM. Elias *et al*^[44] (2009) compared systemic irinotecan-oxaliplatin chemotherapy with CRS-HIPEC. Global survival in the CRS-HIPEC group (2 years: 81%, 5 years: 51%) was significantly ($P < 0.05$) improved compared to the systemic chemotherapy (2 years: 65%, 5 years: 13%). Franko *et al*^[45] (2010) analyzed systemic chemotherapy with irinotecan, oxaliplatin, bevacizumab, and cetuximab. MS in the CRS-HIPEC treatment group (34.7 mo) was significantly ($P < 0.01$) longer than systemic chemotherapy (16.8 mo) (Figure 4B). It was emphasized that the best results

Figure 2 Kaplan-Meier survival curve of metastatic colorectal cancer stratified according to the metastatic locations (peritoneal carcinomatosis vs non peritoneal carcinomatosis) and chemotherapy protocols (fluorouracil, leucovorin and oxaliplatin; fluorouracil, leucovorin and irinotecan; irinotecan and oxaliplatin)^[7] (with permission). Kaplan-Meier survival curve of Metastatic Colorectal Cancer stratified by peritoneal metastatic status and chemotherapy protocols^[7]. systemic chemotherapy.

For gastric PM, studies also showed a benefit in terms of survival. The prospective randomized clinical trial GYMSSA^[46] compared survival in patients treated with CRS-HIPEC and systemic chemotherapy vs systemic chemotherapy treatment alone. Within the limitation of a small number of patients, it showed a longer MS (11.3 mo vs 4.3 mo) for CRS-HIPEC treatment trial arm.

Likewise, Yang *et al.*^[47] showed in a phase III randomized clinical trial the importance of connecting CRS with HIPEC, in the treatment of PM of gastric cancer origin. The CRS-HIPEC association vs CRS alone significantly ($P = 0.046$) increased MS: 11 mo (95%CI: 10-11.9 mo) vs 6.5 mo (95%CI: 4.8-8.2 mo) (Figure 5).

A meta-analysis of randomized clinical trials performed by Yan *et al.*^[48] showed that in advanced gastric cancer, HIPEC associated with surgery led to a significant increase in survival, compared with patients benefiting from surgery alone.

In addition to randomized clinical trials (the gold standard in the treatment implementation), there are a series of multi-center studies showing survival results for patients treated with CRS-HIPEC.

Thus, several multi-center studies, focused on pseudomyxoma peritonei, colorectal and ovarian cancers, were conducted in France (Figure 6). For the treatment of

were achieved by associating CRS-HIPEC treatment with

Figure 4 Kaplan-Meier survival curve comparing hyperthermic intraperitoneal chemotherapy to standard treatment, for colorectal peritoneal carcinomatosis^[35] (with permission) (A) and comparing cytoreductive surgery and hyperthermic intraperitoneal chemotherapy treatment to systemic chemotherapy alone, for colorectal peritoneal carcinomatosis^[45] (with permission) (B). A: Kaplan-Meier survival curve comparing HIPEC to standard treatment, for Colorectal PM^[35]. CRS-HIPEC: Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy; PM: Peritoneal metastases.

pseudomyxoma peritonei, CRS-HIPEC was designated the “gold standard” due to the yielded results (at 5 years: 73% global survival, 56% disease-free survival)^[49]. Favorable results were shown for colorectal cancer (at 5 years: 27% global survival, 10% disease-free survival)^[50], and also for ovarian cancer (global survival: Advanced forms 35.4 mo, recurrent forms 45.7 mo)^[51].

The results were also confirmed by a long-term data analysis in the Netherlands, after the implementation of the CRS-HIPEC treatment: MS was 33 mo (95%CI: 28-38 mo) in colorectal cancer and 130 mo (95%CI: 98-162 mo) in pseudomyxoma peritonei (Figure 6)^[52].

The experience of a reference center for PM treatment (St. George's Hospital, Sydney) sustains the higher results obtained by the use of CRS-HIPEC treatment in

Figure 5 Kaplan-Meier survival curves comparing cytoreductive surgery and hyperthermic intraperitoneal chemotherapy treatment to cytoreductive surgery alone, for gastric peritoneal carcinomatosis^[47] (with permission). CRS-HIPEC: Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy; PM: Peritoneal metastases.

pseudomyxoma peritonei (MS 104 mo; 5-year survival 75%) and colorectal cancer (MS 33 mo; 3-year survival 46%)^[53].

A series of systematic reviews were conducted under the leadership of Sugarbaker, demonstrating a better survival for CRS-HIPEC treatment compared to conventional systemic chemotherapy. PMs of different origins were analyzed: Colorectal^[54], gastric^[48], ovarian^[55] cancers, and malignant peritoneal mesothelioma^[56]. Other systematic review studies also reported higher results for CRS-HIPEC in colorectal^[57] and gastric^[58] cancers.

All these studies (numerous and enrolling an increased number of patients) shows joint international efforts to identify the role of CRS-HIPEC in multimodal PM treatment. They have allowed the development of an important medical database which, by confirming the higher results in terms of survival and disease-free survival, upholds this treatment strategy. This is also confirmed by the evidence-based medicine approach studies^[59].

The MS, as a result of CRS-HIPEC treatment, related to the tumor entities and study type, were presented in Table 1.

As a recognition of the foundation-laying treatment of PM with CRS-HIPEC, this was included in the treatment guidelines in France^[60], Germany^[61], United Kingdom (<http://www.nice.org.uk/guidance/IPG331/PublicInfo>), the Netherlands^[52,62]. There are a number of ongoing symposia focused on Peritoneal Surface Malignancies, under the patronage of the European Society of Surgical

Oncology, as well as a world congress.

The view of those who consider that multimodal PM treatment is "more of an experimental kind, based on common-sense evidence rather than on solid data"^[63,64] is already obsolete. Even so, the confirmation of CRS-HIPEC, as an effective treatment approach by medical studies, such as randomized clinical trials, is not mandatory^[65]. And more than that, the life of patients could be endangered by denying them a treatment resource, since the validation process may take as long as 40 years^[66].

Aspects

Unfortunately, there is no single perfect treatment

option, valid in any setting, so the problems raised were concerned with treatment risk (morbidity, mortality, medical team risk), costs and with the indication of CRS-HIPEC, in terms of prognostic factors.

In the beginning, morbidity and mortality were the key factors initiating distrust among patients and physicians^[67]. The causes of morbidity and mortality may well be suspected to belong to either CRS (surgery proper), or HIPEC (thermal effects of circulating fluid and toxic cytostatic drug effects). In a systematic-review study, morbidity was 21.5% and mortality 4.8%^[68], but literature reports data within a large range: Morbidity 12%-67% and mortality 0%-9%. The main complications include digestive fistulae, postoperative bleeding, pleural-pulmonary complications, bone marrow suppression, hemodynamic instability and renal failure. Protective ileostomy, chest drain and postoperative thoracic imaging are routinely used.

However, it was shown that morbidity and mortality were not significantly increased, compared to extensive organ resection surgery (e.g., Whipple's operation)^[69]. Treatment complications were significantly correlated with the number of Peritonectomy procedures, left diaphragmatic Peritonectomy, duration of surgery and the number of large bowel anastomoses^[70]. The global incidence for the 1st to 4th degree of gastrointestinal toxicities (according to the Common Terminology Criteria for Adverse Events) was 17%, and for symptomatic surgical site infections incidence reached 35.85% (with a global morbidity of 45%)^[71].

The learning curve must be respected by any medi-

cal procedure, even more so when it implies new skills for the surgeon. The “breaking points” of the learning curve in achieving complete CRS, of a morbidity less than 3th degree and an absence of treatment-related mortality are evaluated to be 141, 158 and 144 cases, respectively (the Milan experience), or 126, 134 and 60 cases, respectively (the Bentivoglio experience)^[72].

As the Dutch model of CRS multimodal treatment implementation was analyzed, it was proven that, unlike in the initial stage (experience gathering), in the stage of treatment becoming standard, the percentage of radical surgeries increased significantly (66% vs 86%, $P < 0.001$) and major morbidity (3th-5th degree) decreased significantly (64% vs 32%, $P < 0.001$)^[73].

If there existed accreditation centers and HIPEC registers, coursing through the learning curve could be faster^[74]. Suggestions were made for training in CRS-HIPEC to begin during the residency programmer^[75].

As for the risks the medical team are exposed to during HIPEC, it was shown in several pharmacological studies that, in relation to the HIPEC method (closed/open), with required training, these risks may be reduced to a minimum^[76-78].

The costs implied by CRS-HIPEC treatment are definitely high, but financial calculations show that it is a better solution in terms of treatment results^[53,79-81]. This is why in Germany, HIPEC is adopted, considered a surgical procedure and coded as such^[61].

Patient selection

One of today's challenges in treating PM is patient selection. This is why literature studies are focused on factors/variables correlating with survival.

The randomized clinical trial performed by Verwaal *et al.*^[35] showed that in colorectal cancer, the variables with the highest impact are extension of PM and the radical feature of CRS ($P < 0.0001$) (Figure 7). The GYMSSA randomized clinical trial^[46] also showed that essential conditions for a significant increase in survival in gastric cancer are complete CRS and a PCI ≤ 15 .

A single-center experience, the most comprehensive in terms of the number of patients (1000 patients), shows that the prognostic factors significantly correlated with survival ($P < 0.001$) are: The performance index, the location of the primary tumor, the CCRS, and the center experience^[82]. Another single-center experience (109 patients) correlated survival to the following factors: Histology of non-adenocarcinoma ($P = 0.001$), appendiceal location ($P = 0.001$), absence of liver metastases ($P = 0.01$), and complete resection of all gross disease ($P < 0.001$)^[83].

A multi-center French study shows that in colorectal cancer, CCRS is the most important prognostic factor for MS: 32.4 mo for complete vs 8.4 mo for incomplete CCRS ($P < 0.001$) (Figure 8)^[33]. The multi-center SITILO study^[84] also reveals in colorectal cancer the following independent prognostic variables correlated with survival: PCI, CCRS, and presence of hepatic metastases.

The consensus conference on PM treatment in

colon cancer statutes that the indication of CRS-HIPEC treatment should be based on complete CRS^[85].

All those prognostic factors are in dynamics, the trend being towards broadening the indication range, except for the radical feature of CRS: It is absolutely necessary that this should be complete, or at least optimal. Traditionally, the treatment approach in PM was reserved for colon or appendicular cancer, pseudomyxoma peritonei and peritoneal malignant mesothelioma, but now the range of indications includes rectal, gastric and ovarian cancers. The importance of PCI is not an absolute one, it must be correlated with primary tumor location (colonic PM origin vs gastric), histological grading (well and moderate differentiated vs poorly differentiated and undifferentiated), and the anatomical sites involved (Treitz ligament, porta hepatis and suprahepatic veins, coelic axis and mesenteric vessels). The presence of other systemic dissemination (abdominal or extra-abdominal) was a contraindication for the treatment approach in PM, but this is no longer (Figure 9) the case provided that complete CRS can be obtained^[86-89].

Except for the patient status (evaluated by the performance index), the main CRS-HIPEC treatment contraindication is small bowel involvement^[90], which is regarded as an independent prognostic factor^[91-93].

A series of studies have confirmed the prognostic value of tumor grading in colorectal cancer. The “signet-ring cell” vs other types of differentiation has a significantly poorer MS (14.1 mo vs 35.1 mo; $P < 0.01$) and an increased relapse rate (68.8% vs 43.7%; $P = 0.05$)^[94]. CRS-HIPEC treatment carries no survival benefit in colorectal PM with signet-ring cell histology, unless complete CRS is obtained^[95]. Also, for the aggressive type of pseudomyxoma peritonei, systemic chemotherapy is indicated instead of CRS-HIPEC treatment^[96].

In some studies, the prognostic factors were grouped into scores. The Peritoneal Surface Disease Severity Score may be used to stratify patients in clinical trials^[97]. Different scores used in PM of colorectal origin are: The Peritoneal Surface Disease Severity Score, the Prognostic Score, and the Colorectal Peritoneal Score. The Colorectal Peritoneal Score (value ≥ 6) identifies patients with an unfavorable prognosis in terms of survival, and it does so better than PCI (value > 20) or the other two scoring systems^[98].

Controversies

At the same time, there are also reserved attitudes regarding the CRS-HIPEC approach of PM. This is mainly the position of oncologists, who are refractory to this treatment option, using the argument of the risk/benefit ratio. The theoretical premise they use is based on the lack of difference (pathophysiology, evolution, and treatment) between PM and other systemic dissemination. The treatment is not adapted, so different protocols of systemic chemotherapy (from the classic de Gramont chemotherapy to oxaliplatin, irinotecan and biological molecular agents) are given in different clinical

Figure 7 Kaplan-Meier survival curve of colorectal peritoneal carcinomatosis treated by cytoreductive surgery and hyperthermic intraperitoneal chemotherapy, stratified according to the size of residual tumors (A) and the number of regions with residual tumors (B)^[35] (with permission). Kaplan-Meier survival curve of CRS-HIPEC treatment, for Colorectal PM, stratified by the number of regions affected (A) and the number of regions with residual tumors (B)^[35]: <http://click.info.copyright.com/?qs=2b7046b10dd0c5471bbbb8bac0096e00e895f442c0326423c4ec2ccdd7b4701b99fd4bd5b32f0283>. CRS-HIPEC: Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy; PM: Peritoneal metastases.

trials, without considering the variances between the specific dissemination biology^[99-101]. The indispensable condition that oncologists require for inclusion in a clinical trial is the presence of measurable lesions. In the case of PM, this condition is almost impossible to meet. Imaging modalities have a low sensitivity in detecting the peritoneal dissemination, and this is true for computer tomography as well as for magnetic resonance imaging. The only parameters based on which the results of CRS-

HIPEC treatment may be assessed are disease-free survival and global survival.

Furthermore, concerning the oncologists' perspective, there is at least one more important argument supporting the dedicated multimodal treatment of PM: The studies matching hepatic metastases vs PM. These have shown that the pathway of dissemination are different and the treatment results are comparable (Figure 10), if treatment is potentially radical^[102-104].

Figure 8 Kaplan-Meier survival curve of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy treatment, for colorectal peritoneal carcinomatosis, stratified by completeness of cytoreduction score^[33] (with permission). Kaplan-Meier survival curve of Colorectal PM alone and PM with Hepatic Metastases^[86]. Available from: URL: <http://click.info.copyright.com/?qs=2b7046b10dd0c5471bbb8bac0096e00e895f442c032642364879a25688a50cc82757e6f8509f6e1>. PM: Peritoneal metastases.

Nowadays, in colorectal cancer, by analogy with Hepatic Metastases, multimodal CRS-HIPEC treatment has been adopted and is the indicated approach for CP, in most institutions in the United States^[31].

PM MULTIMODAL TREATMENT - RESEARCH PATHWAYS (2010-2014)

Currently, there is reason to talk about a higher level, where the problem of timing for CRS-HIPEC is raised. There are studies showing that PM prophylaxis is a valid approach.

Figure 10 Kaplan-Meier survival curve for colorectal peritoneal metastases and colorectal hepatic metastases, who achieved optimal treatment^[102] (with permission). Kaplan-Meier survival curve for Colorectal PM and Colorectal Hepatic Metastases, with optimal treatment^[102]. Available from: URL: <http://click.info.copyright.com/?qs=751ae7c8f8e03ecb0a4741c79a3b341599b5318899e258b3d458148f31158885e37d98de5cb03229>. PM: Peritoneal metastases.

“Proactive management” defines a treatment concept, targeting patients with a high risk to develop PM, and prescribes surgery with HIPEC. In colorectal cancer, this has brought about a significant results ($P < 0.03$), related to control group (only surgery), in terms of PM developed and local recurrence (4% vs 28%, over a 48-mo follow-up period). Patients had also significant longer MS (59.2 mo vs 52 mo; $P < 0.04$) and disease-free survival ($P < 0.05$)^[105].

There was a hypothesis of second-look surgery at 1 year in patients at high risk for PM, after the first radical surgery for colorectal cancer. PM might be identified and treated at an earlier stage in about 55% of patients^[106]. Such researches were also led for gastric cancer, with promising preliminary results^[107,108].

In the same context of colorectal PM prophylaxis, the HIPEC laparoscopic approach was described and indicated after a mean interval of 6 wk (3-9 wk). This approach showed its feasibility^[109].

The main issue is selecting high-risk patients for developing PM. The debated risk factors are: Invasion of or beyond the serosa (pT3, pT4), perforated tumors, positive peritoneal cytology (augmented by immunohistochemistry), occurrence of Krukenberg tumors and mucinous type of tumor^[110]. Following a systematic review, three situations were identified to be associated with an increased frequency of metachronous PM development: Synchronous PM, ovarian metastases, and perforated tumor^[111].

Despite all human and material efforts dedicated to CRS-HIPEC treatment, there are patients in whom evolving disease occurs. The right question is whether

Table 2 Key aspects and peritoneal metastases model in the evolution of multimodal treatment

Period	PM treatment	Key aspects	PM model
All the period	"Conventional" systemic chemotherapy	Significant lower survival for PM <i>vs</i> other type of metastases	Colo-rectal
1950-1980	"Dedicated" intraperitoneal treatment - Palliative treatment	The basis for developing further cytostatic drugs	Malignant ascites
1980-2000	"Dedicated" intraperitoneal treatment - Multimodal radical treatment	Regional intraperitoneal normothermic and hyperthermic chemotherapy Peritonectomy procedures Define PCI and CCRS	Appendicular
2000-2010	Multimodal radical treatment - confirmation, aspects, patient selection, controversies	Significant higher survival <i>vs</i> palliative surgery and diverse systemic chemotherapy regimes Acceptable morbidity and mortality, no significant risk for medical team Respect de learning curve High costs Define the prognostic factors Position of oncologists Comparison with hepatic metastases	Colo-rectal Appendicular Pseudomyxoma peritonei Malignant peritoneal mesothelioma Gastric Ovarian PM with hepatic metastases
2010-2014	Multimodal treatment - research pathways	PM prophylaxis Laparoscopic HIPEC Integration of chemotherapy with surgery Extension of CRS	High-risk patients for developing PM Recurrent PM

PM: Peritoneal metastases; CCRS: Completeness of cytoreduction score; CRS-HIPEC: Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy; PCI: Peritoneal cancer index.

iterative treatment of PM might be a solution. There are at least three problems: Estimate the morbidity/mortality associated with the iterative treatment; documentation the prognostic factors; estimation the treatment results in terms of survival. The only few related studies define no clear attitude, supported by statistically significant data. Morbidity/mortality does not seem to differ significantly^[112-114], only one single study reporting increased values^[115].

HIPEC remains an important tool in the treatment of recurrent PM. Age ($P = 0.049$), time lapse between surgeries ($P = 0.08$), association of HIPEC ($P = 0.005$), and small bowel resections ($P < 0.001$) are statistically correlated with survival in PM appendiceal origin and malignant peritoneal mesothelioma^[113]. The iterative approach of colorectal PM results in a MS of 22.6 mo, with the following survival percentages: 1 year - 94%; 2 years - 48%; 3 years - 12%^[114].

The iterative approach treatment of the patient with PM and Hepatic Metastases has also promising results^[116].

An important research pathway is the way by which chemotherapy might be integrated into various treatment approaches: Perioperative neoadjuvant; HIPEC; bidirectional intraoperative; early postoperative intraperitoneal. The multidisciplinary approach of PM is based on treatment with complete CRS. Unfortunately, this cannot be achieved in approximately 70% of patients^[31].

The place of systemic chemotherapy in PM mul-

timodal treatment is difficult to assess. There are definite reports regarding the results of perioperative neoadjuvant chemotherapy, demonstrated by histological response in colon cancer^[117] and by increased survival in appendix cancer^[118]. Likewise, in gastric cancer, survival benefits have been shown for perioperative neoadjuvant and early postoperative intraperitoneal chemotherapy^[119].

The complexity of multimodal treatment approach is also certified by the wide range of cytostatic drugs and the occurrence of new principles. It is possible that Mitomycin C, in colorectal PM, in the context of complete CRS, may yield superior survival results compared to oxaliplatin^[120]. For gastric PM, catumaxomab seems to confirm positive results^[119], but in colorectal PM, bevacizumab leads to a double mortality rate after CRS-HIPEC treatment^[121].

Furthermore, as far as the array of CRS treatment is concerned, along with visceral resection and Peritonectomy procedures, surgery on the urinary tract was assessed. Partial cystectomy and ureter segmental resection were the most used. There was no further increase in the recorded morbidity or mortality and survival was comparable to that of patients with CRS-HIPEC without urinary tract surgery^[122,123]. The same statute was dedicated to the hepatobiliary procedures^[124].

At present, there are over 50 clinical trials underway, aimed at assessing multimodal radical PM treatment (<http://clinicaltrialsfeeds.org/clinical-trials/results/?term=HIPEC>). Out of these, some were reported in the literature: GASTRICHIP (D2 gastric resection and HIPEC

for locally advanced gastric cancer)^[125], COMBATAC (multimodal treatment of PM of appendiceal and colorectal origin)^[126], NCT01095523 (second-look and CRS-HIPEC treatment for colorectal cancer at risk for PM)^[127].

Key aspects and PM model in the evolution of multimodal treatment strategies

We summarized the key aspects of the evolution of multimodal treatment strategies in Table 2.

CONCLUSION

Initially marked by nihilism and fear, but benefiting from a remarkable joint effort of human and material resources (multi-center and -institutional research), over a period of 30 years, CRS-HIPEC found its place in the multimodal treatment of PM. The next 4 years were dedicated to the refinement of multimodal treatment, by launching research pathways. In selected patients, with requires training, it demonstrated a significant survival results (similar to the Hepatic Metastases treatment), with acceptable risks and costs. Also, CRS-HIPEC opens a lot of new opportunities with reference to the patients' selection and adopted methodology of this multimodal treatment.

The main debates regarding CRS-HIPEC were based on the oncologists' perspective and the small number of randomized clinical trials. It is hard to find a common view on different challenges, raised by CRS-HIPEC in the treatment of PM. Probably, Dr. Bernard Fisher met the same mistrust as he revolutionized breast cancer treatment and the same could be said about the surgical approach to metastatic melanoma. Indeed, there is a discrepancy between the great number of multi-center, -institutional studies and the small number of randomized clinical trials.

We may say that there are a series of determining factors, for the long-term assessment of multimodal PM treatment and the bias in medical studies type. Treatment complexity, results from the interaction between different therapeutic principles (surgery, chemotherapy, and hyperthermia), are an essential factor. Also, the peritoneal cavity is a complex anatomical space, and the pathogenesis of PM is indeed multifactorial conditioning (loco-regional and systemic dissemination). Not least, the multidisciplinary approach of PM implies the teamwork of specialists with different training, treatment concepts and results assessment, making it difficult to find a common view.

It is important to statement the patients with colorectal, appendicular, gastric, and ovarian peritoneal carcinomatosis, as well as patients with pseudomyxoma peritonei and peritoneal malignant mesothelioma must be informed about CRS-HIPEC as a valid treatment resource. The eligibility criteria for patients' selection will be assessed by multidisciplinary teams, in high level, dedicated treatment centers, according to the performance index, PCI, histological grading, the perspective to obtaining a complete CRS, and the availability of sustaining chemotherapy protocols.

Abstract

Colorectal cancer (CRC) is the third most frequent cancer type and the incidence of this disease is increasing gradually per year in individuals younger than 50 years old. The current knowledge is that early-onset CRC (EOCRC) cases are heterogeneous population that

includes both hereditary and sporadic forms of the CRC. Although EOCRC cases have some distinguishing clinical and pathological features than elder age CRC, the molecular mechanism underlying the EOCRC is poorly clarified. Given the significance of CRC in the world of medicine, the present review will focus on the recent knowledge in the molecular basis of genetic and epigenetic mechanism of the hereditary forms of EOCRC, which includes Lynch syndrome, Familial CRC type X, Familial adenomatous polyposis, MutYH-associated polyposis, Juvenile polyposis syndrome, Peutz-Jeghers Syndrome and sporadic forms of EOCRC. Recent findings about molecular genetics and epigenetic basis of EOCRC gave rise to new alternative therapy protocols. Although exact diagnosis of these cases still remains complicated, the present review paves way for better predictions and contributes to more accurate diagnostic and therapeutic strategies into clinical approach.

Key words: Early-onset; Colorectal cancer; Epigenetic mechanism; Genetic mechanism; Clinical outcome

INTRODUCTION

Colorectal cancer (CRC) is the third most frequent cancer type and despite improvements in diagnosis and treatment, this disease is the second leading cause of cancer death in developed countries^[1]. The highest incidence of CRC is observed in Western Europe, North America and Australia in western populations. It is notable that although the rate of this disease is relatively lower in the communities of the sub-Saharan Africa, South America and Asia, the rate is gradually increasing depending on assimilating life-style and dietary habits of the western countries^[2]. In more developed countries, screening programs for 50 years and elder people leads to early detection of CRC and opportunity for more satisfactory treatments; thus, death rates reduced approximately 2% per year^[3-5]. However, CRC screening is not common for young adults (between 20-40 ages), the incidence of this disease is increasing gradually per year in individuals younger than 50 years^[6]. The tumors of early-onset patients are more aggressive than elder cases^[7,8].

Because of the advances in our understanding concerning the molecular mechanism of elder age CRC, we can describe the presenting phenotype depending on the molecular characteristics of the tumor in majority of the cases^[9]. This vital knowledge contributes to the available studies in the literature for individual-specific and targeted therapies for CRC patients related to their drug responses. However, the molecular mechanism underlying the early-onset CRC (EOCRC) is poorly clarified in the relevant literature. Recent studies have revealed that EOCRC might evolve in a different pathway and the molecular basis of these cases may be unique for individuals^[10]. Therefore, determining identifiable markers of this disease for early diagnoses is required to develop unique treatment protocols and increase the survival of the patients. However, to date, little knowledge has been gained about the molecular basis of young age. Given this gap to be highlighted, the aim of our review is to synthesize and evaluate the current literature regarding the genetic and epigenetic pathogenesis of EOCRC at molecular level.

MOLECULAR PATHOGENESIS OF EOCRC

In comparison to elder CRC, EOCRC cases have some distinguishing clinical and pathological features^[11,12]. These tumors are pathologically recognized with low-grade tumor differentiation, mucinous component and high signet ring cells frequency^[11,13]. Polyp development is contently observed during the follow-up period of EOCRC^[10]. The majority of early-onset tumors occur in the distal colon and the rectum^[14]. Previous studies underlined the significance of heritance as an indicator of EOCRC^[11,12]. Supporting these views, early-onset and hereditary forms of CRC demonstrate similar well-known pathological features^[11,13]. Nevertheless, the current knowledge is that EOCRC is a heterogeneous disease

with both familial and sporadic cases. The molecular basis of this heterogeneity has not yet been fully clarified in the literature, however, the severe histopathological properties and a possible genetic feature of the tumor may predispose to expedited tumor growth in young age patients as reported^[15,16].

HEREDITARY FORMS OF EOCRC

In the hereditary forms of CRC, the disease can be observed in one or more first and/or second degree relatives of the patient. Thus, familial CRC counts approximately 20% of all CRC patients^[17]. With almost 3% observation rate, the most frequently occurring familial CRC is Lynch syndrome (LS)^[18]. On the other hand, polyposis syndromes, such as familial adenomatous polyposis (FAP), MUTYH-associated polyposis (MAP), Juvenile polyposis syndrome (JPS) and Peutz-Jeghers syndrome (PJS), are less often observed familial colorectal syndromes^[17].

LS

LS is frequently right-sided, an autosomal dominant cancer predisposition. The majority of these tumors are synchronous and metachronous. Extracolonic sites of patients, such as brain, ovary, endometrium, renal pelvis, ureter, stomach, small intestine and skin, are also among a high cancer risk^[18]. LS is caused by various germline DNA mismatch repair (MMR) gene mutations^[19-21]. Approximately 90% of the identified LS mutations are observed in *MLH1* or *MSH2* genes and approximately 10% of the LS mutations were identified in *MSH6* and *PMS2* genes^[17,22]. The prevalence and characteristics of these mutations vary widely among populations. In 2010, we defined two frame-shift mutations (*MLH1* c.1843dupC and *MLH1* c.1743delG) and three missense mutations (*MLH1* c.293G < C, *MLH1* c.954_955delinsTA and *MSH2* c.2210G < A) uniquely in Turkish LS cases^[23]. In a study of Italian LS families, c.643_648 dupA, c.2156_2157 dupT, c.684_685 dupC and c.1701_1704 delT frameshift mutations and c.2206 G < T, that cause a truncating protein were first time determined in *MLH1* gene. Other truncating protein causing mutations, c.1089 G < T and c.2634-2 A < G, that results with a splice defect was originally reported in *MSH2* gene^[24]. In Malaysia population, two novel mutations, c.3341_3342insC and c.3885_3891delTAAAGC were characterized in *MSH6* and c.2395C > T mutation was defined in *PMS2* gene^[25]. Recently, an unidentified mutation of *MLH1*, c.2044_2045del was linked to LS in a Caribbean Hispanic family^[26].

Deficient MMR function of LS cases usually promotes microsatellite instability (MSI)^[27,28]. MSI is characterized by length alterations within simple repeated sequences that are called microsatellites^[28]. MSI is essential for deregulation of cell growth, differentiation and death^[29]. MSI also plays roles in modulating the response of patients to various chemotherapeutic agents^[27]. Losing the expression of MMR proteins *via* inactivation of MMR-

deficient crypt foci genes causes an MSI phenotype^[30]. In these patients, the mutation rates of *ACVR2*, *TAF1B* and *ASTE1*, microsatellite-bearing target genes are higher than 80%^[29-33]. Recent studies indicated that in MSI cases, frameshift mutations of apoptotic genes, such as *APAF1*, *BAX* and *FLASH*, lead to intratumoral heterogeneity^[28]. The study of Markowitz *et al*^[34] demonstrated the relation with DNA repair defects with a specific pathway of CRC progression and three different mutation of *TGFBR2* gene in 1995^[34]. However, the latest study of de Miranda *et al*^[35] showed the transcription and translation of *TGFBR2* with a 1 nucleotide deletion at its microsatellite sequence still produced a functional *TGFBR2* protein. This protein is required for phosphorylation of *SMAD2*, which is phosphorylated in most of the MSI CRC tissues^[35].

The *MMR* gene modifications of LS occur by two hit usually point mutations or large rearrangements may give rise to the first hit. Accordingly, gene conversion or loss of the wild-type allele evokes the second hit^[36]. However, recent observations demonstrated the high rate of promoter methylation occurrence as the second hit^[37,38]. These findings emphasize the role of epigenetic events in formation of LS^[37,38]. Indeed, depending on the studies, germ line hemiallelic methylation of *MLH1* and epimutations of *MSH2* lead to LS with insufficient *MLH1* or *MSH2* protein expression in mutation negative families^[39-42]. Ligtenberg *et al*^[43] state that germ line 3' end deletions of *EPCAM* gene that is located upstream of *MSH2*, correlate with MSI and a loss of *MSH2* protein even though there was no identifiable mutation in *MSH2* gene^[44]. Kuiper *et al*^[44] found *EPCAM* deletions in approximately 2.3% of *MSH2*-deficient families. This study affirms the epigenetic transgenerational inheritance and the possibility of aberrant promoter methylation occurrence in neighbouring tumor suppressor genes by loosing of polyadenylation signals^[28]. In addition, current evidence in the empirical studies supports the role of miRNAs that is responsible for translational rearrangement of proteins, in regulation of MMR genes expressions^[45]. In comparison to sporadic MSI tumors, LS patients have a typical miRNA profile. Valeri *et al*^[46]

demonstrated the association of reduced expression of *MSH2*, *MLH1* and *MSH6* and induction of a mutator phenotype and MSI with over expression of miR-155 in LS. In another study, Balaguer *et al*^[47] determined the up-regulation of miR-622 and miR-1238 in these patients. MSI status modulates the miRNA expression levels^[48]. Earle *et al*^[48] defined the increased expression of miR-155, miR-31, miR-223 and miR-26b in MSI tumors. In addition, Earle *et al*^[48] linked over expression of miR-31 and miR-223 to LS. Not only miRNA regulates gene expression in an epigenetic way but also miRNA expressions may be regulated epigenetically. With containing a CpG island in the promoter region, most of the miRNAs are favorable for aberrant methylation which can give rise to dysregulation of miRNA^[49,50]. Kaur *et al*^[49] identified a correlation between miR-345 and miR-132 hypermethylation and MMR deficiency (Table 1).

Familial CRC type X

MMR germline mutations are observed in approximately 60% of the families, fulfilling clinical criteria for LS^[51]. Although familial colorectal cancer type X (FCCTX) accomplish the same clinical criteria with LS, the morphological features, such as right-sided tumor location, poor differentiation, expansive growth pattern, tumor-infiltrating lymphocytes, peritumorous lymphocytes, Crohn-like reactions and lack of dirty necrosis, are not common in FCCTX as LS^[52]. In addition, despite these, families demonstrate clinical features in which CRCs with MSI, FCCTX is not related to germline MMR gene mutations^[51,53]. The age onset of FCCTX is relatively older than LS cases and this disease differ from LS with the tumorigenic pathways^[54,55]. Basically, two individual molecular pathways involve in these families. One of these pathways is loosing of tumor suppressor gene loci genes, such as *TP53*, *APC*, *SMAD4* and *DCC*, somatic mutations of *APC* and *KRAS* and *MGMT* promoter methylation. At the second partway, there is no loosing of tumor suppressor gene loci genes and rarely presenting promoter methylation^[56]. Therikildsen *et al*^[57] linked to FCCTX tumors with gain of genetic material in two separate regions encompassing, 20q12-13.12 and 20q13.2-13.32. This study revealed that gain of material on chromosome 20q and loss on chromosome 18 differentiate FCCTX from LS. Findings of Dominguez-Valentin *et al*^[58] showed that gaining mutations of *GNAS* gene which is located in 20q13.32 and encodes for the Gα-subunit may cause FCCTX *via* activation of the Wnt and ERK1/2 MAPK signalling pathways. Moreover, other 20q located genes, *CDH26*, *SRC* and *ASIP* that play role in proliferation and migration may have a potential to cause FCCTX^[58]. Dominguez-Valentin *et al*^[58] defined the up-regulation of *PTGER1* in these tumors which can cause tumor growth through altered prostaglandin E2 function^[59,60]. Recently, an *SEMA4A* gene variant c.232G > A was determined in Austrian kindred with FCCTX. This study revealed that *SEMA4A* (V78M) lead to activation of MAPK/Erk and PI3K/Akt signaling. Moreover, *SEMA4A* mutations, c.1451G > C and c.977C > T and the single-nucleotide polymorphism c.2044C

> T were determined as associated with the FCCTX phenotype^[61]. Recent knowledge about the molecular characterization of FCCTX is summarized in Table 2.

FAP

FAP is an autosomal dominant cancer syndrome^[62]. FAP is diagnosed with 100 or more adenomatous polyps in colon or rectum in patients with younger than 40 age^[62]. Patients with FAP carry germline mutations of the adenomatous polyposis coli (*APC*) gene located on chromosome 5q21-q22^[63]. *APC* protein is a large scaffolding protein which involves in Wnt signaling pathway. In this protein complex, *APC* leads to down regulation of b-catenin activity and play a central role in a destruction complex of Axin, GSK-3 β and casein kinase 1. This complex directs a series of phosphorylation events on β -catenin that target it for ubiquitination and subsequent proteolysis^[64]. In the absence of *APC* protein, b-catenin binds to several transcription factors of the TCF/LEF and initiates the altered expression of genes associated with proliferation, differentiation, migration and apoptosis. Moreover, the depletion of *APC* can lead to abnormal chromosome segregation and aberrant mitosis^[65,66]. FAP occurs when there are mutations between codons 168-1580 and with severe disease between codons 1250-1464 of *APC* gene^[67,68]. The majority of *APC* mutations are either frameshift or nonsense mutations resulting in a truncated protein^[69]. The two most frequently described germline mutations are located at codon 1309 (c3927_3931delAAAGA) and codon 1061 (c.3183_87delACAAA)^[70]. Although two-thirds of FAP patient disease is inherited, the rest of the cases have no family history and carry unique mutations. Almost all *APC* mutations results with a colonic phenotype but variable for extra-colonic manifestations, such as desmoid tumor, hepatoblastoma, thyroid carcinoma, medulloblastoma, a litany of benign lesions and brain tumors, particularly medulloblastomas^[71-73]. Lamberti *et al*^[74] found that *GSTT1* polymorphism showed an uncertain association

with extra-intestinal manifestations in a study of 411 FAP patients. Recent studies demonstrated the enrichment of pyloric gland adenomas of the stomach, in addition to fundic gland polyps and foveolar-type adenomas in patients with FAP^[75,76]. Hashimoto *et al*^[75] analyzed the genetic alterations in these FAP-associated gastric lesions and they demonstrated that, as well as *APC* mutations, these cases had *GNAS* and *KRAS* mutations.

KRAS mutations have been observed in the early development of approximately 40% of colon cancers. Simultaneous *APC* depletion and *KRAS* mutation results with an augmentation in adenomas^[76] and induce the spread of stem cell marker carrying cells within the tumor epithelium^[77]. Phelps *et al*^[78] stated that in FAP adenomas, intestinal differentiation is required two consecutive steps. In the first step, after *APC* loss, CtBP1 contributes to adenoma initiation and in the following step, *KRAS* activation and β -catenin nuclear localization promote adenoma progression to carcinomas. On the other hand, Obrador-Hevia *et al*^[79] analysed somatic *APC* and *KRAS* mutations, beta-catenin immunostaining, and qRT-PCR of *APC*, *MYC*, *AXIN2* and *SFRP1* genes in sixty adenomas from six FAP patients with known pathogenic *APC* mutations. Based on this study, the Wnt pathway was constitutively activated in all *APC*-FAP tumors, with alterations occurring both upstream and downstream of *APC*. Thus, Obrador-Hevia *et al*^[79] suggest that for Wnt signalling activation in *APC*-associated FAP adenomas, oncogenic *KRAS* is not essential.

FAP may also pursue a different way to Wnt signalling pathway alterations through epigenetic mechanisms. Although epigenetic alterations of Wnt signalling are an effective factor for FAP formation, *APC* mutations exist in almost all FAP patients. Romero-Giménez *et al*^[80] evaluated the possible role of germline hypermethylation of the *APC* promoter in FAP families that were negative for *APC* mutations in 21 FAP families and they did not identify signs of abnormal promoter methylation, indicating that this form of epigenetic silencing is not a common cause of FAP. However, Kámory *et al*^[81] observed promoter hypermethylation that causes somatic inactivation of *APC* in 21 sporadic cases (30%). In the study of Zhang *et al*^[82] within FAP families, although methylation was not present in normal tissues, hypermethylation was determined in tumor tissues of one proband and her son. In addition, loss of heterozygosity was observed in another patient from the same FAP family. Segditsas *et al*^[83] declared similar findings with Zhang *et al*^[82]. They detected *APC* promoter methylation in 27%-45% of colorectal tumors and cell lines but did not detect in normal colorectum. However, they substantially observed that methylation was independent of the *APC* mutations and was not associated with the CpG island methylator phenotype. Although methylation caused the loosing of 1A isoform mRNA and a reduction in total *APC* transcript levels, *APC* gene expression was retained from promoter 1B^[83]. Moreover, a recent study of Pavicic demonstrated that promoter 1B deletions of *APC* are not very common^[84]. Thus, all these studies imply that

even though *APC* promoter methylation occurs in early during colon neoplasia progression, it does not result in complete gene inactivation or act as a "second hit"^[84] and promoter-specific alterations of *APC* rarely leads to mutation-negative FAP^[84].

In addition to *APC*, hypermethylation of other genes are usually observed in both FAP-related and sporadic duodenal carcinomas^[85]. Wynter *et al*^[86] study showed that the methylation of *MGMT*, *p14ARF* and *p16INK4* genes promoter regions are frequently observed in both sporadic and familial adenomas. Berkhout *et al*^[85] defined the high methylation rate of the *IGSF4*, *TIMP3*, *ESR1*, *APC* and *CDH13*, in both of these cases, however, in the same study, *PAX6* gene was determined as hypermethylated only in FAP-related carcinomas. Recently, the role of altered miRNA expression in Wnt signalling regulation and FAP development has also been evaluated. Lately, the studies indicated the decreased expression of miR-143, miR-145, miR-126 and miR-20b as an early event of colorectal carcinogenesis in FAP tumors^[87,88]. Specifically, miR-126 and miR-20b play role in angiogenesis^[88]. Thus, downregulation of these miRNAs is an important genetic event for the initiation step in colorectal tumor development^[87]. Besides *APC* alterations, other genetic and epigenetic events determined in FAP patients were summarized in Table 3.

MAP

MAP is an autosomal recessive polyposis syndrome. Approximately 0.3%-1% of all CRCs is associated with MAP^[89,90]. Cases with MAP typically present multiple colon adenomas, thus at the first glance, these cases may be diagnosed as FAP. However, because they also can have *MMR* gene mutations, it can reverberate to phenotype as LS^[91]. Although existing of multiple colon adenomas, there is not any alteration in *APC* gene of these cases, but further analyses identified mutations in

Table 4 *MUTYH* mutations that vary with ethnicity

<i>MUTYH</i> mutation	Ethnicity	Ref.
c.231 C > T	Japan	Miyaki <i>et al</i> ^[99]
c.934-2A > C	Japan	Miyaki <i>et al</i> ^[99]
c.1376C > A	Finland	Alhopuro <i>et al</i> ^[100]
c.933 + 3A > C	North-Eastern Italy, Germany	Pin <i>et al</i> ^[101]
c.536A > G	Caucasians	Yamaguchi <i>et al</i> ^[92]
c.1187 G > A	Caucasians	Yamaguchi <i>et al</i> ^[92]

MUTYH gene which is a component of a base excision repair system and involves in protecting DNA from oxidative damage^[92]. Farrington *et al*^[93] reported that mutations of both *MUTYH* gene alleles increase the risk of endometrial tumors. These cases are rare and well known *MUTYH* mutations are linked to this disease are c.494A > G and c.1145G > A^[94-96]. However, *MUTYH* mutations can vary with ethnicity^[97]. c.536A > G and c.1187G > A in Caucasians, c.231 C > T and c.934-2A > C in Japan, c.1227_1228dup in Portugal, c.1376C > A in Finland were determined as the most frequent *MUTYH* mutations^[98-100]. In the North-Eastern Italy, c.933+3A > C (IVS10 + 3A > C), accounts for nearly 1/5 of all *MUTYH* mutations^[101]. In addition, because this mutation is also common in Germany, it is supposed to have a common origin in Western Europe^[101]. *MUTYH* mutations that vary with ethnicity are summarized in Table 4.

Germline *MUTYH* mutations may also lead to the mutation of cancer-related genes, such as the *APC* and/or the *KRAS* genes, via G to T transversion^[92]. In the study of Venesio *et al*^[102], mutated *MUTYH*-associated-polyposis adenomas exhibited only c.34G > T transversion in codon 12, or mutations in codon 13. They affirm that neither of these mutations was found in classical/attenuated familial polyposis adenomas.

JPS

JPS is a rare autosomal dominant disorder. JPS is diagnosed with numerous colon and rectum polyps or polyps with family history or juvenile polyps inside and outside of the intestine^[103]. 20%-50% of JPS demonstrates familial pattern and the average disease onset of cases are 16 to 18^[103]. JPS may coexist with Osler-Weber-Rendu syndrome [hereditary hemorrhagic telangiectasia (HHT)]. The most frequently encountered symptoms of HHT are Skin telangiectasia, epistaxis, intracranial haemorrhage, development of pulmonary arteriovenous fistulas, brain cavernous angioma and haemangioma^[104]. Almost 60% of JPS cases demonstrate mutations in *SMADH4* and *BMPRI1A* genes that are connected with TGF- β /BMP signal pathway^[105].

To date, a number of mutations leading JPS and/or HHT have been described in *SMAD4* gene. These mutations include point mutations that are resulting with a stop codon or a change in the coded amino acid into another one, codons 361, 533 and 534 mutations, small deletions and insertions^[103]. Specifically, Howe *et al*^[106] determined the mutation, c.1244-1247delAGAC, in the hot spot of the *SMAD4* gene which leads to a

Table 5 Pathogenic germline mutations of juvenile polyposis syndrome

Mutation	Effect	Ref.
<i>SMAD4</i> c.1244-1247delAGAC	Hotspot mutation serious course of JPS with numerous cases of polyps, tumors located in the stomach and intestines	Howe <i>et al</i> ^[106]

JPS: Juvenile polyposis syndrome.

serious course of JPS with numerous cases of polyps and tumors located in the stomach and intestines. In addition, a considerable proportion of mutations in the *BMPRI1A* gene are nucleotide changes generating a stop codon (nonsense) or leading to amino acid changes (missense). These mutations are distributed evenly in the entire gene sequence, intronic mutations (intron 1, 3, 4 and 5) and deletions between codon 224 and 359^[103]. Yamaguchi *et al*^[107] identified a *BMPRI1A* mutation, which involves a duplication of coding exon 3 (c.230p452_333p441dup1995) that causes a frameshift mutation, producing a truncated protein (p.D112NfsX2) in a patient with JPS (Table 5).

In addition to mutations in *SMAD4* and *BMPRI1A* genes, Juvenile polyps also was observed in Cowden, Bannayan-Zonana, and Gorlin syndromes. Cowden and Bannayan-Zonana syndromes is occurred by *PTEN* mutations and Gorlin syndrome develops *via* germline *PTCH* mutations. *PTEN* and *PTCH* mutations have been excluded as the causative mutations in almost all JPS patients^[108-110].

To the best of our knowledge, there is a lack of knowledge about epigenetic regulation of JPS so far. However, recently, Ling *et al*^[111] defined *SMAD4* as a miR-224 target as a metastasis factor, yet the relation of miR-224 and *SMAD4* expression in formation of juvenile polyps has not been clarified.

PJS

PJS is a rare (approximately 1 in 200000 observation rate) autosomal dominant disease^[112,113]. PJS is characterized by occurrence of benign hamartomatous, Peutz-Jeghers-type polyps in the gastrointestinal tract in association with mucocutaneous pigmentation on the lips and oral mucosa^[114]. PJS is diagnosed with presence of a hamartoma associated with two of the following three signs: Family history of PJS, mucocutaneous lentiginosis or polyposis of the small-bowel^[115]. PJS patients face with abdominal symptoms during the first 10 years of life, almost 50% of patients experience the symptoms before the age of 20 years and they have an increased risk of developing gastrointestinal and extradigestive cancers^[115-117]. Cancer development localized in small intestine, stomach, pancreas and colon in most of the cases^[116]. In 93% of the affected individuals, there is a

risk of developing complicating cancers between aged 15-64 years^[116].

Percent of eighty to 90% of patients with PJS have family history^[118] and according to genetic analysis, 40%-60% of these cases have germline STK11 (also known as LKB1) mutations as the major cause of this disease^[112]. Because the downstream signalling pathway of STK11 has not been fully clarified, the knowledge about the mechanism of hamartomatous polyp formation and mucocutaneous pigmentation also insufficient at present. Studies demonstrated that induced *COX-2* gene expression has also been involved in the promotion of tumor formation from PJS polyps^[119,120]. On the other hand, PJS cases with wild-type STK11 demonstrates multiple causative loci such as chromosome1p, a pericentric inversion in chromosome 6, a second PJS locus at 19q13.4 and a heterozygous germline mutation in the MYH11 gene^[121-125]. Lately, Wang *et al*^[121] performed sequence analysing in three Chinese individuals with PJS and identified 2 variants, OR4C45 c.767-768insAG and ZAN c.5767insG, which occur in PJS cases independently of STK11.

More than 145 different STK11 germline mutations have been reported in the literature result in a truncated premature protein or in transcriptional splicing errors^[121,126-129] (Table 6). On the other hand, transcriptional silencing of this tumor suppressor gene by promoter hypermethylation has been shown as an alternative inactivation mechanism^[130-133]. In addition to germline mutations, and promoter methylation, Wang *et al*^[121] discovered four mutations in pre-microRNAs, MI0003131, MI0003530, MI0014206, and MI0005525, of which the corresponding mature miRNA, hsa-mir-492, hsa-mir-487b, hsa-mir-323b, hsa-mir-300 respectively.

SPORADIC FORMS OF EOCRC

The most well-defined hereditary form of CRC, LS, account for 2%-4% of total CRC and one-third of EOCRC cases^[134,135]. FAP cases are observed in less than 1% frequency in total CRC cases. Thus, 70% of all CRC and the majority of EOCRC cases are introduced in sporadic form^[136-138]. Sporadic EOCRCs are classified into two major groups. Chromosome unstable CRC (CIN) is characterized by gross chromosomal abnormalities and MSI^[135]. Although MSI tumors behave less aggressively compared to CIN, CIN or MSI tumors do not always appear separately^[139-141].

Sporadic EOCRC are morphologically characterized with poor cell differentiation, colloid component and lymphocytic stromal reaction^[8,12,142]. Therefore, these cases are likely to be confused with LS patients. However, while MMR defects are observed *via* MSI pathway in LS, in sporadic cases MSI is not frequent. Studies to date imply that colorectal tumors characterized by MSI may be distinct from microsatellite stabile (MSS) tumors in many molecular aspects, such as an association with the methylator phenotype, a higher frequency of *BRAF* mutations and a lower frequency of *KRAS*, *APC*, and *TP53* mutations. Thus, MSI and MSS colon tumors

Table 6 *STK11* mutations associated with colorectal cancer caused by peutz-jeghers syndrome

originate from different molecular backgrounds^[143]. In sporadic cases, MMR deficiency occurs mainly through epigenetic inactivation of the *MLH1* gene through biallelic promoter methylation instead of MSI^[136]. Both genetic and epigenetic inactivation of MMR genes result in a mutator phenotype, mutations in cancer related genes and CRC development^[144]. Kirzin *et al*^[137] identified *CTNWB1* as one of the most over-expressed genes in MSS-young patients compared to MSS-old patients and this leads to an over-activation of beta catenin in sporadic EOCRC. In addition, Fernandez-Rozadilla *et al*^[145] determined a heterozygous deletion in the 10q22-q23 region involving *BMPRI1A* gene of EOCRC cases with MMR proficiency. According to Luo *et al*^[146] CDC42, TEX11, QKI, CAV1 and FN1 proteins are representative elements of EOCRC specific networks. Moreover, we defined *REG1A*, *CK20* and *MAP3K8* gene expressions strongly upregulated (more than twofold) in early-onset MSS CRC compared with MSI CRC tumors^[147]. *CK20* expression is observed in the majority of colorectal tumors^[148,149], however, a limited number of studies have evaluated the relationship between *CK20* expression levels and MSI status^[147]. In one study, it was suggested that reduced or absent *CK20* expression in CRC is associated with both sporadic and hereditary MSI^[150]. In another study associated with EOCRC, *CK20* expression levels were also identified as relatively reduced in MSI tumors^[10]. It was determined that *CK20* expression levels are inversely correlated with numbers of aberrant microsatellite locus^[150]. We determined the upregulation of *CK20* expression levels in MSS tumors compared with MSI-low (MSI-L) and MSI-high (MSI-H) tumors^[150]. According to McGregor *et al*^[150] regulation of *CK20* gene expression involves molecular pathways that are altered by MSI-H. We defined 3.98-fold high *CK20* gene expression levels in MSS tumors with lymph nodes metastases than in MSI tumors with lymph nodes metastases^[147]. In addition, 17.5-fold upregulation was identified in *CK20* expression levels in low-grade MSS tumors of patients with recurrence and distant metastases^[147]. These results indicate that upregulation of *CK20* expression, specifically, is related to poor prognosis in patients with MSS tumors. Therefore, the results of our study indicate that *CK20* expression in MSS tumors allows for the determination

of the biological characteristics of EOCRC tissues^[147]. The encoded protein by *MAP3K8* gene is a member of the serine/threonine protein kinase family. In one of our study, *MAP3K8* expression in CRC was determined significantly elevated compared with normal mucosa^[149]. In addition, we determined *MAP3K8* expression levels more than two fold upregulated in early-onset MSS CRC compared with MSI CRC tumors^[147]. *MAP3K8* expression levels were significantly higher in the MSS tumors of patients with a short median survival. Thus, our observations revealed that upregulated *MAP3K8* expression was associated with a poor prognosis in patients with MSS tumors^[147]. Human *REG1A* belongs to the superfamily of calcium-dependent lectins. In several previous studies, *REG1A* was found to be upregulated in CRC^[151-153]. We also found that *REG1A* is upregulated in the tumors of early-onset sporadic CRC patients. Furthermore, 25.8-fold high *REG1A* gene expression levels were observed in MSS tumors with lymph nodes metastases. In addition, median survival and disease-free survival were significantly longer only for patients with MSI tumors with low *REG1A* expression compared with those with high expression of this gene. This result indicates that upregulated *REG1A* expression may be related to sporadic EOCRC tumor formation and characterization^[147]. Additionally, a recent study from Sengupta *et al*^[154] defined a relation with MSS CRC tumors and deletion in *RBFOX1* gene which encodes a highly conserved RNA-binding protein that regulates tissue-specific alternative splicing indicating important basic functions in development and differentiation in a British Bangladeshi MSS CRC population. This study showed that loss of *RBFOX1* activity may lead to aberrations in the splicing of genes associated with CRC^[154].

Different from MSS tumors, some sporadic EOCRC tumors belong to the MSI pathway^[28]. Sporadic EOCRC with MSI is likely to arise from sessile serrated polyps through the serrated neoplastic pathway^[155]. The *BRAF* gene, which plays an important role in the mitogen-activated protein kinase signalling pathway, is frequently mutated in these cases. *BRAF* V600E mutation is widely accepted as a prognostic factor of sporadic CRC with MSI and methylated *MLH1*^[156]. Although the frequency of *BRAF* V600E mutation is high in MSI tumors, this mut-

Figure 1 Genetic algorithm of early-onset colorectal cancer. MMR: Mismatch repair; EOCRC: Early-onset colorectal cancer; MSI: Microsatellite instability; APC: Adenomatous polyposis coli; FAP: Familial adenomatous polyposis; MAP: MUTYH-associated polyposis; LS: Lynch syndrome; JPS: Juvenile polyposis syndrome; PJS: Peutz-jeghers syndrome.

ation is not observed in LS cases, thus, this discrepancy between sporadic MSI cancer and LS might be used in a strategy for the detection of LS^[156].

The different attitude of sporadic and hereditary forms of EOCRC may also be caused by epigenetic modifications, such as miRNA expressions and their methylation patterns^[47,157]. Balaguer *et al.*^[47] demonstrated that miR-622, miR-362-5p and miR-486-5p could accurately classify the LS and sporadic MSI cases. The similarity of miRNA expression status of LS and sporadic MSI cases may be explained with occurrence of frameshift mutations in *TARBP2*, a miRNA processing gene, in both of these diseases^[158]. Moreover, in one of our study, using miRNA polymerase chain reaction arrays, the expression profiles of 38 different miRNAs associated with CRC were evaluated in 40 sporadic Turkish EOCRC patients^[157]. The expression of miR-106a was found to be upregulated, and miR-143 and miR-125b levels were found to be downregulated in sporadic EOCRC tissues compared with the normal tissues. In addition, 2.42-fold high expression level of miR-106a and 2.42-fold low expression level of miR-125b were observed in tumors with lymph node metastases compared with the normal colorectal mucosa samples^[157]. On the other hand, epigenetic regulations of sporadic EOCRC tumors also differ between each other depend on MSI status. Earle *et al.*^[48] described the different expression profile of miR-223, miR-155, and miR-92 between MSI and MSS CRCs. So far, Kaur *et al.*^[49] have investigated the association of miR-132 methylation and sporadic MSI CRC tumors located in

the proximal colon in a comparative study of Finnish and Australian population. In addition, different from MSS tumors, hypermethylation of miR-345 had a significant association with sporadic MSI in Finnish CRCs^[49].

CLINICAL OUTCOME OF GENETIC AND EPIGENETIC FEATURES OF EOCRC

A major challenge in CRC therapy is drug resistance. The current knowledge of CRC genetics has increased the sufficiency of applied conventional cytotoxic chemotherapy and targeted therapy. Genetic screening of EOCRC patients for hereditary cancer syndrome is determinative not only for the rate of cancer risk of relatives but also for appropriate treatment. A pyrimidine analogue, 5-fluorouracil (5-FU) which is widely used in CRC therapy, involves in induction of DNA replication stress response in cells through inhibiting thymidylate synthase. However, studies showed that *APC* mutations reduces the sensitivity to 5-FU^[159]. On the other hand, performance of MSI test is advisable for patients with strongly suspected on the basis of a known family history of colorectal and extracolonic cancers in the case of LS (Figure 1). Studies revealed that while adjuvant chemotherapy with a fluoropyrimidine does not have a beneficial effect on MSI cases and may even worsen the clinical picture, combination of oxaliplatin and infusional 5-FU/leucovorin regarded as more beneficial for these cases^[160,161]. According to Violette *et al.*^[162] increased expression of Reg genes caused *in vitro* resistance to

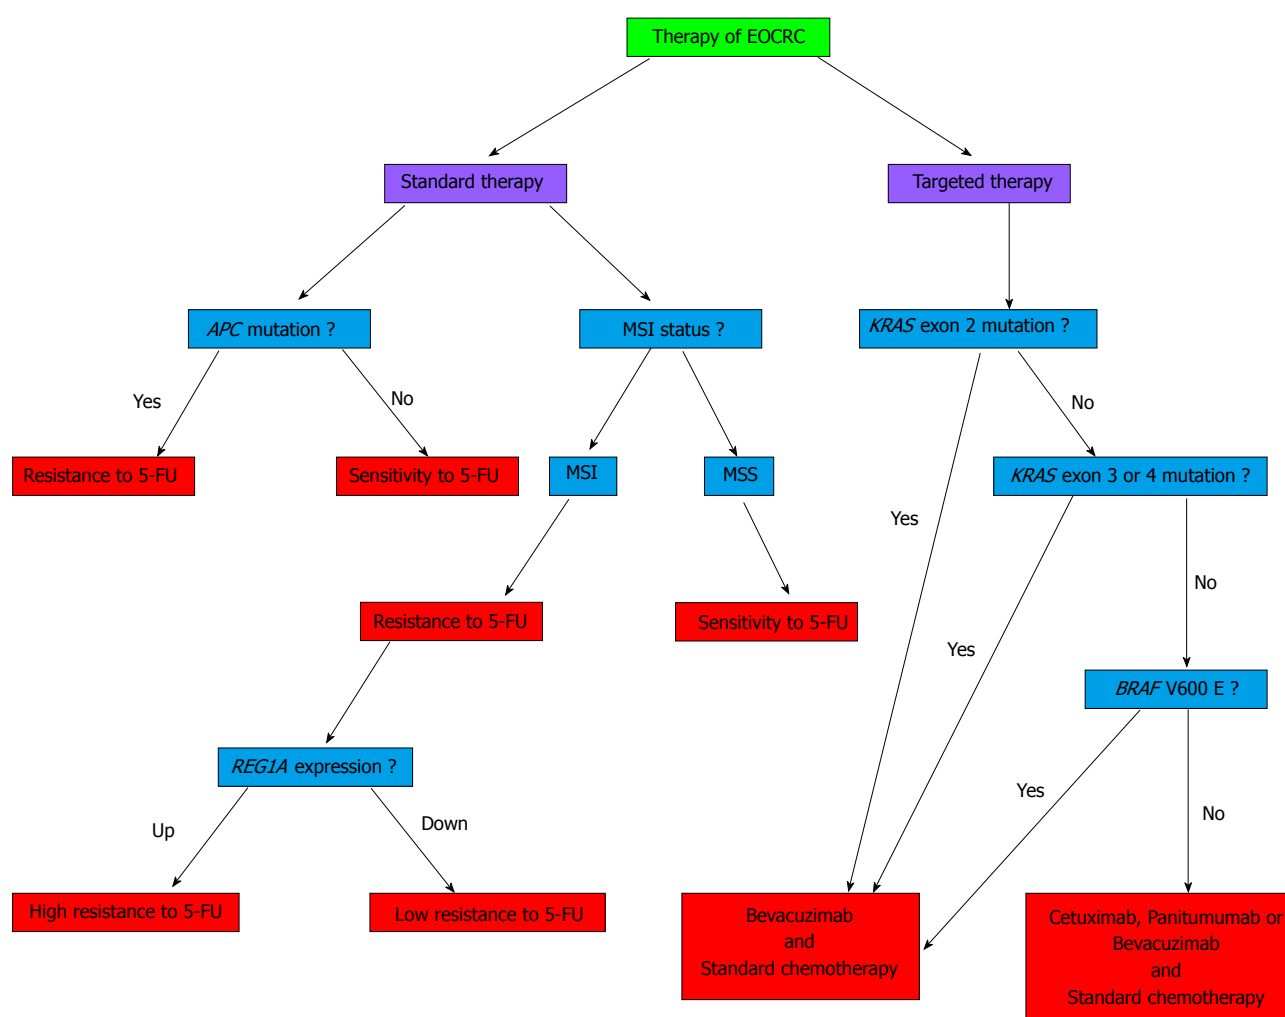

Figure 2 Therapy of early-onset colorectal cancer. EOCRC: Early-onset colorectal cancer; MSI: Microsatellite instability; MSS: Microsatellite stabile; 5-FU: 5-fluorouracil.

the 5-FU. Bishnupuri *et al*^[163] observed a mitogenic effect of the Reg IV protein, with subsequent changes in the expression of genes associated with apoptosis and metastasis. The Reg proteins are previously unappreciated regulators of antiapoptotic proteins in early tumorigenesis and may contribute to increased resistance to apoptotic death during therapy^[163]. As another mechanism of resistance to therapy, the result of our study of the poor prognosis of MSI tumors supports the hypothesis that high *REG1A* expression may contribute to increased resistance to apoptotic death during therapy in MSI tumors^[147]. Because of the important role of *REG1A* in tumorigenesis and development of metastasis in MSI tumors, the use of *REG1A*-specific inhibitors in CRC patients have MSI that may represent a novel significant approach to the treatment of cancer. In addition, according to recent studies, alterations in epigenetic regulation of these genes may also lead to resistance to chemotherapeutic agents. For example, Deng *et al*^[164] found out that reduced expression of miR-21 plays role in resistance to 5-FU therapy *via* targeting *MSH2*. However, miRNA studies have been performing in *in vitro* conditions and to prove the decisive importance of these markers further

advanced studies required.

Nowadays, the application of targeted therapy for CRC has been increasing. The goals of these therapies are interrupting the survival and proliferation of cancer cells^[165]. To date, United States Food and Drug Administration has approved several targeted drugs, such as cetuximab and panitumumab, the anti-EGFR antibodies that suppress the tumor angiogenesis and bevacizumab, an anti-VEGF antibody. Recently, different from bevacizumab, aflibercept and regorafenib have been used as new antiangiogenic agents^[166-168]. Although EGFR is overexpressed in most of the CRC cases, because of the down-stream modifications of EGFR signalling pathway, patients demonstrated different response to this therapy^[169]. Particularly, *KRAS* activating mutations in exon 2 avoid the sufficient therapy with EGFR inhibitors^[170,171]. A small number of patients with wild type *KRAS* exon 2 were demonstrated to have mutations exons 3 and 4 that are also caused *KRAS* activation^[172]. Activating mutations in the other genes that play role in downstream pathway of EGFR signalling, *NRAS*, *BRAF*, *PIK3CA* and *PTEN* are able to lead to resistance to anti-EGFR therapies^[173]. Thus, to predict the success of anti-EGFR monoclonal antibody

therapy, examination of downstream mutations of EGFR signalling pathway should be required before receiving an EGFR inhibitor^[170] (Figure 2). Second targeted signal pathway for CRC therapy is angiogenesis pathway. Bevacizumab is a monoclonal antibody that binds to VEGF-A preventing its interaction with VEGFR-2^[174]. Regorafenib demonstrated a multikinase inhibitor activity against VEGFR-2, VEGFR-3, TIE-2, PDGFR, FGFR, RET, c-Kit and RAF/MEK/ERK pathway^[175]. Aflibercept is a recombinant fusion protein and play a role in the inhibition of interactions between VEGF-A, VEGFB proteins and their specific receptors by acting as a trap receptor binding to VEGF-A and VEGFB^[176]. Thus, the blockage of the genes that encoded these proteins enhances the success of the therapy.

CONCLUSION

Genetic predispositions have been identified in EOCRC clearly distinct from the other types of CRC. The current knowledge about the molecular and genetic basis of EOCRC provides information regarding prognosis of this disease and response to therapies. A proportion of EOCRCs are hereditary forms. Hence, cases should be evaluated for existing of a germline mutation in one of the several MMR genes for suspicion of LS, in the APC gene for suspicion of FAP, or in one of the genes associated with a more uncommon syndrome. Identification of a hereditary syndrome in individuals also provides predictive mutational testing for non-symptomatic relatives. They are found to be positive for the mutation can take precaution for reduction of the risk of cancer-associated morbidity and mortality in this way. In addition, a better understanding of the genetic mechanism of EOCRC is highly likely to lead to develop more beneficial targeted therapies. To date, specifically, studies on MSI CRC, such as LS, herald new diagnostic and therapeutic strategies into clinical approach. It is notable that further research remains to be conducted to more finely characterize the underlying mechanism of sporadic EOCRC, which could allow improved prevention, diagnosis, and treatment of these cases.

Abstract

Over the past couple of decades considerable prog-

ress has been made in the management of metastatic colorectal cancers (mCRC) leading to a significant improvement in five-year survival. Although part of this success has been rightly attributed to aggressive surgical management and advances in other adjunct treatments, our understanding of the pathogenesis of cancer and emergence of newer molecular targets for colon cancer has created a powerful impact. In this review article we will discuss various targeted therapies in the management of mCRC. Newer agents on the horizon soon to be incorporated in clinical practice will be briefly reviewed as well.

Key words: Metastatic colorectal cancer; Molecular targeted drugs; Anti-angiogenesis inhibitors; Epidermal growth factor receptor inhibitors; Novel therapeutic agents

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This article reviews the novel agents in the management of metastatic colorectal cancer. The core principles and the evidence behind the use of these agents are discussed. Clinically relevant features are highlighted to help the health care provider involved in the care of metastatic colorectal cancer patients.

Pai SG, Fuloria J. Novel therapeutic agents in the treatment of metastatic colorectal cancer. *World J Gastrointest Oncol* 2016; 8(1): 99-104 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/99.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.99>

INTRODUCTION

In 2015, a total of 132700 new cases of colorectal cancer are expected to be diagnosed in the United States accounting for about 8% of all new cancer diagnoses. In this same year 49700 patients will die of metastatic colorectal cancers (mCRC), which will contribute to 8.4%

of all cancer related mortality^[1]. With the widespread use of screening colonoscopy and newer modalities like Stool DNA based screening, we can expect early diagnosis and curative treatments in patients diagnosed with early disease and hence better survival. However up to > 25% of patients will present with metastatic disease, where systemic treatment options will be desired. Widespread use of genetic screening and sharing platforms like the cancer Genome Atlas has led to a better understanding of carcinogenesis and as a consequence newer molecular targets for colon cancer have been discovered^[2]. In this review article we will discuss some of the well-known targetable pathways as well as shed light on some of the novel pathways where we can expect newer therapies to emerge.

ANTI-ANGIOGENESIS AGENTS

Anti-angiogenesis was proposed as an anticancer therapy over four decades ago^[3]. We know that angiogenesis is required for invasive tumor growth and metastasis and is an integral part of cancer progression^[4]. Angiogenesis is mediated through vascular endothelial growth factor (VEGF), the altered regulation of which is associated with several diseases including malignancy. VEGF is a heparin-binding growth factor specific for vascular endothelial cells that is able to induce angiogenesis *in vivo*^[5]. Three notable anti-VEGF agents have been approved by United States Food and Drug Administration (USFDA) for treating mCRC and will be reviewed here.

Bevacizumab

Bevacizumab is a recombinant humanized IgG-1 antibody against soluble VEGF-A which has a high binding specificity with VEGF-A. Once bound, Bevacizumab prevents its interaction with receptors on vascular endothelial cells and thereby truncates the abnormal downstream signaling. After success in early phase trials, this agent was tested in phase 3 clinical trials^[6]. In the pivotal trial which had 813 previously untreated patients with mCRC randomized to the two arms, the median duration of survival was 20.3 mo in the Irinotecan, 5-Fluorouracil and Leucovorin (IFL) plus Bevacizumab group, as compared with 15.6 mo in the IFL plus placebo group, corresponding to a hazard ratio for death of 0.66 ($P < 0.001$)^[7]. An Eastern Cooperative Oncology Group Study (E3200) showed median duration of survival for the group treated with FOLFOX4 and Bevacizumab was 12.9 mo compared with 10.8 mo for the group treated with FOLFOX4 alone (corresponding hazard ratio for death 0.75, $P < 0.001$), and 10.2 mo for those treated with Bevacizumab alone. Bevacizumab is approved by the USFDA in combination with either an Irinotecan or Oxaliplatin based regimen for the treatment of mCRC^[8,9].

Bevacizumab is generally well tolerated when administered in combination with chemotherapy for mCRC. Hypertension, proteinuria, epistaxis and thrombosis are

some of the common adverse events associated with its use^[6]. No clear guidelines exist on the management of hypertension but in most patients it is usually possible to control hypertension with standard antihypertensive medications. On occasion, it may be necessary to temporarily or permanently discontinue Bevacizumab if hypertension is severe or persistent^[10].

Routine use of Bevacizumab as maintenance therapy is controversial. A recent study found no clear benefits of continuing Bevacizumab after 4-6 mo of standard first-line chemotherapy plus Bevacizumab and given the cost and lack of clear benefit, it was not recommended^[11]. Whether a certain subgroup with high-risk disease such as high metastatic burden would benefit from this approach needs further investigation^[12].

Ziv-Aflibercept

Ziv-Aflibercept is a fusion protein consisting of human VEGF receptor extracellular domains fused to the Fc portion of human immunoglobulin G1, and works by inhibiting VEGF receptor. Aflibercept was used in a large phase 3 trial in combination with 5-Fluorouracil, Irinotecan and Leucovorin (FOLFIRI) and was found to confer a statistically significant survival benefit over FOLFIRI combined with placebo in patients with mCRC previously treated with an Oxaliplatin based regimen^[13]. Adding Aflibercept to FOLFIRI showed an improved overall survival relative to placebo plus FOLFIRI (HR = 0.817, 95%CI: 0.713-0.937, $P = 0.0032$) with median survival times of 13.50 mo vs 12.06 mo, respectively. Efficacy was maintained across demographic and baseline characteristics and stratification factors at randomization, irrespective of prior treatment with Bevacizumab, with a similar safety profile^[14].

Ramucirumab

Ramucirumab is a recombinant human monoclonal anti vascular endothelial growth factor-receptor 2 antibody which was recently approved by USFDA for use in combination with FOLFIRI for the treatment of patients with mCRC whose disease has progressed on first line Bevacizumab, Oxaliplatin- and Fluoropyrimidine-containing regimen. Approval was based on a study that enrolled 1072 patients (536 in each group) and patients were randomized either to receive Ramucirumab or placebo^[15]. PFS was significantly improved in patients who received Ramucirumab in combination with FOLFIRI compared to placebo [Median PFS was 5.7 and 4.5 mo; HR = 0.79 (95%CI: 0.70-0.90, $P < 0.001$]. Median overall survival was 13.3 mo (95%CI: 12.4-14.5) for patients in the Ramucirumab group vs 11.7 mo (10.8-12.7) for the placebo group (HR = 0.844, 95%CI: 0.730-0.976, log-rank $P = 0.0219$). Diarrhea, hypertension and fatigue were the common adverse events with the use of Ramucirumab, consistent with the previously known safety profile established in previously approved indications.

EPIDERMAL GROWTH FACTOR RECEPTOR AND OTHER KINASES

The epidermal growth factor receptor (EGFR) autocrine pathway has been known to affect a number of processes important to carcinogenesis including cell proliferation, apoptosis and angiogenesis. This has been the rationale for developing EGFR inhibitors, both monoclonal antibodies to prevent ligand binding as well as small molecule inhibitors of the tyrosine kinase enzymatic activity to inhibit auto-phosphorylation and downstream intracellular signaling^[16]. Although monoclonal antibodies like cetuximab were initially developed to treat head and neck cancer, traditionally known to highly express EGFR on immunohistochemistry, their use was extended to treating colorectal cancer.

Cetuximab: Cetuximab is a chimeric (mouse/human) monoclonal antibody used in the management of mCRC, which was initially approved by USFDA as a third line single agent in patients who have failed Oxaliplatin- or Irinotecan- based chemotherapy and who are intolerant to Irinotecan. In the pivotal trial which compared FOLFIRI plus Cetuximab vs FOLFIRI plus Bevacizumab as first-line treatment for patients with mCRC, 592 patients with KRAS exon 2 wild-type tumors were randomly assigned and received treatment. Median progression-free survival was 10.0 mo (95%CI: 8.8-10.8) in the Cetuximab group and 10.3 mo (95%CI: 9.8-11.3) in the Bevacizumab group (HR = 1.06, 95%CI: 0.88-1.26, $P = 0.55$); however, median overall survival was 28.7 mo (95%CI: 24.0-36.6) in the Cetuximab group compared with 25.0 mo (22.7-27.6) in the Bevacizumab group (HR = 0.77, 95%CI: 0.62-0.96, $P = 0.017$). Anti-EGFR monoclonal antibodies are well tolerated, the most important adverse event being cutaneous reaction including rash, pruritus, and nail changes. These adverse reactions can usually be medically managed and patients tend to continue on the drugs. Occasionally the drug may need to be discontinued due to intolerable side effects.

Panitumumab

Panitumumab is a fully humanized monoclonal antibody specific to EGFR. The efficacy of Panitumumab was established in the PRIME study which showed that in the wild-type KRAS stratum, Panitumumab-FOLFOX4 significantly improved PFS compared with FOLFOX4 (median PFS, 9.6 mo vs 8.0 mo, respectively; HR = 0.80; 95%CI: 0.66-0.97, $P = 0.02$). Also noted was a nonsignificant increase in OS for Panitumumab-FOLFOX4 vs FOLFOX4 (median OS, 23.9 mo vs 19.7 mo, respectively; HR = 0.83, 95%CI: 0.67-1.02, $P = 0.072$)^[17]. In an open-label, phase 3 head-to-head study of Panitumumab vs Cetuximab which enrolled patients with chemotherapy-refractory mCRC Panitumumab was non-inferior to Cetuximab. Median overall survival was 10.4 mo (95%CI: 9.4-11.6) with Panitumumab and 10.0 mo (9.3-11.0) with Cetuximab (HR = 0.97,

95%CI: 0.84-1.11)^[18]. Panitumumab has been shown to induce pathological near complete response or complete response when given along with neoadjuvant concurrent radiation therapy in patients with KRAS wild-type locally advanced rectal cancer^[19]. Panitumumab is generally well tolerated and has a similar side effect profile as Cetuximab.

Ras testing and use of egfr antibodies

EGFR expression as measured by immunohistochemistry on many occasions does not predict clinical benefit with the use of EGFR inhibitors^[20,21]. It has also been shown that mutations in the KRAS exon 2 (codons 12 and 13), which was down stream to EGFR, dictated the response to EGFR antibodies. Additional mutations like KRAS exon 3 (at codons 59 and 61) and exon 4 (at codons 117 and 146), NRAS exon 2 (at codons 12 and 13), exon 3 (at codons 59 and 61), and exon 4 (at codons 117 and 146), have been demonstrated to be negative predictive biomarkers for EGFR antibody treatment. These additional mutations now account for approximately 17% of patients with wild-type KRAS exon 2 status who harbor a mutation in other RAS exons^[22]. Testing for extended EGFR mutation is highly recommended and if truly wild type then use of EGFR antibodies is justified in those cases.

TYROSINE KINASE INHIBITORS

Regorafenib (BAY 73-4506) is a novel oral diphenylurea based multikinase inhibitor, shown to be a potent inhibitor of a wide variety of Tyrosine kinases which include several angiogenic, stromal receptor and oncogenic tyrosine kinases as well as intracellular signaling kinases in preclinical studies^[23]. A phase III trial in refractory mCRC, (CORRECT) randomized 760 patients between Regorafenib ($n = 505$) and placebo ($n = 255$). It showed a small but statistically significant improvement in OS (median 6.4 mo vs 5 mo, one-sided P value 0.005) and progression-free survival (median 1.9 mo vs 1.7 mo, one-sided P value < 0.000001) for Regorafenib^[24]. The most common side effects of Regorafenib are fatigue, hand-foot skin reaction (palmar-plantar erythrodysesthesia), diarrhea, mucositis and weight loss for which the patients need to be monitored closely^[25]. A novel germline mutation of PDGFR-beta might be associated with clinical response of colorectal cancer to Regorafenib^[26].

EMERGING AGENTS

Targeting cancer stem cells

Human cancers have been shown to harbor cancer stem cells which are thought to play an important role in cancer recurrence and metastasis. With the recent discoveries of small molecules that target highly conserved cell homeostasis pathways which have been implicated in the pathogenesis of colorectal cancer, gives us an

Table 1 Ongoing clinical trials in Immunotherapy in colorectal cancer

Drug name	Class	Phase	ClinicalTrials.gov Identifier	Sponsor	Remarks
AMP-224	PD-1 inhibitor	1	NCT02298946	NCI	Combination with stereotactic body radiation therapy
MPDL3280A	Engineered anti-PDL1 antibody	1	NCT01375842	Genentech	Administered as single agent
Varlilumab and nivolumab	Monoclonal antibodies that binds to CD27 and PD-1	1/2	NCT02335918	Celldex therapeutics/bristol-myers squibb	Phase II to determine objective response rate
MPDL3280A and bevacizumab	Engineered anti-PDL1 antibody	1b	NCT01633970	Genentech	Assess the safety, pharmacology and preliminary efficacy of the combination
Avelumab	Antibody targeting PDL-1	1	NCT01772004	EMD serono	Open-label, dose-escalation trial
MEDI4736	Anti PDL-1	2	NCT02227667	Memorial sloan Kettering cancer center	Study to evaluate the efficacy of MEDI4736

Available from: URL: <http://www.clinicaltrials.gov>, accessed on 4/25/2015.

exciting avenue in treating mCRC. BBI608, an orally-administered first-in-class cancer stem cell inhibitor, has been tried in a Phase 1 study after excellent preclinical evidence. This has shown some promising anticancer activity in patients with CRC^[27]. An open label, multicenter, Phase 2 study of BBI608 in combination with cetuximab, Panitumumab or Capecitabine in patients with advanced colorectal cancer is ongoing (ClinicalTrials.gov Identifier: NCT01776307). Another phase 1 dose escalation study with LGK974 is currently ongoing and recruiting patients with special emphasis on those with B-RAF mutant colorectal cancer with documented Wnt pathway alteration (ClinicalTrials.gov Identifier: NCT01351103).

BRAF

BRAF mutations have been shown to be the cause of sporadic CRCs through altered mismatch repair pathway and occur mutually exclusive of KRAS mutations^[28]. At this time BRAF mutation is known to confer a poor prognosis in mCRC, but is not a validated target for anti-cancer therapy^[29,30]. Although this mutation is found in a relatively small proportion of CRC (5%-8%), targeting BRAF has been unsuccessful as feedback stimulation of EGFR pathway has been suggested as the reason for the treatment failure^[31]. Current studies are focused on dual blockade of BRAF and EGFR or of the subsequent downstream pathway. Initial experience of combining BRAF inhibitor Vemurafenib with EGFR inhibitor Panitumumab has been safe, although the response has been modest^[32]. Another Phase II Study of Irinotecan and Cetuximab with or without Vemurafenib in BRAF mCRC is still recruiting patients (ClinicalTrials.gov Identifier: NCT02164916). Another potential strategy is the use of ERK inhibitor that is thought to suppress MAPK activity, which is usually upregulated in patients on RAF inhibitors and may overcome resistance. ERK inhibitors are currently in early phase clinical trials^[33].

Immunotherapy

The advent of immune check point blockade has been an exciting field in cancer immunotherapy. Already of considerable success in other types of cancers like melanoma and squamous cell lung cancer where Anti

PD-1 drugs are approved by USFDA, various groups are studying the efficacy in colorectal cancer. Mismatch-repair status has been useful in predicting clinical benefit of immune checkpoint blockade with Pembrolizumab, with higher response in Microsatellite Instability High (MSI-High) tumors^[34]. The table summarizes the current ongoing trials mainly targeting PD-1 - PDL-1 immune checkpoint pathway (Table 1).

Targeting kras with reolysin

Biological strategies like Reovirus Serotype 3 - Dearing Strain (Reolysin), a naturally occurring ubiquitous, non-enveloped human Reovirus, have been explored in mCRC for targeting KRAS. Reovirus has been shown to replicate selectively in RAS-transformed cells causing cell lysis. Activating mutations in RAS or mutations in oncogenes signaling through the RAS pathway may occur in as many as 80% of human tumors and can be targeted by this approach. A multicenter phase 1 study Reolysin in combination with FOLFIRI and Bevacizumab in FOLFIRI naive patients with KRAS mCRC is ongoing (ClinicalTrials.gov Identifier: NCT01274624).

TAS-102

TAS-102 is a novel oral nucleoside and works as an antimetabolite. TAS-102 is a combination of trifluridine, a nucleoside analog, and tipiracil hydrochloride, a thymidine phosphorylase inhibitor. In a double-blind, randomized, placebo-controlled phase 2 trial, 112 patients were allocated to TAS-102 and 57 allocated to placebo. Median overall survival was 9.0 mo (95%CI: 7.3-11.3) in the TAS-102 group and 6.6 mo (4.9-8.0) in the placebo group (hazard ratio for death 0.56, 80%CI: 0.44-0.71, 95%CI: 0.39-0.81, $P = 0.0011$) on a median follow up of 11.3 mo (interquartile range 10.7-14.0 mo). Hematological toxicities were the important side effects to consider in patients on TAS- 108 arm, 57 (50%) neutropenia of grade 3 or 4, 32 (28%) leucopenia and 19 (17%) experiencing anemia. Serious adverse events were reported in 21 (19%) patients in the TAS-102 group. Recent data from RECURSE study has shown that median overall survival improved from 5.3 mo with placebo to 7.1 mo with TAS-102. Hazard ratio for death

in the TAS-102 group vs the placebo group was 0.68 (95%CI: 0.58-0.81, $P < 0.001$), and this data led to its FDA approval^[35].

CONCLUSION

In conclusion, mCRC treatment is a rapidly evolving field with many novel agents under investigation. Although many targeted drugs have been approved and are already in clinical use, there is a clear need for further research and development of more effective treatments. Over the coming years, as understanding of the biology of the disease improves, newer treatment modalities will be investigated. The optimum use and sequencing of these agents, especially in combination with chemotherapy and other targeted agents will need to be better defined.

the time of initial diagnosis in cases of colorectal cancer. Emergency surgery has been classically considered the treatment of choice in these patients. However, in the majority of studies, emergency colorectal surgery is burdened with higher morbidity and mortality rates than elective surgery, and many patients require temporal colostomy which deteriorates their quality of life and becomes permanent in 10%-40% of cases. The aim of stenting by-pass to surgery is to transform emergency surgery into elective surgery in order to improve surgical results, obtain an accurate tumoral staging and detection of synchronous lesions, stabilization of comorbidities and performance of laparoscopic surgery. Immediate results were more favourable in patients who were stented concerning primary anastomosis, permanent stoma, wound infection and overall morbidity, having the higher surgical risk patients the greater benefit. However, some findings laid out the possible implication of stenting in long-term results of oncologic treatment. Perforation after stenting is related to tumoral recurrence. In studies with perforation rates above 8%, higher recurrences rates in young patients and lower disease free survival have been shown. On the other hand, after stenting the number of removed lymph nodes in the surgical specimen is larger, patients can receive adjuvant chemotherapy earlier and in a greater percentage and the number of patients who can be surgically treated with laparoscopic surgery is larger. Finally, there are no consistent studies able to demonstrate that one strategy is superior to the other in terms of oncologic benefits. At present, it would seem wise to assume a higher initial complication rate in young patients without relevant comorbidities and to accept the risk of local recurrence in old patients (> 70 years) or with high surgical risk (ASA III/IV).

Core tip: Self-expanding metal stents placement as a bridge to surgery in patients with obstructive left-colon cancer is controversial. Stent insertion is beneficial regarding perioperative morbidity, being patients with advanced age or with important comorbidity the ones who could obtain more benefit of transforming emergency surgery into elective surgery. But, on the other hand, an increase of local recurrence rate has been shown after stent placement when compared with emergency surgery, compromising oncologic outcome of these patients. Without definitive data, it seems cautious to consider emergency surgery and assume a higher initial complication rate in young patients without relevant co-morbidities avoiding the risk of local recurrence and stenting, accepting the risk of local recurrence but with a lesser perioperative complications rate, in old patients with high surgical risk.

Long-term outcomes after stenting as a “bridge to surgery” for the management of acute obstruction secondary to colorectal cancer. *World J Gastrointest Oncol* 2016; 8(1): 105-112 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/105.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.105>

INTRODUCTION

Colorectal cancer is one of the most frequently diagnosed cancer in developed countries^[1], with over 400000 new cases and more than 200000 cancer related deaths per year in Europe^[2]. Some patients present colorectal obstruction at the time of diagnosis. Although in previous studies this situation was reported in up to 30% of patients^[3], recent papers conclude that obstructive symptoms are present in 8% of cases at the time of initial diagnosis in cases of metastatic tumors^[4] and also independently of the tumoral stage^[5]. Emergency surgery has been classically considered the treatment of choice in these patients, although patients operated on emergency basis have poorer prognosis than those undergoing elective surgery^[6]. Ascanelli *et al*^[7] found a 5-year survival rate of 59% in patients electively operated in contrast with 39% in patients surgically treated on emergency basis. For some authors, this worse prognosis correlates with a lower quality surgery due to the emergency situation^[8,9]. However, other studies suggest that poorer long-term prognosis in patients undergoing emergency surgery is due to a more advanced tumoral stage^[10].

Some studies have been recently published supporting the possibility of performing colonic segmental resection with primary anastomosis in emergency surgery with a complication rate comparable to that of elective surgery. Zorcolo *et al*^[11] analysed surgical outcomes in 323 patients and found that primary

anastomosis can be performed in emergency surgery with low morbidity and mortality rates in selected patients. However, in the majority of studies, emergency colorectal surgery is burdened with higher morbidity and mortality rates than elective surgery. In a series of 989 patients, Tekkis *et al*^[12] proved, after multivariate analysis, that emergency surgery is significantly associated with a higher postoperative mortality (20% vs 12.8%) as well as ASA classification and patient age. In another recent study comparing 171 surgically treated patients with obstructive left colon cancer by means of resection and primary anastomosis after intraoperative lavage and 1053 patients operated on elective basis, emergency surgery patients were older and with a more advanced tumoral stage. Besides, both postoperative mortality (4.1% vs 0.9%: $P = 0.001$) and morbidity (11.7% vs 7.6%: $P = 0.07$) rates were higher in obstructed patients^[13].

In this clinical scenario, not all patients are candidates for surgery with primary anastomosis and so, many patients require temporal colostomy which deteriorates their quality of life and becomes permanent in 10%-40% of cases^[3,14].

BENEFITS OF SELF-EXPANDABLE METAL STENTS

Self-expandable metal stents can restore large bowel transit achieving colonic decompression. Initially used in patients with non resectable malignant tumors, stents were then indicated in patients with resectable colorectal tumors and obstructive symptoms as a bridge to surgery procedure. The aim of stenting is to transform, in left colon cancer, emergency surgery into elective surgery in order to allow, with lower morbidity, mortality and stoma requirements, accurate tumoral staging and detection of synchronous lesions with CT-colonoscopy or conventional colonoscopy^[15,16], stabilization of comorbidities and improvement of the nutritional status before surgery and performance of laparoscopic surgery^[17]. Tejero *et al*^[18] reported the outcomes of the first two patients treated with this strategy in 1994.

Although the definition of clinical success can be different in published papers, the most commonly used is to consider clinical success as the resolution of obstructive symptoms within the first 72 h after stent placement. In a systematic review including 1785 patients and 1845 stents, Watt *et al*^[19] reported a clinical success rate of 92% (46%-100%). Concerning technical success, defined as the passage of the guide wire and the stent across the stricture with further appropriate stent release and expansion, the same authors reported a 96.2% success rate. A multicenter European prospective study, including 182 stented patients under the bridge to surgery indication, reported similar results for both technical (98%) and clinical success (94%) rates^[20].

The advantages of stenting were confirmed in retrospective studies. Watt *et al*^[19] found that the

rate of primary anastomosis performance in patients treated with elective surgery was two-fold higher than in patients operated on emergency basis. Patients electively operated presented lower stoma requirements, lower complication rate and shorter hospital stay. However, results were not so consistent in randomized control trials. Pirllet *et al*^[21] randomized 60 patients with obstructive left colon cancer into two groups, emergency surgery vs stenting plus elective surgery. No differences were found concerning stoma performance (56% vs 43.3%; $P = 0.30$), mortality, morbidity or hospital stay. However, stenting technical success rate was as low as 46.7% with a perforation rate of 6.7%.

In a Dutch study, 98 patients with obstructive left colon tumors were randomized for emergency surgery or emergency stenting. No differences were found regarding 30-d mortality, overall mortality, morbidity and permanent stoma at the end of follow-up. However, patients included in the emergency surgery arm, presented a higher rate of initial stoma confection (absolute risk difference: 0.23, 95%CI: 0.04-0.40, $P = 0.016$) as well as a reduced rate of stoma related complications (between-group difference: -12.0, 95%CI: -23.7-0.2, $P = 0.046$). Stenting technical success rate was 70.2% and perforation rate 12.8%^[22].

The low rates of technical success at the time of stenting in both studies and the high perforation rate of the Dutch publication are surprising, worrisome, and, to a certain extent, question the results of both studies considering that in most published papers reported technical success rates are higher than 85% and perforation rate does not exceed 5%. There is no comment in the French paper about the expertise of participant endoscopists concerning stenting, while the Dutch study mentions that colonic stenting was done by endoscopists who had placed at least 10 colonic stents. According to the recently published clinical guideline of the European Society of Gastrointestinal Endoscopy regarding stenting for obstructive colonic and extracolonic cancer, one of the recommendations is that colonic stent placement should be performed or directly supervised by an experienced operator who has performed at least 20 colonic stent placement procedures^[23]. These data might have influenced the study results.

Nevertheless, perioperative results of SEMS insertion are actually better known. In a recent meta-analysis published by Huang *et al*^[24] including 7 randomized control trials comparing emergency surgery and stenting plus further elective surgery (382 patients), results were more favourable in patients who were stented concerning primary anastomosis (OR = 0.28; 95%CI: 0.12-0.62; $P = 0.002$), permanent stoma (OR = 2.01; 95%CI: 1.21-3.31; $P = 0.007$), wound infection (OR = 0.31; 95%CI: 0.14-0.68; $P = 0.004$) and overall morbidity (OR = 0.30; 95%CI: 0.11-0.86; $P = 0.03$). No differences were found regarding mortality, anastomosis dehiscence and intra-abdominal infection.

Uncovered SEMS has lesser tendency to migrate

than covered SEMS but showed higher tumor in growth rates. Globally, both types are equally effective and safe. Surgery might be performed 5 to 10 d after stent placement^[23].

This benefit may not be the same in all groups of patients and, in old patients these benefits can be greater. Gorissen *et al*^[25] demonstrated that in-hospital mortality of patients older than 75 was higher in patients undergoing emergency surgery than in those who received a stent as a bridge to surgery procedure (21% vs 8%; $P = 0.228$). In a study published in 2007 and based on a decision model (Markov Chain Monte Carlo), authors conclude that stenting is cheaper and more effective than emergency surgery due to a lower mortality and lower permanent stoma requirements. A low perforation rate with stenting and a high surgical risk were determinant factors to obtain these beneficial results with stenting, having the higher risk patient the greater benefit^[26].

STENTING AND LONG-TERM ONCOLOGIC OUTCOMES

Although initial studies were focused on short-term results of bridge to surgery stenting, some results laid out the possible implication of stenting in long-term results of oncologic treatment. Maruthachalam *et al*^[27] could demonstrate that peripheral blood levels of a tumoral marker, CK20 mRNA, increased after stent placement while did not modify after performing a diagnostic colonoscopy in patients with colorectal cancer. The consequence of this finding on tumoral behaviour is unknown. In a recent prospective multicenter study including 519 patients with stage III colonic cancer and receiving adjuvant therapy with FOLFOX, the presence of circulating tumoral cells after surgery did not correlate with a poorer disease-free survival or overall survival^[28].

Another study reported an increased perineural tumoral invasion in patients with obstructive left colon cancer and treated with a stent under the bridge to surgery indication in comparison with patients surgically treated on emergency basis. In spite of this finding, no significant differences were found regarding overall survival or disease-free survival between the two groups of patients. Even more, perineural invasion did not correlate with tumoral recurrence or 5-year survival^[29]. Anyhow, the finding of an increased perineural invasion and lymph node involvement after stenting has been confirmed by other authors^[30].

Kim *et al*^[31] reported a shorter overall survival (38.4% vs 65.6%; $P = 0.025$) and 5-year disease free survival (48.3% vs 75.5%; $P = 0.024$) in patients with obstructive left colon cancer treated with a stent plus elective surgery than in patients with non-obstructive tumors surgically treated on elective basis. Very likely, this poor prognosis associated with stenting is not due to the stent but to the fact that stented patients presented with a large bowel obstruction.

Going beyond these findings with unclear significance, more relevant data are available now.

Perforation after stenting and tumoral recurrence

Results of stent-in 2 trial showed that, although no significant statistical differences were found regarding disease free survival, cancer related survival and overall survival when comparing patients treated with a stent and further elective surgery and patients who underwent emergency surgery, tumoral recurrence was significantly higher in patients who had been stented and presented a colonic perforation than in those also stented but without any secondary complication (4 year disease free survival: 0% vs 45%; $P = 0.007$). However, this fact had no influence on overall survival (4 year overall survival: 50% vs 62%; $P = 0.478$)^[32]. Gorissen *et al*^[25] also reported a slightly higher recurrence rate in the

group of stented patients (31.6% vs 28.2%; $P = 0.824$). This difference was due to an increased local recurrence in these patients (23% vs 15%; $P = 0.443$). Patients younger than 75 years had a significantly higher local recurrence rate (32% vs 8%; $P = 0.038$) and, after multivariate analysis, stenting almost reached statistical significance as a risk factor for local recurrence (OR = 12.45, 95%CI: 0.99-156.08; $P = 0.051$). However, it is paramount to remark that the perforation rate in these two studies was 11.5% and 8% respectively (Table 1).

Oncologic benefits of stenting and further elective surgery

In addition to colonic perforation, other factors can affect oncologic evolution of these patients. Quality of surgery could be better in previously stented patients. Sabbagh *et al*^[33] reported a significant higher lymph node retrieval

Table 2 Data of lymph node count, administration of adjuvant chemotherapy and laparoscopic surgery in studies comparing self-expandable metallic stents by-pass to elective surgery and emergency operation for obstructive colorectal cancer

SEMS: Self-expandable metallic stents; EO: Emergency operation.

in the surgical specimen of patients electively operated after initial bridge to surgery stenting, reaching statistical significance in some published papers. In a French study, the number of removed lymph nodes was 22 in the stenting group and 15 in the emergency surgery group ($P = 0.002$). Results were similar in an Asian publication (23 vs 11; $P = 0.005$)^[34]. Significant differences were not reached in other reports (Table 2). In this sense, several studies have correlated the number of removed lymph nodes with survival^[35,36]. Furthermore, Tung *et al*^[34] reported a higher percentage of curative resection surgery in patients previously stented (91.6% vs 54.1%; $P = 0.01$).

Moreover, stent placement is associated with a decreased postoperative complication rate, which is relevant regarding survival^[24]. In a recent analysis including 12075 patients, it has been shown that post-operative complications are associated with shorter survival (HR = 1.24; 95%CI: 1.15-1.34; $P = 0.001$). Analysing complications, infectious complications had a significant influence on long-term survival (HR = 1.31; 95%CI: 1.21-1.42; $P = 0.001$)^[37].

Another potential benefit could be the percentage of patients receiving adjuvant chemotherapy. A non-statistically significant higher percentage of patients received adjuvant chemotherapy after SEMS placement in seven of ten studies (Table 2).

Finally, the number of patients who can be surgically treated with laparoscopic surgery is larger in patients operated on elective basis after bridge to surgery stenting than in the group of patients undergoing emergency surgery. Laparoscopic surgery could have a beneficial effect on long-term survival. In a randomized study published by Lacy *et al*^[38] including 219 patients with colonic cancer, laparoscopic surgery was significantly related to lower recurrence rate (HR = 0.47; 95%CI: 0.23-0.94, $P = 0.03$), cancer-related mortality (HR = 0.44; 95%CI: 0.21-0.92; $P = 0.03$) and overall mortality (HR = 0.59; 95%CI: 0.35-0.98; $P = 0.04$) when compared with open surgery. A similar finding has been reported from COLOR II trial; in patients with

stage-III rectal cancer disease-free survival rate was 64.9% in the laparoscopic surgery group and 52% in the open surgery group (difference 12.9 percentage points, 95%CI: 2.2-23.6)^[39]. In Gorissen *et al*^[25] publication, 59.6% of stented patients and 23.2% of patients who underwent emergency surgery were operated by means of laparoscopic surgery ($P < 0.001$). Gianotti *et al*^[40] also found significant differences concerning laparoscopic surgery performance when comparing stented patients and emergency surgery patients (63.3% vs 0%; $P = 0.001$) (Table 2).

Stenting vs emergency surgery: Which strategy is more beneficial regarding oncologic outcomes?

At present, there are no consistent studies able to demonstrate that one strategy is superior to the other in terms of oncologic benefits.

In a multicenter French study, 5-year overall survival was lower in the group of stented patients than in the emergency surgery group after excluding patients with colonic perforation or metastases at the time of hospital admission (30% vs 67%; $P = 0.001$)^[33]. However, the type of patient (more stage IV patients in one center) and the type of treatment (stenting only in one center) was different in each participating hospital, fact which was not taken into account in multivariate analysis. Moreover, it really attracts attention that with a similar 5-year cancer related mortality (29% vs 22%; $P = 0.62$), overall survival differences are considered attributable to one therapeutic strategy.

In stent-in 2 trial, there was a non significant benefit in the emergency surgery group concerning 4-year disease free survival (Stenting: 30% vs Emergency Surgery: 49%; $P = 0.149$) and 4-year overall survival (Stenting: 58% vs Emergency Surgery: 67%; $P = 0.468$) in relation to colonic perforation after stenting^[32] and, a higher rate of local recurrence in young patients was reported by Gorissen^[25].

However, these results have not been reproduced in other studies with lower stent-related perforation rates. Kim *et al*^[29] reported a similar overall recurrence rate

in both groups of patients (Stenting: 35%; Emergency Surgery: 35%; $P = 1$), with non-significant better results concerning 5-year disease free survival (66.7% vs 54.8%; $P = 0.948$) and 5-years overall survival (100% vs 77.9%; $P = 0.103$) in the stenting group. In this study no case of local recurrence was registered in the stenting group. Tung *et al.*^[34] also reported an almost significant benefit in the stenting group regarding 5-year overall survival (48% vs 27%; $P = 0.076$) and Gianotti *et al.*^[40] demonstrated that stenting was the only parameter related to long-term survival (HR = 0.412; 95%CI: 0.217-0.785; $P = 0.007$). Stent related perforation rate in these three studies was 3.3%, 0% and 1.2% respectively. In a recent meta-analysis including 8 clinical trials, four of them reporting long-term results, no significant differences were found regarding 1-year survival (HR = 1.07; 95%CI: 0.87-1.31; $P = 0.51$), 2-year survival (HR = 1.14; 95%CI: 0.98-1.34; $P = 0.10$) and 3-year survival (HR = 1.08; 95%CI: 0.90-1.31; $P = 0.39$) although it was always better in the stenting group^[41]. Other studies which evaluate long-term results comparing stenting plus elective surgery vs emergency surgery do not find statistical differences in favour of any of the two strategies. Table 1 includes data regarding stent-related perforation, recurrence and survival. Oncologic evolution seems to be better in stented patients while the perforation rate is lower than 8% (Table 1).

In summary, we can't assure that stenting has a deleterious or beneficial effect on oncologic prognosis unless in those cases in which the patient presents a stent-related perforation.

Quality of life

The relevance of choosing one treatment strategy or the other concerning its influence on patient's quality of life has been seldom studied. In the Dutch study, quality of life was assessed with EORTC QLQ-C30 and QLQ-C38 questionnaires and no differences were found comparing stenting with emergency surgery, in spite of the more frequent stoma-related complications in the stenting group^[22].

Other studies have described different parameters directly related with quality of life. Permanent stoma performance is significantly higher in patients undergoing emergency surgery according to Tung *et al.*^[34] (25% vs 0%; $P = 0.03$) and Gianotti (26% vs 6.3%; $P = 0.01$)^[40] publications. In another paper it was also described that stented patients presented milder abdominal pain (4 vs 5; $P = 0.02$) and lower postoperative requirements of acetaminophen (8 tablets vs 16 tablets; $P = 0.04$) or morphine (40 mg vs 60 mg; $P = 0.001$)^[17]. On the other hand, other studies did not find differences regarding permanent stoma performance^[22,42].

Another interesting aspect to be assessed is the quality of bowel movements, as it is clearly related with the surgical technique. Ghazal *et al.*^[43] showed that patients operated on emergency basis performing a subtotal colectomy had a significantly larger number

of bowel movements than patients treated with a stent and elective surgery (6 vs 2; $P = 0.013$). In this sense, total colectomy was less common in surgically treated patients after bridge to surgery stenting in both Kavanagh *et al.*^[44] (4.3% vs 23%; $P = 0.027$) and Saida *et al.*^[45] (2% vs 30%; P value is not reported) studies.

CONCLUSION

Placement of a bridge to surgery self-expandable metal stent is beneficial for the surgical treatment of patients with an obstructive colorectal cancer. This benefit is not identical for every patient, being those patients with an advanced age or with important comorbidity the ones who would obtain more benefit of transforming emergency surgery into elective surgery.

Stenting has no demonstrated influence on survival although patients who present a stent related perforation have a higher risk of tumor recurrence and shorter disease free survival. In studies with perforation rates above 8%, higher recurrences rates in young patients^[25] and lower disease free survival^[32] have been shown. Each medical team must be well aware of their perforation rate in order to implement improvement measures if needed.

According to the literature, in these clinical setting, we have to choose between a treatment with more perioperative complications and another therapeutic strategy which might increase the risk of tumor recurrence. It seems cautious, as it has been suggested by others^[23,32], to consider emergency surgery and assume a higher initial complication rate in young patients without relevant co-morbidities avoiding the risk of local recurrence and stenting, accepting the risk of local recurrence but with a lesser perioperative complications rate, in old patients (> 70 years) with high surgical risk (ASA III/IV).

Abstract

Acute malignant colorectal obstruction is a complication of colorectal cancer that can occur in 7%-29% of

patients. Self-expanding metallic stent placement for malignant colorectal obstruction has gained popularity as a safe and effective procedure for relieving obstruction. This technique can be used in the palliation of malignant colorectal obstruction, as a bridge to elective surgery for resectable colorectal cancers, palliation of extracolonic malignant obstruction, and for nonmalignant etiologies such as anastomotic strictures, Crohn's disease, radiation therapy, and diverticular diseases. Self-expanding metallic stent has its own advantages and disadvantages over the surgery in these indications. During the insertion of the self-expanding metallic stent, and in the follow-up, short term and long term morbidities should be kept in mind. The most important complications of the stents are perforation, stent obstruction, stent migration, and bleeding. Additionally, given the high risk of perforation, if a patient is treated or being considered for treatment with antiangiogenic agents such as bevacizumab, it is not recommended to use self-expanding metallic stent as a palliative treatment for obstruction. Therefore, there is a need for careful clinical evaluation for each patient who is a candidate for this procedure. The purpose of this review was to evaluate self-expanding metallic stent in the management of the obstruction of the colon due to the colorectal and extracolonic obstruction.

Core tip: Self-expanding metallic stent placement for malignant colorectal obstruction has gained popularity as a safe and effective procedure for relieving obstruction. This technique can be used in the palliation of malignant colorectal obstruction, as a bridge to elective surgery for resectable colorectal cancers, palliation of extracolonic malignant obstruction, and for nonmalignant etiologies such as anastomotic strictures, Crohn's disease, radiation therapy, and diverticular diseases. In this review we

aimed to evaluate the placement technique, indications and complications of self-expanding metallic stent in colorectal obstructions.

INTRODUCTION

Colorectal cancers are one of the most common cancers worldwide, and it is the second most common diagnosed cancer in women and third in men^[1]. Acute malignant colorectal obstruction is a complication of colorectal cancer that can occur in 7%-29% of patients^[2]. It is a life-threatening condition that needs prompt evaluation. Large bowel obstruction causes colonic dilatation, bacterial translocation, and electrolyte and fluid imbalance, and has an increased risk of colonic necrosis and perforation^[3]. The main treatment of malignant colonic obstruction is resection of the tumor; however, in the past two decades, the use of self-expanding metallic stents (SEMS) has drawn interest since it was first reported in 1991 by Dohmoto^[4] for palliation of malignant colonic obstruction.

The major indications of SEMS for colonic stenting are palliation of malignant obstruction and preoperative decompression^[5]. Additionally, extracolonic obstructions due to other malignancies and some benign diseases have been shown to be treated by SEMS^[3]. Although SEMS placement for treating malignant obstruction seems safe and effective and has some advantages over surgery, short term and long term morbidities should be kept in mind. In this review, we aimed to evaluate SEMS in the treatment of colorectal and extracolonic cancers with advantages and disadvantages of this technique over surgery.

STENT PLACEMENT TECHNIQUE

SEMS placement can be performed by using endoscopic guidance with or without the use of fluoroscopy. It can be inserted through the scope (TTS) or over the guidewire^[5]. Most of the SEMS are inserted endoscopically with TTS with the use of fluoroscopy^[6]. SEMS placement with endoscope has advantages over the radiologic placement when the obstruction is proximal to the rectosigmoid region or in the presence of a tortuous colon. Kim *et al.*^[7] evaluated the technical feasibility and clinical effectiveness of fluoroscopically guided placement of SEMS in 42 patients for acute malignant colorectal obstruction; clinical success was achieved in 98% of the patients. They stated that fluoroscopically guided placement was feasible without endoscopic assistance,

even in lesions proximal to the splenic flexure and transverse colon. In a multicenter retrospective study, Geraghty *et al.*^[8] aimed to determine the outcomes after SEMS; TTS endoscopy technique was found to be more successful than radiological placement alone (90.3% vs 74.8%, $P < 0.001$) for large bowel obstruction. In another retrospective study, Kim *et al.*^[9] compared the SEMS placement technique in 111 patients; while the technical success rate was significantly higher in the endoscopic method than in the radiologic method (100% vs 92.1%, respectively, $P = 0.038$), the clinical success rate did not differ significantly between the two groups (91.8% vs 97.1%, respectively, $P = 0.424$). They concluded that endoscopic and radiologic placement technique have their own advantages and disadvantages, but when an obstructive lesion is located in the tortuous, curved angulation of the sigmoid or descending colons, it is more difficult to pass the stenotic lesion using the radiologic method alone.

Bowel preparation before stent placement is not necessary, and oral bowel cleansing is contraindicated in symptomatic bowel obstruction, but enema can be used for facilitating the stent placement by preparing the bowel distal to the stenosis^[5].

Antibiotic prophylaxis before SEMS placement is not recommended routinely because of the low risk of fever and bacteremia after the insertion^[5]. However, antibiotic prophylaxis should be considered especially in patients with complete obstruction who have dilated colon and a risk of microperforation during insertion^[10].

Operator experience is an important matter in the placement of the stents. In a retrospective study, SEMS placement was performed in 334 patients, and technical and clinical success was higher for operators who had performed more than 10 procedures^[8]. In another study, Small *et al.*^[11] reported that the complication rate was higher when stents were placed by endoscopists who were not experienced in pancreaticobiliary endoscopy.

Technical success is usually defined as stent placement appropriately across the entire length of the stenosis, and clinical success is defined as resolution of colonic obstruction within the first days after the stent placement^[6]. Technical and clinical success rates vary between the studies. In a systematic review focusing on 88 studies published in 2007 by Watt *et al.*^[12] the median rate of technical success was 96.2%, ranging from 66.6% to 100%, and clinical success was achieved in 92% of the cases, ranging from 46% to 100%. It was stated that the etiology of the primary obstruction and indication for the stent placement appeared to have little effect on the rates of technical and clinical success. In a recent meta-analysis that included seven randomized clinical trials, pooled data showed a mean success rate of 76.9% (range: 46.7%-100%)^[13]. In another meta-analysis, Cennamo *et al.*^[14] compared randomized trials in terms of endoscopic stenting and surgical decompression for colorectal cancer obstruction; the stents were successfully inserted in 73.5% of patients, with

clinical relief of obstruction in 72% of patients.

Covered and uncovered SEMS can be used for colonic stenting. In a meta-analysis, in which Zhang *et al.*^[15] compared covered and uncovered stents, uncovered stents were found to be associated with a lower late migration rate, a higher tumor ingrowth rate, and a prolonged stent patency. No significant difference was found in technical success, clinical success, tumor overgrowth, early migration, perforation and overall complications between type of stents. In another meta-analysis including a total of 1376 patients, Yang *et al.*^[16] compared covered and uncovered SEMS in terms of technical success, clinical success and stent patency, and no significant difference was found between the two groups. Uncovered stents were found to be more prone to tumor ingrowth, but covered stents had the higher risk of stent migration over uncovered stents. Each type of stent have their own advantages and disadvantages. The main advantage of covered stents is a reduction in the risk of tissue ingrowth, whereas they are more prone to migrate.

INDICATIONS OF SEMS

Palliation of malignant obstruction

Acute malignant colorectal obstruction is a complication of colorectal cancer that can occur in 7%-29% of patients^[2]. Bowel obstruction can be caused by intrinsic disease or extrinsic compression. Large bowel obstruction causes colonic dilatation, bacterial translocation, electrolyte and fluid imbalance, and has an increased risk of colonic necrosis and perforation, so this gastrointestinal emergency needs urgent evaluation. The main treatment modalities for malignant colorectal obstruction are surgical resection or diverting colostomy. Resection is a suitable procedure in patients with less advanced cancer. Permanent stoma creation is a procedure for relieving symptoms of obstruction in patients with nonresectable tumors^[12]. Emergent surgery should be performed for the patients with colonic perforation and ischemia/necrosis. If there are no signs of systemic toxicity, SEMS can be performed in patients with a partial obstruction or with complete obstruction. SEMS is an alternative procedure for relieving the obstruction of the colon. In the literature, several studies have been published showing the feasibility and safety of SEMS in the management of acute malignant obstruction. In 2007, Watt *et al.*^[12] compared the safety and efficacy of SEMS with surgery through a systematic review. SEMS was found to be effective and safe in overcoming left-sided malignant colorectal obstructions, with high levels of technical and clinical success, shorter hospital stay, and lower rate of serious adverse events than surgery. Zhao *et al.*^[17] compared surgery with SEMS in the relief of obstruction in a meta-analysis, and the SEMS group showed a lower clinical success rate (99.8% vs 93.1%, $P = 0.0009$) but shorter length of hospital stay (18.84 d vs 9.55, $P < 0.00001$) and time to initiation of chemotherapy (33.36 d vs 15.53 d, $P < 0.00001$), and

lower rate of stoma formation (54.0% vs 12.7%, $P < 0.00001$). Hospital mortality was significantly lower in the SEMS group, and no difference was found in overall complications between the two groups. Surgery was found to be associated with short term complications and SEMS with late term complications^[17]. Liang *et al.*^[18] compared SEMS with surgery in the same indication mentioned above in a meta-analysis; the success rate of SEMS was found to be 93.9%, and no significant difference was found in mortality between the groups. The hospitalization time was shorter in the SEMS group ($P < 0.01$); however, long term complications were higher than surgery ($P = 0.03$). However, it was mentioned that all of the studies reported only the complications of colostomy or Hartmann's procedure, and none of them considered the complications of the stoma. They stated that morbidity and mortality would be much higher in the multi-stage surgery than with SEMS. In a recent study Young *et al.*^[19] compared the stent insertion and surgical decompression in patients with incurable large bowel obstruction in terms of improving quality of life. Stent related perforations or deaths were not reported. They found that surgery group had significantly reduced quality of life compared with the stent group. The patients in the stent group was found to have significantly lower permanent stoma rates, reductions in post procedure stay, earlier return of bowel function and shorter hospital stay. Thirty-day mortality for the stent group was 8% and for the surgery was 15% ($P = 0.67$). No significant difference was found in survival rates between treatment groups ($P = 0.61$)^[19].

Placement of SEMS as a bridge to elective surgery

SEMS have been suggested to relieve colon obstruction and act as a "bridge to surgery" for resectable colon cancers. There are conflicting results on this subject. In the literature, systematic reviews with meta-analysis have been published in order to evaluate preoperative SEMS placement as a bridge to elective surgery with emergency resection for acute malignant left-sided colonic obstruction. In the most recent meta-analysis that included seven randomized clinical trials, Huang compared emergency surgery and SEMS group. The pooled data showed a mean success rate of colonic stent placement of 76.9% (range: 46.7%-100%). Compared with the emergency surgery group, the SEMS group achieved significantly lower rates of permanent stoma (9% vs 27.4%, $P < 0.01$), primary anastomosis (67.2% vs 55.1%, $P < 0.01$), lower overall complications (33.1% vs 53.9%, $P = 0.03$) and lower wound infections (6.7% vs 18.1%, $P < 0.01$). No significant difference was found between the two groups in anastomotic leakage, mortality, or intra-abdominal infection. In this setting, SEMS placement for relieving obstructive symptoms allows time for the optimization of the medical condition, bowel preparation, and staging the disease^[13]. Although there are some advantages of SEMS placement preoperatively compared to the emergency surgery, long term oncological outcome, especially in patients with

resectable colon cancer, should be kept in mind.

There has been a major concern about the oncological outcome of the patients with resectable colon cancer who received SEMS placement as a bridge to surgery. In the literature, it was shown that placement of SEMS preoperatively in patients with resectable colon cancer impairs the oncological outcome, because of the dissemination of cancer cells during the procedure^[20], and because stent placement will be complicated by perforation and associated with ulceration as well as perineural and lymph node invasion of the tissues^[21]. Alcántara *et al.*^[22] compared short-term results and long-term outcomes of patients who underwent stent placement preoperatively with intraoperative colonic lavage with primary anastomosis. More relapses occurred in the SEMS group, but this finding was not significant, and no differences were found in survival. In another study, Sloothak *et al.*^[23] compared 5-year overall recurrence rates in the SEMS placement as a bridge to surgery group with the emergency surgery group; the SEMS group was found to have higher recurrence rate (42% vs 25%, $P = 0.027$). In a larger prospective study that evaluated the long-term oncological outcome between the same groups, in patients aged ≤ 75 years, stent as a bridge to surgery was associated with a higher local recurrence rate compared with emergency surgery (32% vs 8%, $P = 0.038$) without a difference in the overall survival rates^[24]. These findings suggest that use of SEMS in the treatment of curable patients with left-sided malignant colonic obstruction will impair the oncologic outcome. In the recent guidelines, as stent seems to impact the oncological safety with no reduction in postoperative mortality, SEMS as a bridge to elective surgery in curable patients with left-sided malignant colonic obstruction is not recommended. However, this procedure may be a good option for selected patients with a high risk of postoperative mortality, and patients over 70 years old and/or with American Society of Anesthesiologists score $\geq III$ ^[5].

Palliation of extracolonic malignant obstruction

Colonic obstructions also can occur due to tumor invasion, peritoneal seeding, or extraluminal compression resulting from advanced extracolonic malignancy^[25]. Outcomes of SEMS placement in the treatment of extracolonic malignancies are unclear. There have been published studies that compared the clinical outcomes of SEMS between patients with colon cancer and with extracolonic malignancies. Kim *et al.*^[25] performed SEMS placement for colorectal cancer in 149 patients and for extracolonic malignancy in 60 patients. Advanced gastric cancer, pancreatic cancer, and ovarian cancer were the most common causes of obstruction in that study. The clinical success rates, complications, and stent patency were similar between the two groups. In another study, Kim *et al.*^[26] evaluated the clinical outcomes and complications of SEMS compared with emergency surgery for relieving obstruction; technical and clinical success rates were higher in the emergency surgery

group. SEMS related complications occurred in 64.5% of the patients, including reobstruction (36.8%), stent migration (10.5%), perforation (13.2%), and bleeding (3.9%). In a retrospective study of palliative stent placement for extracolonic malignancies, clinical success was significantly higher in patients with colorectal cancer than in those with extracolonic malignancies (94.1% vs 20%, $P < 0.0001$). Two procedure related deaths occurred in the extracolonic malignancy group. Colon stenting for this purpose was found to be less successful in comparison with patients with colorectal cancer^[27].

SEMS for nonmalignant etiologies

Colonic stents have been used in a variety of non-malignant conditions as colonic strictures, including anastomotic strictures, Crohn's disease, radiation therapy, and diverticular disease^[3]. In a retrospective study, Keränen *et al.*^[28] evaluated a total of 21 patients with 23 SEMS procedures for benign colorectal obstruction; eight of the patients had an obstruction in the surgical anastomosis, two patients had anastomotic strictures due to Crohn's disease, 10 patients had the obstruction due to diverticular disease, and one patient had a stricture after radiation therapy. Technical success was achieved in all patients, and clinical success was achieved in 76% of the patients; complications occurred for 9 patients in 10 out of 23 procedures. They concluded that SEMS placement for benign colon strictures may be a good option for the patients who are not fit for surgery. Pommergaard *et al.*^[29] performed a retrospective study that included 45 patients with benign and malignant colonic obstruction: Technical and clinical success was 97.4% of the patients with malignant etiology, complications occurred in 21%, and mortality rate was 2.6%. For benign etiology, technical success was 85.7%, and clinical success was 71.4%, and complications occurred in 71.4% in this group with a mortality rate of 28.6%.

COMPLICATIONS OF SEMS

Stent related complications can occur in patients with malignant colon obstruction in the palliative or bridge to surgery setting. The most important complications of the stents are perforation, stent obstruction, stent migration, and bleeding. The most seen complication is the stent obstruction because of the tumor ingrowth or overgrowth^[30]. The main stent related complications are discussed above.

Perforation

The incidence of colonic perforation after SEMS placement varies between the studies. Perforation is the most feared complication of SEMS. In a review that included a total of 2287 patients, Datye *et al.*^[31] found overall perforation rate was 4.9%. No significant difference was found in the perforation rates for palliation and bridge to surgery (4.8% vs 5.4%, $P = 0.66$). The mortality rate after perforation was 16.2%. Most of the perforations

Figure 1 Perforation of the rectum due to the self-expanding metallic stent detected intraoperatively.

(over 80%) occurred within 30 d of stent placement, and almost half of these were noted during or within one day of the procedure; the majority of them were related to dilation, the guidewire, or the stent. In another systematic review, Watt *et al*^[12] reported the median rate of perforation caused by either the guidewire or stent was 4.5% (range: 0%-83%). The perforation rate was not found to be affected by the indication for stent placement. Colon perforation can be immediate or delayed, and is more likely to occur in the distal colon where sharp angulation and redundancy make stent deployment challenging^[32]. Baron *et al*^[10] identified the reasons that can cause perforation after stent placement in four different types: (1) guidewire or catheter malpositioning; (2) dilation of the stricture before or after stent placement; (3) stent-induced perforation; and (4) caused by proximal colonic distention away from the site of stent placement because of inadequate colonic decompression or excessive air insufflation. Delayed perforation can be tumor related, drug related (bevacizumab), and stent related^[33]. Figure 1 shows the perforation of the rectum due to the SEMS intraoperatively.

In the literature, published results have shown that patients who have undergone palliative stenting can be treated with chemotherapy without antiangiogenic agents^[34]. Safety of SEMS in the colon or rectum of patients who are receiving the anti-angiogenic agent bevacizumab as a component of chemotherapy has been studied in the literature. Radiotherapy and bevacizumab may increase the risk of perforation. In a retrospective study that includes 201 patients undergoing stenting for incurable malignant obstruction, bevacizumab therapy was found to increase the risk of perforation by 19.6-fold over patients who did not receive bevacizumab^[35]. In another review, Small *et al*^[11] determined long-term efficacy, incidence of complications, and risk factors of SEMS placement for colonic obstruction; the incidence of perforation was higher in patients with bevacizumab treatment compared with untreated patients (15.4% vs 6.8%). The complication rate was found to be associated with SEMS placement in men, completely obstructed bowel, with balloon-dilated strictures, and with post-stent bevacizumab treatment. Given the high risk of

Figure 2 Occluded self-expanding metallic stent due to the tumor ingrowth.

perforation, if a patient is treated or considered to be treated with antiangiogenic agents like bevacizumab, it is not recommended to use SEMS as a palliative treatment for obstruction^[34]. However, there is no strong evidence for the newer antiangiogenic agents like aflibercept and regorafenib, and because of the similar mechanisms, perforation risk should be kept in mind^[5]. Based upon these data, it is suggested that colonic stent placement be avoided if possible in patients who are or who will be receiving bevacizumab.

Stent obstruction

The most common complication is stent obstruction because of the tumor ingrowth or overgrowth^[31]. Figure 2 shows the occluded SEMS due to the tumor ingrowth. In a meta-analysis that included 13 studies, 11 of them reported stent related complications, rate of perforation was 10.1%, stent migration was 9.2%, and stent obstruction was 18.3%^[17]. It is believed that covered stents provide resistance to tumor ingrowth, thus helping to reduce reconstruction events, while uncovered stents are believed to minimize stent migration^[12,36,37]. For the uncovered stents, the main disadvantage is the tumor ingrowth, but the membrane of the covered stents can provide a barrier to prevent this. In a systematic review that compared covered SEMS with uncovered SEMS, uncovered SEMS showed a higher tumour ingrowth rate (RR = 5.99; 95%CI: 2.23-16.10, $P = 0.0004$)^[15]. The factors that are associated with the stent obstruction are: Demographic factors, underlying malignancy, length of stent, site of stricture, degree of stent expansion, and chemotherapy after stent insertion^[30]. However, Im *et al*^[38] performed a study in order to evaluate clinical outcomes, long term complications, and patency of SEMS in patients with malignant colorectal obstruction, and stent patency was not found to be associated with demographic characteristics of patients, site of obstruction, or palliative chemotherapy. In a retrospective study, Suh *et al*^[30] analyzed the predictive factors for stent occlusion, and insufficient stent expansion (< 70%) 48 h after stent insertion was significantly associated with stent occlusion during the follow-up.

If SEMS is inserted for the relief of obstruction in advanced and incurable colorectal cancer, the stent patency should be maintained until the death of the patients^[30]. but if it is used in the preoperative setting, after 1-2 wk, the stent will be removed en bloc at the time of surgical resection^[6]. In a systematic review, 14 studies reported duration of patency; the median of reported study mean durations was 106 d (range: 68-288 d) in the palliative stent population^[12]. Suh *et al*^[30] reported stent patency mean and median 184 and 141 d respectively.

There have been no accurate data in the management of occluded SEMS in malignant colorectal obstruction. In most of the patients with stent obstruction, this can be treated by stent-in-stent placement. In a retrospective case series, Yoon *et al*^[39] determined the effectiveness of stent-in-stent SEMS insertion for the treatment of SEMS obstruction in cases with malignant colorectal obstruction. In this study the clinical success was reported in 75% of the cases; 9 of them had persistent symptoms, 8 of them underwent palliative surgery, but at the end of the follow-up, 16 of 36 patients (44.4%) remained free of obstruction symptoms until death. The success rate was found to be slightly lower than that of primary SEMS placement^[40]. In another study, Yoon *et al*^[39] compared the clinical outcomes of the patients who underwent second intervention because of the obstruction of the first successful SEMS placement for colorectal obstruction with second SEMS insertion or palliative surgery. No significant difference was found in the median overall survival (8.2 mo vs 15.5 mo) and progression-free survival (4.0 mo vs 2.7 mo) between the stent and surgery groups. However, the median lumen patency in the stent group was 3.4 mo and 7.9 mo in the surgery ($P = 0.003$). Male gender and having an obstruction in the right colon were identified as prognostic factors of lumen patency in second SEMS; additional chemotherapy after a second intervention was found to be a prognostic factor with a longer lumen patency in the palliative surgery group.

Stent migration

In a systematic review including 54 studies, Watt *et al*^[12] evaluated stent for all indications reported that median rate of migration was 11%, ranging from 0% to 50%. Stent migration can occur at any time following the insertion, but is usually detected within one week of insertion. Migrations tend to occur with stents which are too narrow in diameter and/or too short in relation to the stricture they are placed in^[41]. In another systematic review, Khot *et al*^[42] reported stent migration in 54 (10%) of 551 technically successful cases; 26% of the stent migration occurred within 3 d, and the remaining occurred after 3 d. Factors that were associated with the migration were laser pretreatment, chemotherapy, and benign tumor. Covered and small diameter (< 24 mm) SEMS were also found to be associated with stent migration^[15,35,36]. Chemotherapy with the mechanism of tumor shrinkage increases the stent migration^[43-45].

Others

After the SEMS placement, abdominal pain and bleeding can occur in the follow-up. Bleeding is usually minor after the procedure, and generally no intervention will be required. Abdominal or rectal pain is common and varies between 7.4% and up to 62.5% in patients with SEMS placement within 5 cm of the anal verge^[46,47]. Mild abdominal pain generally requires no specific treatment; if needed, use of analgesics will be enough for relieving the pain.

CONCLUSION

SEMS placement can be an alternative method in the treatment of patients with colorectal cancer who have acute malignant colorectal obstruction. SEMS offers favourable results compared to surgery in the setting of colorectal obstruction in advanced disease. Use of SEMS in the treatment of curable patients with left-sided malignant colonic obstruction will impair the oncologic outcome; therefore, SEMS as a bridge to elective surgery in curable patients with left-sided malignant colonic obstruction is not recommended. Although SEMS placement seems to be safe and effective and has some advantages over surgery, short term and long term morbidities should be kept in mind, and it will be preferred for patients who are at increased risk for complications of emergency surgery.

Abstract

There are several malignancies of the digestive system (including gastric, pancreatic and colorectal cancers, and hepatocellular carcinoma), which are the most common types of cancer and a major cause of death worldwide. MicroRNA (miR)-7 is abundant in the pancreas, playing an important role in pancreatic development and endocrine function. Expression of miR-7 is downregulated in digestive system malignancies compared with normal tissue. Although there are contrasting results for miR-7 expression, almost all research reveals that miR-7 is a tumor suppressor, by targeting various genes in specific pathways. Moreover, miR-7 can target different genes simultaneously in different malignancies of the digestive system. By acting on many cytokines, miR-7 is also involved in many gastrointestinal inflammatory diseases as a significant carcinogenic factor. Consequently, miR-7 might be a biomarker or therapeutic target gene in digestive system malignancies.

Key words: MicroRNA-7; Digestive system malignancy; Tumor biomarker; Target gene; Inflammation

Core tip: MicroRNA (miR)-7 targets different genes in various complicated pathways and plays diagnostic, prognostic, anti-metastatic, and therapeutic roles in digestive system malignancies. MiR-7 might be a biomarker or therapeutic target gene in digestive system malignancies, even in the precancerous lesions (inflammatory disease).

in digestive system malignancy. *World J Gastrointest Oncol* 2016; 8(1): 121-127 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/121.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.121>

INTRODUCTION

MicroRNAs are small noncoding RNAs consisting of 18-25 nucleotides that post-transcriptionally regulate expression of target genes, and are involved in cell proliferation, epithelial-mesenchymal transition (EMT), apoptosis, migration, invasion and metastasis^[1-3]. miRNAs have emerged as potential critical regulators of carcinogenesis and tumor progression^[4,5].

The digestive system is composed of many ducts and glands, and because of its complicated physiology and anatomy, numerous diseases may occur, especially malignancies including the third, fourth and eighth most common cancers worldwide: Colorectal cancer (CRC), gastric cancer (GC) and esophageal cancer, respectively^[6,7], as wells as the leading cause of cancer-related death: Pancreatic cancer (PC)^[8]. According to the 2014 cancer statistics, the combined cancer mortality rates have been continuously declining for the past two decades. However, the incidence of some digestive system malignancies, including cancers of the esophagus, liver, anus and pancreas, is increasing. Moreover, with rising death rates for cancers of the liver, anus and pancreas, and other non-digestive cancers, cancer is still the second leading cause of death following heart disease^[8]. Therefore, it is necessary for us to explore novel molecular mechanisms, and screen for the most effective therapeutic methods to avoid the majority of patients succumbing to these digestive malignancies.

MicroRNA (miR)-7 is an evolutionarily conserved miRNA that is involved in the development of the eye and pancreas in *Drosophila*. Li *et al*^[9] reported that miR-7 is repressed by the transcription factor Yan, which is degraded while mediating epidermal growth factor receptor (EGFR) signaling. Also, miR-7 is expressed abundantly in human pancreas and endocrine cells and has a specific role in endocrine cell differentiation and function^[10]. It has been demonstrated that miR-7 is a tumor suppressor in breast, lung and ovarian cancers, and glioblastoma, mainly focusing on its relationship with EGFR^[11-15]. Accumulating evidence shows that miR-7 can simultaneously target a variety of mRNAs involved in diverse signaling pathways in different tumors. However, no specific review has described the role of miR-7 in digestive tract malignancies. In this review, we focus on current research on miR-7 in order to elucidate its role in digestive system malignancies or their precancerous lesions, with reference to its expression, signaling pathways, and role as a circulatory biomarker.

EXPRESSION OF MIR-7

By comparing the differential expression of miRNAs in

pancreatic islets (endocrine) and acinar (exocrine) tissue in rats, using microarray and quantitative polymerase chain reaction (qPCR), Bravo-Egana *et al*^[16] revealed that miR-7 was ranked highest among the 17 miRNAs preferentially expressed in islets, suggesting that it acts as an endocrine miRNA. Another two studies reported that miR-7 was expressed at a high level during human pancreatic islet development^[10,17]. For malignancy, it has been demonstrated that miR-7 is downregulated in cancer tissue of digestive malignancies such as GC^[18-20], CRC^[21,22] and hepatocellular carcinoma (HCC)^[23] by comparison with normal tissues, suggesting that it acts as a suppressor. A similar conclusion was drawn in a study of hydroxycamptothecin-resistant GC cells^[24]. In some inflammatory diseases, such as gastritis and Crohn's disease^[25], the level of miR-7 is also lower than that in normal tissue, which suggests that it is an inflammation-related miRNA participating in the process of digestive cancer.

In contrast, using the same method, Suto *et al*^[26] discovered that miR-7 level was higher in CRC tissue than in adjacent normal tissue, induced by EGFR mutations. However, it was found that the aforementioned results would be opposite when the EGFR protein expression was positive in CRC. Finally, they concluded that low miR-7 expression resulted in poorer prognosis than high expression. Ahmed *et al*^[27] identified the expression of miR-7 in stool samples from 40 cases of colon cancer (TNM stages 1-4), and found that miR-7 was one of the 12 increased miRNAs, which they then recognized as a diagnostic gene. In HCC, Fang *et al*^[28] speculated that owing to inactivation of the transcriptional regulators and/or failure to promote miR-7 expression, there is no alteration of its expression between tumor and adjacent normal tissues. However, miR-7 and miR-21 are overexpressed in esophageal squamous cell carcinoma (ESCC) and related to its differentiation^[29].

From Table 1, we can speculate the reasons for the divergent views about the expression of miR-7 under different conditions, including^[30]: (1) heterogeneity of different malignancies/diseases; (2) different study sample sizes; and (3) the standards were not the same (*e.g.*, whether or not to include patients with prior cytotoxic therapy). Based on the published studies, we conclude that miR-7 could be an oncogene or tumor suppressor in the digestive system depending on the specific gene targeted (Table 2).

GC

The pathogenesis of GC has been extensively studied, and there is a consensus that intestinal gastric carcinogenesis is a multistep process starting with chronic gastritis triggered by *Helicobacter pylori*, progressing through atrophy, intestinal metaplasia and dysplasia to carcinoma (Correa model)^[31]. Thus, inflammation is a significant event in gastric carcinogenesis, whereas miR-7 is an inflammation-mediated miRNA inversely

Table 1 Expression of microRNA-7 in the digestive system

Cancer	Sample	Sap No.	Method	Exp	Role	Ref.
Colon	Stool	60	qPCR	↑	Diagnostic	[27]
CRC	Tissue	80	qPCR	↓	Diagnostic/therapeutic	[21]
CRC	Tissue	8	RT-PCR	↓	Therapeutic	[22]
CRC	Tissue	105	qRT-PCR	↑	Prognostic	[26]
ESCC	Tissue	34	Microarray/qRT-PCR	↑	Differentiation	[29]
GC	Tissue	40	ISH/IHC	↓	Inhibits metastasis/EMT	[18]
GC	Tissue	23	Microarray	↓	Inhibits invasion/metastasis	[19]
			qRT-PCR			
GC	Tissue	28	RT-PCR	↓	Represses inflammation	[20]
HCC	Tissue	10	Microarray	-	Therapeutic/diagnostic/prognostic	[28]
			qRT-PCR			
HCC	Tissue	12	qRT-PCR	↓	Tumor suppressor	[23]
HCC	Tissue	429	Chip assay	↓	Prognostic	[43]
CD	Tissue	-	RT-PCR	↓	Therapeutic	[25]

↓: MiR-7 is downregulated; ↑: MiR-7 is upregulated; -: There is no alteration for expression of miR-7, or no mention. Sap No.: Sample number; Exp: Expression; ISH/IHC: *In situ* hybridization/immunohistochemistry; CRC: Colorectal cancer; GC: Gastric cancer; HCC: Hepatocellular carcinoma; ESCC: Esophageal squamous cell carcinoma; EMT: Epithelial-mesenchymal transition; qPCR: Quantitative polymerase chain reaction.

Table 2 Function of microRNA-7 by targeting diverse genes

Cells	Function of miR-7	Target	Ref.
CCA	Reduces migration, invasion and metastasis	LAT1	[41]
CRC	Inhibits proliferation, invasion and metastasis, and induces G1 arrest	PAX6	[21]
CRC	Inhibits proliferation and induces apoptosis	XRCC2	[22]
CRC	Suppresses proliferation, induces G1 arrest, and induces apoptosis	YY1	[37]
GC	Suppresses invasion and metastasis	IGF1R	[18]
GC	Inhibits proliferation, invasion and metastasis	EGFR	[19]
HCC	Decreases invasion and migration	PIK3CD/mTOR/p70S6K	[28]
HCC	Suppresses colony formation and induces cell cycle arrest	CUL5	[23]

CCA: Cholangiocarcinoma; CRC: Colorectal cancer; GC: Gastric cancer; HCC: Hepatocellular carcinoma; miR-7: MicroRNA; XRCC2: X-ray repair complementing defective repair in Chinese hamster cells 2; IGF1R: Insulin-like growth factor 1 receptor; EGFR: Epidermal growth factor receptor; mTOR: Mammalian target of rapamycin; CUL5: Cullin 5.

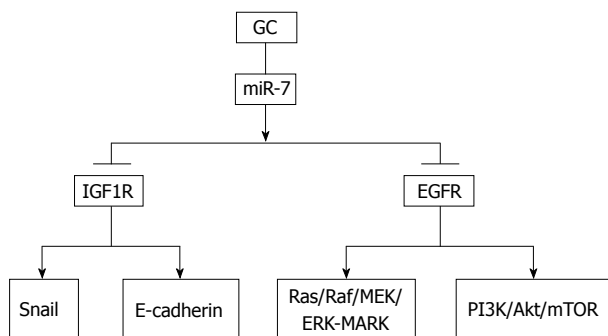

Figure 1 Pathway of microRNA-7 in gastric cancer. It has been revealed that miR-7 targets mainly IGF1R and EGFR. IGF1R: Insulin-like growth factor 1 receptor; EGFR: Epidermal growth factor receptor; GC: Gastric cancer; miR-7: MicroRNA-7; PI3K: Phosphoinositide 3-kinase; mTOR: Mammalian target of rapamycin.

correlated with many proinflammatory cytokines and inflammatory factors such as interleukin-1 β and tumor necrosis factor- α . Three genes, *LPHN2*, *BASP1* and *MAFG*, targeted by miR-7 are induced in the cyclooxygenase (COX)-2/prostaglandin (PG) E2 pathways, which shows that miR-7 plays a significant part in gastric tumorigenesis with an inflammatory response^[20].

MiR-7 suppresses GC cell invasion and metastasis both *in vitro* and *in vivo* by targeting the miR-7/insulin-like growth factor 1 receptor/Snail axis, which shows its EMT function and suggests that it can act as a therapeutic biomarker to prevent GC metastasis^[18]. Xie *et al.*^[19] demonstrated that restoration of miR-7 significantly inhibited tumor cell viability, invasion and migration by suppressing EGFR expression. These results suggest that targeting miR-7 is a potential therapeutic option for GC (Figure 1).

PC

PC is one of the major leading causes of cancer mortality; the 5-year survival rate for pancreatic adenocarcinoma is < 5%, and most patients die within the first 2 years^[8]. Therefore, there is an urgent need to explore novel therapeutic methods. In accordance with the expression of miR-7 in the pancreas, miR-7-3, which is one of the three endogenous genes potentially transcribed in the human genome, is upregulated by targeting mitogen-activated protein kinase (MAPK), suggesting that miR-7 is negatively modulated by an EGFR-MAPK feedback loop^[32]. In an *in vitro* study, in

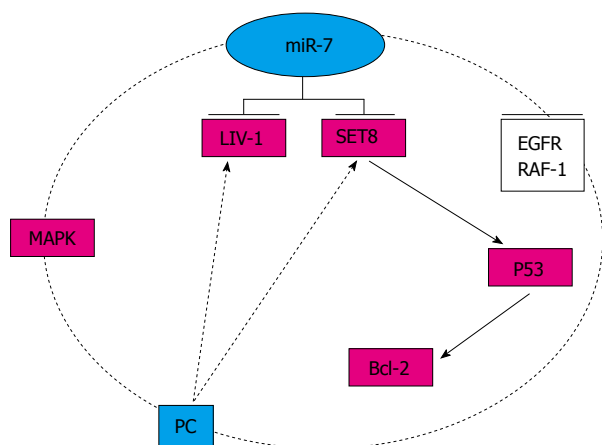

Figure 2 Pathway of microRNA-7 in pancreatic cancer. In PC, there is an EGFR-MAPK-miR-7 negative feedback loop, and LIV-1 and SET8 are two other targets. EGFR: Epidermal growth factor receptor; MAPK: Mitogen-activated protein kinase; PC: Pancreatic cancer; miR-7: MicroRNA-7; SET8: SET domain containing 8.

which miR-7 targeted SET domain containing 8 leading to increased p53 expression and decreased Bcl-2 level, curcumin suppressed cell growth, migration and invasion, and induced apoptosis in PC cells, indicating that targeting miR-7 is a useful therapeutic option for PC^[33]. Although knockdown of LIV-1 (a zinc transporter) can upregulate expression of miR-7 in PC cells, the exact role of miR-7 in the maintenance of cancer-stem-cell-related phenotypes in PC remains unclear^[34]. Future research will focus on identifying the exact pathway of miR-7 in PC, and only in this way, can research proceed from bench to bedside (Figure 2).

CRC

CRC is related to the mutation of genes such as P53, APC, SMAD4, PIK3CA, KRAS, ARID1A, SOX9 and FAM123B. Some minimal tailoring of therapy (selecting a chemotherapeutic agent based on toxicity, or not using anti-EGFR in those with KRAS-mutated tumors) can be offered to patients, however, the dream of truly individualized therapy remains elusive^[35,36]. Based on the present studies, miR-7 can target specific genes to modulate the correlated pathways, and its decreased expression continuously participates in the process of CRC. MiR-7 is a tumor suppressor, which is mediated through the YY1-P53-Wnt signaling pathway, and plays pivotal roles in many cellular processes, such as development, differentiation, proliferation and apoptosis^[37]. By targeting EGFR and *v-raf-1* murine leukemia viral oncogene homolog 1 (RAF-1), a low level of miR-7 suggests poor prognosis for CRC, and miR-7 precursor, alone or in combination with a monoclonal antibody, could be a novel therapy against CRC^[26]. XRCC2 (X-ray repair complementing defective repair in Chinese hamster cells 2) participates in homologous recombination, and its relationship with miR-7 has been studied. *In vitro*, overexpression of miR-7 suppressed

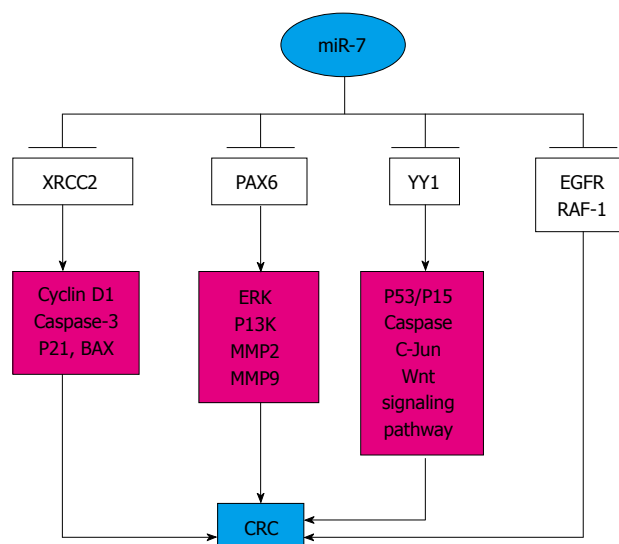

Figure 3 Pathway of microRNA-7 in colorectal cancer. MiR-7 can target various genes involving different pathways and act as a suppressor. CRC: Colorectal cancer; EGFR: Epidermal growth factor receptor; miR-7: MicroRNA-7. XRCC2: X-ray repair complementing defective repair in Chinese hamster cells 2; ERK: Extracellular signal-regulated kinase.

proliferation and induced apoptosis of CRC cells by directly targeting XRCC2 through decreasing cyclin D1 and increasing p21, caspase-3 and BAX expression^[22]. In addition, the expression of paired box (PAX) 6 is inversely correlated with that of miR-7, and simultaneous activation of the extracellular signal-regulated kinase and phosphoinositide 3-kinase (PI3K) signaling pathways and regulation of the levels of matrix metalloproteinase (MMP) 2 and MMP9 could modulate the expression of PAX6 and miR-7 in opposing ways, which suggests that miR-7 is a promising therapeutic target for CRC^[21]. Thus, further mechanisms mediated by miR-7 should be explored, which could be a promising approach for individually tailored therapy of CRC (Figure 3).

HCC

HCC, the third most common cause of cancer mortality worldwide, which develops from activation of cellular oncogenic pathways and abrogation of tumor suppressor pathways including the p53/p21^{WAF1} pathway, the p16^{INK4a}/CDK4/RB1/E2F pathway, the Wnt/ β -catenin signaling pathway, transforming growth factor- α , c-myc, transcription factor NF- κ B, insulin/IGF-I, and receptor tyrosine kinases and their downstream activators^[38,39]. Several studies have shown that miR-7 participates in several pathways by targeting different genes in HCC. MiR-7 regulates the PI3K/Akt/mammalian target of rapamycin *in vitro* and *in vivo*, which functions downstream of EGFR, suggesting that miR-7 is a potential target for treating or diagnosing/prognosing HCC^[28]. Likewise, ectopic expression of cullin 5, a novel target gene of miR-7, inhibits HCC cell proliferation, arrests cell cycle progression, and suppresses colony formation, although the exact pathway remains unclear^[23]. Moreover,

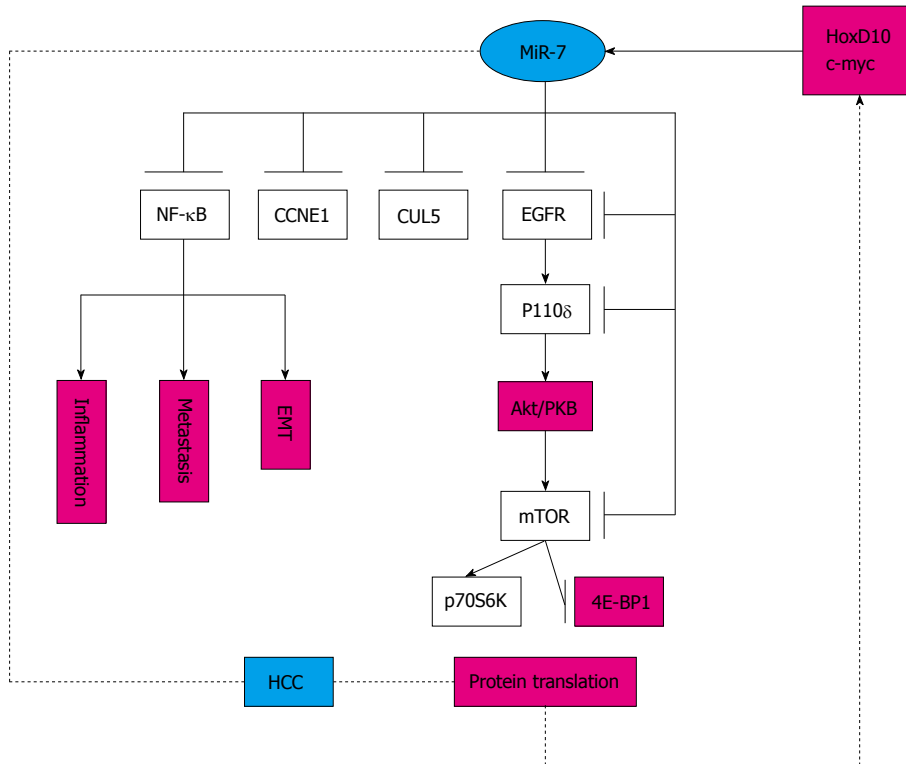

Figure 4 Pathway of miR-7 in hepatocellular carcinoma. MiR-7 can target various genes in the specific signaling pathway. HCC: Hepatocellular carcinoma; miR-7: MicroRNA-7; NF-κB: Nuclear factor κB; CCNE1: Cyclin E1; CUL5: Cullin 5; EGFR: Epidermal growth factor receptor; mTOR: Mammalian target of rapamycin; EMT: Epithelial–mesenchymal transition.

a member of the highly conserved cyclin family, CCNE1 (cyclin E1), is inversely correlated with miR-7 expression in HCC cell lines and clinical samples, indicating that it is a downstream mediator for miR-7, and miR-7 might be a candidate for the treatment of HCC^[40]. Most studies in this field have been *in vitro* experiments, except one^[28]. The detailed mechanisms remain to be elucidated, thus, the exact role of miR-7 in HCC needs further research (Figure 4).

OTHER DIGESTIVE MALIGNANCIES

MiR-7 also plays a role in other digestive tract malignancies such as cholangiocarcinoma and ESCC^[29,41]. However, the expression and exact role of miR-7 in these two malignancies need to be verified.

INFLAMMATORY DISEASE

Inflammation makes a significant contribution to carcinogenesis and progression of malignancies^[42]. In some conditions, inflammation such as chronic atrophic gastritis is defined as a precancerous lesion of GC. MiR-7 also participates in some inflammatory diseases, in addition to malignancies. The role of miR-7 in the progression from chronic inflammation to GC has been studied more thoroughly compared with other inflammatory diseases. Using established mouse models, Kong *et al.*^[20] have demonstrated that downregulation of miR-7 induced by PGE2 associated with inflammation, and activation

of EGFR are critical steps in gastric carcinogenesis. Although the COX-2/mPGES-1/PGE2/EP2 pathway has been identified in gastric tumorigenesis, whether there is a similar mechanism mediated by miR-7 has not been established in other malignancies. It has been revealed that the expression of miR-7 is decreased in actively inflamed colonic tissues from patients with Crohn's disease, which is regulated by hCD98^[25]. Similarly, chronic hepatitis has an important influence on HCC development, and hepatocyte nuclear factor 4α and NF-κB form a feedback circuit, for which miR-7 and miR-124 could be the targets^[43]. These findings suggest that miR-7 is involved in many inflammatory diseases by activating many inflammatory/proinflammatory cytokines, and it will be intriguing to demonstrate the role of miR-7 in the regulation of alimentary inflammatory responses and carcinogenesis.

CIRCULATORY BIOMARKER

The diagnostic and prognostic biomarkers for some digestive malignancies including GC and CRC are still limited. Common circulatory markers such as carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 have inadequate sensitivity, therefore, exploring specific biomarkers is a significant breakthrough.

MiRNAs are stable in serum, plasma and body fluids (*e.g.*, stools and gastric juice), and their expression differs between tumor and non-tumor tissue. Some miRNAs, like miR-21, have been subjected to meta-

analysis and concluded to be diagnostic biomarkers for GC^[44]. Wang *et al.*^[45] designed their study with three phases. In the discovery phase, they detected 723 miRNAs in 80 serum samples using microarrays; in the training phase they experimented on another 112 plasma samples using qPCR; and finally, they confirmed the results with 49 samples using a logistic model, and screened miR-7 as one of a panel that yielded high diagnostic accuracy to diagnose CRC. Compared with CEA, miR-7 has a higher receiver operating characteristic curve, sensitivity and specificity (0.897, 82% and 89%, respectively). Similarly, by analyzing the serum from 12 acute pancreatitis patients and three healthy controls, Liu *et al.*^[46] identified miR-7 as one of the three diagnostic and prognostic biomarkers. Although several systematic reviews^[44,47-49] have investigated biomarkers for GC, none has shown that miR-7 could be a biomarker of GC.

CONCLUSION

Several studies have identified possible mechanisms mediated by miR-7 in specific malignancies of the digestive system, including some inflammatory diseases. No study has investigated miR-7 comprehensively, which may explain why different studies have discovered different targets for miR-7, or it may be because miRNA can form one-to-one, one-to-multiple or multiple-to-one relationships with its target genes^[50]. Disruption of homeostasis in the digestive system is due to many pathways acting together in a complicated manner, which contributes to the progression from inflammatory diseases to malignancy. Furthermore, the genetic abnormalities in tumors are highly heterogeneous, and no two tumors are exactly alike, which raises a serious challenge. Consequently, more research should be conducted to verify whether miR-7 could be a biomarker or therapeutic target gene for digestive system malignancies.

Abstract

AIM: To investigate the impact of *RAS* and *BRAF* mutations on the pattern of metastatic disease and carcinoembryonic antigen (CEA) production.

METHODS: In this retrospective study, we investigated the impact of *RAS* and *BRAF* mutational status on pattern of metastatic disease and CEA production. Only patients presenting with a newly diagnosed metastatic colorectal cancer (CRC) were included. Patients' characteristics, primary tumor location, site of metastatic disease and CEA at presentation were compared between those with and without *RAS* and *BRAF* mutations.

RESULTS: Among 174 patients, mutations in *KRAS*, *NRAS* and *BRAF* were detected in 47%, 3% and 6% respectively. *RAS* mutations (*KRAS* and *NRAS*) were more likely to be found in African American patients (87% vs 13%; *P* value = 0.0158). *RAS* mutations were associated with a higher likelihood of a normal CEA (< 5 ng/mL) at presentation. *BRAF* mutations were more likely to occur in females. We were not able to confirm

any association between mutational status and site of metastatic disease at initial diagnosis.

CONCLUSION: No association was found between *RAS* and *BRAF* mutations and sites of metastatic disease at the time of initial diagnosis in our cohort. Patients with *RAS* mutations were more likely to present with CEA levels < 5 ng/mL. These findings may have clinical implications on surveillance strategies for *RAS* mutant patients with earlier stages of CRC.

Key words: *RAS*; *BRAF*; Carcinoembryonic antigen; Pattern of metastatic disease; Surveillance

Core tip: We investigated the impact of *RAS* and *BRAF* mutations on pattern of colorectal cancer (CRC) metastases and carcinoembryonic antigen (CEA) production. Patients with *RAS* mutations were more likely to present with CEA levels < 5 ng/mL. No association was found between *RAS* and *BRAF* mutations and sites of metastatic disease at the time of initial diagnosis in our cohort. Our study is the first study to link low CEA production with a *RAS* mutant status at the time of initial presentation of metastatic CRC. These findings may have clinical implications on surveillance strategies for *RAS* mutant patients with earlier stages of CRC.

Impact of *RAS* and *BRAF* mutations on carcinoembryonic antigen production and pattern of colorectal metastases. *World J Gastrointest Oncol* 2016; 8(1): 128-135 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i1/128.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i1.128>

INTRODUCTION

Colorectal cancer (CRC) continues to be the second leading cause of cancer-related death in the United States. It is projected that 136830 individuals will be diagnosed with CRC in 2014 in the United States, 50310 of whom will succumb to this disease^[1]. While significant progress has been made in the treatment of metastatic CRC (mCRC) over the last two decades, cure amongst these patients remains rare and is only achievable in approximately 20% of patients who are amenable to metastases resection^[2,3].

It is estimated that 20% of patients with CRC present with metastatic disease while another 30% develop metastatic disease after an initial presentation with local or regional disease^[2,4]. Patients with limited oligometastatic disease are the ones who benefit the most from aggressive surgical strategies^[5]. Therefore, early identification of metastatic disease remains key in improving the outcome of patients with metastatic disease. Indeed, intensive surveillance strategies in

patients with earlier stages of CRC have been associated with an increased rate of metastectomies in several prospective and retrospective clinical trials^[6]. However, these surveillance strategies are not standardized amongst different medical societies and do not take into account the molecular heterogeneity of CRC^[7]. It has been recently shown that certain oncogenic alterations have significant impact on disease biology, response to treatment, and overall outcome. For example, *BRAF* mutations, present in 5%-10% of CRCs, are associated with worse prognosis, a worse overall survival after disease recurrence, and a tendency to metastasize to the peritoneum and distant lymph nodes^[8,9]. The impact of *KRAS* and *NRAS* mutations, which occur in approximately 50% of CRCs, on the pattern of metastatic disease at initial presentation has been more controversial^[10-13].

To better understand the impact of the commonly tested *RAS* (*KRAS* and *NRAS*) and *BRAF* mutations on metastatic disease pattern and on surveillance strategies, we conducted a single institute retrospective study that investigates the impact of *RAS* and *BRAF* mutations on the pattern of metastatic disease and carcinoembryonic antigen (CEA) production.

MATERIALS AND METHODS

Study population

We retrospectively reviewed all cases with metastatic colon cancer patients who presented to City of Hope Comprehensive Cancer Center from 2007 to 2014. Inclusion on study required all the following criteria: (1) confirmed CRC by pathology; (2) availability of imaging studies confirming metastatic disease at the time of presentation; (3) availability of *KRAS* or *BRAF* testing by PCR or by ONCO44 or ONCO48 next generation sequencing; and (4) available CEA level at the time of presentation of metastatic CRC.

Patients' characteristics including age, gender, race, location of the primary tumor, CEA, and sites of metastatic disease at the time of presentation were reviewed and collected from corresponding electronic medical records. Primary tumor location was categorized as right or transverse colon, left colon, and rectum. Metastatic sites were categorized into 3 groups: (1) lung; (2) liver; and (3) mesenteric or distal lymph nodes or peritoneum. The study was approved by the local institutional review board.

RAS and *BRAF* analysis

To allow for a more powerful sample size, we included *RAS* and *BRAF* analysis performed by either a CLIA certified next generation sequencing or a CLIA certified PCR assay.

Onco 44: Genomic DNA is extracted from micro-dissected cells from formalin-fixed, paraffin-embedded tissue with minimum 30% tumor cellularity. A targeted DNA library is generated using the Ion AmpliSeq™ Cancer

Hotspot Panel Kit, and sequenced by semiconductor-based next-generation sequencing technology on an Ion Torrent PGM. The Onco 44 panel is designed to target 713 mutations in 44 key cancer genes that include *KRAS*, *NRAS*, and *BRAF*. Tested *KRAS* mutations include codon 12, 13, 61 and 146. Tested *NRAS* mutations include codon 12, 13, 61.

Onco 48: The Onco48 Panel is designed to target 2800 mutations in 48 key cancer genes. The difference between Onco 44 and 48 is the additional sequencing of 4 target genes: *EZH2*, *GNA11*, *GNAQ*, and *IDH2*. In addition, the Onco48 panel identifies the rare *KRAS* codon 117 and *NRAS* codon 146 mutations.

***KRAS*-PCR:** DNA was extracted from micro-dissected cells from formalin-fixed, paraffin-embedded tissue with minimum 30% tumor cellularity. A PCR based fragment analysis with 5% sensitivity using "Shift Termination" technology was used to detect mutations in the *KRAS* gene. This assay is CLIA approved and detects 6 mutations on codon 12 and 1 mutation on codon 13 of exon 2.

***BRAF*:** Genomic DNA is extracted from micro-dissected cells from formalin-fixed, paraffin-embedded tissue with minimum 30% tumor cellularity. A real-time PCR assay with 1% sensitivity was performed to detect the c.1799 T > A (V600E) mutation in the *BRAF* gene.

CEA assay

CEA was tested via Siemens Advia Centaur chemiluminescent immunoassay and normal range is 0.5 ng/mL to 4.5 ng/mL.

Statistical analysis

We tested for differences in proportions between rate of mutations vs clinical and demographic factors with Fisher's Exact Tests. We also tested for differences in proportions between rate of mutations vs site of metastatic disease, location of primary disease, and CEA (cut point of 5 ng/mL) with Fisher's Exact Tests. For testing the association between metastases site and CEA as a continuous variable, we transformed CEA using

the natural logarithm and used it as the independent variable in a logistic regression. The dependent variable in the logistic regression was presence or absence of a given metastases location.

KRAS and *NRAS* mutations were categorized under *RAS* mutations, irrespective of the testing methodology. Comparative analysis was performed on 4 distinct subgroups: *RAS* mutant, *RAS* wild type, *BRAF* mutant, and *BRAF* wild type populations.

RESULTS

The study population consisted of 174 patients who presented with metastatic colon cancer patients and documented *RAS* and *BRAF* mutational analysis. Genomic evaluation for *KRAS*, *NRAS*, and *BRAF* was performed by next generation sequencing using ONCO44 or ONCO48 in 122 patients. 52 patients were evaluated for *KRAS* (no *NRAS* evaluation) and *BRAF* mutation by PCR. Eighty-seven (50%) of patients had an identifiable *RAS* mutations (47% *KRAS* and 3% *NRAS*). Only 11 patients (6%) had *BRAF* mutation (Table 1).

RAS and *BRAF* mutations and patients' demographics

The median age of the study population was 60 years (range 23 to 87 years). There was no difference in *RAS* or *BRAF* mutation status by age, or gender. However, females had a trend towards a higher incidence of *BRAF* mutation. No distinct variations were noted in *KRAS* or *BRAF* mutations by race, with the exception of an increased rate of *RAS* mutations among African Americans. However, African American representation on this study was low (5%), limiting the interpretation of this finding (Table 1).

RAS and *BRAF* status, primary tumor location and pattern of metastases

There was no difference in primary tumor sites by *KRAS* or *BRAF* status, with the exception of a lower likelihood of *BRAF* mutations among rectal cancers. In addition, no difference in tumor spread pattern at the time of metastatic disease presentation was noted among the 4 molecular subgroups (Table 2).

***RAS* and *BRAF* status and CEA production**

Thirty-four percent of the total cohort were non-CEA producers (CEA < 5 ng/mL). Patients with liver metastases were more likely to produce CEA (OR = 0.639; *P* < 0.0001) while patients with peritoneal/mesenteric metastases were less likely to produce CEA (OR = 1.315; *P* = 0.0010). Patients with *RAS* mutation were more likely to be low-CEA producers at the time of metastatic disease presentation (Table 3). There was no significant association between *BRAF* mutation status and CEA production.

DISCUSSION

In this study we sought to explore correlations between *RAS* and *BRAF* mutational status, patient demographics, metastatic disease pattern, and CEA production. No distinct demographic characteristics were associated with *RAS* or *BRAF* status, with the exception of *BRAF* mutations which were less likely to occur with a rectal primary. Although not statistically significant, females were more likely to harbor a *BRAF* mutation. These findings are consistent with prior reports^[9,12,14,15]. We were not able to confirm an association between *BRAF* mutations and age or a right colon primary, contrary to previous reports^[9,12,14,15]. This discordance is likely related to our more limited sample size, especially that the percentages of *RAS*-mutant and *RAS*-wild type patients with right colonic primaries were in line with the above referenced studies. We also investigated the impact of race on *RAS* and *BRAF* mutational status. The only positive association was for *RAS* mutation and African American race. Several studies have previously evaluated the impact of race on *RAS* and *BRAF* mutational status^[16,17]. The N0147 adjuvant clinical trial in patients with stage III colon cancer reported an

increased likelihood of *BRAF* mutation amongst White and an increased *KRAS* mutation frequency in African Americans^[18]. In addition, N0147 reported a lower frequency of *KRAS* mutations in Asians, a finding not supported by our study.

Contrary to the current literature, we did not find an association between *BRAF* mutation and peritoneal metastases at the time of presentation, likely due to our small *BRAF* mutant sample size. Several studies have reported an increased likelihood of peritoneal dissemination in *BRAF* mutant mCRC patients^[8,9,19]. Yaeger *et al*^[9] reported that patients with *BRAF* mutations were more likely to present with peritoneal metastases at initial diagnosis and less likely to have liver-limited metastases. Moreover, the 2-year cumulative incidence of peritoneal metastases was higher with *BRAF* mutated tumors^[9]. Tran *et al*^[8] reported a higher rate of peritoneal and distant lymph node metastases and a lower rate of lung metastases in *BRAF* mutated tumors. Similarly, Russo *et al*^[19] reported a higher likelihood of *BRAF* mutations in patients with distant lymph node metastases at the site of first recurrence. Finally, Kawazoe *et al*^[12] retrospectively studied the clinical-pathological features of *BRAF* mutations in Japanese patients with metastatic CRC and found that peritoneal metastases are more frequently observed in *BRAF* mutated patients. Since the presence of peritoneal metastases has been identified as a poor prognostic factor, a higher incidence of peritoneal metastases in *BRAF* tumors may partly explain the poor prognosis associated with this subgroup^[12,20,21]. These studies are summarized in Table 4.

Our study did not confirm an association between *RAS* mutations and lung metastases at initial mCRC presentation. There is discordance among studies on the impact of *RAS* mutational status on lung metastases at the time of initial mCRC presentation. However,

clinical studies have consistently shown an association between *KRAS* mutation and lifetime likelihood of lung metastases in patients with mCRC, but not at initial presentation (Table 5). In our previous study, conducted on a different patient data set, Sharma *et al*^[22] reported no predictive role for *KRAS* mutations on the site(s) of metastatic disease at the time of presentation. Pereira *et al*^[13] retrospectively evaluated patients with mCRC who were tested for *KRAS* mutation at MD Anderson Cancer Center. They did not report an increase rate of lung

metastases in *KRAS* mutated patients at the time of diagnosis of mCRC. However, *KRAS* mutation was found to have a shorter time to lung metastases and a two-fold greater odd of developing lifetime lung metastases in a cohort of a liver-limited CRC. However, several other studies reported that *KRAS* mutant patients were more likely to present with lung metastases than *KRAS* wild type patients. Kim *et al*^[23] reported on the initial metastatic disease patterns in South Korean patients with mCRC. Lung metastases were more frequent

as the initial metastatic site in *KRAS* mutant patients while liver and distant lymph node metastases were less likely^[23]. Yaeger *et al.*^[11] reported on the impact of *KRAS* mutations on the pattern of metastatic spread in CRC. In this retrospective study, *KRAS* mutant patients had a higher incidence of lung metastases at initial presentation compared to *KRAS* wild type patients. In addition, *KRAS* mutated patients had higher cumulative incidence of lung, bone and brain metastases at two years from initial mCRC presentation. Fewer patients had liver-limited disease at the initial presentation in *KRAS* mutated patients than *KRAS* wild type patients^[11]. *KRAS* mutations have also been associated with a higher risk of lung relapse while *NRAS* mutations were associated with increased local recurrence after curative resection of primary CRC or after curative intent hepatectomy^[10,24,25]. Review of patients with stage II and III primary CRC who participated in VICTOR clinical trial showed an association between *KRAS* mutations and an increased relapse rate in the lung. Relapse in the liver was similar between *KRAS* mutant and wild type patients^[10]. Kemeny *et al.*^[24] reported on the pattern of metastatic disease recurrence in patients who underwent hepatic resection and adjuvant HAI plus systemic chemotherapy. The three-year cumulative incidence of lung metastases was higher in the *KRAS* mutant patients. The cumulative incidence of bone and brain metastases was also increased in the *KRAS* mutant patients. Similarly, Vauthey *et al.*^[25] reported that patients with *KRAS* mutant tumors who underwent curative intent liver resection at MD Anderson cancer center had a lower three-year lung RFS in comparison to patients with *KRAS* wild type tumors. Based on the above studies (summarized in Table 5), *KRAS* mutant mCRC patients have an increased lifetime risk of developing lung metastases. However, the impact of *KRAS* mutational status on the incidence of lung metastases at the initial time of diagnosis of metastatic disease remains controversial. Whether the lack of association between lung metastases at presentation and *KRAS* mutations is related to a limited sample size on those studies vs being the result of tumor biology remains unclear.

We have studied the impact of *RAS* and *BRAF* mutational status on CEA levels at the time of initial diagnosis of metastatic disease. We did not find any difference in CEA levels between *BRAF* mutant and *BRAF* wild type mCRC at initial presentation. In contrast, *RAS* mutant mCRC patients were more likely to be non-CEA producers (62% *RAS*-MT vs 38% *RAS*-WT) (Table 3). Our findings are in contrast to a study by Selcukbiricik *et al.*^[26] which reported a higher percentage of patients with CEA > 5 ng/mL among the *KRAS* mutant cohort. Selcukbiricik study was limited by stage heterogeneity (stages I-IV) and did not include an analysis of the impact of *RAS* mutation within the stage IV disease cohort. Our study also showed an association between CEA levels and site of metastatic disease. CEA was more likely to be elevated in patients with liver metastases

and lower in patients with peritoneal or mesenteric recurrence, which is consistent with prior reports^[27].

Our study has several limitations. This is a single institution study with a relatively small size. Modest associations between *RAS* and *BRAF* status and other clinical variables may have therefore been missed due to the lack of adequate power. In addition, the diagnosis of metastatic disease on this study could have been made during surveillance for disease recurrence or during the work-up of symptomatic disease. Therefore, the conclusions derived from this study may not be clearly generalizable to the surveillance population or to the population presenting with symptomatic stage IV disease. Other limitations include the inclusion of patients with *KRAS* PCR mutation assay (no ONCO48 analysis). This implies that some patients may have been assigned to the *RAS* wild type subgroup without ruling out the possibility of *NRAS* or non-exon 2 *KRAS* mutations. The likelihood of this event impacting our overall results is low as only 52 patients (30%) of our study population was analyzed by *KRAS*-PCR only. Given that less than 10% of the general population carries a non-exon 2 *KRAS* mutation or *NRAS* mutations, we expect that less than 10 patients may have been inappropriately labeled.

In summary, our study is the first study to link low CEA production with a *RAS* mutant status at the time of initial presentation of metastatic CRC. If validated in larger studies, especially in surveillance settings, our findings would have major clinical significance. It has been recently confirmed that *RAS* mutations increase the risk of systemic disease recurrence after a curative resection in patients with stage III colon cancer^[28]. Reliable screening strategies are especially important in this high risk population in order to diagnosis early recurrence and increase the likelihood of curative-intent metastectomies. If CEA is confirmed as a less reliable screening strategy, intense radiographic screening will be especially important as a complement to CEA screening in this population.

COMMENTS

Background

It is estimated that 20% of patients with colorectal cancer (CRC) present with metastatic disease while another 30% develop metastatic disease after an initial presentation with local or regional disease. Patients with limited oligometastatic disease are the ones who benefit the most from aggressive surgical strategies. Therefore, early identification of metastatic disease remains key in improving outcome. It has been recently shown that certain oncogenic alterations have significant impact on disease biology, response to treatment, and overall outcome. To better understand the impact of the commonly presented *RAS* (*KRAS* and *NRAS*) and *BRAF* mutations on metastatic disease pattern and on surveillance strategies, the authors conducted a single institute retrospective study that investigates the impact of *RAS* and *BRAF* mutations on the pattern of metastatic disease and carcinoembryonic antigen (CEA) production.

Research frontiers

BRAF mutations, present in 5%-10% of CRCs, are associated with worse prognosis, a worse overall survival after disease recurrence, and a tendency to metastasize to the peritoneum and distant lymph nodes. The impact of *KRAS* and *NRAS* mutations, which occur in approximately 50% of CRCs, on the

pattern of metastatic disease at initial presentation has been more controversial. No studies have reported on the impact of either *RAS* or *BRAF* mutations on CEA production.

Innovations and breakthroughs

The authors did not find any difference in CEA levels between *BRAF* mutant and *BRAF* wild type mCRC at initial presentation. In contrast, *RAS* mutant mCRC patients were more likely to be non-CEA producers (62% *RAS*-MT vs 38% *RAS*-WT).

Applications

The study is the first study to link low CEA production with a *RAS* mutant status at the time of initial presentation of metastatic CRC. If validated in larger studies, especially in surveillance settings, the authors' findings may indicate that CEA surveillance is less reliable in curatively resected *RAS* mutant CRC patients. Alternative surveillance strategies may be required in this patients population.

Terminology

The ONCO 44/48 is the next-generation sequencing technology at the City of Hope which is designed to target 713 mutations in 44 and 48 key cancer genes.

Peer-review

It is a well-written paper.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Mehdi Ouaisi, MD, PhD, Doctor, AP-HM, Department of Digestive and Visceral Surgery, Timone Hospital, F-13385 Marseille, France

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Approximately thirty percent of patients with gastric

cancer undergo an avoidable lymph node dissection with a higher rate of postoperative complication. Comparing the D1 and D2 dissections, it was found that there is a significant difference in morbidity, favoured D1 dissection without any difference in overall survival. Subgroup analysis of patients with T3 tumor shows a survival difference favoring D2 lymphadenectomy, and there is a better gastric cancer-related death and non-statistically significant improvement of survival for node-positive disease in patients with D2 dissection. However, the extended lymphadenectomy could improve stage-specific survival owing to the stage migration phenomenon. The deployment of centralization and application of national guidelines could improve the surgical outcomes. The Japanese and European guidelines enclose the D2 lymphadenectomy as the gold standard in R0 resection. In the individualized, stage-adapted gastric cancer surgery the Maruyama computer program (MCP) can estimate lymph node involvement preoperatively with high accuracy and in addition the Maruyama Index less than 5 has a better impact on survival, than D-level guided surgery. For these reasons, the preoperative application of MCP is recommended routinely, with an aim to perform "low Maruyama Index surgery". The sentinel lymph node biopsy (SNB) may decrease the number of redundant lymphadenectomy intraoperatively with a high detection rate (93.7%) and an accuracy of 92%. More accurate stage-adapted surgery could be performed using the MCP and SNB in parallel fashion in gastric cancer.

Key words: Gastric cancer; Surgery; Lymphadenectomy; Sentinel node biopsy; Maruyama computer program

INTRODUCTION

In most cases, modern, optimal treatment of patients with different neoplasms can be achieved with a stage adapted, combined modality therapy according to international protocols. In case of solid tumors, the lymph node (LN) involvement and its exact number is the most important prognostic factor. Adjuvant chemotherapy, as well as the oncological outcome is terminated by the tumor-node-metastasis stage. Preoperative imaging techniques provide a much more accurate determination of the T and M stage than that of the N stage. The correct status of LN metastases can be obtained only by histology following an optimally extended node dissection. The removal of further LNs on the other hand, increases operative time, the rate of complications, and if negative may be considered unnecessary.

Almost three hundred thousand patients with gastric adenocarcinoma do not have LN metastasis in the one million new cases each year^[1,2]. The depth of tumor invasion^[3,4], the metastatic LN status and R0 resection are the most important independent prognostic factors for overall and disease free survival (OS, DFS)^[5-7]. Moreover, a lot of study proved that LN metastasis is an independent risk factor for local recurrence as well as the time interval between radical gastrectomy and hepatic metastasis in patients after R0 resection^[8-10].

The aim of this review is to report the latest issues from 2014 according to lymphadenectomy in gastric cancer and compare these results with earlier studies.

LN INVOLVEMENT

Successful estimation of LN involvement may help to define which patients would or would not benefit from an extended LN dissection in association with gastrectomy^[11]. However, preoperative diagnostic tools have a low sensitivity and specificity for defining these patient subpopulations. Sensitivity, specificity and accuracy of spiral computer tomography for detection of pathologic LN involvement are 73.1%, 50.0% and 84.2%, respectively^[11,12]. Endoscopic ultrasonography has an accuracy of 68.6%, with a sensitivity and specificity of 66.7%

and 73.7%, respectively^[11,13]. The real problem of these imaging procedures is that exclusion of endoscopic ultrasonography, only the size of the LNs is taken into account.

In association with T stage, LN involvement can be found in 15% of patients with carcinoma confined to the mucosa, whereas LN metastases were detected in 23.4%, 48.2%, and 69.8% of patients with carcinoma invading the submucosa, muscularis propria and serous layer, respectively^[14]. Gertler *et al.*^[15] showed that not only infiltration of the submucosa but also lymphatic vessel invasion, multifocal tumor growth, younger patient age and poor tumor differentiation were associated with nodal disease. Besides T stage, LN involvement can also be influenced by tumor size. The overall accuracy of tumor size for preoperative N staging was 82.13%^[16]. The incidence of LN metastasis in patients with a cancer size of 3-5 cm is 64.9%, 80% in patients with a cancer size of 5-7 cm and 84.3% in patients with a cancer size of > 7 cm^[14]. Additionally, early gastric cancer (EGC) has nodal metastases in 38.9% in poorly differentiated or undifferentiated types of tumor, in 41.7% with Lauren diffuse type and in 33.3% with a size larger than 3 cm^[17]. Yang *et al.*^[18] found that venous invasion, submucosal invasion or antral tumor location were independent predictors for LN metastasis in multivariate analysis. The rates of LN metastasis were 1.1% for patients with one or no predictor and 17.8% for those with two or more predictors^[18].

While the prognostic significance of macrometastasis in the LNs is obvious, the role of lymphovascular invasion (LVI) or micrometastasis (MM) is controversial. Lee *et al.*^[19] confirmed that the recurrence-free survival is lower in N0/LVI(+) patients than in N0/LVI(-) patients, however they did not find any effect of LVI+ on overall survival. The incidence of LN MM is lower than 10% in patients with node negative EGC^[20] but it is higher in histologically diffuse type tumors^[21]. The presence of MM influenced DFS, although the OS analysis revealed no significant difference between MM-positive and MM-negative patients^[19]. The reverse transcriptase polymerase chain reaction proved to be the most sensitive method in the detection of MM^[22].

Meanwhile, a multivariate survival analysis concluded that the number of examined LN (eLN) was an independent predictor of overall survival of patients with node-negative gastric cancer. According to the cut-point analysis, T2-T4 patients with 11-15 eLN had a significantly longer mean OS than those with 4-10 eLN or 1-3 eLN. Patients with ≤ 15 eLN were more likely to experience locoregional and peritoneal recurrence than those with > 15 eLN^[23]. However, this trend was not observed when the number of examined LN exceeded 30^[24].

These results are potentially associated with the elimination of MM in negative LNs^[25]. Based on these findings, LVI and MM should be considered in postoperative management of gastric cancer^[19].

LYMPHADENECTOMY

D1 vs D2 lymphadenectomy

The adequate extension of lymphadenectomy differs significantly between East Asian and Western countries. Extended lymphadenectomy (D2) is the standard of care in Japan and South Korea, while for example, the majority of United States patients receive at most a limited lymphadenectomy (D1)^[26,27]. This controversy may originate from different factors. First, the incidence of gastric cancer is significantly higher in Asia than in European Union, or in the United States^[27,28].

Second, centralization of treatment has not yet been solved in the latter regions; 80% of Medicare patients with gastric cancer in the United States go through surgery in centers performing less than 20 procedures per year^[29] and there is a significant number of low-volume surgeons performing less than two cases annually^[30,31].

Table 1 shows the primary and revised results of prospective randomized trials (RCT) comparing D1 to D2 lymphadenectomy in association with postoperative morbidity, mortality, frequency of splenectomy and pancreatectomy and long term oncological outcomes such as relapse risk and overall survival (OS). The three earliest studies found a higher morbidity and mortality rate following extended LN dissection of patients with gastric cancer when compared to those undergoing D1 dissection only^[11,32-34]. These higher rates were related mostly to splenectomy and pancreatectomy. Although Dent *et al.*^[32] did not perform resection of these organs, this study should be evaluated with reservations because of the small series size. Furthermore, limited surgical experience could explain these results. The quality control of lymphadenectomy was inadequate, as the non-compliance rate (absence of LNs from more than two LN stations that were supposed to be harvested) was 51% in the D2 group in the Dutch trial^[34,35] and, in the extended group of the British trial, the dissection of LN station no.7 was 63.5%, and was less than 50% in station no.8 and no.9^[36].

Moreover, extended LN dissection did not have any effect on oncological outcomes. The relapse risk and survival were similar in these studies. Only the revision of the Dutch trial showed better survival in advanced disease in the D2 group, after 11-year follow-up^[37]. The 15-year follow-up results revealed that cancer-related death rates were lower (37% vs 48%) with a lower rate

of local recurrence in the D2 lymphadenectomy group (Table 1)^[38]. Subgroup analysis of this trial demonstrated significantly higher survival for females (35% vs 21%) and in stage II disease (33% vs 15%) in the D2 arm. The 15-year survival in patients without pancreatico-splenectomy was significantly higher with D2 than D1 dissection (35% vs 22%)^[38].

The two latest randomized trials from the 21st century did not present significant differences in postoperative mortality between the D1 and D2 group^[35,39]. The morbidity rate was higher with D2 lymphadenectomy in the Taiwanese trial (which compared D1 to D3 dissection; however their D3 lymphadenectomy is similar to the current definition of D2 dissection). The Italian study did not show this difference and proved that D2 dissection could be performed safely without splenectomy and distal pancreatectomy, with comparable mortality and morbidity to those with D1 dissection in specialized centers^[39,40]. These rates are comparable to the Japan Clinical Oncology Group (JCOG) 9501 trial and the nationwide Japanese registry where the mortality was less than 2% after D2 dissection^[41,42]. Neither did the latter study find any survival benefit from the extended lymphadenectomy^[43]. Subgroup analyses showed a 5-year disease-specific survival benefit for patients with pathological tumor 1 (pT1) disease in the D1 group (9% vs 83% for the D2 group; *P* = 0.015), and for patients with pT2-4 status and positive LNs in the D2 group (59% vs 38% for the D1 group; *P* = 0.055). However, the non-compliance rate was 33.6%^[43]. It was concluded that the contamination (over-extensive nodal dissection) (18%) and the higher rate of stage IA disease in the D1 group and of stage IV in the D2 arm, apparently nullified the effect of correct extended dissection^[41,43]. The other randomized trial from Taiwan proved a better (*P* = 0.041) survival with D2 dissection^[44].

The results of these recent studies call attention to the importance of the learning curve and the necessity of standardized procedures with routine preservation of the spleen and pancreas in experienced centers^[40].

Besides the RCT, the latest meta-analysis found significant differences in morbidity, anastomotic leakage, pancreatic leakage, reoperation rates, wound infection, pulmonary complications and postoperative mortality, all of which favoured D1 dissection. The conclusion was that there is no difference in OS when comparing the D1 and D2 arm. Subgroup analysis of patients

with T3 tumor shows a survival difference favoring D2 lymphadenectomy (25.9% vs 11.5%), and there is a trend towards a lower risk of gastric cancer-related death among patients having a D2 dissection with preservation of the spleen or pancreas and non-statistically significant improvement of survival for node-positive patients^[40,45]. Unfortunately, the main problem of meta-analysis was that it was not possible to match patient groups for treatment with age, sex, type of gastrectomy, pathological stage, tumor location, co-morbidity, treatment strategies, surgeon experience, hospital case volume and extent of LN dissection, all of which affect postoperative complications and overall survival rates^[40].

Keeping this in mind, the comparison of oncological outcomes of D1 and D2 dissections in association with different T and N stages could be problematic due to the concept of stage migration. The reason for this is that a limited lymphadenectomy can not represent the adequate staging of LN involvement. Conversely, extended lymphadenectomy could improve stage-specific survival due to the stage migration phenomenon. Furthermore, Xu *et al.*^[46] demonstrated that it is necessary to examine at least 16 LNs for accurate pathological examination of gastric cancer, even in node-negative gastric cancer patients^[25], and Datta *et al.*^[47], who analyzed the data of more than 22000 patients found that the examination of 15 or more LN is a reproducible prognostic factor for gastric cancer outcomes in the United States and should continue to serve as a benchmark for the quality of care.

In addition to the quality of surgery, the pathologist plays a large role in the proper identification and examination of the extracted LN^[48].

EXTENSION OF LYMPHADENECTOMY BEYOND SUGGESTED LIMITS

The latest issue of the Japanese Gastric Cancer Association treatment guideline contains the standard lymphadenectomies regarding the type of gastric resection: Total gastrectomy with D2: D1 (Nos.: 1-7) + Nos. 8a, 9, 10, 11p, 11d, 12a; distal gastrectomy with D2: D1 (Nos. 1, 3, 4sb, 4d, 5, 6, 7) + Nos. 8a, 9, 11p, 12a; pylorus-preserving gastrectomy with D1+: D1 (Nos. 1, 3, 4sb, 4d, 6, 7) + Nos. 8a, 9; and in proximal gastrectomy with D1+: D1(Nos. 1, 2, 3a, 4sa, 4sb, 7) + Nos. 8a, 9, 11p^[49].

In the field of tumor-location specific LN involvement recent studies can be divided into 2 cohorts depend on the position of the gastric tumor (proximal vs middle and distal).

Proximal gastric cancer

The frequency of metastasis in station no.4d, 5 and 6 LNs in patients with proximal gastric cancer is more than 10%^[14,50]. The incidence of station no.10 LN metastasis is 11.82% in upper third advanced gastric cancer (AGC). The estimated OS were 46% and 37% regarding station

no.10 dissection or not, which was not statistically significant. Authors suggest high-quality studies with larger sample sizes to determine the clinical significance of no.10 LN removal^[51]. Following an 18 mo follow-up of 108 patients Li *et al.*^[52] concluded that routine no.10 lymphadenectomy may be unnecessary for advanced, upper third gastric cancer without serosal invasion, unless T3 tumors are located in the greater curvature.

Middle and distal gastric cancer

LN metastasis in station no.2 LNs from distal gastric cancer is only 1.0%, while the metastasis in station no.4 LNs is more than 20%. Since station no.11p is immediately adjacent to stations no.7 and no.9, in the case of distal gastric cancer, station no.11d should be preserved; however, both no.11p and no.11d stations should be removed in cases of proximal gastric cancer^[14]. According to Japanese gastric cancer treatment, as station no.14v is closely adjacent to station no.6, station no.14v LNs should also be removed if suspicion of metastasis to the LNs in station no.6 arises^[14,49].

As the LN metastasis rate in station no.7 was similar to that of perigastric LNs in 570 patients with advanced distal gastric tumor it is reasonable to include LNs in the no.7 station in the D1 LN dissection^[53]. Evaluating LN involvement after total gastrectomy, Galizia found that the incidence of nodal involvement of stations no.10, no.11d, and no.12a was 5%, and the 5-year DFS rate was zero; they concluded that modified D2 lymphadenectomy confers the same oncologic adequacy as standard D2 lymphadenectomy, with a significant reduction of postoperative morbidity^[54].

During investigation of LN involvement of the hepato-duodenal ligament (HDLN) a logistic regression analysis showed that no.5 and no.12a LN metastases were associated with a 6.9 and 11.3 fold increase respectively, for risk of no.12p and no.12b LN metastases. In addition, significant differences in 5-year OS of patients with and without no.12p and no.12b LN metastases were observed^[55]. However, the clinical significance of removing these LN was not evaluated. Analyzing the data of 1872 patients, LN involvement in station no.12 was 3.6% whereas HDLN metastasis was not a significant factor for survival in multivariate analysis and the 5-year survival rate of 41 patients with HDLN metastasis without distant metastasis at any other site was significantly higher than that among 120 patients with stage IV disease without HDLN metastasis. It is suggested that the inclusion of HDLN in the distant metastatic LN group in gastric cancer is inappropriate and that the seventh American Joint Committee on Cancer criteria for node grouping should be revised^[56].

The incidence of no. 14v LN metastasis was 5.0% in 1661 patients who underwent curative resection for middle or lower third gastric cancer. In clinical stages I and II, no.14v LN dissection did not affect overall survival; in contrast, no.14v LN dissection was an independent prognostic factor in patients with clinical stage III/IV

Figure 1 Prediction of lymph node involvement by the Maruyama computer program in a 65-year-old male patient. The tumor histology was well differentiated adenocarcinoma, showing muscular mucosa involvement, early cancer type 2B. The lesion was found in the anterior wall in the lower third of the stomach and had a maximal diameter of 30 mm.

Involvement of no.13 nodes is defined as M1 in the current version of the Japanese classification. However, excision of this LN may be an option in a potentially curative gastrectomy for tumors invading the duodenum^[49].

Para-aortic nodal dissection

In overall 5-year survival Zhang *et al*.^[62] could not demonstrate a significant difference between patients underwent D2 plus PAND surgery and those underwent D2 surgery. He suggests that this "over-extended" dissection should only be recommended for T3-4 and N2 stage

gastric tumor and should not be utilized for EGC and total gastrectomy^[62].

So, the D2 lymphadenectomy is the gold standard in R0 resection by the Japanese^[49] and European guidelines^[27].

The American NCCN guidelines recommend a D1+ or a modified D2 LN dissection, the latter performed by experienced surgeons in high-volume centers^[27,63]. To support this, the deployment of centralization and implementation of national clinical guidelines in Denmark resulted in a decrease in mortality from 8.2% to 2.4% and the proportion of patients with at least 15 LNs removed has increased from 19% to 76%^[64].

MARUYAMA COMPUTER PROGRAM

Figure 2 Sentinel lymph node mapping following submucosal marking by an endoscopist.

93%^[72].

Our study demonstrated a similar degree of reliability of MCP to those cited above, with 90.2% of sensitivity, 63.3% of specificity and 78.4% of accuracy. The rate of false negatives was 9.8%^[73]. These studies demonstrate that the results of the computerized prediction of LN metastases are superior to those of the standard pre-operative imaging techniques.

Another advantage of the MCP is that it can determine long term oncological results. Hundahl defined the Maruyama Index (MI) at first in 2002 as a measure of unresected regional nodal disease in gastric cancer using the data of the Intergroup 0116 trial and he proved it is an independent predictor of survival^[74,75]. Peeters *et al*^[76] reanalyzed the data of the Dutch D1-D2 trial using univariate and multivariate analyses and showed that the MI is an independent predictor of overall survival ($P = 0.016$, HR = 1.45) and relapse risk ($P = 0.010$, HR = 1.72). It was concluded that the MI is a quantitative yardstick for assessing the adequacy of lymphadenectomy in gastric cancer patients^[75,76]. Later, Hundahl evaluated autopsy findings from the Dutch D1-D2 trial and showed that MI < 5 or a low MI for surgery is associated with enhanced regional control and survival^[76,77]. Dikken *et al*^[78] proved the prognostic significance of low MI in a 2-year survival rate (82% vs 59%), as did Sachdev, who demonstrated that lower MI correlated with better survival, as a continuous ($P < 0.02$) and categorical ($P < 0.04$) variable^[79].

Overall these results suggest that a Maruyama Index less than 5 has a better impact on survival, than D-level guided surgery. For these reasons, the preoperative application of MCP is recommended routinely, with an aim to perform "low Maruyama Index surgery". In addition, the application of MCP to predict LN involvement can influence the indication for neoadjuvant chemo-therapy, and furthermore a "high Maruyama Index" could indicate the necessity for postoperative oncological treatment.

SENTINEL LYMPH NODE BIOPSY

While the MCP calculates the probability of LN involvement preoperatively, the concept of sentinel lymph

Figure 3 Subserosal marking by a surgeon.

node biopsy (SNB) can determine the existence of LN metastases intraoperatively. The first potentially affected LN, the sentinel lymph node (SLN), reliably reflects the status of the nodes in the second and third line, which is supported by data of numerous publications. If the SLN contains tumor deposit(s), extended dissection is warranted, but if findings are negative, the patient could be spared additional complications associated with extended dissection. However, the method of dye/tracer injection and the tracer's selection is controversial. Some authors use dye alone (patent blue, indocyanine green, isosulfan blue)^[11,80-82], Kitagawa *et al*^[83] handle 99m Tc colloid, and Aikou *et al*^[84] uses the combination of these tracers. The latest systematic review concluded that the SLN's identification rate is the same with the dual or single mapping method^[85]. It is eminent that body-mass index (BMI) affects the sentinel LN detection rate^[86]. The Hungarian study proved that the identification of sentinel LNs in obese patients can be difficult owing to the feathering of blue dye in the fatty tissues^[11]. This was concluded as the only patient in whom marking did not occur had a BMI significantly higher than average (26.8 vs 22.8)^[11]. Then again, the application of blue dye for SNB has a beneficial side effect, as it significantly increased the number of harvested LN and the ratio of the number of the harvested LN per time^[87]. To avoid quick dispersal to multiple LNs Kong applied ICG/poly- γ -glutamic acid complex, which remained longer than diluted ICG in animal models^[88].

Yaguchi, Lee and Tóth have compared the subserosal to the submucosal labeling method (Figures 2 and 3) without any significant difference and they suggest the endoscopic injection of a tracer in cases of non-palpable tumors and/or laparoscopic procedures^[89-91].

The cardinal problem in the SNB concept is the intraoperative false negative rate. The JCOG 0302 trial called attention to the importance of the learning curve and the inadequacy of the pick-up method. The demand for only five patients per institute provided an insufficient learning period which presented a 46% false negative rate^[92].

Lee *et al*^[93] proved that the removal of entire nodal basins can significantly decrease this rate against the pick-up method, and Kumagai *et al*^[94] called attention to the opportunity of introducing the one-step nucleic acid

amplification test for the intraoperative diagnosis of LN metastasis with similar results to postoperative 2-mm-interval histological examination.

Miyashiro *et al.*^[95] demonstrated that an extensive surgical experience is necessary for application of SNB concept and standardization of SLN mapping technique, using improved tracer, and guideline to evaluate the positiveness of SLN specimen should be planned to incorporate SNB in routine practice^[96]. Recent studies and the latest meta-analysis of SLN mapping have shown a high detection rate (93.7%) and an accuracy of 92%^[97] and suggest that the SNB concept could be suitable for tumors following endoscopic resection^[98] and could represent a new era of sentinel node navigation surgery in EGC^[99,100]. Moreover, its success rate did not correlate to tumor grade^[101].

Based on the results of the largest prospective multicenter trial from Japan with an identification rate of 97.5% and an accuracy of 99%^[102], a phase III multicenter trial for individualized surgery for EGC based on SLN mapping has been commenced in the Eastern Asian countries. The long-term results of these studies will be available between 2018 and 2020.

CONCLUSION

The latest RCT comparing D1 and D2 dissections represents a higher surgical quality (more contamination, less non-compliance, low morbidity and mortality rate) than previous trials^[43]. This could lead to a trend towards the execution of the less limited D1 lymphadenectomy for more experienced and well-trained surgeons, and hopefully the results of western surgeons will achieve a level similar to those of the Asian surgical outcomes in the near future.

On the other hand, the era of multimodal treatment and the increase in elderly patients with serious comorbidities indicates the necessity of a stage- and patient-adapted, individualized surgery in gastric cancer. It was conceived at an expert panel, also: "A D2 lymphadenectomy is preferred for curative-intent resection in advanced, non-metastatic gastric cancer; in patients with EGC or substantial comorbidities, a D1 lymphadenectomy is more appropriate"^[103]. The Japanese guidelines enclose that the AGC should be treated with D2 lymphadenectomy. D1 or D1+ should be recommended as a choice for EGC. D1+ can be an alternate for D2 in high-risk patients^[104]. Inokuchi *et al.*^[105] suggested that the presence of heart or liver disease is a significant risk factor for postoperative morbidity in patients who undergo laparoscopic gastrectomy. Although it did not reduce complications, insufficient LN dissection (for example, D1+ for advanced gastric cancer) might be permissible in high-risk patients as it had no negative impact on gastric cancer-specific survival. More accurate stage-adapted surgery could be performed using the MCP and SNB in parallel fashion.

It is generally accepted that metastases in the SLNs warrant a D2 lymphadenectomy. The authors analyzed

the relevance of MCP in sentinel node positive patients in an earlier study^[73]; while the efficiency of SNB method is superior to MCP, the positive predictive value of MCP and SNB was proven equivalent in the sentinel node positive group and the accuracy of MCP in these cohort of patients was 10% higher. For these reasons it would be interesting to find the appropriate combination of these techniques in the future and we suggest using them simultaneously in the operating room.

Abstract

Helicobacter pylori (*H. pylori*) infection is highly prevalent in human, affecting nearly half of the world's population; however, infection remains asymptomatic in majority of population. During its co-existence with humans, *H. pylori* has evolved various strategies to maintain a mild gastritis and limit the immune response of host. On the other side, presence of *H. pylori* is also

associated with increased risk for the development of various gastric pathologies including gastric cancer (GC). A complex combination of host genetics, environmental agents, and bacterial virulence factors are considered to determine the susceptibility as well as the severity of outcome in a subset of individuals. GC is one of the most common cancers and considered as the third most common cause of cancer related death worldwide. Many studies had proved *H. pylori* as an important risk factor in the development of non-cardia GC. Although both *H. pylori* infection and GC are showing decreasing trends in the developed world, they still remain a major threat to human population in the developing countries. The current review attempts to highlight recent progress in the field of research on *H. pylori* induced GC and aims to provide brief insight into *H. pylori* pathogenesis, the role of major virulence factors of *H. pylori* that modulates the host environment and transform the normal gastric epithelium to neoplastic one. This review also emphasizes on the mechanistic understanding of how colonization and various virulence attributes of *H. pylori* as well as the host innate and adaptive immune responses modulate the diverse signaling pathways that leads to different disease outcomes including GC.

Core tip: Although the incidence and mortality of gastric cancer (GC) is declining in recent decades but it still remains a major threat in developing countries as compared to developed one. Among various etiological agents, *Helicobacter pylori* (*H. pylori*) play a detrimental role in development of GC. Through this review we focus on the recent progress in the field of research on *H. pylori* induced GC and providing the brief insight into *H. pylori* pathogenesis, the role of major virulence factors of *H. pylori* that modulates the host environment

and transform the normal gastric epithelium to neoplastic one.

Khatoon J, Rai RP, Prasad KN. Role of *Helicobacter pylori* in gastric cancer: Updates. *World J Gastrointest Oncol* 2016; 8(2): 147-158 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i2/147.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i2.147>

INTRODUCTION

In 1984 Marshall and Warren^[1] identified *Helicobacter pylori* (*H. pylori*) from gastric biopsy culture. In 1994, *H. pylori* was recognized as definite carcinogen by International agency for research on cancer. *H. pylori* induced gastric cancer (GC) is accountable for 5.5% of global cancer burden^[2].

H. pylori is spiral shaped, gram-negative, microaerophilic, flagellated human pathogen that successfully colonizes gastric mucosa of majority of individuals^[3]. Epidemiologically, the *H. pylori* infection exists all over the world, but colonization rates vary considerably; high in developing compared to the developed world^[4]. *H. pylori* acquisition thought to occur in early childhood. Fecal-oral or oral-oral were considered as possible route of *H. pylori* transmission^[4,5]. *H. pylori* urease is among the various virulence factors that aids in colonizing the highly acidic environment of stomach via breakdown of urea into ammonia, generating hospitable locale for its colonization^[6] (Figure 1). Among the majority of *H. pylori* infected individuals only a small percentage of colonized individuals develop severe clinical disease such as GC. Determining factors responsible for variation in clinical outcomes of *H. pylori* infection are still not well studied. For a longer period of time association between *H. pylori* and GC was debatable. A study from Japan on 1526 patients gives a clear evidence that *H. pylori* infection is significantly associated with risk of developing GC^[6]. Proof that *H. pylori* has an influence on early stages of gastric carcinogenesis is demonstrated by randomized prospective studies which shows association between *H. pylori* eradication and reduction of premalignant tumors^[7,8]. Research on experimentally challenged Mongolian gerbils, provide evidence concerning *H. pylori* eradication with attenuation of developmental process related to GC progression^[9,10]. Together these studies authenticate that *H. pylori* plays a key role in development of GC and indicate that *H. pylori* eradication provide protection against *H. pylori*-induced GC. Interaction among environmental factors, host genetic polymorphism and bacterial virulence attributes collectively influence the clinical outcome of *H. pylori* infections^[11].

This review aims to highlight recent progress in *H. pylori* pathogenesis, especially the bacterial and host factors that are involved in the host-pathogen interaction during persistent colonization. It also highlights the host immune response towards *H. pylori* colonization

and its effect on diverse clinical outcomes, especially on advancement leading to GC.

EPIDEMIOLOGY OF GC

GC is a multifactorial disease. Correa's model describes array of event beginning from chronic active gastritis, atrophic gastritis, intestinal metaplasia, dysplasia and eventually leads to GC^[12] (Figure 2). Risk factors for the development of the GC include interaction among the pathogen, environmental and host-related factors^[13]. World Health Organization recognized *H. pylori* as class I carcinogen in 1994. GC is identified as the fifth most common malignancy and third leading cause of cancer-related morbidity globally, constituting 9.7% of all cancer-related mortality^[14]. Highest age-standardized mortality rate (ASMR) is predicated for Eastern Asia (28.1 per 100000 in men, 13.0 per 100000 in women), the lowest ASMR in North America (2.8 and 1.5 per 100000, respectively)^[15]. Studies reported high mortality rates are from East Asia, Central and Eastern Europe, Central and South America^[15]. Developing countries have high burden of GC compared to the developed world and GC accounts for approximately 70% of both new cases and deaths^[16]. Categorizing on basis of gender, 466900 cases of males were reported from developing as compared to 173700 cases from developed countries and for females the corresponding disease load was 247000 and 102000 cases, respectively. GC is associated with age incidence; commonly occurs in age group of 55 to 80 years, rare among young individual. Frequency of GC rates are two fold higher in males than females^[17].

Over past decades in western nations, GC has considerably declined. The possible reasons behind this reduction include fall in *H. pylori* prevalence accompanied by better hygienic practices and innovative medical diagnostic facility. Despite the decline in GC incidence in developed world, the scenario of developing world is diverse. GC incidence and mortality rate remain very high in the developing nations, particularly in regions of East Asia and South America^[17]. It is expected that if appropriate measures are not implemented the number of estimated GC cases are likely to increase in future.

PATHOLOGICAL DIFFERENTIATION

Majority of gastric malignant tumors are adenocarcinomas. Histologically Lauren categorized gastric adenocarcinoma in intestinal and diffuse subtypes. Intestinal type adenocarcinoma is event dependent, start from chronic atrophic gastritis to intestinal metaplasia to dysplasia and finally carcinoma. Intestinal type adenocarcinoma is more frequent in developing world, common in male, and associated with age incidence, whereas diffuse type occurs more often in younger patients having family history of cancers, more frequent in females, background of atrophic gastritis is not prerequisite condition for its occurrence^[18,19]. Anatomical site of origin is another way of differentiation of gastric adenocarcinoma. Tumors

Figure 1 Interaction between *Helicobacter pylori* type IV secretion system and virulence determinants such as CagA, CagL, lipopolysaccharides, peptidoglycan and vacuolating cytotoxin gene, with mucosal epithelial cells, resulting in alteration of signal pathways, cell polarity disruption and vacuolation, which ultimately leads to death. arising in the cardia region of the stomach are said to be proximal, and those from body and antrum (non-cardia region) as distal. Histological subtypes represent etiological and epidemiological differences between the two tumor sub sites. Globally GC incidence is declining. However, studies show rise in incidence of cardia carcinoma which may be partly due to more accurate reporting and fall in incidence of distal cancers^[20].

H. PYLORI AS A RISK FACTOR FOR GC

Colonization of the stomach by *H. pylori* causes development of gastritis. *H. pylori* is truly an “opportunistic” bacterium that uses various well defined virulence factors as tool for attachment and persistent colonization of human gastric mucosa. The possible transmission route is fecal-oral, but contaminated food or water are also reported^[21,22]. The most likely sources are person-to-person contact in families and/or exposure to a common source of infection such as contaminated water or food as supported by majority of data^[23]. This notion is supported by studies of children in custodial care where the prevalence of infection is higher than expected and from studies of crowded families in which there is at least one infected child^[24].

Before attachment of *H. pylori* to gastric epithelium, it has to first cross the thick mucus layer by adhering to the mucosal surface. This is aided by the presence of unipolar sheathed flagella, which allows *H. pylori* to quickly move from inhospitable low pH of gastric lumen to surface epithelium where pH is high and favorable for its successful colonization despite efforts made by the host to get rid of this bacterium. Non-motile mutant *H. pylori* strains fail to colonize the stomach of gnotobiotic piglets^[25,26]. In majority of infected individuals

colonization results in development of inflammatory and immune responses against *H. pylori*, but in some subjects *H. pylori* infection becomes chronic and leads to induction of gastric inflammation which can eventually lead to destruction of normal gastric glands and their replacement by intestinal-type epithelium resulting in atrophy of gastric mucosa.

The risk for atrophic gastritis depends on pattern as well as extent of distribution of chronic active inflammation. The individuals with lower acid output show a higher tendency towards atrophy^[27]. Reduction in gland size and level of intestinal metaplasia were associated with rise in GC risk by 5- to 90-folds depending on the extent and severity of atrophy^[28].

Increased odds ratios were evident from case-control studies that aimed to seriously study the signs of earlier *H. pylori* infection in GC patients and controls for development of non-cardia GC in presence of *H. pylori* infection^[29]. This fact is supported by data from animal models including Mongolian gerbil model, in which *H. pylori* infection induces atrophic gastritis and GC^[30-32]. A small number of subjects for research purposes were deliberately infected with pathogenic *H. pylori* strain and individuals developed acute inflammation of gastric mucosa with neutrophilic infiltration^[33,34]. Volunteers after several decades when exposed repeatedly to intragastric pH-electrodes contaminated with *H. pylori* developed conditions called “epidemic hypochlorhydria”^[34]. Such hypochlorhydric gastritis can either resolve spontaneously or change into chronic gastritis.

ROLE OF HOST GENETICS

H. pylori infection results in three possible outcomes. First is corpus-predominant gastritis beginning from

Figure 2 Combination of host, bacterial and environmental factors, which act in a synergetic way, resulting in development of precancerous cascade that ultimately leads to development of gastric cancer. ZO-1: Zonula occludens 1; CagPAI: Cag pathogenicity island; JAM: Junctional adhesion molecule; VacA: Vacuolating cytotoxin; CytC: Cytochrome.

atrophic gastritis to hypochlorhydria and finally to GC. Second type results in a pangastritis having slightest impact on the host gastric acid production. Duodenal ulcer is third outcome, where an antrum-predominant gastritis leads to hyperchlorhydria. There arises controversy that infections of *H. pylori* can predispose to two equally exclusive situations. The possible explanation why some people are more expected to develop GC phenotype when compared with others may be due to disparity among individual host response to *H. pylori* infections (Figure 1). Initial evidence for the importance of host genetic polymorphisms was reflected in the study where a rise in incidence of atrophic gastritis and hypochlorhydria was evident from relatives of *H. pylori* induced GC patients than controls^[35].

Pro-inflammatory cytokine like interleukin-1 β (IL-1 β) act as a powerful negative regulator of acid secretion. IL-1 β gene is now considered as a potential contender for host genetic polymorphisms that may elevates GC risk. Individuals possessing IL-1 β gene cluster polymorphisms have 2–3-folds increased risk of non-cardia cancer^[36,37] (Figure 2). Elevated levels of TNF- α in gastric mucosa of *H. pylori* infected individuals were evident from numerous studies. However, down regulation of anti-inflammatory cytokine IL-10, that suppresses the level of pro-inflammatory cytokines including IL-1 β , TNF- α and interferon- γ (IFN- γ) is also reported^[36].

The risk associated with GC development in *H. pylori* infected individuals upsurges 27-folds in individuals with three or four polymorphisms^[38]. This evidently illustrates that interaction between host genetics and environment

plays a key role in progression of GC, by regulating hosts adaptive immune response resulting in transformation of normal gastric mucosa to neoplastic one.

IL-8

Higher expression of chemokine IL-8 and polymorphism (promoter region) has been reported in studies and linked with increased risk for GC^[39]. Study on Caucasian populations proved that relationship among functional polymorphism within Toll like receptor 4, risk of GC and decrease in production of anti-inflammatory cytokine IL-10^[40]. These studies reflect that host genetic polymorphisms are capable of modulating the innate immune response which results, severe inflammation and premalignant lesions in *H. pylori* infected individuals (Figure 2). These studies raises a query that whether *H. pylori* strain characteristics are responsible for increasing cancer risk employed by host genotypes, needs to be studied further. Odds ratios for non-cardia GC were highest for individuals with elevated IL-1 β expression, colonized by *H. pylori* vacAs1-type strains^[41].

It is evident from case-control studies that *H. pylori* successfully form a vital equations with host by its ability to send and receive signals from its hosts^[42,43]. Only certain *H. pylori* strains enhance the possibility of carcinogenesis because the equilibrium is likely different for each colonized individual. For example, individual infected with CagA strains leads to severe gastritis, which results in rise of proinflammatory cytokines levels that are responsible for both amplifying the mucosal inflammatory response as well as reducing the acid

production. This creates a milieu encouraging growth of *H. pylori* that promote inflammation and continually produce oxidative stress, thus augmenting risk for transformation of normal mucosa to neoplastic through series of events (Figure 2).

Cyclooxygenase

H. pylori triggers numerous forms of proinflammatory cyclooxygenase (COX) enzymes. Production of endoperoxide from arachidonic acid is brought by COX enzymes. Enzymes prostaglandin synthases produces prostaglandins and various eicosanoids from endoperoxide^[44]. Important role is played by prostaglandins in regulating physiologic processes for instance immunity and development. Two COX isoforms (COX-1 and COX-2) have been categorized on the basis of variances in expression characteristics and inhibition profiles for nonsteroidal anti-inflammatory drugs (NSAIDs). COX-2 expression is inducible while COX-1 is constitutively expressed in cells and tissues^[45-47]. Expression of COX-2 can be stimulated by proinflammatory cytokines, growth factors such as TNF- α , IFN- γ and IL-1. COX-2 expression are raised in *H. pylori* infected human gastric mucosa, gastric premalignant and malignant lesions^[47-49]. Inhibitors of COX (aspirin and NSAIDs) are associated with reduced risk of non-cardia GC^[50]. Numerous studies demonstrate substantial role of COX-2-generated products involved in promoting neoplasia. Mechanisms like apoptosis inhibition, regulation of expression of cell surface adhesion, and production of promoting factors of neoplasia leads to malignancy^[51,52] (Figure 2).

H. PYLORI VIRULENCE FACTORS

Cag pathogenicity island

H. pylori have genetically heterogeneous genome. A number of *H. pylori* virulence factors are supposed to play an essential role in diverse clinical outcome of *H. pylori* infections. The Cag pathogenicity island (CagPAI) is a 40-kb region, consisting of 32 genes, flanked by 31-bp direct repeats. CagPAI is an island consisting of virulence genes, which are acquired by horizontal transfer. CagPAI encodes a type IV secretion system (T4SS) that is responsible for the entrance of a most remarkably investigated *H. pylori* virulence determinant effector protein CagA^[53-55] (Figure 1). Positive association of CagA was found with peptic ulcer disease^[56,57]. Due to its association with several gastroduodenal pathologies, initially CagA was considered as an indicator for presence of the entire CagPAI but as research speeded up, studies demonstrated that despite its presence, CagPAI intactness and clinical outcome varied.

More or less 70% of *H. pylori* strains from western world and nearly 100% of East Asian strains express virulent protein CagA^[54,58,59]. Majority of *H. pylori* strains induces superficial gastritis but the risk for chronic gastritis, atrophic gastritis, metaplasia, and non-cardia GC with intact CagPAI is much higher compared to those

that lacked it^[56,57,60-66]. Among 32 genes of CagPAI, 18 genes are thought to code for structural parts of a T4SS, this system is responsible for exporting peptidoglycans and cagA into host gastric epithelial cells, *via* forming a pilus like assembly connecting bacterial and host epithelial membrane (Figure 1).

CagA

CagA is terminal gene product of the CagPAI. Classifying *H. pylori* strains on the basis of presence and absence of cagA into cagA-positive and cagA-negative strains. After the *H. pylori* attachment to epithelial cell, CagA is internalized through T4SS apparatus. After translocation, CagA is tyrosine phosphorylated at glutamate-proline-isoleucine-tyrosine-alanine (EPIYA) motif, *i.e.*, EPIYA motif which is associated with cell morphological changes known as "the hummingbird phenotype," which results in increased cellular migration^[67-71].

Polymorphic region of CagA, has been identified within the carboxy-terminal and distinguished by different amino acid sequences. Till date, four distinct EPIYA motifs (EPIYA-A, -B, -C and D) are known^[72,73]. EPIYA-A and -B motifs are present in strains all over the world, whereas EPIYA-C is specific to western world (Europe, North America, and Australia). Variation in number of EPIYA-C sites occurs, while majority of CagA proteins contain a single EPIYA-C site (A-B-C type). The level of phosphorylation of EPIYA-C sites is greater than EPIYA-A and EPIYA-B sites. Risk for development of GC is found to be associated with the number of cagA EPIYA-C in western strains^[74]. EPIYA-D motif is exclusive to East Asian strains (from Japan, South Korea, and China), and strains possessing this motif produces higher level of IL-8 from gastric epithelial cells as compared to strains harboring western A-B-C-type CagA^[72,75].

CagA phosphorylation-dependent host cell signaling

Kinase families of Abl and Src are responsible for phosphorylation of CagA into phospho-CagA. Interaction between phosphorylated CagA and various intracellular effectors, triggers an eukaryotic tyrosine phosphatase (SHP-2), which results in continuous stimulation of extracellular signal-regulated kinases 1 and 2 (ERK1/2), Crk adaptor^[76] and C-terminal Src kinase in a tyrosine phosphorylation-dependent manner. In East Asian A-B-D types, negative response is induced by interactions of phospho-CagA with C-terminal Src kinase resulting down regulation of Src signaling^[77] (Figure 3).

Experimental studies on cell lines revealed that CagA internalization give rise to "hummingbird phenotype". These alterations are characterized by cell elongation and cell scattering^[69,78]. Additional study also indicates that interplay among phosphorylated CagA, dephosphorylation of SHP-2 and down-regulation of focal adhesion kinase, causes cell elongation^[69,79]. A different mechanism of cell elongation by phosphorylated CagA is by making a defect in cell retraction; yet the signaling molecules prerequisite for this phenotype remain vague^[80].

Figure 3 Schematic representation of multiple pathways of *Helicobacter pylori* pathogenesis involved type IV secretion system and internalization of virulence determinants like CagA and oncoproteins; CagA-phosphorylation dependent and CagA-phosphorylation independent pathways leads to cytoskeletal reorganization, increase proinflammatory and mitogenic gene expression. Another major virulent factor, VacA is responsible for alteration of junction and cell polarity by binding with tight junction molecules such as E-cadherin, ZO. VacA also causes mitochondrial membranes depolarization, Cytochrome release from mitochondria to cytosol and caspase-3 activation followed by cell apoptosis. T4SS: Type IV secretion system; VacA: Vacuolating cytotoxin; ZO: Zonoccludins; Cyto: Cytochrome; *H. pylori*: *Helicobacter pylori*.

Phosphorylated CagA obstructs the enzymatic activity of c-Src, which leads to tyrosine dephosphorylation of actin binding proteins such as cortactin, ezrin, and vinculin, ultimately results in cell elongation^[81-83] (Figure 3).

CagA phosphorylation-independent host cell signaling

Non-phosphorylated CagA have a different way of exerting effects within the cell. CagA translocation without phosphorylation leads to aberrant catenin activation, apical-junctional complex disruption and cellular polarity loss^[84-89]. Relation between non-phosphorylated CagA and epithelial tight junction scaffolding proteins, zonula occludens 1 and junctional adhesion molecule A, results in imperfect association of tight junctions at located sites of bacterial attachment. Additional molecules includes E-cadherin, hepatocyte growth factor receptor c-Met, phospholipase C gamma (PL), adaptor protein Grb2, and kinase partitioning defective 1b/microtubule affinity-regulating kinase 2 (PAR1b/MARK2) resulting in mitogenic responses, interruption of cell-cell junctions and cell polarity destruction^[84,87,88,90] (Figure 3). Recent study revealed that CagA directly binds to the cell polarity regulator such as PAR1b/MARK2. This binding prevents kinase PAR1b/MARK2 activity and deregulates the formation of mitotic spindle by cells which affects cell polarity^[88,91].

Studies on transgenic mice revealed the correlation between CagA and oncogenesis by showing that CagA expression led to gastric epithelial cell proliferation and neoplastic changes. However, the following modifications were not detected in mice expressing phosphorylation-resistant CagA^[52].

Presence of contradictory documentation on functionality of CagA as a bacterial oncoprotein in mammals exists besides solid proof provided by animal models.

Pathological alterations described for transgenic CagA mice followed by absence of inflammation, which reflects disparity to what is seen in humans^[52]. Although CagA act as oncoprotein, it remains to be explored why only few individuals inhabited by CagA-positive *H. pylori* develop GC. Recent study demonstrate that *H. pylori* prompts the presence of a host phospholipid, phosphatidylserine where CagA can explicitly interact and gain entry into the cells^[92]. Focus of future research should be to define the exact mechanism of CagA internalization in gastric epithelial, factor responsible for regulation of this process and when during chronic infection CagA delivery in human epithelial cells.

VacA

Another important *H. pylori* virulence gene is vacuolating cytotoxin (VacA), which encodes a bacterial toxin (VacA) that induces series of cascades leading apoptosis of epithelial cells *via* induction of cytoplasmic vacuoles (Figure 4). VacA is found throughout the *H. pylori* strains. The diverse polymorphic form of VacA are related with clinical outcomes^[93]. Considerable genetic variations are found in: The s (signal) region with alleles s1a, s1b, s1c, or s2; the m (middle) region with m1 or m2 alleles; and the i (intermediate) region with type i1 or i2 alleles (Figure 4).

H. pylori strains having combination VacAs1/m1 or vacAs1/m1/i1 are associated with increased risk of progression to premalignant lesion and GC than vacA s2/m2 or vacAs2/m2/i2 strains^[94] (Figure 5).

OTHER RISK FACTORS

Besides *H. pylori*, the following other environmental factors are considered to contribute in the pathogenesis of GC.

Diet

The variations in GC incidence are due to environmental inputs, particular in dietary pattern. Previous accumulating studies have been indicated that downward trend in GC occurrence. This may be due to the advent of widespread refrigeration of foodstuff and reduction in dependency on food preservation. In addition, other studies have suggested that a preventive role of diet containing fresh vegetables and fruits. However, data from European prospective study failed to show an overall association between fresh fruits and vegetables intake and GC risk^[95]. Recent studies being conducted on this field revealed that a significant association between total dietary vegetables contents (onion and garlic intake) and intestinal GC subtypes.

Additional studies are required for demonstration of positive association between *H. pylori* eradication and prevention of cancer. The controversy related to point of no return in case of atrophy and metaplasia is still debatable. Proposed studies on side effects and expenses of such preventive measures are required in future for proper management and treatment of GC, therefore GC prevention remains a key part of research on *H. pylori*.

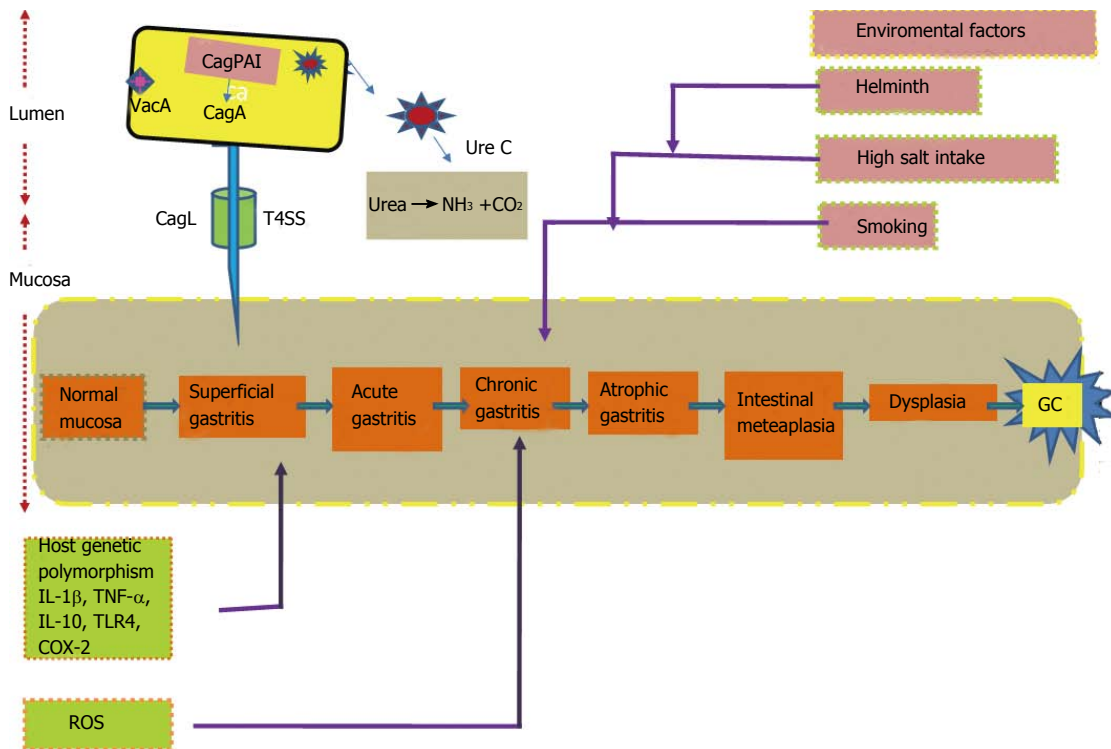

Figure 4 Representation of *Helicobacter pylori* major virulence factor, vacuolating cytotoxin containing three domain 1: signal sequence(S) 2: middle region (m) 3: recently identified intermediate region (i) s, m and i region are further stratified into the subtypes s1, s2, m1, m2 and i1, i2 respectively. TLR4: Toll like receptor 4; T4SS: Type IV secretion system; VacA: Vacuolating cytotoxin; CagPAI: Cag pathogenicity island; GC: Gastric cancer; ROS: Reactive oxygen species.

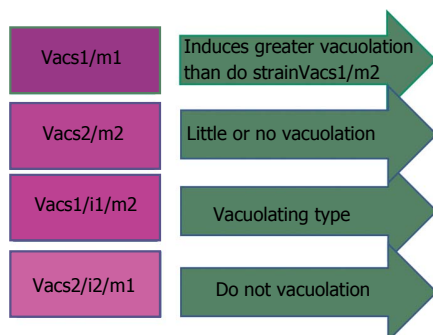

Figure 5 Vacuolating cytotoxin of *Helicobacter pylori* may have any combination of signal sequence and mid region with different virulence activities as stated above. Vac: Vacuolating cytotoxin.

Salt

H. pylori is not the only the culprit for the development of GC; other influential causes include host polymorphisms and environmental elements (Figure 2). High dietary salt intake was found to be uniformly been associated with an increased risk of GC^[12,96]. Two studies, one study from Japan and other a case-control study from South Korea stated that *H. pylori*-infected subjects taking high-salt diet had an greater risk of GC than those with lower levels of salt^[97,98]. Association between the frequency of *H. pylori* infection and amount of dietary salt intake is reported in another study^[99].

Research on Mongolian gerbils had shown that the *H. pylori* presence and usage of a more salt containing

diet applied concerted effects on development of precancerous satge^[100,101]. Additional study on *H. pylori*-infected gerbils demonstrates that there is a positive association between level of severity of gastric inflammation and rate of proliferation of epithelial cells in gerbils consuming high-salt diet than those consuming a normal diet^[100]. Similar studies on gerbils infected with *H. pylori*, when treated with carcinogen (N-methyl-N-nitroso urea) shows that higher frequency of GC related with animals consuming high-salt diet as compared to animals with a normal diet^[101,102].

Mechanisms behind the high-salt diet increases the risk of development of GC in humans remains unclear. Among various explanations, one plausible hypothesis is that salt may lower the threshold for malignant transformation by altering the physiology of gastric epithelium thus allowing entry of carcinogens into gastric tissue and resulting in damage to gastric mucosa. Another possibility is that high salt intake might be regulating the gene expression in *H. pylori*. Two independent studies suggested that consumption of excess amount of salts in diet leads to higher expression of *H. pylori* virulence factors^[103,104].

Dietary antioxidants

Many studies had proved the antioxidants present in food in green vegetables and fruits plays a preventive role against progression of GC^[105]. There is scarcity on studies on association of *H. pylori* infection with nutritive elements in gastric carcinoma. A case-control study

recommended that consistent excessive consumption of vitamin C and carotene might be able to curtail the casual for developing GC in subjects having infection of *H. pylori*^[106].

A randomized study on population susceptible for GC development demonstrated that combination of vitamin C and carotene dietary supplements and *H. pylori* eradication increases the preneoplastic lesions regression at 6 years of follow-up; at another 6 years follow-up lacking dietary supplements, the protective role of vitamin C and carotene gradually end up^[7]. These results were also validated by other studies^[95,106]. A similar study from Hawaii proof that consumption of fresh vegetable among *H. pylori* infected individuals provided a little protection against GC occurrence^[107]. On the contrary, other studies fail to provide a positive association between *H. pylori* infection and plasma vitamin C level, with risk of GC incidence^[108]. Additional research is required to determine whether antioxidants are capable of providing protection against GC among *H. pylori* infected patients.

Cigarette smoking

It is evident from various studies that cigarette smoking is associated with risk of developing GC in *H. pylori* infected subjects. In Japan, cigarette smoking and *H. pylori* infection together are considered as potential threat for developing GC^[109]. Swedish and German population-based case control studies also demonstrated combination of cigarette smoking and infection by CagA positive *H. pylori* strains increased the risk of developing GC (Figure 2). Los Angeles study also reported a tendency toward increased risk of GC in smokers^[59,110]. On collectively analyzing studies, it emerges that there exists relationship between *H. pylori* infection and smoking with increased risk of developing GC.

Helminth infection

H. pylori co-infection with helminths may have some impact in disease pathogenesis. Reduced Th1 response associated with higher levels of Th2 cytokines was reported in one study^[111]. Another study on Colombian children from a coastal region having infection of both helminths and *H. pylori*, showed a higher Th2 associated IgG1 response^[112]. Further studies are needed to assess the impact of *H. pylori* and helminthes co-infection in disease pathogenesis.

FOCUS OF FUTURE ENDEAVORS

Gastric cancer remains a major threat to mankind. Improvement in living standards, increase awareness in sanitation and hygiene practices, reduction in intake of salted food products and advent of refrigeration in households resulted in measurable decline both in incidence of *H. pylori* infection and GC. Although both *H. pylori* infection and GC are showing decreasing trends in the developed world, they still remain a major threat to

human population in the developing countries. Therefore, there is a need for improvement in early diagnosis, identification of risk factors, and development of preventive strategies and initiation of timely therapeutic interventions, especially focused for the developing countries. Further, it remains to be investigated why a small fraction of individuals colonized by *H. pylori* develop GC, and future research should focus on bacterial, host genetics, environmental and dietary factors.

There is need to formulate clear cut recommendation for screening and timely intervention of high risk population with family history of GC. Whether all high-risk areas should undergo routine screening of *H. pylori* infection is still questionable. Since the patients having atrophic gastritis or dysplasia in the gastric mucosa are at increased risk of developing GC, there is a need for special recommendations including endoscopic surveillance for such patients.

Abstract

Because of the aging of the population, prevalence of

medical checkups, and advances in imaging studies, the number of pancreatic cystic lesions detected has increased. Once these lesions are detected, neoplastic cysts should be differentiated from non-neoplastic cysts. Furthermore, because of the malignant potential of some neoplastic pancreatic cysts, further differentiation between benign and malignant cysts should be made regardless of their size. Although endoscopic ultrasound (EUS) has a very high diagnostic performance for pancreatic cystic lesions among the various imaging modalities, EUS findings alone are insufficient for the differentiation of pancreatic cysts and diagnosis of malignancy. In addition, cytology by EUS-guided fine-needle aspiration (FNA) has a high specificity but a low sensitivity for diagnosing malignancy in pancreatic cystic tumors. The levels of amylase, lipase, and tumor markers in pancreatic cystic fluid are considered auxiliary parameters for diagnosis of benign and malignant cysts, and a definitive diagnosis of malignancy using these parameters is difficult. Thus, in addition to EUS, cytology by EUS-FNA, and cystic fluid analysis, new techniques based on EUS-guided through-the-needle imaging, such as confocal laser endomicroscopy and cystoscopy, have been explored in recent years.

INTRODUCTION

Because of the aging of the population, prevalence of medical checkups, and advances in imaging studies, the number of incidentally detected pancreatic cystic lesions has increased. Pancreatic cystic lesions include a variety of entities, including non-neoplastic pancreatic pseudocysts, such as those resulting from pancreatitis, and retention cysts, as well as neoplastic pancreatic cysts and solid tumors with cystic degeneration. As differential diagnosis of these lesions is important in the consideration of therapeutic strategies^[1], it is essential to differentiate between neoplastic pancreatic cysts, including intraductal papillary mucinous neoplasm (IPMN), mucinous cystic neoplasm (MCN), and serous cystic neoplasm (SCN), and to further determine whether they are benign or malignant^[1].

Diagnostic imaging modalities used in the evaluation of pancreatic cystic lesions include abdominal ultrasound (US), contrast-enhanced computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), and endoscopic retrograde pancreatography (ERP). US is a non-invasive method but is affected by the presence of gastrointestinal gas, making the evaluation of the entire pancreas difficult. Although CT is superior in depicting solid lesions, radiation exposure and allergic reactions to contrast media, limit its application. MRCP is superior in depicting pancreatic cystic lesions, while EUS is highly valued, as it provides high image resolution despite the presence of gastrointestinal gas, allowing close observation of the entire pancreas. Although ERP is superior in depicting details of the pancreatic duct and allows a pathologic diagnosis by cytology of the pancreatic juice at same time, attention should be paid to pancreatitis as a potential complication of endoscopic retrograde cholangiopancreatography (ERCP). At present, the lesions are comprehensively diagnosed by a combination of these methods. In recent years, EUS, EUS-guided fine-needle aspiration (FNA), contrast-enhanced EUS, and other modalities of interventional EUS, have been especially useful in the accurate differentiation of pancreatic cystic tumors^[1,2].

TRANSPAPILLARY DIAGNOSIS

A transpapillary approach is significant for the diagnosis

of either, main-duct or branch-duct type of IPMNs formed in the pancreatic duct^[3]. This approach allows to demonstrate the presence of mucus, and is also effective in the diagnosis of concurrent pancreatic ductal carcinoma. However, for the diagnosis of SCNs and MCNs, which generally do not communicate with the pancreatic duct, the transpapillary diagnostic approach not only lacks significance but may also causes pancreatitis after ERCP. IPMN are pancreatic cystic tumors in which transpapillary diagnosis is significant.

Pancreatic juice cytology

As the pancreatic juice in IPMNs is viscous and often difficult to aspirate, pancreatic juice cytology is used to improve the diagnostic performance of ERCP by allowing the collection of pancreatic juice *via* an implanted endoscopic naso-pancreatic drainage tube. Branch-duct type IPMN, which communicates with the main pancreatic duct, is well indicated for this technique because mucus-containing abundant tumor cells are found in the main pancreatic duct.

IPMNs are high mucous-producing and often well-differentiated adenocarcinomas, even when they are cancerous. Therefore, the diagnosis of this type of tumors using pancreatic juice cytology is difficult. To overcome these limitations, the genetic analysis of pancreatic juice is being studied to aid the objective evaluation of malignancy. Such studies show that tumor markers, including carcinoembryonic antigen (CEA), telomerase activity, matrix metalloproteinase activity, human telomerase reverse transcriptase, mRNA, sonic hedgehog, K-ras, and p-53, present in pancreatic juice may be useful in the assessment of cancer risk in patients undergoing ERP, while complementing pancreatic juice cytology findings^[4-10].

EUS DIAGNOSIS

The differential diagnosis of pancreatic cystic lesions can be made by focusing on EUS findings, *i.e.*, size, number, overall cyst shape, state of cyst walls, and features of cystic contents, as well as the presence of underlying lesions^[11]. Sedlack *et al*^[12] classified 34 resected pancreatic cystic lesions into two groups: A group of benign pancreatic cysts, including simple cysts, pseudocysts, and SCNs, and a group of malignant or malignant potential lesions including MCNs, IPMNs, neuroendocrine tumors with necrotic lesions, and cystic adenocarcinomas. Comparison of the diagnostic performance between the 2 groups showed that EUS had a sensitivity, specificity, and diagnostic accuracy of 91%, 60% and 72%, respectively. Song *et al*^[13] evaluated 75 pancreatic cysts (58 neoplastic pancreatic cysts and 17 pancreatic pseudocysts) using EUS, and showed that, while intracystic debris and pancreatic parenchymal changes were characteristic EUS findings of pancreatic pseudocysts, the presence of septa and nodes were typical of neoplastic pancreatic cysts. Song *et al*^[13] reported that although EUS is useful in the diffe-

rential diagnosis of pancreatic cystic lesions, it might be insufficient on its own, to completely differentiate pancreatic cysts. In addition, in a multicenter study conducted by Brugge^[14] to evaluate the performance of EUS in the diagnosis of pancreatic cyst malignancy, low sensitivity, specificity, and diagnostic accuracy values of 56%, 45% and 51%, respectively, were observed. Moreover, Ahamad *et al.*^[15] demonstrated that the diagnostic accuracy of EUS for pancreatic cysts and non-cystic lesions varied from 40% to 93% among 8 endoscopists, indicating that experience and skills influence the diagnostic performance of this method.

DIFFERENTIATION OF PANCREATIC CYSTIC LESIONS USING CONTRAST-HARMONIC EUS

Differentiation between neoplastic (IPMNs, MCNs, and SCNs) and non-neoplastic pancreatic cystic lesions is important. Although there are sporadic reports on the use of B-mode imaging for pancreatic cystic lesions diagnosis^[16,17], reports on similar studies using contrast-harmonic (CH)-EUS are limited. However, because CH-EUS clearly depicts the internal structure and shape of lesions, it appears to be useful for picking up the characteristic imaging findings of each lesion. Compared to conventional B-mode imaging, CH-EUS facilitates pancreatic duct observation by depicting it as a structure without blood flow. In consequence, communication between a lesion and the pancreatic duct, an important aspect for differentiation of pancreatic cystic lesions, can be easily confirmed. In cases of IPMN in which a structure is observed in the dilated pancreatic duct, differentiation between a mucinous mass or tumor resulting from papillary growth by B-mode imaging, is often difficult. However, the CH mode allows their differentiation according to the presence or absence of blood flow.

EUS-FNA DIAGNOSIS

In Japan, because of a reported incident of peritoneal metastasis caused by EUS-FNA for IPMN^[18], doctors have become reluctant to perform the procedure. However, EUS-FNA is commonly used for the diagnosis of pancreatic cystic tumors worldwide, as well as for the evaluation of pancreatic cystic fluid, in terms of its nature (mucinous or serous), cytology, and measurement of CEA/amylose levels^[19].

The nature of the cystic fluid collected by EUS-FNA is important for differentiation of pancreatic cystic tumors. IPMNs and MCNs, or SCNs should be suspected if the fluid is mucinous, or serous, respectively.

The cytology of pancreatic cystic tumors by EUS-FNA, has a high specificity for diagnosis of malignancy similar to that of ERP, albeit with a low sensitivity. Moreover, in cases of multilocular cysts, sufficient specimens may not be collected due to the small diameter of each cyst or

high viscosity of the cystic fluid, which limits its aspiration with a puncture needle. The inability to collect sufficient amounts of cells seems to be the cause of the low sensitivity. The rate of successful collection of specimens required for cytology is reported to be approximately 80%, and the differential diagnostic accuracy for pancreatic cysts ranges from 13%-96%^[12,15,20-26]. In addition, the diagnosis of malignancy has a specificity of 86%-100% and a sensitivity of 25%-88%. The international guidelines for the differential diagnosis between benign and malignant lesions, therapeutic strategies, and follow-up procedures of main-duct and branch-duct type IPMNs were revised in 2012. According to the revised guidelines, the cytological assessment of especially worrisome features (main pancreatic duct diameter of 5-9 mm and absence of either nodes or growth in main-duct and branch-duct type, respectively) is important. The results of a meta-analysis showed that, despite the high specificity and diagnostic accuracy of cytology, its sensitivity is low, with a possibility of misdiagnosing malignant lesions as benign, concluding that cytology needs to be complemented by the additional measurement of CEA, carbohydrate antigen (CA) 19-9, micro-RNA, *etc.*^[27].

Amylase, CEA, and CA19-9 levels in cystic fluid are highly useful for IPMNs, MCN, and SCN differentiation. Amylase levels in cystic fluid are high in IPMNs because they communicate with the pancreatic duct. By contrast, as MCNs and SCNs do not communicate with the pancreatic duct, their amylase levels are typically low. In addition, a cut-off amylase value in cystic fluid set at 250 U/L, has a sensitivity and specificity of 44% and 98%, respectively, for excluding pancreatic pseudocysts from the diagnosis of pancreatic cystic lesions^[28].

CEA levels in cystic fluid are useful for differentiation between MCN (including IPMN) and SCN. A CEA cut-off value in cystic fluid of 192 ng/mL, had a 79% diagnostic accuracy for MCN, which was higher than that of 59% using diagnostic imaging by EUS^[22]. In a cyst containing ≥ 800 ng/mL of CEA in cystic fluid, or diagnosed as malignant by cytology, the specificity for diagnosing the cyst as MCN was 98%-100%. Moreover, a CEA level in cystic fluid ≤ 5 ng/mL had a 95% specificity for the diagnosis of a pancreatic cyst as benign, of which, 6% were, however, MCNs^[28].

A CA19-9 level in cystic fluid ≤ 37 U/mL has an accuracy and specificity for diagnosing a pancreatic cystic tumor as benign of 46% and 94%, respectively. CA19-9 is useful for complementing diagnosis of benign and malignant pancreatic cystic tumors^[28].

Thus, analysis of amylase, CEA, and CA19-9 levels in cystic fluid improves the ability to differentiate mucinous from serous pancreatic cystic tumors. Because malignant SCN is rare, its reliably diagnosis is important. However, levels of amylase, CEA, and CA19-9 in cystic fluid are reportedly not helpful for differentiation of cancer among MCN^[29].

Various attempts have been made to improve the diagnosis of malignancy in pancreatic cystic tumors. As

a reason for the low sensitivity of cystic fluid cytology is the scarcity of cell components in cystic fluid, attempts to collect more cells have been reported. These include, abrasion of cystic wall by brushing^[30]. Abrasion/puncture of cystic wall with the tip of a puncture needle while cystic fluid is aspirated^[31], and direct biopsy of cystic wall with miniature biopsy forceps that can be passed through a puncture needle^[32]. Although of cystic fluid specimens collected by all of these techniques contain more cell components than those collected by conventional aspiration, they have failed to improve the diagnostic performance for malignancy. This is attributed to the fact that the grade of atypism is not always consistent in the cystic wall itself. If target biopsy of nodular lesions can be performed, diagnostic performance may be improved.

Procedural accidents

While serious complications or procedural accidents associated with EUS-FNA for pancreatic cystic lesions have not been reported, pancreatitis (0.5%-4%)^[33], cyst infection (< 1%)^[20,33,34], and intracystic hemorrhage (< 1%)^[15,20,35], rarely occur. Cyst infections can be prevented by infusion of antibiotics before EUS-FNA or oral administration of antibiotics for 2 to 5 d after puncture, while EUS-FNA can be safely performed using a 22-gauge puncture needle^[15,33].

EUS-GUIDED THROUGH-THE-NEEDLE IMAGING OF PANCREATIC CYSTIC TUMORS

Confocal laser endomicroscopy

In many reports, confocal laser endomicroscopy (CLE) has been described as useful for virtual biopsy and provides images similar to pathological images during endoscopic observation^[36]. There are a CLE device that incorporates an endoscope and probe-based CLE (pCLE) in which a probe is inserted through the forceps channel of the endoscope for observation. These devices are reported to be useful for detailed examination of the gastrointestinal tract before therapeutic endoscopy.

Needle-based CLE

A prototype device (Cellvizio AQ-Flex-19®, Mauna Kea Technologies, Paris, France) with a diameter smaller than that of pCLE has been developed. This device can be inserted in an EUS-FNA 19-gauge needle and used to perform EUS-guided needle-based CLE (nCLE) for the diagnosis of pancreatic cysts.

The *in vivo* CLE Study in the Pancreas With Endosonography of Cystic Tumors trial^[37], compared the findings of EUS-guided nCLE with those of pathological analysis. When the findings of nCLE were classified into 3 categories, *i.e.*, epithelial structure, non-epithelial structure, and intracystic floating components, an abnormal epithelial structure, mainly including papillary projections, was a characteristic finding of mucinous

tumors. In addition, nCLE of IPMNs revealed dark aggregates with high cell density in areas suspected of dysplasia, while blood vessels, which are non-epithelial structures, were seen as white bands in other areas. SCNs, only showed non-epithelial structures, whereas no epithelial structure was observed. Although the specificity of the findings of EUS-guided nCLE was 100%, the sensitivity was low, with a value of 57.9%. According to a report indicating that findings reflecting hypervascular patterns of cystic walls and septa of SCNs are useful, there was no technical problem, whereas it was difficult to puncture lesions of the pancreatic head with a 19-gauge needle^[38].

Cystoscopy

Cystoscopy is a diagnostic procedure in which a pancreatic cystic tumor is punctured with a 19-gauge FNA needle, and a SpyGlass probe made of optic fiber directly is inserted into the pancreatic cyst to observe cystic contents and the nature of the cystic wall. According to cystoscopy, the cystic fluid in IPMNs and MCNs is mucus. Regarding the cystic wall, IPMNs have papillary projections or communicate with the pancreatic duct, while MCNs have a smooth cystic wall. However, the cystic fluid of SCNs is clear, while the cystic wall is smooth and has abundant blood vessels.

Combination of cystoscopy and nCLE

In the Diagnosis of Pancreatic Cysts: EUS-guided Through-the-needle Confocal Laser-induced Endomicroscopy and Cystoscopy Trial (DETECT study)^[39], the contribution of the cystoscopy and nCLE combination to further improve diagnostic performance, was evaluated. For the diagnosis of mucinous cysts, the specificity of both cystoscopy and nCLE was 100%, whereas their sensitivity was also relatively favorable with values of 71% and 77%, respectively. Furthermore, when these 2 modalities were combined, the specificity remained at 100%, and the sensitivity was elevated to 88%, indicating an improved diagnostic performance. However, in terms of diagnosis of malignancy, the image quality of cystoscopy and nCLE decreased as the diameter of a probe reduced. Therefore, the image quality of this technique is insufficient at present.

CONCLUSION

We have described the endoscopic diagnosis of pancreatic cystic tumors. While the diagnosis of benign and malignant cysts is especially important, the diagnostic performance of endoscopy is still insufficient. Further advances, mainly in EUS technology are thus awaited in the future.

Abstract

Pancreatic cancer (PC) is a major health problem. Conventional imaging modalities show limited accuracy for reliable assessment of the tumor. Recent researches suggest that molecular imaging techniques with tracers provide more biologically relevant information and are benefit for the diagnosis of the cancer. In addition, radiopharmaceuticals also play more important roles in treatment of the disease. This review summaries the advancement of the radiolabeled compounds in the theranostics of PC.

Key words: Pancreatic cancer; Diagnosis; Therapy; Radiopharmaceuticals; Positron emission tomography

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This review describes the development of radiopharmaceuticals in diagnosis and therapy of pancreatic cancer. We herein discuss the role of the radiolabeled compounds in the preoperative diagnosis, staging, post-therapeutic monitoring, prognosis and the treatment of the disease.

INTRODUCTION

Pancreatic cancer (PC) is a major health problem due to low 5-year survival rate^[1-3]. Surgery is the only curative treatment but less than 20% of cases are suitable to

be respectable during diagnosis for the late onset of the symptoms^[4-6]. Therefore, suitable diagnosis and staging is essential for management of the disease.

Computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS), *etc.*, provide information regarding tumor size, location, and morphology, which can be used for initial staging, tumor evaluation and follow-up. However, it also remain suboptimal in the preoperative diagnosis and may hamper the treatment. The discrimination between benign and malignant lesions are still challenging with these methods^[7,8].

Molecular imaging techniques are important tool capable of providing high sensitive non invasive and quantitative images of various cancer^[9-11]. Radiopharmaceuticals is a key factor in the non-invasive molecular imaging technique which enables specific cellular and molecular processes to be functionally visualized. The development of molecular imaging agents target for specific biomarkers could provide more sensitive and specific cancer detection.

Meanwhile, a number of compounds labeled with therapy radionuclides have been employed for cancer treatment through intratumoral administration^[12-15]. Compared with traditional high-dose external radiation, intratumoral administration delivers more radioactivity to the tumor than the normal structure^[16].

Here, we review the pertinent literatures and the advancement in treatment and diagnosis of PC with radiopharmaceuticals was discussed.

SMALL MOLECULE TRACERS FOR TUMOR IMAGING

¹⁸F-fluorodeoxyglucose

Over the past decade, positron emission tomography (PET) is an important molecular imaging methods in various malignancies^[17-20]. ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) is an analogue of glucose. After injected into the body, it is actively transported *via* glucose transporters (GLUT) into cells, then phosphorylated by hexokinase in the same pathway as glucose. However, unlike normal glucose, the reactions of ¹⁸F-FDG do not proceed further and the corresponding product remains in the cells^[21,22]. Overexpression of GLUT-1 and hexokinase-II has been reported in PC^[23]. In patients with PC, several studies have demonstrated that ¹⁸F-FDG PET/CT was an important key factor for in staging, detecting postoperative recurrence, and evaluating the response to treatment^[24-28]. The recent typical researches and interest findings were listed in the follow.

Preoperative diagnosis: Ergul *et al.*^[29] compared the values of ¹⁸F-FDG PET/CT, multidetector row computed tomography (MDCT), MRI and EUS in the diagnosis and management of the tumor. It revealed that sensitivity of PET/CT were equal to EUS (100%) and higher than those of MDCT and MRI. Meanwhile, Specificity of MDCT

was significantly lower than PET/CT. It suggested that ¹⁸F-FDG PET/CT is an useful imaging techniques for management of the disease^[29].

Maximum standardized uptake value (SUVmax) reflects tumor aggressiveness as a marker of tumor glucose metabolism. Hu *et al.*^[30] found that the SUVmax of benign lesions significantly lower than that of malignant tumors (2.9 ± 2.0 vs 6.3 ± 2.4 respectively). A positive correlation between the SUVmax and Ki-67 was existed. It suggested that the SUVmax of ¹⁸F-FDG can be applied in the differential diagnosis and can also benefit for monitoring the proliferative status of PC^[30].

Nagamachi *et al.*^[31] compared ¹⁸F-FDG PET/CT and ¹⁸F-FDG PET/MRI fusion image in diagnosing tumor. ¹⁸F-FDG PET/MRI fusion image significantly improved accuracy. Results showed that this image technique was useful in differentiating diagnosis^[31].

Zhang *et al.*^[32] reviewed 116 patients with pancreatic cystic tumors who had been treated with different imaging modalities. Compared with CT and EUS, PET had the best sensitivity, specificity and accuracy for detecting malignant cystic tumors^[32].

When the conventional imaging modalities or biopsies are unavailable, PET also plays an important role in diagnosis of PC. Based on the ¹⁸F-FDG uptake pattern, sensitivity, specificity, positive predictive value, negative predictive value, and accuracy for FDG-PET/CT in differentiating benign and malignant lesions were all greater than 85% respectively^[33].

Diagnostic performance of diffusion-weighted MRI and ¹⁸F-FDG PET/CT in the detection of pancreatic malignancy was also obtained by Wu *et al.*^[34]. When diagnosing patients with pancreatic malignancy, the sensitivity of PET/CT was higher than MRI but the specificity of the former was lower than the latter^[34].

Staging: Wang *et al.*^[35] evaluate the value of ¹⁸F-FDG PET/CT on the pre-operative staging of the disease. The sensitivity and accuracy of the imaging modality to detect distant metastasis especially metastatic lymph nodes are significantly higher than those of MDCT. It showed that the extra staging information PET/CT provided could be helpful for screen of surgery^[35].

¹⁸F-FDG PET/CT scans were performed at 17 patients in baseline and six weeks post-CRT. SUVmax significantly decreased during CRT (median pre- 8.0 and post- 3.6). It revealed that the baseline ¹⁸F-FDG PET was benefit for definition of the biological target volume for non-uniform dose prescriptions^[36].

Topkan *et al.*^[37] evaluated the impact of ¹⁸F-FDG PET/CT restaging on management decisions and outcomes in patients with LAPC scheduled for concurrent CRT. According with PET/CT before therapy, these individuals were classified into non-metastatic (M0) and metastatic (M1) groups then received different treatment. Twenty-six point eight percent of distant metastases were detected *via* PET/CT not by conventional staging. Three additional regional lymph nodes were found by PET/CT restaging and the volumes of the tumors were larger

than CT-defined borders. The initial management decisions of 26 patients were changed through PET/CT.

Median overall survival (OS) and progression-free survival (PFS) of M0 patients were greater than those of M1 patients. These findings conformed that PET/CT-based restaging may benefit for screening patients suitable for CRT^[37].

Post-therapeutic monitoring: Picchio *et al.*^[38] evaluated the role of ¹⁸F-FDG PET/CT in screening patients with locally advanced PC for suitable treatment and monitoring the efficacy. Results showed that PET/CT play more important factors in designing the treatment plans for individual patient than conventional CT^[38].

Kittaka *et al.*^[39] performed ¹⁸F-FDG PET in patients classified as responders and nonresponders before and after preoperative CRT. A pre-CRT SUV > 4.7 was seen in 15 (71%) of 21 responders and in 6 (32%) of 19 nonresponders. A regression index > 0.46 was observed in 15 (71%) responders and 5 (26%) nonresponders. It showed that the SUV based on FDG-PET/CT is a useful implement for predicting the response of treatment^[39].

To study whether FDG-PET parameters can predict relatively long-term survival in patients, Chang *et al.*^[40] assess the effect of coregistered ¹⁸F-FDG PET in monitoring radiographically occult distant metastasis (DM) in patients with LAPC. Patients with a baseline standardized uptake value (SUV) < 3.5 and/or SUV decline ≥ 60% had significantly better OS and PFS than those having none, even after adjustment for all potential confounding variables. ¹⁸F-FDG PET can spare one-third of patients with occult DM from the potentially toxic therapy. ¹⁸F-FDG PET parameters including baseline SUV and SUV changes may serve as useful clinical markers for predicting the prognosis in LAPC patients^[40].

Prognosis: Several prognostic factors for PC recurrence have previously been reported including tumor size, T stage, lymph node metastasis, tumor differentiation, lymphovascular invasion, involvement of the surgical margin, and serum carbohydrate antigen 19-9 (CA19-9) level. Yamamoto *et al.*^[41] evaluated whether preoperative ¹⁸F-FDG PET can predict the resectable PC. Among the patients, 34 cases with an SUVmax ≥ 6.0 developed recurrence within half year, however only 3 patients with an SUVmax < 6.0 exhibited early recurrence. The median OS time of patients with a SUVmax < 6.0 was significantly greater than those of patients with an SUVmax ≥ 6.0. Therefore, an SUVmax ≥ 6.0 maybe a significant predictor of recurrence of PC^[41].

The histopathological grade of differentiation is also one of the significant prognostic factors in the disease, especially in the patients with unresectable PC. It was found that a significant correlation of SUVs and pathologic grades existed by ¹⁸F-FDG PET scans in 102 patients with histologically proven pancreas adenocarcinoma. It showed that ¹⁸F-FDG SUV is related with histologic grade and might be competitive predictor for survival^[42].

Xi *et al.*^[43] determined ¹⁸F-FDG SUVmax in patients

with PC at 1 h and 2 h post injection, and the retention index (RI) was defined as the percentage change between the values of two time points. It was found that there existed a significant positive correlation among RI and the tumor, node, and metastasis stage^[43].

Shinoto *et al.*^[44] evaluated whether ¹⁸F-FDG PET can be used as an indicator of preoperative carbon-ion radiotherapy (CIRT) for PC patients. SUVmax was significantly correlated with DMFS and OS. The DMFS and OS in high-SUVmax group were significantly lower than those in low SUVmax group. ¹⁸F-FDG PET might be suitable for determining the indication of preoperative short-course CIRT for patients with resectable PC^[44].

The prognostic role of ¹⁸F-FDG PET/CT in the prediction of PFS and chemotherapeutic response in patients with locally advanced or metastatic PC was also investigated by Moon *et al.*^[45] PFS of the low SUVmax (< 6.8) group was significantly longer than those of the high SUVmax (≥ 6.8) group. Resulted showed that SUVmax may be useful in independent predicting PFS of PC^[45].

The prognostic value of volumetric parameters on preoperative ¹⁸F-FDG PET/CT was assessed. Results revealed that metabolic tumor volume and total lesion glycolysis are independent prognostic factors for predicting RFS and OS. Thus, ¹⁸F-FDG PET/CT can provide useful prognostic information for patients undergoing resection of PC with curative intent irrespective of neoadjuvant treatment^[46].

Choi *et al.*^[47] evaluated the prognostic value of ¹⁸F-FDG PET in patients with resectable PC. The OS and DFS were significantly longer in the low SUVmax group than those of high SUVmax group^[47].

Hwang *et al.*^[48] reviewed retrospectively the medical records of 165 patients with a diagnosis of PC. Patients were allocated to high (> 4.1) and low (≤ 4.1) SUV groups, and median survivals of these patients were 229 d and 610 d, respectively. Furthermore, SUVmax was found to be significantly related to survival in each stage. The median survival was also found to be significantly related to tumor size, site, serum level of CA19-9, distant metastasis, and type of treatment^[48].

Epelbaum *et al.*^[49] evaluated the possibility of dynamic ¹⁸F-FDG PET/CT parameters used as an indicator in the tumor. The OS of patients with a high ¹⁸F-FDG influx was significantly lower than that of patients with a low ¹⁸F-FDG influx (5 and 6 mo vs 15 and 19 mo respectively). Quantitative ¹⁸F-FDG kinetic parameters in newly diagnosed PC correlated with the aggressiveness of disease^[49].

Limitation: Although significant advances have been achieved in ¹⁸F-FDG PET diagnostic technologies, it has some limitations in detecting cancer. Due to increased glycolytic metabolism, ¹⁸F-FDG can also accumulate in the inflammatory cells^[50]. As a result, it often yields false positive interpretations for PET. Kato *et al.*^[51] evaluated the efficacy of ¹⁸F-FDG PET/CT for the differential diagnosis in 47 individuals. It showed that differentiation is difficult by ¹⁸F-FDG PET/CT due to overlapping in

SUVmax between the two diseases. In addition, elevated serum glucose levels may decrease the uptake in tumors for competitive inhibition, which decreased the sensitivity of ^{18}F -FDG PET in hyperglycemic patients^[51]. Therefore, a numbers of other small molecule-based tracers were designed and developed for PET imaging of PC.

3-Deoxy-3-18F-fluorothymidine

A surrogate marker of DNA synthesis, 3-Deoxy-3-18F-fluorothymidine (^{18}F -FLT), is another potential tracer for visualization of proliferating tissues^[52-55]. For differentiation of pancreatic tumors, ^{18}F -FLT PET showed a lower sensitivity but higher specificity than ^{18}F -FDG PET/CT (70% vs 91% and 75% vs 50% respectively)^[56].

RADIOLABELED PEPTIDES FOR PC IMAGING

Peptides and their derivatives have been successfully developed for the tracer due to favorable characteristics such as low antigenicity, high specificity, fast clearance from blood and rapid tissue penetration. Radiolabelled receptor-binding peptides have become important radiopharmaceuticals for diagnosis and therapy in tumor^[57-61]. Recently, a few radiolabeled peptides have been successfully used for PC imaging. It may be a promising imaging strategy for PC diagnosis and treatment.

Radiolabeled RGD analogs

Angiogenesis is necessary for tumor growth and metastasis, and the integrin $\alpha\text{v}\beta 3$ receptor plays an important role in promoting, sustaining, and regulating the angiogenesis^[62]. *In vitro* analysis demonstrated that integrin $\alpha\text{v}\beta 3$ receptor was expressed in 60% of invasive pancreatic ductal carcinomas and would be an excellent target for the early detection of malignant PC^[63]. Radiolabeled Arg-Gly-Asp (RGD) peptides are widely used as integrin $\alpha\text{v}\beta 3$ receptor imaging agents in various types of tumors^[63]. Yoshimoto *et al*^[64] employed ^{111}In -DOTA-c(RGDfK) for the early detection of PC in pancreatic carcinogenesis model. PC lesions as small as 3 mm in diameter as clearly were visualized after injection with the tracer. High tumor-to-normal pancreatic tissue radioactivity ratios were found by ARG analysis. There existed a significant relationship between the uptake of ^{111}In -DOTA-c(RGDfK) and $\alpha\text{v}\beta 3$ -integrin expression. It also found that the false-positive rate of ^{111}In -DOTA-c(RGDfK) was lower than that of ^{18}F -FDG. It revealed that SPECT with ^{111}In -DOTA-c(RGDfK) was benefit for the early accurate diagnosis of PC^[64].

Trajkovic-Arsic *et al*^[65] used ^{68}Ga -NODAGA-RGD PET for $\alpha\text{v}\beta 3$ integrin receptor *in vivo* imaging of spontaneous pancreatic ductal adenocarcinoma (PDAC) occurring in mice. It showed that $\alpha\text{v}\beta 3$ integrin is expressed in human and murine PDAC and can be detected by molecular imaging technologies in PDAC. This strategy can further be exploited for identification of patients with $\alpha\text{v}\beta 3$ integrin positive and application of $\alpha\text{v}\beta 3$ targeted

therapies^[65].

Aung *et al*^[66] performed a preclinical evaluation of ^{64}Cu -RAFT-RGD in a clinically relevant orthotopic xenotransplantation model of PC. It was confirmed that the uptakes of ^{64}Cu -RAFT-RGD in tumor was greater than those of normal tissues. Meanwhile, the tumor to background uptake ratios of the tracers was higher than those of ^{18}F -FDG. It suggested that ^{64}Cu -RAFT-RGD PET imaging might be useful in the diagnosis of PC^[66].

Radiolabeled exendin-4 analogs

Insulinomas are the most frequent hormone-active tumors of the pancreas arising from pancreatic β cells^[67-69]. Recently, glucagon-like peptide-1 receptor (GLP-1R) was found to be massively overexpressed in gut and lung neuroendocrine tumors, especially insulinomas. It provides an attractive target for the cancers^[70-72].

Several radioligands towards GLP-1 receptor have been developed for GLP-1R-positive tumor imaging. At first, the analog of native receptor ligand, GLP-1(7-36) amide, was labeled with ^{123}I and used for GLP-1R imaging. Although preclinical data showed ^{123}I -GLP-1(7-36) amide possessed high accumulation in a RINm5F insulinoma tumor, the low stability of the peptide due to rapid degrading of GLP-1 by the enzyme dipeptidyl peptidase IV (DPIV) limited its clinical use^[73].

Exendin-4 arised from the salivary gland of the gila monster lizard and has a 53% amino acid homology with GLP-1. It is more resistant to the DPIV digestion and binds with great affinity to the GLP-1R^[73]. ^{111}In - and $^{99\text{m}}\text{Tc}$ -labeled exendin-4 analogs have been evaluated for SPECT imaging of GLP-1R in rodents and humans, respectively, and promising results were obtained^[74-77].

The sensitivity, imaging contrast and spatial resolution of PET was significantly higher than SPECT. In the past few years, exendin-4 analogs have been labeled with PET radionuclides for preclinical insulinomas imaging. Exendin-4 labeled with radio metals (^{68}Ga , ^{64}Cu) showed significant uptake in INS-1 insulinoma xenografts^[78,79]. However, the substantial kidney uptake may limit their use in clinical practice due to high radiation exposure to the organs.

^{18}F is the commonly used isotope. It has nearly optimal nuclear decay characteristics and chemical properties for peptide-based receptor imaging studies. In the past few years, exendin-4 analogs have been modified with either a C-terminal or N-terminal cysteine to allow site-specific labeling with a maleimide-selective prosthetic reagent, ^{18}F -FBEM^[80]. *In vivo* study showed that the INS-1 tumor uptake of ^{18}F -FBEM-Cys⁴⁰-exendin-4 was higher than that of ^{18}F -FBEM-Cys⁰-exendin-4^[80]. Based on the above results, other Cys⁴⁰-exendin-4 analogs were developed for GLP-1R imaging^[81,82].

In vitro receptor competitive binding study confirmed that the nine amino acid sequence at C-terminal of exendin-4 was not key for the biological activity or binding to the receptor. Meanwhile, serine is almost same as cysteine except for the difference in hydroxy and sulfhydryl group. Thus, replacing Ser³⁹ with Cys³⁹ could

provide a unique site for attachment of a radiolabeling thiol-reactive group (such as ^{18}F -FBEM) and may have less impact on the binding affinity of the peptide to the receptor^[83]. Xu *et al.*^[83] synthesized a novel ^{18}F -labeled exendin-4 analog, ^{18}F -FBEM-Cys³⁹-exendin-4. The tracer showed specific binding to GLP-1R and had better tumor to background radioactivity ratio and lower abdominal backgrounds than those of ^{18}F -FBEM-Cys⁴⁰-exendin-4^[83]. It suggested that ^{18}F -FBEM-Cys³⁹-exendin-4 may be a potential probe for insulinomas imaging^[83].

Despite the encouraging results, the tedious radio-synthesis would hinder the tracer to widespread use. Recently, a one-step simple procedure for preparing ^{18}F -labeled peptides *via* chelating ^{18}F FAI with NOTA has been reported^[84]. Xu *et al.*^[84] conjugated Cys³⁹-exendin-4 with NOTA-MAL and obtained NOTA-MAL-Cys³⁹-exendin-4. The compound was simply radiolabeled with ^{18}F FAI complex by one step in 30 min^[85]. ^{18}F FAI-NOTA-MAL-Cys³⁹-exendin-4 shows favorable characteristics for insulinoma imaging in mice bearing INS-1 tumor and may be translated to clinical studies^[85].

THERAPY WITH RADIOPHARMACEUTICALS

Recently, only few patients have resectable disease. High-dose external radiation to the pancreas may damage the surrounding organs. The intratumoral administration of radiopharmaceuticals delivers the maximum amount of radioactivity to the tumor with limiting side effects^[86-88].

During the past several decades, implantation of radioactive isotopes for the treatment has been used. Some basic research indicated that ^{125}I seed with continuous low dose rate irradiation may be beneficial to PC^[86-88]. Zhongmin *et al.*^[89] implanted ^{125}I seeds into PC under CT guidance in thirty-one patients with inoperable PC. It was found that overall responding rate was greater than 60% and median survival time was about 10 mo^[89]. The efficacy of intraoperative ultrasound-guided implantation of ^{125}I seeds was also assessed for the treatment of unresectable PC by Wang *et al.*^[90]. Most of the patients achieved favorable pain relief. These studies revealed that ^{125}I seeds implantation was benefit for the treatment of PC patients^[90].

Phosphorus 32 is another ideal unsealed therapeutic radionuclide. Colloid ^{32}P has been applied for the treatment of intracavitary malignancies^[91-93]. Preclinical study showed that ^{32}P -chromic phosphate colloid (^{32}P -CP) through intratumoral injection mainly accumulated in the BxPC-3 human tumor and retained for a long time^[94]. The safety and efficacy of the therapy to PC was also confirmed^[94].

Poly (L-lactic acid) (PLLA) has been widely used as a drug delivery system due to excellent biocompatibility and biodegradability^[95-99]. ^{32}P -CP-PLLA microparticle was successfully prepared and used for brachytherapy in several tumor models^[95-99]. Yang *et al.*^[100] evaluated

its biodistribution, bioelimination, and therapeutic effect in mice bearing BxPC-3 human PC. Results showed that ^{32}P -CP-PLLA was mostly remained at the tumor (> 95% ID) and almost no radioactivity excretion was observed in urine and feces. As compared, some radioactivity (over 5% ID) of ^{32}P -CP colloid was found in the normal organs^[100]. Meanwhile, the tumor volumes was significantly decreased after treatment with ^{32}P -CP-PLLA microparticle^[100]. It showed that ^{32}P -CP-PLLA microparticle might be benefit for the management of PC^[100].

CONCLUSION

Radiopharmaceuticals are favorable diagnostic and therapy facility for PC. The development of new tracers may be beneficial to personalized management of the disease.

Abstract

Hepatocellular carcinoma is the fastest growing cause of cancer related death globally. Sorafenib, a multi-targeted kinase inhibitor, is the only drug proven to improve outcomes in patients with advanced disease offering modest survival benefit. Although comprehensive genomic mapping has improved understanding of the genetic aberrations in hepatocellular cancer (HCC), this knowledge has not yet impacted clinical care. The last few years have seen the failure of several first and second line phase III clinical trials of novel molecularly targeted therapies, warranting a change in the way new therapies are investigated in HCC. Potential reasons for these failures include clinical and molecular heterogeneity, trial design and a lack of biomarkers. This review discusses the current crisis in HCC drug development and how we should learn from recent trial failures to develop a more effective personalised treatment paradigm for patients with HCC.

Key words: Hepatocellular carcinoma; Molecular targets; Genomics; Sorafenib; Tyrosine kinase inhibitors

Core tip: This review discusses the current drug therapy landscape for advanced hepatocellular carcinoma, in particular the reasons for failure of several clinical trials of molecularly targeted therapy and future directions of research to address these problems.

Thillai K, Ross P, Sarker D. Molecularly targeted therapy for advanced hepatocellular carcinoma - a drug development crisis?

INTRODUCTION

Hepatocellular cancer (HCC) is the sixth most prevalent cancer worldwide and accounts for over 745000 deaths a year^[1]. Despite the implementation of screening programs for high-risk individuals, the majority of patients present with incurable disease. Median overall survival for advanced disease remains poor at less than 12 mo and there is an urgent need for more effective treatments^[2]. Global epidemiological patterns vary depending on the prevalence of risk factor. Incidence rates are highest in East Asia in areas where hepatitis B and C are endemic^[3]. However, improved management of early viral hepatitis in Japan has seen a reduction in new HCC cases^[4]. By contrast the upward trends of HCV, obesity and metabolic syndrome in North America and Europe contribute to HCC being the fastest growing cause of cancer related mortality in these regions^[5]. Resection, radiofrequency or microwave ablation, and liver transplantation comprise the mainstay of treatment for early disease offering the only chance of cure, but only one third of patients present with disease suitable for these treatments^[6]. Loco-regional therapy with trans-arterial chemoembolization (TACE) can lead to sustained disease control for intermediate stage HCC^[7,8]. Sorafenib, a multi-targeted tyrosine kinase inhibitor (TKI), remains the only systemic therapy that is effective in advanced disease offering marginal survival benefit without significant improvement in cancer related symptoms or quality of life^[2]. After many years of disappointing results with chemotherapy, sorafenib was thought to herald a new era in HCC treatment with great optimism for molecularly targeted therapies. Disappointingly, several negative first and second line phase III clinical trials ensued. However, the combination of recent extensive genomic studies and biomarker based clinical trials, provide hope for the development of a more personalised treatment paradigm. This review discusses the current concepts and management of advanced HCC with a particular focus on the failure of molecular targeted therapy beyond sorafenib and outlines how this should be addressed.

Current therapy for advanced disease

Despite only marginal benefits with chemotherapy reported in single arm studies, lack of alternative treatments meant its use was routine prior to the advent of sorafenib. Challenges with toxicities (especially in patients with underlying liver disease) led to chemotherapy being reserved for patients with good performance status and preserved hepatic function. Single agents such as doxorubicin, cisplatin and fluorouracil offer response rates of 10%^[9-11]. This increases to 20% with combination regimens, none of which impact survival^[9,12]. The recently

reported EACH trial, a phase III study conducted in China, Taiwan, Korea and Thailand randomly assigned 371 patients with advanced disease to receive either combined oxaliplatin and fluorouracil/leucovorin (FOLFOX4) or doxorubicin^[13]. The trial failed to demonstrate a significant survival difference between each arm, although a trend towards improved outcomes with FOLFOX4 was noted (median overall survival was 6.4 mo for FOLFOX4 and 4.97 mo for doxorubicin; $P = 0.7$; HR = 0.8; 95%CI: 0.63-1.02).

The search for more efficacious treatments eventually led to two large randomised phase III trials that reported a significant survival benefit with sorafenib in close succession. The first, conducted in a European, Australian and American population, demonstrated a median overall survival (OS) of 10.7 mo for patients treated with sorafenib (400 mg BD) compared with 7.9 mo for placebo (HR = 0.69; 95%CI: 0.55-0.87; $P < 0.001$)^[2]. The latter, conducted in the Asian-Pacific region reported that patients treated with sorafenib led to a median overall survival of 6.5 mo compared with 4.2 mo (HR = 0.68; 95%CI: 0.50-0.93; $P = 0.014$)^[14]. The survival advantages in both trials were modest and neither study established any improvement in cancer symptoms or quality of life. Yet this benefit was sufficient for sorafenib to become the new standard of care for patients with advanced disease. Data extracted from the prospectively maintained GIDEON database (Global Investigation of Therapeutic Decisions in Hepatocellular Carcinoma and of its Treatment with Sorafenib) showed that in 3202 patients treated with HCC, adverse events were comparable between patients with Child-Pugh A and Child-Pugh B cirrhosis^[15]. Yet the frequency of serious adverse events was higher in the Child-Pugh B group (60.4% for Child-Pugh B and 36.0% for Child-Pugh A) and median overall survival was shorter 5.2 mo (4.6-6.3) for Child-Pugh B and 13.6 mo (12.8-14.7) for Child-Pugh A (Table 1).

Four separate phase III trials exploring different multi-targeted TKIs have now failed to show superior outcomes to sorafenib. HCCs are vascular tumours and both VEGF and angiopoietin-2 (Ang2) were independent prognostic markers during the SHARP trial and have been associated with tumour growth and metastatic spread^[16]. The success of sorafenib was thought to be predominantly related to its anti-angiogenic properties and subsequent studies aimed to identify more potent anti-angiogenic drugs. Sunitinib, a multi-kinase inhibitor targeting VEGFR, PDGFR, c-KIT and FLT-3 has been approved for use in gastro-intestinal stromal tumours and renal cell carcinomas and was more potent than sorafenib in preclinical models^[17,18]. Phase II studies showed modest benefit in HCC at best although did highlight potential biomarkers such as interleukin-6, stromal-derived factor1alpha and soluble c-KIT, as changes in tumour vascular permeability and circulating inflammatory molecules were associated with poorer outcome^[19-21]. Adverse events in these phase II studies were concerning with liver related toxicities including encephalopathy and hepato-renal syndrome and 5%-10%

Table 1 First line trials with molecular targeted therapies in advanced hepatocellular cancer

of patients died from treatment related causes. The daily dose of 50 mg that is routinely used in other tumour types was deemed too high for patients with HCC where it precipitated liver toxicities including portal hypertension, encephalopathy, oesophageal variceal bleeding, ascites and thrombocytopenia. A subsequent head-to-head phase III study of 1074 patients randomised to either sunitinib or sorafenib patients terminated early due to both futility and safety concerns^[22]. The most frequent grade 3/4 adverse events in the sunitinib group were thrombocytopenia (29.7%) and neutropenia (25.7%) and in the sorafenib group were hand-foot syndrome (21.2%). Overall survival was also significantly lower in the sunitinib arm (7.9 mo *vs* 10.2 mo $P = 0.0014$). Temporary treatment discontinuation was more frequent with sunitinib (76.6% *vs* 58.7%). The failure of sunitinib was likely related to a combination of inadequate dosing, toxicities and trial design, and highlights the need for caution in over-interpretation of phase II data and decision to move to Phase III trials.

Pre-clinical studies identified linifanib as a more potent dual vascular epidermal growth factor receptor (VEGFR) and platelet derived growth factor receptor (PDGFR) inhibitor than sorafenib ($IC_{50} = 25$ nmol for linifanib and $IC_{50} = 57$ nmol sorafenib) and VEGFR ($IC_{50} = 8$ nmol for linifanib and $IC_{50} = 90$ nmmol for sorafenib)^[23]. A single arm phase II trial in the first line setting resulted in a median overall survival of 9.7 mo (10.4 mo in patients with Child-Pugh-A status), which led to a non-inferiority phase III trial with sorafenib^[24]. The study of 1035 patients failed to reach its end-point with an overall survival of 9.1 mo for linifanib and 9.8 mo for sorafenib (HR = 1.04; 95%CI: 0.89-1.22; $P = 0.001$)^[25]. Toxicities of hypertension and hepatic toxicities including encephalopathy were also higher in the linifanib arm.

A single arm first line phase II study of 55 patients treated with brivanib, an ATP competitive inhibitor of several kinases including VEGFR2 ($IC_{50} = 25$ nmol), FGFR-1 (148 nm) and VEGFR1 (380 nmol), resulted in a median overall survival of 10.0 mo^[26,27]. Phase II studies confirmed that brivanib was well tolerated and one patient had a completed response, three had a partial response and twenty-two had stable disease. Yet BRISK-FL, the subsequent phase III direct comparison

trial of brivanib and sorafenib, failed to establish a significant survival benefit (9.5 mo for brivanib *vs* 9.9 mo for sorafenib; HR = 1.06; $P = 0.31$)^[28]. Due to the trial design, in order to demonstrate non-inferiority, brivanib needed to produce a hazard ratio between 1 and 1.08, which it narrowly failed to reach. The BRISK-FL trial highlighted the difficulties in extracting comprehensive survival data from non-randomised phase II trials. Grade 3/4 toxicities for sorafenib and brivanib were hyponatraemia (9% and 23% respectively), elevated liver enzymes (17% and 14%), fatigue (7% and 15%) and hand-foot reaction (15% and 2%). Even if this trial had met its end-point of non-inferiority, the significant toxicity and economic profiles were not more favourable than sorafenib, and thus would have been of little meaningful clinical benefit.

Erlotinib, an epidermal growth factor receptor (EGFR) TKI was tested in a first-line phase III trial in combination with sorafenib compared to placebo/sorafenib in a study of 720 patients with advanced disease^[29]. The combination had not previously been tested in phase II trials, with two single arm phase II studies demonstrating modest disease control^[29-31]. The combined treatment did not improve overall survival (9.5 mo compared with 8.5 mo for sorafenib alone HR = 0.92; $P = 0.2$). Toxicities in the combination arm were also higher resulting in a reduced median treatment duration that may have contributed to its diminished efficacy. This trial demonstrates both the danger of proceeding to large-scale phase III trials without a clear signal of efficacy from earlier phase studies and the difficulties in combining therapies for HCC (especially for drugs that have overlapping toxicities). Robust HCC-specific phase I / II studies are needed to identify optimal dosing of combination regimens (Table 2).

FGF has been pursued as a potential target in HCC and recent data suggests the FGF signalling pathway may play a key role in the development of resistance to anti-VEGF therapies by activating alternative proangiogenic signalling pathways^[32]. Forty-six patients who had not responded to prior anti-angiogenic therapies were treated with brivanib in a single arm phase II study^[33]. The results were promising with a median overall survival of 9.7 mo. A subsequent phase III trial that was conducted in parallel to the BRISK-FL trial compared brivanib with placebo

Table 2 Second line trials with molecular targeted therapies in advanced hepatocellular cancer

Trial	Drugs	Design	n	Median survival	HR	P value
BRISK-PS	Brivanib <i>vs</i> placebo	Superiority	263	9.4	0.89	0.33
			132	8.2		
EVOLVE-1	Everolimus <i>vs</i> placebo	Superiority	362	7.6	1.05	0.68
			184	7.3		
REACH	Ramucirumab <i>vs</i> placebo	Superiority	277	9.2	0.87	0.14
			276	7.6		

as second line treatment failed to meet its end point^[34]. Patients treated with brivanib had a median overall survival of 9.7 mo compared with 8.2 mo in the placebo arm ($P = 0.3$). Yet significant improvements were seen in the secondary end points of overall response rate (10% for brivanib *vs* 2% for placebo $P = 0.003$), disease control rate (61% *vs* 40% $P \leq 0.001$) and alpha-feto protein reduction in 74% of patients with elevated baseline levels ($> 50\%$ reduction seen in 54% *vs* 7%). These indicate that brivanib has anti-tumour activity despite the negative primary outcome. Furthermore, despite stratification the placebo cohort had fewer patients with macro-vessel invasion and a numerically lower median AFP level. The unexpectedly long survival of patients in the placebo cohort has been cited as one of the reasons for treatment failure. As expected, there were also higher rates of treatment discontinuation and elective patient withdrawal from the brivanib arm, which may have reduced efficacy in this group.

Mammalian target of rapamycin (mTOR) is upregulated in many solid tumours including HCC and appears to have a critical role in pathogenesis^[35,36]. A second line study with the mTOR inhibitor everolimus, offered no survival advantage over placebo (7.6 mo for everolimus *vs* 7.3 mo; HR = 1.05; $P = 0.68$)^[37]. Ramucirumab is a fully human monoclonal antibody against vascular endothelial growth factor receptor 2 (VEGFR2), which also failed to improve survival compared with placebo (median overall survival for ramucirumab was 9.2 mo compared with 7.6 mo; HR = 0.86, $P = 0.13$) in the REACH trial^[38]. However, a pre-planned sub-group analysis revealed that in patients with elevated baseline alpha-feto protein (AFP) of more than 400 ng/mL, ramucirumab extended both overall and progression free survival. Grade 3 toxicities that occurred more frequently in the ramucirumab arm included hypertension (12% compared with 4%) and fatigue (5% compared with 2%), but its toxicity profile is otherwise favourable compared to the multi-targeted TKIs. Due to this data, a phase III trial with second line ramucirumab in a select population with AFP > 400 ng/mL is ongoing.

In the majority of patients with HCC, the cancer arises predominantly as a consequence of liver injury secondary to a variety of causes. It is clear that underlying liver pathology affects both outcome and treatment response, suggesting trials need to be stratified according to aetiology as well as Child-Pugh status, histological grade and stage^[39]. Whilst patients with hepatitis B had longer overall survival and shorter time to progression following treatment with sorafenib in the SHARP trial, these results may have been confounded by the imbalance in numbers between patients with hepatitis B and C^[2]. Without prior stratification, it is difficult to analyse the survival between sub-groups, highlighting the need for careful trial design.

Limited understanding of oncogenic drivers mean all recent negative phase III trials were for “all comers”, yet there is marked molecular heterogeneity amongst HCC tumours. Extensive genomic studies have revealed multiple genetic aberrations with more than 30 somatic mutations per tumour^[40,41]. The challenge lies in distinguishing which are oncogenic drivers and which are bystander passenger mutations. Once drivers are identified, trials can be tailored to pertinent pathways. However, several studies have challenged the idea that single biopsies can represent the mutational landscape of the whole cancer. With highly mutated tumours such as HCC, the key is finding the so-called “trunk” mutations that exist in all tumour sites^[42]. Even if a driver is found, inhibiting pathways may induce resistant mutations. Whilst “liquid” biopsies evaluating circulating DNA are under evaluation, further research is needed to validate these techniques before their use in the clinical setting^[43]. One of the barriers to drug development is that many previous HCC trials did not mandate a tissue diagnosis, relying on clinical criteria alone. Several studies have now highlighted histological changes following treatment with loco-regional therapy such as TACE. In a prospective analysis of 80 nodules found in explant livers following transplantation for HCC, 14 cases of mixed hepatocholangiocellular tumours were found in patients who had received TACE whilst none were seen in the treatment-naïve group, implying differentiation into a cholangiocellular phenotype for some patients^[44]. Furthermore, the lack of histology arguably impedes both predictive and prognostic biomarker development. For example, a phase II trial with the selective non ATP competitive c-MET inhibitor tivantinib, did not offer a survival advantage in patients with advanced HCC but a post study sub-group analysis revealed that the overall survival was longer in patients

REASONS FOR THE FAILURE OF PHASE

III TRIALS

Clinical and molecular heterogeneity

So far all phase III trials have unexpectedly failed to reach their end-points. There are several reasons for this.

with high baseline expression of c-MET (overall survival was 7.2 mo for tivantinib and 3.8 mo for placebo HR = 0.38, $P = 0.01$)^[45]. A phase III trial for patients with tumours over-expressing c-MET in the second line setting is on going (NCT01755767). Therefore, several agents that have failed in phase III trials may still be efficacious in sub-groups of patients, emphasising the urgent need for tissue collection and more sophisticated trial designs that accommodate molecular stratification.

Underlying liver cirrhosis

Another challenge when treating patients with HCC is the presence of underlying liver cirrhosis. Historically, clinical trials were reserved for patients with good hepatic reserve so that competing liver morbidity does not overshadow outcomes from malignancy. Yet even in patients with preserved baseline hepatic function, reaching the optimal maximum tolerated dose in patients can be limited by hepatotoxicity. Treatment duration in these trials may have been insufficient to elicit a response. Liver dysfunction and co-existing cirrhosis may affect drug metabolism and due to the consequent changes in the pharmacokinetic and pharmacodynamics profiles of drugs, there is now a trend to conduct HCC-specific phase trials rather than extrapolate results from "all-comer" phase 1 studies conducted in patients with normal or near normal liver function.

There are no approved therapies in patients who progress on sorafenib and who retain well preserved liver function and good performance status. Many centres use cytotoxic chemotherapy (usually with FOLFOX due to results of the EACH trial) despite the lack of clear evidence supporting its use. Due to the lack of effective second-line therapy, patients are encouraged to enter clinical trials of novel agents. By definition, patients suitable for second line trials are more likely to have less aggressive disease than the wider HCC population in whom performance status often deteriorates rapidly on progression and is associated with decompensation of liver function. In a number of the recent second-line phase III trials comparing novel therapies to placebo, there has been unexpected prolonged survival in the placebo cohort, potentially diminishing the survival differences between groups. Although the trend for overall survival favoured brivanib in the second line BRISK-PS trial, the results were non-significant suggesting the study was not sufficiently powered to detect benefits with brivanib against a placebo controlled population in whom survival was unexpectedly long^[34].

Novel direct-acting antivirals (DAA) that target HCV-encoded proteins necessary for viral replication, can offer patients with hepatitis C sustained virological responses (SVR). The increasing use of these novel agents are expected to have a future impact on the incidence of HCV related HCC. Yet the presence of advanced fibrosis will continue to pose a risk for oncogenesis, even in the absence of a detectable viral load, and screening high risk individuals is still required^[46]. The development

of molecular predictive biomarkers could help identify patients that require ongoing surveillance. Furthermore, biomarker based stratification could be used to enrich HCC chemoprevention trials^[47].

Response evaluation

Finally, response criteria in trials must be chosen carefully. Traditional endpoints such as tumour shrinkage relate to chemotherapy treatments and may not be applicable when assessing the benefits of targeted treatments, which can be cytostatic rather than cytoreductive^[48]. Drugs that have been deemed failures in phase III studies may have therapeutic activity in HCC, but insufficient potency to improve conventional end-points in phase III trials^[49]. Furthermore liver disease can elicit an inflammatory response, which can be mistaken for progression resulting in premature cessation of treatment. Thus the use of traditional imaging has been highlighted as insufficient in assessing response in HCC whereby functional imaging provides more useful information. RECIST criteria that is routinely used to measure disease response in many solid tumours, has been recognised as insensitive in HCC. In the SHARP trial, despite an improvement in overall survival, only 2% of patients treated with sorafenib underwent a response by RECIST criteria. The RECIST response criteria were amended to incorporate tumour necrosis induced by treatment. The modified RECIST (mRECIST) measures arterially enhancing lesions that are more representative of residual viable tumour^[50,51]. Large multi-centre clinical trials in patients with HCC pose unique challenges and future study designs must accommodate these in order to exploit the true potential of novel agents in this disease^[52,53].

THE GENETIC BACKGROUND OF HCC

In malignancies such as melanoma, key driver mutations have now been identified, leading to the use of effective targeted therapy that directly translates to improved patient survival^[54]. Despite the presence of more than 40 somatic mutations, there does not appear to be solitary frequent genetic defects in the majority of HCC tumours^[40,41,55,56]. Polydonality has been noted in patients with HCC reflecting a complex genetic landscape. The recently proposed concept of "trunk vs branch" heterogeneity can be applied to HCC, whereby key mutations that drive tumorigenesis exist in both primary and secondary lesions (trunk) and need to be distinguished from those that are only present in a minority of tissue (branch)^[42]. The question remains as to whether the vast number of genetic alterations in HCC reflect multiple "trunk" mutations that would each require inhibition, or if the majority are mere passenger alterations that do not need treating. Recent advances in high throughput sequencing have uncovered several mechanisms of genetic changes, including somatic mutations, copy number alterations, HBV integration and somatic changes of retrotransposons^[55,57]. Whole genome sequencing of 88 primary HCC tumours with

matched adjacent liver tissue revealed the predominant oncogenic mutation was beta catenin (15.9%) which is mutually exclusive with the most frequently mutated tumour suppressor gene Tp53 (35.2%) echoing results from previous genomic studies^[41,55,58,59]. Further mutations have been found in ARID1 and 2 (both of which regulate chromatin remodelling pathways) and rare mutations in RPS6KA3 which codes for RSK2 (a serine threonine kinase of the MAPK pathway)^[60]. A larger study of 503 HCC liver genomes revealed 30 driver genes implicating 11 core pathways in tumorigenesis. Recurrent focal amplifications were seen in 25% of cases, including telomerase reverse-transcriptase (TERT) and CCND1-FGF19. Key oncogenic pathways included TP53-RB, Wnt and mTOR-PIK3CA^[61]. Frequently altered in HCC, somatic TERT mutations have also been found in pre-cancerous cirrhotic nodules and hepatic adenomas, suggesting they play a pivotal role in malignant transformation. Sequencing of the promoter region of tissue taken from 305 HCCs revealed recurrent TERT mutations in 179 samples (59%) at two common mutually exclusive hot spots^[62]. Yet despite a greater understanding of the role of TERT in HCC, its potential as a druggable target remains unknown. A small early phase II study of a telomerase derived peptide, GV1001, failed to elicit any responses, although the trial was not enriched for TERT mutated tumours^[63].

HCC can be classified into two distinct sub-groups based on genetic aberrations^[64-67]. The proliferative subclass is characterised by activation of RAS, mTOR and IGF signalling and has been associated with poor outcomes. This group can be further divided into those with Wnt/transforming growth factor (TGF)- β activation and the progenitor cell group that have higher progenitor cell, epithelial cell adhesion molecules and type 1 cytoskeletal 19 markers. By comparison, the non-proliferative group is more heterogeneous with less shared mutations. The Wnt/beta catenin and JAK/STAT signalling pathways are the most frequently affected pathways, with alterations in as many as 50%-62.5% and 45% of cases respectively^[66,68,69]. Several distinct protein-altering JAK1 mutations have been identified, the majority of which affect the kinase domain^[55,70]. HCC development is often attributed to chronic inflammation triggered by both viral infection and cell necrosis and the JAK/STAT pathway has been identified as a promoter of carcinogenesis in a sub-set of HCC *via* cytokine-induced JAK/STAT pathway activation^[55,71].

Copy number analyses using array based comparative genomic hybridization (aCGH) have revealed recurrent amplifications in genes for p53, Wnt signalling, proliferation pathways with recurrent deletions of genes involved in the immune response, chromatin remodelling and NF- κ B pathways^[72,73]. Furthermore, the DNA virus hepatitis B (HBV), a leading cause of HCC, integrates into the host genome affecting gene expression. Deep sequencing of HCC samples on a background HBV found direct genetic disruption, aberrations of viral promoter-driven transcription, viral-human transcription and copy number changes confirming theories that alternate aetiologies

lead to distinct genetic alterations^[74,75]. Whole exome sequencing of 243 liver tumours revealed mutational signatures that appeared to correlate with specific risk factors for HCC development including CTNNB1 (alcohol) and TP53(HBV)^[76]. In addition, different mutations were associated with varying clinical outcomes. Early stage disease harboured TERT promoter mutations whereas FGF, CCND1, TP53 were associated with more aggressive pathology.

Conclusions from these extensive genetic studies have highlighted not only the heterogeneity of HCC tumours but also the significant differences in key oncogenic drivers of HCC compared with many other solid malignancies. In breast, colorectal and lung for example, MAPK and PI3K as well as EGFR activated pathways dominate progression in distinct cohorts^[77-79]. However, for HCC Wnt/ β -catenin and JAK/STAT pathways have consistently been identified as responsible for key oncogenic signalling. These differences are likely to explain the failures of therapies in HCC that have provided benefit in other malignancies. Comprehensive genetic mapping will undoubtedly aid drug development for HCC but a major challenge is that the majority of pathways found remain "undruggable" and interacting protein kinases must be targeted instead (Figure 1). A selection of key pathways and novel agents recently or currently under investigation are discussed below.

EMERGING TARGETS IN DRUG DEVELOPMENT

MEK inhibition

The RAF/MEK/ERK pathway plays a pivotal role in several cellular process including proliferation, apoptosis and migration^[80,81]. Although RAS and RAF mutations are uncommon in HCC, there is evidence that this pathway is activated in the majority of HCC tumours. Selumetinib, a potent selective MEK 1/2 inhibitor, was assessed in a single arm phase 2 trial in 19 patients who had not received prior systemic therapy. There were no responses and time to progression was short (8 wk). The trial was subsequently terminated at the interim analysis^[82]. Examination of pre and post treatment tissue revealed that four out of five patients achieved significant inhibition of phospho-ERK1/2 in tumours suggesting the failure of selumetinib was not due to lack of target inhibition. A small study assessing in combination with sorafenib resulted in three partial responses and six with stable disease. Whilst these numbers were small and therefore difficult to interpret, it suggests that perhaps this combination should be assessed further^[83]. A phase II study assessing the efficacy and safety of combination inhibition using sorafenib and the MEK inhibitor refametinib, resulted in a median time to progression of 122 d and median OS of 290 d^[84]. Toxicities however were significant with rash, diarrhoea, elevated liver enzymes and vomiting and the majority of patients required dose reductions. Interestingly the best responders harboured a RAS mutation and a proof of concept phase II trial using this combination for

Figure 1 Novel compounds under investigation and their predominant targets. EGFR: Epidermal growth factor receptor; VEGFR: Vascular endothelial growth factor receptor; PDGFR: Platelet derived growth factor receptor; FGFR: Fibroblast growth factor receptor; PI3K: Phosphatidylinositol-4,5-bisphosphate 3-kinase; mTOR: Mammalian target of rapamycin.

patients with RAS mutations is on going (NCT01915602). Crucially, this study is one of the first attempts to select a specific cohort of HCC patients based on molecular genotype utilising cfDNA to detect mutations in RAS. The study raises a number of important issues regarding feasibility and cost given the incidence of RAS mutation is approximately 3%-5%, requiring a large cohort of patients to be prescreened to identify the small group with aberrant genotype (Table 3).

Anti-angiogenic therapy

HCC is a hyper vascular tumour enriched with high levels of angiogenesis due to the presence of growth factors such as vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF)^[85]. A meta-analysis assessing the prognostic value of VEGF expression confirmed that tissue and serum VEGF levels seemed to predict poor disease free and overall survival^[86]. Biomarker data from the SHARP trial also demonstrated that VEGF and angiopoietin-2 [(Ang2) a further critical molecule in angiogenesis] were independent prognostic markers but not predictive of response^[16]. Sorafenib has anti-angiogenic properties and its success fuelled the search for more potent, selective anti-angiogenics. Yet several negative clinical trials have questioned the emphasis on VEGF inhibition in HCC, supporting theories that multiple mechanisms may be in play. As discussed the VEGF inhibitors, sunitinib, linifanib and brivanib failed to prove non-inferiority compared with sorafenib. Some commentators have therefore argued that an antiangiogenic monotherapy "ceiling" has been reached, and combination strategies will be required to extend survival beyond this^[87]. Trials of sorafenib

in combination with other antiangiogenic therapy (bevacizumab), chemotherapy (doxorubicin or FOLFOX) or other molecularly targeted therapy (e.g., everolimus and temsirolimus) are on-going. In order to ensure optimal results with these agents, the development of predictive biomarkers is needed to select patients who are most likely to benefit.

HGF/c-MET pathway

In vitro studies suggest that c-Met may play a role in proliferation, angiogenesis and metastatic spread in HCC and the hepatocyte growth factor (HGF)-cMET axis is therefore an attractive target. Whilst HGF expression in HCC tumours is low compared with surrounding liver tissue, over-expression of cMET has been observed in nearly a quarter of HCC cases and there is some evidence to suggest c-MET expression is a poor prognostic marker^[88-90]. Biomarker data from the SHARP trial revealed that HGF levels correlated with tumour size^[16]. There is also evidence of an interaction between c-MET and both EGFR and VEGF^[91]. Preliminary data from c-MET inhibition with cabozantinib is promising and as previously discussed a phase III trial with tivantinib in patients with high levels of MET expression is on going^[92].

FGFR inhibition

Fibroblast growth factors are trans membrane receptor kinases that signal downstream pathways including the RAS-RAF-MAPK. FGF3/4 is expressed in normal tissue including benign hepatocytes^[93]. Gene array studies and Immunohistochemical expression assays have shown overexpression of FGF3 and FGF4 in HCC tumours that mediate proliferation, cell death and alpha

Table 3 Novel agents currently under evaluation in clinical trials

feto protein (AFP) levels^[94]. Brivanib, in addition to its anti-angiogenic properties as discussed above, is an ATP competitive inhibitor of FGF1-3. Although it failed to improve survival in the first and second line setting, further multi-kinase inhibitors that also target FGFR are currently underway. The lack of response to brivanib may be partly explained by its use in an unspecified population and biomarkers may aid selection of patients likely to respond to inhibition. Lenvatinib, an oral multi-targeted tyrosine kinase inhibitor of VEGFR-1, FGFR1-4, PDGFR β , RET and KIT is currently under evaluation in a non-inferiority study with sorafenib following a phase II trial which resulted in a median time to progression of 12.8 mo (95%CI: 7.23-14.7) and median OS of 18.7 mo NCT01761266^[95]. The REFLECT phase III trial comparing sorafenib to lenvatinib has recently been completed. This trial has attempted to learn the lessons from the previous high profile failures described in this article by utilising stricter criteria for trial entry, excluding poor prognosis groups such as those patients with greater than 50% liver involvement, bile duct invasion, or main branch portal venous infiltration.

Dovitinib, an FGFR, VEGFR and PDGFR TKI demonstrated efficacy in xenograft mouse models and is currently under investigation in a phase II trial^[96,97]. FGF19, located on chromosome 11q13, a region amplified in 10%-15% of HCC tumours, is a potential predictive biomarker for FGF inhibitors and FGF19 targeted antibodies are under investigation in *in vitro* models^[97]. *In vivo* studies with murine models suggest that dual targeting with FGFR and mTOR inhibition impaired tumour growth unlike treatment with the FGFR inhibitor alone providing support for combination trials^[98].

TGF- β signalling

TGF- β signalling plays a role in the micro-tumour en-

vironment promoting epithelial-mesenchymal transition (EMT), dysplastic nodule formation and subsequent HCC development^[99-101]. Patients with higher levels of TGF- β signalling are associated with larger less differentiated tumours with higher levels of AFP^[102]. It remains unclear whether TGF- β plays a role in a sub-group of patients, or in the carcinogenesis of all HCCs due to its dual role in tumour suppression in normal tissue and tumour promotion in HCC. TGF- β inhibitors modulate EMT leading to reduced tumour growth in pre-clinical models. Galunisertib, a selective TGF- β TKI is currently under investigation in a phase II trial (NCT02178358).

Immunotherapy

Recent years have seen a resurgence in the use of immunotherapy, led partly by the success of anti-CTL4 antibodies in solid tumours such as melanoma and more recently antibodies targeting the programmed death (PD) receptor and its ligand^[103,104]. Immunotherapy works by enhancing anti-tumour response, an important mechanism in HCC as the surrounding micro-tumour environment is rich in immune cells. Tremelimumab, a fully human IgG2 monoclonal anti-CTL4 antibody was assessed in a phase II study of 24 patients with HCC on a background of HCV. The drug had a good safety profile and a partial response of 17.6% and disease control rate of 76.4%. Time to progression was 6.48 m (95%CI: 3.95-9.14). Changes were also seen in the predominant variants of HCV as well as a reduction in viral loads. These early reports are promising and suggest that immunotherapy may have the dual benefit of treating both HCC and underlying viral hepatitis. Anti-programmed death ligand 1 (PDL1) inhibitors are checkpoint inhibitors that block T cell activation when bound by PD ligands 1 and 2. Patients with tumours that over-express PD-L1 are associated with a poorer prognosis. In a recently reported phase I / II dose

escalation study, patients received 0.1 to 10.0 mg/kg of the anti-PDL1 agent nivolumab intravenously for up to 2 years. 2 patients had a complete response (CR) and a further 7 patients had a partial response (PR)^[105]. The overall survival rate at 6 mo was 72%. Although these results are from a very small early phase trial, they are highly encouraging and a number of trials using checkpoint inhibitors are now planned in both first and second line settings.

CONCLUSION

The era of personalised medicine and treatment stratification has yet to impact clinical practice of HCC and the failure of several clinical trials has been disappointing. Nevertheless our understanding of this unique disease has improved significantly with the benefit of genomic sequencing and biomarker data from clinical trials. Proof of concept studies such as the ongoing phase II trial with refametinib for RAS mutated cancers and tivantinib for c-MET positive tumours are a step forward in designing adequate trials to maximise potential benefit of novel agents in pre-determined sub groups. Molecular testing, improved clinical trial design and the development of predictive biomarkers should finally see an improvement in survival for this global disease.

Abstract

This review summarizes the current status of neoadjuvant radiation approaches in the treatment of pancreatic cancer, including a description of modern radiation techniques, and an overview on the literature regarding neoadjuvant

radio- or radiochemotherapeutic strategies both for resectable and irresectable pancreatic cancer. Neoadjuvant chemoradiation for locally-advanced, primarily non- or borderline resectable pancreas cancer results in secondary resectability in a substantial proportion of patients with consecutively markedly improved overall prognosis and should be considered as possible alternative in pretreatment multidisciplinary evaluations. In resectable pancreatic cancer, outstanding results in terms of response, local control and overall survival have been observed with neoadjuvant radio- or radiochemotherapy in several phase I / II trials, which justify further evaluation of this strategy. Further investigation of neoadjuvant chemoradiation strategies should be performed preferentially in randomized trials in order to improve comparability of the current results with other treatment modalities. This should include the evaluation of optimal sequencing with newer and more potent systemic induction therapy approaches. Advances in patient selection based on new molecular markers might be of crucial interest in this context. Finally modern external beam radiation techniques (intensity-modulated radiation therapy, image-guided radiation therapy and stereotactic body radiation therapy), new radiation qualities (protons, heavy ions) or combinations with alternative boosting techniques widen the therapeutic window and contribute to the reduction of toxicity.

Key words: Pancreatic cancer; Neoadjuvant; Radiation therapy; Review; Radiation techniques

INTRODUCTION

Multimodal treatment of patients with pancreatic cancer remains one of the largest challenges in gastrointestinal oncology. Surgery is the cornerstone of curative intent treatment^[1], however only 10%-20% of the patients are deemed resectable at presentation while 30%-40% already suffer from locally-advanced, irresectable disease and the remaining group shows distant metastases^[2]. Given a median survival of approximately 24 mo and a 5-year overall survival rate of roughly 10%-20% even in the most favourable group with primarily resectable, locally confined disease, pancreatic cancer remains a disease with one of the most dismal prognosis in oncology^[3].

While neoadjuvant strategies are already part of the standard approaches in most other gastrointestinal tumors (e.g., rectal cancer, esophageal cancer)^[4,5], surgery followed by adjuvant treatment still represents the standard of care for resectable pancreatic cancer. Adjuvant chemotherapy seems the preferred approach in Europe based on the Conko-001 trial^[6], while adjuvant chemoradiation is frequently used in the US based on the GITSG trial^[7] and several non-randomized single-center studies with excellent results^[8-10]. In primarily non-resectable locoregionally confined tumors, mainly definitive-palliative strategies have been used so far, which either consist of systemic therapy alone, combined chemoradiation or various combinations of both^[11-13]. However, the mentioned strategies show limited success in terms of overall prognosis. On the other hand, the high rates of microscopically incomplete resections^[14] with consecutively significant local recurrence rates^[15] and the high frequency of locoregionally confined but primarily non-resectable tumors in combination with the clear advantages of neoadjuvant treatment strategies shown in other gastrointestinal tumor diseases despite clearly more favourable resectability, may form a strong rationale for the use of neoadjuvant strategies both for locally-advanced non-resectable as well as for primarily resectable pancreatic cancer patients.

Such strategies have different aims and include different possible advantages dependent on the resectability of the primary lesion: (1) in primarily non-resectable locoregionally confined pancreatic cancer, the main aim of neoadjuvant chemoradiation consists of tumor shrinkage including a drawback of the tumor from the major vessels to achieve secondary resectability; and (2) in primarily resectable cases, the main aim consists in enhanced local control either by increased probability of microscopic complete resection (R0) due to tumor shrinkage or by sterilization of microscopic tumor remnants in case of a microscopically incomplete (R1) resection. Substantial potential benefits further exist independent of the resection margin: (1) neoadjuvant treatment allows a local response evaluation which may reflect the overall disease prognosis; (2) neoadjuvant chemoradiation usually requires several weeks, which enables a stratification of patients with response or stable disease vs patients with rapid systemic progress. This may allow a potential omission of major surgery in those patients who are unlikely to benefit. The radiation therapy component thereby prevents patients without rapid systemic progression from a worsened overall prognosis due to local progression caused by locally insufficient effects of systemic therapy alone; (3) efficacy of radiation is enhanced in the neoadjuvant setting in comparison to postoperative radiotherapy because of the increased oxygenation of the untreated tissue; (4) the probability that additional therapy must be cancelled due to postoperative complications is reduced; and (5) target volume definition is simplified, resulting in smaller safety margins with consecutively lower dose to organs at risk and reduced toxicities.

Due to the complexity of the disease and the different aims in distinct stages, a variety of neoadjuvant concepts exist. They include chemotherapy, radiation therapy, chemoradiation or combinations like induction-chemotherapy followed by chemoradiation. This review focuses mainly on neoadjuvant radiotherapeutic strategies (radiation alone, radiation with concurrent chemotherapy) and advances in radiation technique rather than neoadjuvant concepts using chemotherapy alone or induction chemotherapy.

Due to the complexity of the disease and the different aims in distinct stages, a variety of neoadjuvant concepts exist. They include chemotherapy, radiation therapy, chemoradiation or combinations like induction-chemotherapy followed by chemoradiation. This review focuses mainly on neoadjuvant radiotherapeutic strategies (radiation alone, radiation with concurrent chemotherapy) and advances in radiation technique rather than neoadjuvant concepts using chemotherapy alone or induction chemotherapy.

NEOADJUVANT RADIOTHERAPEUTIC TECHNIQUES AND CONCEPTS

3D-conformal radiation therapy

3D-conformal radiation therapy has been the standard radiation technique for the treatment of pancreatic cancer for the last two decades. This technique includes three-dimensional treatment planning based on computed tomography as first step. In the neoadjuvant setting, the target volume includes the primary tumor and the regional lymph nodes with a safety margin for daily repositioning error and tumor motion. If and to what extent the regional lymph node areas have to be included into the target volume is indeed part of an ongoing discussion. Multiple radiation fields are arranged in a way to ensure sufficient coverage of the target volume with best possible sparing of organs at risk at the same time (so called forward treatment

Figure 1 Example for a 9-beam intensity modulated radiation therapy treatment plan in a pancreatic cancer patient with simultaneously integrated boost. SD: Single dose; TD: Total dose in 25 fractions; SIB: Simultaneously integrated boost.

planning) with small bowel and kidneys representing the main dose-limiting structures. Usually total doses of 45-54 Gy are applied in conventional fractionation (5-6 wk overall treatment time) in combination with simultaneous 5-FU or gemcitabine based chemotherapy.

Intensity-modulated radiation therapy

Treatment of irregularly shaped target volumes directly adjacent to radiation sensitive organs at risk can generally be improved by the use of so called "complex" photon irradiation techniques like intensity-modulated radiation therapy (IMRT). In contrast to 3D-conformal therapy, IMRT allows the delivery of different doses to certain segments of the same radiation field, creating a so called "fluence matrix" for every beam. By addition of multiple segments within several beams, superior coverage of irregularly shaped target volumes can be achieved. At the same time, steep dose gradients are possible, allowing improved sparing of directly adjacent organs at risk remain possible. Treatment planning is called "inverse" planning, because in contrast to 3D-conformal therapy the field geometry is usually not directly adjusted by the planner. Instead, doses are prescribed to the target volume(s) and to the outlined organs at risk (so called "dose constraints") with a prespecified arrangement of beams. The treatment plan is then generated by an iterative computer-aided process by adjusting the fluence matrix and/or the constraints. This technique further allows the treatment of regions inside the target volume (for example gross tumor) with a higher dose, and other regions (for example elective nodal areas) with a lower dose within the same fraction. This enables dose escalation in certain areas within an unchanged number of fractions (so called "SIB = simultaneously integrated boost", Figure 1).

Numerous dosimetric studies showed clear advantages

for intensity-modulated techniques compared to 3D-conformal treatments. In particular, lower doses in small bowel and liver could be achieved^[16] and the possibility of a dose escalation up to 65 Gy was suggested^[17]. Further on, several clinical studies have clearly confirmed, that these dosimetric advantages translate into reductions of acute and late side effects^[18].

Image-guided radiation therapy

In general, several sources of uncertainty must be addressed in external beam radiation therapy regarding the coverage of target volumes with the prescribed dose. Intrafractional motion is mainly caused by respiration. On the other hand interfractional variations are the result of a combination of different factors. One major source is the displacement of the target by different filling of adjacent distensible structures like stomach or small bowel. Another source is the so-called "set-up error", i.e., the uncertainty due to variation in daily positioning of the patient. All these variations must be compensated by safety margins. However, if directly adjacent organs at risk are present, every increase of safety margins consequently leads to increased side effects, which builds up the rationale for image-guided radiation therapy (IGRT). In doing so, three-dimensional datasets in treatment position are generated with imaging devices directly mounted on the linear accelerators (so called "on-board imaging"). These allow a comparison of the actual situation with the one during treatment planning and a real time correction of the position prior to irradiation. The increased precision of treatment application consequently allows a reduction of the safety margin. Several analyses have shown, that the safety margins needed to compensate for set-up error in the upper abdominal region can be reduced from 10 to 5 mm if IGRT is used^[19]. In a tumor with 5 cm diameter, this margin reduction would lead to a 30% decrease of irradiated volume^[18] with a significant dose reduction in small bowel, kidneys and liver^[20].

Intrafractional respiratory motion differs from patient to patient, but can reach several centimeters^[21]. Different strategies have been used to reduce the safety margins needed to account for such large variations. First, the individual respiratory motion can be measured for example by 4-dimensional computed tomography and allow definition of individualized anisotropic margins. This strategy can result in a mean reduction of the target volume by one third compared to the use conventional margins^[20]. Some modern linear accelerators also allow gating, i.e., on board detection of tumor motion and application of radiation only at distinct positions of the tumor in its motion cycle. Another technique supported by some accelerators is a continuous adjustment of the beams to the particular tumor position (so-called "tracking"). Especially for these methods, the implantation of fiducials into the tumor may further increase the precision of dose application^[22].

Adaptive radiation therapy strategies

In contrast to the mentioned techniques, adaptive

Figure 2 Intraoperative electron radiation therapy. A: Placement of the applicator after resection; B: Schematic dose distribution.

strategies use regular imaging to adapt the radiation treatment plan semi-automatically to anatomical changes during the radiation therapy series, for example due to tumor shrinkage. Although the models for routine use of these techniques are currently still under development, theoretical studies suggest marked reductions in dose to several organs at risk, for example duodenum^[23].

Intraoperative radiation therapy

Although modern radiation techniques allow an improved sparing of surrounding organs at risk, dose-limitations in external beam therapy still exist, mainly due to directly adjacent structures with low radiation tolerance. Intraoperative electron radiation therapy (IOERT) offers an elegant possibility to overcome these dose-limitations after neoadjuvant radio (chemo)therapy. Due to its unique opportunity to guide a high single dose directly to the tumor bed or residual tumor during surgery, while adjacent organs at risk can be manually removed, IOERT can effectively prevent adjacent organs at risk from radiation exposure. Further advantages of IOERT in comparison to an external beam boost include at least theoretically smaller field sizes (because safety margins for daily positioning errors can be omitted) and the higher biological effectiveness of a single dose compared to the same amount of fractionated radiation therapy^[24-29]. If typical dose concepts for the combination are used (10-15 Gy IOERT + 45-54 Gy EBRT), total doses can be reached which are biologically equivalent to 70-90 Gy of conventionally fractionated external beam radiation therapy without markedly increased toxicity^[24-29]. Practically, an applicator of appropriate size is placed inside the abdominal cavity under visual control to cover the tumor bed/residual tumor after performed/attempted resection and manual removal of adjacent structures at risk. After moving and adjusting the patient below the accelerator, the irradiation itself is performed inside the operation theater, lasting about 1-2 min. Adequate depth coverage is achieved by appropriate selection of the electron energy (Figure 2). Unfortunately, this technique is only available at a limited number of centers so far (although numbers are heavily increasing in the recent years). Efficacy of IOERT remains difficult to assess, since many series report

only single-center experiences covering large observation periods. Regarding primarily resectable pancreatic cancer, several Italian series reported significantly decreased local recurrence rates with the addition of IOERT^[30,31]. Reni *et al*^[32] confirmed these results in a larger comparison vs surgery alone. Beside an increased local control rate, they also found a significantly improved median overall survival in the subgroup of patients with early stages without increased perioperative morbidity. A multi-institutional series from Japan described a local recurrence rate of only 15% in 210 patients after gross complete resection with IOERT^[33] and a European pooled analysis reported a very encouraging median overall survival of 30 mo for the combination of neoadjuvant chemoradiation, surgery and IOERT in a series of 270 patients^[34]. Regarding primarily unresectable pancreatic cancer, IOERT can be used for dose escalation after neoadjuvant chemoradiation both in case of achieved secondary resectability as well as in case of further irresectability, resulting not only in improved local control but in the achievement of durable pain control in 75%-90% of the patients^[35]. The Mayo group reported a series of 115 patients with unresectable pancreatic cancer and found that the addition of IOERT during explorative laparotomy after neoadjuvant irradiation resulted in a significantly increased 1-year local control rate (48% vs 82%)^[36]. Shibamoto *et al*^[37] compared EBRT, EBRT + IOERT and IOERT alone in a cohort of 150 patients and described an improved survival for the combination in the subgroup of patients with an initial CA 19-9 < 1000. The MGH group reported a median overall survival of 12 mo for the combination of EBRT and IOERT in their series of 194 patients with irresectable pancreatic cancer^[38]. If the combined local treatment was further enhanced by a systemic treatment component, several series consistently reported median overall survival times of 16-18 mo with 2-year local control rates around 70%^[39,40]. Even in patients with isolated local pancreatic cancer recurrences, the combination of EBRT, surgery and IOERT resulted in high local control and encouraging overall survival rates^[26].

In summary, IOERT provides an elegant possibility to escalate dose allowing total doses which could not be achieved by EBRT alone even with the use of the most sophisticated techniques. In resectable pancreatic

cancer, IOERT seems clearly to improve local control, while its influence on overall survival cannot be finally assessed at present. In primarily irresectable pancreatic cancer, it can be suggested based on large single-center experiences, that especially the combination of EBRT, IOERT and chemotherapy achieves improved quality of life due to durable pain control, high local control rates and encouraging overall survival rates compared to other treatment approaches, although no phase III data currently exists to confirm these results.

Stereotactic body (ablative) radiation therapy

Stereotactic radiation therapy was primarily developed to treat small intracranial tumor lesions (for example brain metastases) and was successfully used in these situations for several decades. Initially it was defined as a treatment with a high single dose, which was guided precisely to the target using a stereotactic frame as external coordinate system for target localisation and very rigid patient fixation systems to reduce safety margins to a minimum (also known as radiosurgery). After expansion of the technique to extracranial sites and introduction of image guided radiation therapy, the definition of stereotactic body radiation therapy (SBRT) has widened. Today it summarizes different methods, which consistently apply so called "ablative" doses (biologically equivalent doses far beyond those achievable by conventional fractionation) in one to few fractions with optimal precision aiming at durable control of macroscopic tumor lesions. This technique has for example emerged as the standard of care in medically inoperable patients with early stage non-small cell lung cancer^[41]. Currently it is used also in pancreatic cancer, although due to the lower contrast to the surrounding tissue (compared with lung cancer) implantation of fiducials is usually needed to achieve a safe detection of tumor position and motion with simple imaging modalities. Fiducial based approaches can additionally be combined with motion compensating radiation techniques (gating or tracking) to reduce safety margins to a minimum.

The present clinical experience for SBRT in pancreatic cancer is based mainly on small series of patients with irresectable locally-advanced pancreatic cancer^[42]. Although very different dose schemes ($1 \times 15\text{-}25$ Gy, $3 \times 8\text{-}15$ Gy, 5×6.5 Gy) have been used^[42], these series consistently report very high local control rates of 80%-100% with partially very encouraging overall survival especially if combined with sequential chemotherapy^[43-45]. However, the therapeutic window of this technique is narrow and therefore dose to directly adjacent organs at risk (like duodenum) must be strictly limited to avoid major complications^[46], as shown by the range of gastrointestinal grade 3 complications reaching from 14% to 79% in the major series, and depending mainly on target volume size and dose to the duodenum^[45,47]. Adaptive dose prescriptions depending for example on the distance between tumor and duodenum seem to be beneficial^[44].

Recently, SBRT has also been introduced into

neoadjuvant treatment approaches. One series describes the use of SBRT in 73 patients of whom 56 were deemed borderline resectable^[48]. Treatment consisted of 3 cycles induction-chemotherapy followed by SBRT which guided 35-50 Gy to the vessel-approaching tumor parts and 25-30 Gy to the remaining tumor parts in 5 fractions. Seventy-seven percent of the borderline resectable patients responded and were surgically explored. Resection was possible in 56% of the patients (97% R0), showing a significantly improved survival. Severe gastrointestinal toxicity (grade 3) was observed only in 5% of the patients^[48].

In summary, SBRT yields high local control rates, which seem so be superior to the results of conventionally fractionated RT. However, SBRT in the upper abdomen remains a demanding technique with a narrow therapeutic window and has been so far investigated mainly in irresectable pancreatic cancer. Nevertheless, it seems to be a promising approach also in the neoadjuvant setting especially if combined with systemic therapy.

Particle therapy

A least theoretically, more advantages could be exploited by the use of radiation qualities like protons or heavy ions. In contrast to photons, particle beams deposit most of the dose in a narrow range of tissue depth depending on the beam energy. This so-called "Bragg-peak" can be used to focus the dose very precisely to the target volume, while adjacent tissues can be safely spared (Figure 3). Especially heavy ions further show an enhanced biological effectiveness, because they generate a different pattern of DNA-damage in the tumor cells which is less easily repaired by cellular DNA-repair mechanisms in comparison to damages set by photon therapy. Some drawbacks remain in the upper abdomen due to difficulties to account for bowel gas movement during treatment planning. These can lead to large dosimetric uncertainties compared to photons^[49]. Nevertheless several encouraging preliminary results have been reported by several centers. For example, the MGH group showed a very low severe gastrointestinal toxicity rate of 4% during chemoradiation in a phase I / II trial, where neoadjuvant proton radiotherapy with 5×5 Gy combined with simultaneous capecitabine and followed by resection and adjuvant gemcitabine was evaluated in primarily resectable pancreatic cancer. With a median follow-up of 38 mo, they reported a local recurrence rate of 16% and a median overall survival of 17 mo^[50]. Investigators from Chiba (Japan) launched a phase I trial including 26 patients with resectable pancreatic cancer, treated with increasing doses of 30-36.8 Gy in 8 fractions with carbon ions of whom 81% proceeded to surgery. They reported a local control rate of 100% with 1- and 5-year survival rates of 89% and 52% in resected patients^[51]. Irresectable pancreatic cancer patients were also included into a dose escalation trial with doses of 38.4-52.8 Gy in 12 fractions at the same center resulting in 81% local control and 60% overall survival after one year^[52].

Figure 3 Schematic comparison of the depth dose curves of photons and particles. Lower dose distribution in the radiation path before and after the target with particles by exploiting the Bragg-peak.

In summary, particle radiation therapy seems to be a promising modality with regard to high local control rates with low toxicity. However, the current knowledge is based only on a few studies with low patient numbers and short follow-up and has therefore to be regarded as preliminary. Due to the known uncertainties in dose calculation because of bowel gas movement, patients with pancreatic cancer should be treated only in prospective studies at experienced centers.

Current status of neoadjuvant radio (chemo) therapy in locally-advanced primarily non-resectable pancreatic cancer

The interpretation of the literature regarding the optimal therapy for locally-advanced pancreatic cancer is difficult for different reasons. First of all, very different treatment strategies exist, ranging from aggressive approaches with curative intent such as multimodal neoadjuvant treatment including regular surgical exploration to purely palliative systemic treatment approaches, with all conceivable steps in between. Further on, even if only series using very similar neoadjuvant approaches aiming at secondary resectability are assessed, they differ extensively in terms of patient selection. The distinction between resectable and irresectable lesions is flawed by a certain subjectivity, which clearly correlates with the experience of surgeon and center. Even if a lesion is deemed primarily irresectable, different sub-terms are in use. In most of the US literature, patients are sub-divided in borderline-resectable and unresectable depending on the extent of vessel involvement, while this differentiation is not commonly used in most parts of Europe and Asia. This results in the inclusion of very different advanced lesions in neoadjuvant approaches compromising reasonable comparisons. The primary aim of neoadjuvant approaches in patients with locally-advanced irresectable pancreatic cancer is the induction of tumor shrinkage and thereby the achievement of secondary resectability *per se* and the increase of the rate of microscopic negative (R0) resections. Secondary aims are response evaluation for further treatment stratification and improvement of quality of life by prevention of local symptoms in case of persistent irresectability. The impact of neoadjuvant

radio(chemo)therapy has been evaluated in numerous retrospective and prospective studies. These show a wide range of results and therefore seem less reliable when taken individually^[53]. However, Gillen *et al*^[2] described some fundamental findings in an impressive metaanalysis including 111 studies with 4400 patients. They included trials evaluating primarily resectable and primarily irresectable patients but analyzed them separately. In the group deemed primarily resectable they found a final resection rate of 74% after neoadjuvant therapy which is very similar to the rate reported for surgery alone. In the group primarily deemed irresectable, they observed a final resection rate of 33% after neoadjuvant (mainly radiochemo-) therapy. Radiological response assessment after neoadjuvant therapy described complete and partial remission in 4% and 29% with a 21% progression rate. These rates were not different between resectable and irresectable patients. However, the most important finding was a median survival of 21 mo and a 2-year overall survival rate of 50% in the group of patients, who reached secondary resectability after neoadjuvant treatment. This equals the result in the primarily resectable group (median survival 24 mo, 2-year overall survival 47%), while patients in whom resection was not achieved showed a significantly worse overall survival (median 10 mo), independent of their initial resectability status. Morganti *et al*^[53] performed another metaanalysis including 13 trials with 510 patients, which were deemed irresectable and had received neoadjuvant chemoradiation with at least 45 Gy. Interestingly, they reported similar results: final resection rate was 27% with 88% being complete (R0). Median survival after secondary resection (24 mo) was significantly improved in comparison to persistent irresectability (10 mo)^[53]. One of the largest single center analyses from Heidelberg again showed similar results^[54]. In 257 patients treated with neoadjuvant (mainly radiochemo-) therapy and surgical exploration, secondary gross total resection rate was 40% with a median survival of 25 mo after R0-resection^[54]. Postoperative morbidity and mortality does not seem to be increased after neoadjuvant chemoradiation compared to surgery alone^[55,56]. In summary, neoadjuvant radiochemotherapy for patients with primarily irresectable, locally-advanced pancreatic

cancer results in secondary resectability in a substantial portion (30%-40%) of the patients, accompanied by a significantly improved prognosis in this subgroup. The median survival time (median approximately 24 mo) is similar to patients with primary resection and adjuvant chemotherapy. Even if secondary resectability is not achieved, the results after neoadjuvant chemoradiation are found at the upper end of the range reported for chemotherapy alone in the current literature, including the advantage of improved quality of life due to durable prevention of local complications by tumor progression.

Current status of neoadjuvant radio (chemo) therapy in primarily resectable pancreatic cancer

The rationale for neoadjuvant treatment approaches in resectable pancreatic cancer is based on several findings. First of all, locoregional progression is at least a component of disease progression in 50%-75% as shown by pattern of recurrence analyses after resection alone^[57]. Even with the use of adjuvant chemotherapy, several studies reported local recurrence rates of 30%-60%. This suggests that eradication of locally persistent tumor cells by chemotherapy alone is not safely ensured^[6,58]. As locoregional recurrences often result in local complications, the aim of achieving adequate local control seems justified with regard to quality of life.

Neoadjuvant strategies have replaced or at least supplemented sole adjuvant approaches as the standard of care in many other resectable gastrointestinal tumors, for example rectal cancer or esophageal cancer^[5,59]. Unfortunately, no randomized data comparing neoadjuvant and adjuvant approaches in resectable pancreatic cancer have been published so far, although neoadjuvant approaches are investigated increasingly because of their potential benefits. Benefits include an improved local control rate for example due to an increased R0-resection rate, early initiation of at least a systemic therapy component to control potentially existing distant micrometastases, a simplified access to additional therapies and of course an optimal patient selection by exclusion of patients with early distant failure. The ongoing development will be illustrated exemplarily by the work of the MDACC group, which designed and performed a number of consecutive phase II trials over nearly 2 decades. They started with conventionally-fractionated radiation therapy combined with 5-FU^[60], went on with a shortened radiochemotherapy with additional IOERT^[61] and ended up with paclitaxel^[62] and finally gemcitabine-based preoperative chemoradiation^[63]. The last concept was evaluated in a phase II trial with 86 patients, who received a shortened radiation therapy (10 × 3 Gy in 2 wk) in combination with weekly gemcitabine 400 mg/m² over 7 wk. Resection was finally achieved in 74% of the patients. The median overall survival for the entire cohort was 23 mo with a 5-year survival rate of 27%. Resectable patients had a significantly improved median survival of 34 mo compared to 7 mo in irresectable patients. The same was true for the 5-year survival rate (36% vs 0%). The local control rate in resected patients was 89%^[63].

The authors concluded, that neoadjuvant chemoradiation allows a good selection of patients, who probably will not profit from major surgery. They recommended further investigation of neoadjuvant gemcitabine-based chemoradiation in resectable patients based on the very encouraging overall survival results^[63], especially because a parallel trial by the same group with additional induction chemotherapy showed no further benefit^[64]. The consistency regarding definition of resectability, surgical treatment and histological examination further suggests a good comparability of the results in the different MDACC trials^[65]. Gemcitabine-based radiochemotherapy resulted in improved response rates, improved R0-resection rates and longer median survival in comparison to combinations with 5-FU or paclitaxel^[65]. A pooled analysis of the MDACC studies including 240 patients treated with surgery after neoadjuvant therapy finally revealed a median disease-free survival of 15 mo and a median overall survival of 34 mo^[66]. The potential benefit of neoadjuvant radiation therapy for resectable pancreatic cancer is further supported by a SEER-analysis on more than 3800 patients, which described a significant improved median survival of 24 mo after neoadjuvant radiation therapy compared to 17 mo with adjuvant and 12 mo without radiation therapy^[67].

In summary, neoadjuvant radio- or radiochemotherapy offers several potential benefits compared to adjuvant strategies, although no randomized data are currently available to support this assumption. Nevertheless, neoadjuvant radio(chemo)-therapy has shown outstanding results in terms of response, local control and overall survival at least in phase II trials. These results clearly justify further investigation of neoadjuvant radiation therapy approaches. In this context, further shortening of neoadjuvant radiation therapy schemes might be beneficial, as currently investigated in several prospective trials evaluating modern photon or proton techniques^[28,50].

Future directions

As mentioned earlier, this article focuses on radiotherapeutic strategies including radiotherapy alone or combined with concurrent chemotherapy in the neoadjuvant setting. Within such approaches, chemotherapy is used mainly as a radiation sensitizer rather than as systemic treatment resulting in low doses and usually single drug treatment to keep combined toxicity acceptable. However, recently new chemotherapy agents and combinations like Gemcitabine/nab-Paclitaxel^[68] or FOLFIRINOX^[69] have been successfully introduced into the treatment of metastatic pancreatic cancer and resulted in improved response and overall survival. Therefore it seems reasonable to use these schemes also in the neoadjuvant setting either to target possible distant micrometastases as early as possible in patients with resectable disease or to induce tumor shrinkage in irresectable patients to achieve secondary resectability. Due to the increased toxicity profile of these potent combinations, concurrent application of radiation does not seem possible even with the most sophisticated radiation techniques. Therefore sequential

applications for example induction chemotherapy with FOLFIRINOX followed by chemoradiation with 5-FU or gemcitabine seem to be very promising and are currently under investigation (for example in the German CONKO 007 study), with some groups already showing very encouraging preliminary results^[70]. Therefore additional aims for future radiation research in pancreatic cancer should include the evaluation of optimal sequencing of systemic and radiotherapeutic approaches as well as the identification of biomarkers to predict the pattern of disease progression in the individual patient.

Biomarker for stratification

One of the main challenges in the treatment of pancreatic cancer remains the insufficient possibilities for an early prediction of disease progression. This compromises a reasonable stratification of patients in terms of treatment combinations. Established and new biomarkers could be helpful. This will be illustrated exemplarily in the following with CA 19-9 serving as example for an established and SMAD for a new marker. Several groups established an association between increased pretreatment CA 19-9 levels and an unfavourable outcome^[71], with very high values indicating an already disseminated disease. Kim *et al.*^[72] for example showed stage-dependent median CA 19-9 levels between 40 and 748 U/mL in stage IA-III compared to a median CA 19-9 level of 3239 U/mL in stage IV. However, two major disadvantages limit the value of pretreatment CA 19-9 levels for prediction of disease prognosis: 5%-10% of patients with pancreatic cancer show negative CA 19-9 levels due to a defect in the gene coding for Lewis enzyme^[73] and CA 19-9 levels can be heavily influenced by other factors, for example cholestasis. Therefore increasing interest has been paid to new markers like SMAD4. The SMAD family of proteins plays a role in TGF- β signaling, which is heavily involved in the regulation of cell proliferation, differentiation and apoptosis^[74]. SMAD4 has been recently suggested as the most important candidate in regard to pancreatic cancer because it has been linked not only with tumor development but also with the pattern of disease progression^[75]. In this context, the presence of intact SMAD4 seems to be associated with a rather locally-destructive growth, while loss of SMAD4 correlates with early distant metastasis^[76]. These findings were supported by a trial performed by Crane *et al.*^[77], which found that 73% of the patients with intact SMAD4 showed locoregional progression while 74% of the patients with inactive SMAD4 developed distant failure. In summary, although current knowledge about biomarkers seems premature in regard to treatment stratification, this might be an encouraging opportunity to allow an improved allocation of patients to locally-aggressive vs systemic treatment approaches to strengthen personalized medicine also for pancreatic cancer in the future.

SUMMARY

In the absence of randomized data, published studies

show consistently that neoadjuvant chemoradiation for locally-advanced, primarily non- or borderline resectable pancreas cancer results in secondary resectability in a substantial proportion of patients with consecutively markedly improved overall prognosis in this subgroup. Even if the goal of secondary resectability is not reached, radiation therapy may contribute to improved quality of life by the prevention of local complications. Neoadjuvant chemoradiation should therefore be considered as possible alternative in multidisciplinary pretreatment evaluations.

In resectable pancreatic cancer, outstanding results in terms of response, local control and overall survival have been observed with neoadjuvant radio- or radiochemotherapy in several phase I / II trials. These undoubtedly justify further evaluation of this strategy. In this context, further shortening of the radiation therapy series to allow a simplified integration into multimodal concepts is evaluated in ongoing trials.

Further investigation of neoadjuvant chemoradiation strategies should be performed preferentially in randomized trials in order to improve comparability of the current results with other treatment modalities. This should include the evaluation of optimal sequencing with newer and more potent systemic induction therapy approaches. Advances in patient selection based on new molecular markers might be of crucial interest in this context.

Finally modern external beam radiation techniques (IMRT, IGRT, SBRT), new radiation qualities (protons, heavy ions) or combinations with alternative boosting techniques (IOERT) widen the therapeutic window and contribute to the reduction of toxicity by improving normal tissue sparing and/or increasing efficacy by dose escalation or enhanced biological effectiveness. These techniques offer innovative treatment strategies, which should be further evaluated in prospective controlled trials.

Abstract

The ubiquitin proteasome system (UPS) is important for the degradation of proteins in eukaryotic cells. It is involved in nearly every cellular process and plays an important role in maintaining body homeostasis. An increasing body of evidence has linked alterations in the UPS to gastrointestinal malignancies, including esophageal, gastric and colorectal cancers. Here, we summarize the current literature detailing the involvement of the UPS in gastrointestinal cancer, highlighting its role in tumor occurrence and development, providing information for therapeutic targets research and anti-gastrointestinal tumor drug design.

Key words: Ubiquitin proteasome system; Gastrointestinal cancer

Core tip: The ubiquitin proteasome system (UPS) is involved in almost every cellular process, playing an important role in maintaining body homeostasis. Increasing evidence indicates that alterations in the UPS are correlated with gastrointestinal malignancies. Here, we review current information describing UPS members involved in gastrointestinal cancer, providing a resource for further study and clinical application.

INTRODUCTION

The ubiquitin proteasome system (UPS) is important for the degradation of proteins in eukaryotic cells. Approximately 80%-90% of intracellular proteins involved in every cellular function are degraded through the UPS^[1]. Compared with the lysosomal system, the UPS is highly selective. It can regulate the proteins that it degrades *via* the ubiquitination-proteasome-deubiquitination mechanism to maintain homeostasis in the body. When regulatory proteins are stabilized by a decrease in degradation or are lost due to accelerated degradation, an imbalance is generated and diseases such as cancer occur.

Gastrointestinal cancer is a cancer of different organs of the digestive system, the most frequently occurring cancers of which are esophageal, gastric and colorectal. Despite improvements in diagnostic and therapeutic methods, gastrointestinal cancers remain a significant threat to patients^[2]. Recently, growing evidence has indicated that the UPS is linked to the development of gastrointestinal cancer. In this review, we discuss the members of the UPS thought to be involved in gastrointestinal cancer and highlight their roles in tumor occurrence and development.

The UPS is an important pathway for intracellular protein degradation

In cells, there are two main systems utilized for protein degradation: The autophagy-lysosome system and the UPS^[3,4]. The lysosomal pathway degrades extracellular proteins imported into the cell by endocytosis or pinocytosis, while the UPS controls the degradation of intracellular proteins^[5,6].

The UPS is composed of ubiquitin, ubiquitination enzymes, deubiquitination enzymes (DUBs), and proteasomes.

Ubiquitin is a highly conserved 76 amino acid protein, wild-expressed in eukaryotic cells^[7]. During the ubiquitination process, multiple ubiquitin proteins can be covalently attached to a target protein by ubiquitination enzymes^[8]. These ubiquitination enzymes include ubiquitin activating enzyme (E1), ubiquitin carrier protein (E2), and ubiquitin protein ligase (E3). Initially, E1 activates ubiquitin in an ATP-dependent manner, forming a thioester linkage between the carboxy-terminal glycine residue of ubiquitin and a cysteine in the active site of the E1 enzyme. Activated ubiquitin is then transferred from an E1 enzyme to a cysteine residue of an E2 enzyme. E3 then catalyzes the final step of the ubiquitination process by transferring ubiquitin to lysine residues of targeted proteins, forming a polyubiquitin chain that earmarks the targeted proteins^[8-10]. Humans possess two E1 enzymes (UBA1 and UBA6), several dozen E2 enzymes, and several hundred E3 enzymes^[11-13]. The specificity of the E3 enzymes determines the specific recognition of target proteins, providing selectivity in which proteins are targeted to the proteasome for degradation^[10,14,15].

Upon ubiquitination, targeted protein is degraded by

the 26S proteasome in an ATP-dependent manner^[16,17]. The 26S proteasome is a complex consisting of a proteolytic core particle (20S proteasome) that is capped at both ends by 19S regulatory particles (19S regulatory complex). The 20S proteasome is a barrel-shaped complex comprised of four stacked rings and contains multiple catalytic centers in the chamber. The 19S proteasome recognizes a polyubiquitinated protein, unfolds it, liberates it from the polyubiquitin chain, and translocates the protein into the proteasome chamber for degradation. The ubiquitin molecules are recycled, and the peptides generated are used for antigen presentation or are degraded into amino acids that are recycled for new protein synthesis^[9,10,17].

DUBs are a cluster of enzymes that oppose the action of the E3 ligases by cleaving the isopeptide bonds between lysine residues of targeted proteins and the C-terminal glycine of ubiquitin. They play important roles in maintaining the balance of the UPS. Analysis of the human genome has indicated the presence of ~ 100 functional DUBs^[18-20].

Tumorigenesis consists of several steps, including self-sufficiency in growth signals, insensitivity to growth inhibitor signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis^[21-24]. The UPS is an important regulator of protein degradation that is involved in every cellular function, including cell proliferation, apoptosis, migration and invasion. Thus, deregulation of this system may lead to tumorigenesis.

The UPS in esophageal cancer

Esophageal cancer (EC) is the eighth most common type of cancer, and ranks as the sixth leading cause of cancer-related mortality worldwide. The incidence of EC varies internationally, with the highest rates found in Eastern Asia and in Eastern and Southern Africa^[2,25].

Several E2 enzymes, including ubiquitin-conjugating enzyme H10 (UBCH10, also known as UBE2C), ubiquitin-conjugating enzyme E2L3 (UBE2L3, also known as UBCH7), E2-EPF ubiquitin carrier protein (UCP), and ubiquitin-conjugating enzyme E2D3 (UBE2D3) have been shown to be involved in the development of EC. UBCH10 is expressed in cancerous and dysplastic esophageal lesions, but not in normal tissue. Its expression is positively correlated with lymph nodes metastasis (LNM), TNM classification, and clinical stages, and negatively correlated with relapse-free survival period. Down-regulation of UBCH10 can inhibit cell proliferation and induce the sensibility to the treatment of MG-262^[26,27]. Knockdown of UBE2L3 expression can reduce the anoikis resistance of EC cells^[28]. Higher level of UCP has been linked to a greater tumor burden, poor response to neoadjuvant therapy, and worse overall survival for EC patients. Furthermore, UCP down-regulation can inhibit the proliferation, migration and invasion of EC cells, probably through the VHL/HIF-1 α -TGF- β 1 pathway^[29]. UBE2D3 expression is significantly lower in EC tissues and is correlated with histological grade, N stage, and

recurrence, suggesting that it acts as a tumor suppressor in EC. UBE2D3 may be involved the hTERT signal pathway, which can promote the development of invasive esophageal squamous cell cancer by interacting with the epidermal growth factor receptor and p53^[30,31].

Numerous E3 enzymes participate in the development of EC, some of which promotes tumor development. C-terminal Hsp-interacting protein (CHIP) exhibits a higher expression level in metastatic lymph nodes and is positively correlated with a poor survival rate in stage III EC patients^[32]. F-box protein 31 (FBXO31) is an ubiquitin ligase whose cytoplasmic expression is concordant with the nuclear expression of cyclin D1. In EC tissues, higher FBXO31 expression level is significantly correlated with depth of tumor invasion, clinical stage, and poorer prognosis^[33]. p53-associated cellular protein-testes derived (PACT) is highly up-regulated in EC. Experimental studies have revealed that knockdown of PACT significantly attenuates the p53-Hdm2 interaction, reduces p53 polyubiquitination, and enhances p53 accumulation, leading to both apoptosis and cell growth retardation^[34]. SMAD specific E3 ubiquitin protein ligase 2 (Smurf2) targets TGF pathway-restricted Smad2. In EC, high expression of Smurf2 is correlated with depth of invasion, LNM, and poor survival rate. High expression of Smurf2 can down-regulate Smad2, which in turn regulates the TGF signaling pathway^[35]. S-phase kinase-interacting protein 2 (Skp2) can interact with the S-phase kinase Cdk2/cyclinA and is involved in the ubiquitin-dependent degradation of p27. Skp2 expression is closely correlated with TNM stage. High expression of Skp2 is associated with poor overall survival in resectable EC. Further study reveals that knockdown of Skp2 inhibits cell migration and invasion and sensitizes cancer cells to anoikis, at least in part through the phosphoinositidyl 3-kinase-Akt pathway^[36,37]. Ubiquitin-like with PHD and ring finger domains 1 (UHRF1) is overexpressed in EC tissues. Its expression is correlated with the T-stage and N-stage as well as with differentiation. Down-regulation of UHRF1 can enhance the radio-sensitivity of TE-1 cells by altering cell cycle progression, increasing apoptosis and decreasing DNA damage repair capacity^[38].

Some E3 enzymes act as tumor suppressors in EC. F-box protein 4 (FBX4) is a ubiquitin ligase that directs the ubiquitylation of cyclin D1. Increased FBX4 function can enhance the normal activity of EC cells, and 14-3-3 ϵ is involved in regulating its function^[39]. F-box and leucine-rich repeat protein 19 (FBXL19) functions as an antagonist of Rac3 by regulating its stability, and it also regulates the TGF β 1-induced down-regulation of E-cadherin. Over-expression of FBXL19 attenuates TGF β 1-induced E-cadherin down-regulation and the elongation phenotype of EC cells^[40,41]. F-box and WD repeat domain containing 7 (FBXW7, E3 ubiquitin protein ligase) can induce the degradation of positive cell cycle regulators, such as Myc, cyclin E and Jun. In EC tissues, a decrease in FBXW7 copy number regulates FBXW7 mRNA expression, and reduced expression of FBXW7 is an independent prognostic factor in EC^[42].

Besides, there are still some E3 enzymes play controversial roles in EC. MDM2 (MDM2 proto-oncogene) is a key negative regulator of P53, but its expression state and clinicopathological parameters in esophageal squamous cell carcinoma are controversial. This may be due to a lack of sufficient case numbers in each study or the use of different methods to detect MDM2 expression. Meta-analysis suggests that MDM2 acts as a potent marker of early primary tumor stages but poses a high risk of regional LNM in EC. Notably, the MDM2 309GG genotype may be associated with an increased risk of EC among Asians^[43,44].

DBUs, including ubiquitin specific peptidase 7 (USP7), ubiquitin specific protease-9X (USP9X), Ubiquitin-specific protease 22 (USP22), ubiquitin carboxyl-terminal hydrolase 37 (UCH37), and ubiquitin carboxyl-terminal hydrolase1 (UCHL1) are correlated with EC development. USP7 can deubiquitylate p53 and protect it from proteasome-mediated degradation. EC cells can be protected against metformin-induced growth inhibition by siRNA against USP7^[45]. Up-regulation of USP9X in EC tissues plays an important role in the formation and progression of precancerous lesions, and its increased expression is significantly correlated with poorer survival rate in EC patients^[46]. High expression of the USP22 protein is significantly associated with tumor progression, relapse and poor prognosis^[47]. The expression of UCH37 is higher in EC tissues and is associated with outcome and recurrence. UCHL1 is silenced by promoter region hypermethylation in EC, and the restoration of its expression suppresses EC cell colony formation^[48,49].

The UPS in gastric cancer

Gastric cancer (GC) is the second most common cause of cancer-related death, and its incidence rates are highest in Eastern Asia^[2].

The E2 enzyme UBCH10 is known to be involved in GC. UBCH10 is expressed at higher levels in primary stomach tumors compared with corresponding normal tissues^[50].

The oncogenic E3 ubiquitin ligases involved in GC are discussed in detail below. Autocrine motility factor receptor (AMFR) expression is significantly increased in GC tissues and is associated with invasion depth and LNM. Its expression is correlated with poor overall survival and an increased risk of recurrence in GC cases. AMFR is thought to participate in the EMT pathway because its expression is negatively correlated with E-cadherin expression and is positively correlated with N-cadherin^[51]. Cullin 1 (CUL1) overexpression is significantly correlated with GC TNM stage, depth of invasion, LNM, worse overall survival rate, and 3-year survival rate in GC patients. Experimental studies have demonstrated that CUL1 knockdown inhibits cell growth by up-regulating p27 expression and decreases cell adhesion by suppressing the expression of Src family kinases and focal adhesion kinase^[52]. MDM2 protein level is significantly up-regulated in GC and is significantly correlated with clinicopathologic

characteristics and a shorter overall survival of GC patients. Similar to its role in EC, the MDM2 309GG genotype may be significantly associated with an increased risk of GC^[43,53]. Makorin ring finger protein 1 (MKRN1) can simultaneously induce p53 and p21 ubiquitination as well as proteasome-dependent degradation. In GC cells, MKRN1 could affect gastric tumorigenesis by repressing cellular senescence and tumor-suppressive effects through the down-regulation of p14ARF in either a p53-dependent or -independent manner^[54]. RING box protein-1 (RBX1) exhibits a higher expression level in GC tissues, and silencing it significantly inhibits the proliferation of GC cells *in vitro*^[55].

E3 ubiquitin ligases with tumor suppressor activity in GC are discussed in detail below. checkpoint with forkhead and ring finger domains (CHFR) is reported to promote the ubiquitination and degradation of oncogenic proteins such as Aurora A and polo-like kinase 1^[56]. It is frequently down-regulated in GC as a result of CHFR promoter methylation, suggesting that it acts as a tumor suppressor in GC. Methylation of the CHFR promoter is correlated with tumor differentiation. CHFR methylation is significantly higher in poorly differentiated GC samples^[57]. Moreover, CHFR promoter methylation is a sensitive marker of the effect of docetaxel in GC patients^[58]. CHIP expression is significantly lower in GC tissues. CHIP down-regulation is correlated with LNM and tumor differentiation. Further study has demonstrated that CHIP down-regulation results in increased angiogenesis and contributes to GC progression and a poor prognosis, probably through the NF- κ B signaling pathway^[59-61]. FBXO31 expression is dramatically decreased in GC tissue and is significantly associated with tumor size, infiltration, clinical grade and patient prognosis. *In vitro*, FBXO31 overexpression significantly decreases colony formation, induces a G1-phase arrest, and inhibits the expression of CyclinD1 in GC cells. *In vivo*, ectopic expression of FBXO31 dramatically inhibits xenograft tumor growth in nude mice^[62]. FBXW7 mRNA expression in GC samples is markedly decreased, and its deregulation is associated with the presence of LNM and GC stage III-IV, as well as poor prognosis. Reduced FBXW7 expression is associated with MYC overexpression and a more invasive phenotype in GC cells^[63]. Neural precursor cell expressed, developmentally down-regulated 4-like (NEDD4L) is strongly related to the invasion and metastasis of GC. Tumors lacking NEDD4L expression exhibit a greater extent of LNM, lymphatic invasion, and venous invasion, and present poor clinical outcomes for GC patients^[64]. RNF180 (Ring finger protein 180) acts as a tumor suppressor in GC, and the methylated CpG site count of the RNF180 DNA promoter is highly associated with patient survival^[65]. Zinc and ring finger 3 (ZNR3) is down-regulated in gastric adenocarcinoma tissues. There is also a correlation between the down-regulation of ZNR3 and poor tissue differentiation. Further study has revealed that ZNR3 inhibits GC cell growth and promotes cell apoptosis by affecting the Wnt/ β -

catenin/TCF signaling pathway^[66].

E3 ubiquitin ligases with controversial functions in GC are discussed in detail below. Cbl proto-oncogene B (CBLB) is highly expressed in GC tissue with EGFR, and their expression levels have been linked to the invasion and development of GC. However, some studies have revealed that CBLB represses IGF-I-induced EMT, likely by targeting IGF-IR for degradation and further inhibiting the Akt/ERK-miR-200c-ZEB2 axis in GC cells^[67,68]. Constitutive photomorphogenic 1 (COP1, also known as RWD2) has been shown to regulate c-Jun and p53. One study found that COP1 mRNA was significantly decreased in GC tissues, and knockdown of COP1 in GC cells promoted cell proliferation and the expression of MMP1, MMP7 and MMP10^[69]. However, another study showed that COP1 overexpression was associated with poor prognosis in primary GC^[70]. Neural precursor cell expressed, developmentally down-regulated 4 (NEDD4) is a regulator of PTEN and plays a complicated role in GC. One study revealed that overexpression of NEDD4 was tightly associated with TNM stage and a lower GC survival rate. And knockdown of NEDD4 dramatically inhibited GC cell migration and invasion^[71]. However, another study demonstrated that NEDD4 increased in intestinal metaplasia compared to normal gastric mucosa and decreased in gastric carcinoma compared to dysplasia^[72].

The DUBs involved in GC are discussed in detail below. UCHL1 is frequently methylated in primary GCs and has been found to be more frequently methylated in diffuse-type GCs than in intestinal-type GCs. Moreover, UCHL1 is involved in galangin-induced apoptosis in human GC cells^[49,73]. Ubiquitin-specific protease 10 (USP10) is expressed at lower levels in GC tissues and cells compared to their wild-type equivalents. A lack of USP10 expression results in a marked propensity toward gastric wall invasion, LNM, highly malignant biological behavior, and poor survival^[74].

The UPS in colorectal cancer

Colorectal cancer (CRC) is the third most commonly diagnosed cancer in males and the second in females. The highest incidence rates are in Australia and New Zealand, Europe, and Northern America.

The E2 enzymes related to CRC are discussed in detail below. UBCH10 is highly expressed in CRC. The depletion of UBCH10 hinders tumorigenesis both *in vitro* and *in vivo*, probably by regulating the expression of cell cycle proteins such as cyclin A and cyclin B1. Furthermore, n-acetyl-leu-leu-norleucinal (ALLN) treatment is more effective in tumors with lower UBCH10 expression^[75]. Ubiquitin-conjugating enzyme E2Q family member 2 (UBE2Q2) expression is increased in 65.11% colorectal carcinoma tissues compared with their corresponding normal tissues^[76]. Ubiquitin-conjugating enzyme E2I (UBE2I) RNAi suppresses the 3D growth of KRAS mutant CRC cells *in vitro* and attenuates tumor growth *in vivo*^[77].

The oncogenic E3 ubiquitin ligases in CRC are discussed in detail below. F-box and leucine-rich repeat

protein 20 (FBXL20) is overexpressed in human colorectal adenocarcinoma. Moreover, the inhibition of FBXL20 expression can effectively suppress cell proliferation and promote apoptosis in CRC cells, while the overexpression of FBXL20 promotes the invasive ability of CRC cells, possibly by inducing the degradation of SET and E-cadherin through caspase activation^[78,79]. HECT, UBA and WWE domain containing 1 (HUWE1) is required for the growth of CRC cells in culture and in orthotopic xenograft models. HUWE1 shRNA suppresses the clonogenic growth of CRC cells, and small molecule inhibitors of HUWE1 can inhibit MYC-dependent transactivation in CRC cells but not in stem and normal colon epithelial cells^[80]. UHRF1 expression is up-regulated in approximately two-thirds of CRC specimens and is particularly expressed in right compared with left hemicolon cancer. High UHRF1 expression tends to be associated with the depth of invasion and with E2F-1 expression. Knockdown of UHRF1 suppresses cellular growth in colon cancer cell lines^[81-83]. Ubiquitin-like with PHD and ring finger domains 2 (UHRF2) is up-regulated at both the transcriptional and translational levels in tumor tissues. Overexpression of UHRF2 is highly linked to clinical stage, depth of invasion, nodal involvement, tumor histologic grade and the presence of metastases. Patients with UHRF2-positive tumors have a much lower disease-free survival and overall survival^[84]. Skp2-siRNA effectively inhibits proliferation, increases the level of apoptosis, and induces G0/G1 phase arrest of colon cancer cells, along with increasing p27 and p16 protein levels. Tumorigenicity experiments show that the inhibition of Skp2 significantly increases the survival. Skp2 is associated with a poor therapeutic response and adverse outcomes in rectal cancer patients treated with neoadjuvant chemoradiotherapy^[87].

E3 ubiquitin ligases exhibiting tumor suppressor activity in CRC are discussed in detail below. CHIP is down-regulated, predominantly in the late stages of CRC, and the CHIP promoter is hypermethylated in CRC specimens. Overexpression of CHIP results in impaired tumor growth in nude mice and decreased migration and invasion abilities of tumor cells. Further study reveals that CHIP negatively regulates NF- κ B signaling by promoting the ubiquitination and degradation of p65. The suppressive effect of CHIP leads to decreases in the expression of NF- κ B-targeted oncogenes, including Cyclin D1, c-Myc, MMP-2, VEGF and IL-8^[88]. Neural precursor cell expressed, developmentally down-regulated 4-like (NEDD4L) mRNA is significantly down-regulated in all CRCs. NEDD4L protein is significantly decreased in CRC compared to adjacent normal mucosa. Moreover, NEDD4L inhibits canonical Wnt signaling at or below the level of β -catenin *in vitro*^[89]. Neuregulin receptor degradation protein-1 (NRDP1) is significantly decreased in CRC tissues. Knockdown of NRDP1 enhances the proliferation of CRC cells, while the overexpression of NRDP1 inhibits the proliferation of CRC cells. Further analysis shows that NRDP1 may induce the degradation of its target ErbB3 to inhibit the activation of both the

ERK/MAPK and PI3K/Akt pathways in CRC cells, which seems to affect cell proliferation *via* the nuclear retention of a major cell-cycle inhibitor, p27. In addition, NRDP1 inhibits the expression of MMP7, which is required for cell invasion^[90,91]. Ring finger protein 43 (RNF43) can negatively regulate Wnt signaling, and its gene mutations in this gene has been found in over 18% of colorectal adenocarcinomas. Truncating mutations of RNF43 are more prevalent in microsatellite-unstable tumors and show mutual exclusivity with inactivating APC mutations in colorectal adenocarcinomas. These results indicate that RNF43 is one of the most commonly mutated genes in CRC^[92].

FBXW7 plays a controversial role in CRC. On one hand, FBXW7 mRNA expression is significantly lower in tumor tissues, an expression pattern correlated with poorer prognosis. *In vitro*, FBXW7-specific siRNA enhances the expression of c-MYC and cyclin E and promotes cell proliferation^[93]. Moreover, studies have found that the FBXW7 mutation is correlated with colorectal tumorigenesis^[94]. On the other hand, a large-scale study has revealed that there is no strong association between patient prognosis and FBXW7 mutation^[95].

The DUBs involved in CRC are discussed in detail below. OTU deubiquitinase, ubiquitin aldehyde binding 1 (OTUB1) is overexpressed in CRC tissues, and its expression level is associated with metastasis. A high OTUB1 expression level is also associated with poor survival, and OTUB1 serves as an independent prognostic factor in multivariate analysis. Further study has revealed that OTUB1 promotes the metastasis of CRC cell lines *in vitro* and *in vivo* by regulating EMT^[96]. Ubiquitin specific peptidase 11 (USP11) overexpression is frequently observed in CRC tissues and is correlated with poor survival. CRC cell lines expressing high levels of USP11 exhibit strong resistance to Smac mimetic-induced cIAP2 degradation. Furthermore, USP11 down-regulation sensitizes these cells to apoptosis induced by TRAIL and BV6, and suppresses tumor growth in a xenograft model^[97]. Ubiquitin-specific protease 22 (USP22) expression is significantly higher in primary CRCs than in the paired non-cancerous tissues at both the mRNA and protein levels. Higher USP22 expression is significantly associated with shorter periods of disease-specific survival and shorter disease-free survival. In addition, USP22 expression is significantly correlated with BMI-1, c-Myc and cyclin D2 and is a novel regulator of the SIRT1-STAT3 signaling pathway^[98-100]. Ubiquitin-specific protease 28 (USP28) deletion results in the fewer intestinal tumors of the murine model in CRC. And in established tumors, USP28 deletion reduces tumor size and dramatically increases lifespan^[101]. Ubiquitin-specific protease 33 (USP33) expression is down-regulated in CRC samples, and a reduced USP33 mRNA level is correlated with increased tumor grade, LNM and poor patient survival. USP33 acts as a tumor suppressor in CRC by mediating the inhibitory function of Slit-Robo signaling on CRC cell migration^[102]. USP44

Table 1 The roles of ubiquitin proteasome system members in gastrointestinal cancer

Enzyme	Esophageal cancer			Gastric cancer			Colorectal cancer

¹Tumor promoter role; ²Tumor suppressor role; ³Controversial role. AMFR: Autocrine motility factor receptor; CBLB: Cbl proto-oncogene B; CHFR: Checkpoint with forkhead and ring finger domains; CHIP: C-terminal Hsp-interacting protein; COP1: Constitutive photomorphogenic 1; CUL1: Cullin 1; DUB: Deubiquitination enzymes; FBXO31: F-box protein 31; FBX4: F-box protein 4; FBXL: F-box and leucine-rich repeat protein; FBXW7: F-box and WD repeat domain containing 7; HUWE1: HECT, UBA and WWE domain containing 1; MDM2: MDM2 proto-oncogene; MKRN1: Makorin ring finger protein 1; NEDD4: Neural precursor cell expressed, developmentally down-regulated 4; NEDD4L: Neural precursor cell expressed, developmentally down-regulated 4-like; NRDP1: Neuregulin receptor degradation protein-1; OTUB1: OTU deubiquitinase, ubiquitin aldehyde binding 1; PACT: p53-associated cellular protein-testes derived; RBX1: RING box protein-1; RNF: Ring finger protein; Smurf2: SMAD specific E3 ubiquitin protein ligase 2; Skp2: S-phase kinase-interacting protein 2; UBCH10: Ubiquitin-conjugating enzyme H10; UBE2L3: Ubiquitin-conjugating enzyme E2L3; UBE2D3: Ubiquitin-conjugating enzyme E2D3; UCP: E2-EPF ubiquitin carrier protein; UHRF: Ubiquitin-like with PHD and ring finger domains; UCH37: Ubiquitin carboxyl-terminal hydrolase 37; USP: Ubiquitin specific protease; UCHL1: Ubiquitin carboxyl-terminal hydrolase1; UBE2Q2: Ubiquitin-conjugating enzyme E2Q family member 2; UBE2I: Ubiquitin-conjugating enzyme E2I; ZNRF3: Zinc and ring finger 3.

is hypermethylated in all CRC cell lines and in most colorectal adenomas, but rarely in normal mucosa samples^[103]. UCHL1 plays a controversial role in CRC. Some investigations have shown that UCHL1 is more frequently methylated in CRC tissues than in normal colorectal tissues, whereas other studies have indicated that high UCHL1 expression is related to colorectal tumor progression, invasion, LNM, and poor clinical outcome^[104].

CONCLUSION

The UPS plays an essential role in controlling every cellular process and in maintaining the homeostasis of the body. In this review, we discussed the members of the UPS known to be involved in gastrointestinal cancer. Among the UPS, the dysregulation of the enzymes E2, E3 and DUBs play the most prominent role in tumorigenesis and development. As shown in Table 1, some enzymes may be just involved in one type cancer, while others may be involved in two or three types. Moreover, a single enzyme may play different roles in different cancers, as is the case for CHIP and UCHL1. This suggests that these enzymes may exhibit tissue specificity or may function through different mechanisms in different situation. Further study is necessary to better understand the biological function of the UPS and for the development of new therapeutic targets and anti-tumor drugs.

Abstract

AIM: To study the association of colorectal carcinoma (CRC) with diet, smoking, alcohol, physical activity, body mass index, family history and diabetes.

METHODS: All consecutive patients with CRC confirmed by histopathology diagnosis were included. Age (± 5 years) and gender matched controls were selected among the patients admitted in surgery ward for various conditions without any co-existing malignancy. Food frequency questionnaire (FFQ) was developed and validated after pretesting by investigator trained in data collection techniques. Cases and controls were interviewed ensuring privacy, in similar interview setting, with same duration of time for both cases and controls without any leading question. Biological variables like family history of CRC in first degree relatives, history of diabetes mellitus; behavioral factors like tobacco use both smoking and smokeless form, alcohol consumption and physical activity were recorded. Dietary details were recorded using a FFQ consisting 29 food items with seven categories. Analysis was done using appropriate statistical methods.

RESULTS: Ninety-four histopathologically confirmed cases of CRC and equal number of age and gender

matched controls treated over a period of two years were studied. Age distribution, mean age, male to female ratio, education level and socioeconomic status were similar in cases and controls. Intake of food items was categorized into tertile due to skewed distribution of subjects as per recommended cut off for consumption of food item. On univariate analysis red meat [OR = 7.4 (2.935-18.732)], egg [OR = 5.1 (2.26-11.36)], fish, fried food and oil consumption were found to be risk factors for CRC. On multivariate analysis red meat consumption of more than 2-3 times a month (OR = 5.4; 95%CI: 1.55-19.05) and egg consumption of more than 2-3 times a week (OR = 3.67; 95%CI: 1.23-9.35) were found to be independent risk factors for the development of CRC.

CONCLUSION: Egg and red meat consumption found to be independent risk factors for CRC. Smoking, alcohol, physical activity and family history were not associated with increased risk.

Key words: Dietary factors; Smoking; Rectal cancer; Red meat; Colorectal malignancy

Core tip: In this hospital based case control study, egg consumption of 2-3 times a week and red meat consumption of 2-3 times a month were found to be independent risk factors for the development of colorectal carcinoma. On the other hand smoking, alcohol, physical activity, diabetes and family history were not associated with an increased risk. There was no conclusive evidence to suggest that fruits and vegetable consumption has protective effect on colorectal carcinoma. Since red meat and egg had an increased risk, the community needs to be educated to reduce the consumption of red meat such as mutton and egg.

INTRODUCTION

Colorectal cancer (CRC) is one amongst the leading cause of cancer related morbidity and mortality. CRC share 10% of the total cancers worldwide and accounts for 8% of all cancer related mortality; caused 608000 deaths worldwide^[1,2]. In India data from population based cancer registry at Bangalore, Chennai and Delhi showed significantly increased incidence of CRC from 1982-2006^[3].

Epidemiological studies have estimated that up to 70%-80% of CRCs could be ascribed to dietary,

environmental and lifestyle factors; suggesting majority of the risk factors are modifiable^[4]. It has been demonstrated that diet significantly influences the risk of developing CRC, and up to 70% reduction in the cancer burden can be achieved by changing the food habits^[5]. Many epidemiological studies across the globe have tried to evaluate the role of dietary and life style factors in the development of CRC, however a fair share of controversies exist among the observations^[6]. Majority of the studies that investigated the role of high vegetable and fruit diet failed to prove any significant reduction in the incidence of CRC.

For a long time, it was believed that low meat intake and high fiber vegetarian diet by Indian population is the reason for the low incidence of CRC in India. It was found that only two studies have been reported in literature from India regarding factors associated with CRC^[7,8]. Identifying the factors associated with decreased CRC incidence among Indian population may help in the prevention of CRC. Hence an attempt was made to study these factors through a case control study. The objective of the study was to find the association of CRC with life style variables (diet, smoking, alcohol, physical activity) and Biological Variables [body mass index (BMI), family history of CRC in 1st-degree relatives, history of diabetes mellitus].

MATERIALS AND METHODS

The study was conducted in Department of Preventive and Social Medicine in collaboration with department of Surgery in a tertiary care referral and research institute of India. This study was conducted from period of two years. This study was approved by the Institute Ethics Committee. The nature, methodology of the study was explained to the patient and informed consent was obtained. All the information collected was kept confidential and patient was given full freedom to withdraw from the study at any point during the study. All provisions of the Declaration of Helsinki were followed in this study.

All consecutive patients with confirmed histopathology diagnosis were included. Histopathology was done either pre-operatively or postoperatively. Diagnosis of CRC was confirmed by per-rectal sigmoidoscopic or endoscopic biopsy. In case where resection for colorectal malignancy was done as an emergency surgical procedure, the diagnosis was confirmed post operatively. CRC patients with co-existing malignancy were excluded. Age (\pm 5 years) and gender matched controls were selected among the patients admitted in Surgery ward for various conditions like inguinal hernia, varicose veins, necrotizing fasciitis and diabetic foot.

Patients with co-existing malignancies, familial adenomatous polyposis and patients admitted with any abdominal disorders were excluded from the study. Controls were selected within one week after selecting the case. When more than one control was eligible then

control was selected by simple random methods using lots. During initial phase of the study, food frequency questionnaire (FFQ) was developed and face validation was carried out by circulating among the faculty who were involved in the study. Pre-testing was done among 10 patients admitted in the surgery ward by investigator trained in data collection techniques. It helped to estimate the average time taken for questionnaire administration, examination and to check for comprehensibility of participants to the questions.

After pre-testing of questionnaire necessary modifications were carried out. After obtaining informed consent cases and controls were interviewed ensuring privacy, in similar interview setting, with same duration of time for both cases and controls without any leading question. Average time taken for each interview was around 45 min. Anthropometric measurements was taken at the end of the interview. Pre-tested questionnaire which elicited information on demographic parameters like name, age, gender; Social variables like education, occupation, income, presenting complaints; biological variables like family history of CRC in first degree relatives, history of diabetes mellitus; behavioral factors like tobacco use both smoking and smokeless form, alcohol consumption and physical activity.

The alcohol consumption among study participants was measured and classified as per the World Health Organization STEPwise approach to surveillance of non-communicable diseases. The STEPS questionnaires used for the study are available in the internet from: http://www.who.int/ncd_surveillance/en/steps_framework_dec03.pdf. The alcohol consumption pattern of drinkers (amount, type and frequency) was noted and converted in terms of average alcohol consumed in grams per day. These were further classified as abstainers (who never consumed alcohol in past 12 mo), grade 1 (< 39.9 g/d), grade 2 (40-59.9 g/d) and grade 3 (> 60 g/d). The physical activity was measured using international physical activity questionnaire-short version. Metabolic equivalent (MET) levels for walking, moderate and vigorous intensity activities were taken as 3.3, 4.0 and 8.0. The activities were measured separately (MET level × minutes of activity/day × days per week) and expressed as total MET min/wk. Based on the total scores, study participants were categorized in to low (< 600 MET min/wk), moderate (600-3000 MET min/wk) and high (> 3000 MET min/wk) level of physical activity.

Dietary details were recorded using a FFQ consisting 29 food items with seven categories (never or hardly ever, once a month, 2-3 times a month, once a week, 2-3 times a week, 4-6 times a week, once a day or more) for egg, chicken, mutton, beef, pork, fruits, vegetables, fried foods, type of oil, type of food, tea, coffee; anthropometric measurements including weight, height, hip circumference, waist circumference also were recorded.

Sample size was calculated using *n* Master software 2.0 for matched case control study, taking exposure in controls for non-vegetarian food as 58% and OR 3.38

Table 1 Socio demographic details of study population, *n* (%)

Variable	Cases	Controls
Age (yr)		
< 40	9 (9.6)	7 (7.4)
40-49	21 (22.3)	18 (19.1)
50-59	28 (29.8)	29 (30.9)
60-69	30 (31.9)	32 (34)

at 95%CI, 80% power the minimum sample size was 93^[9].

Analysis was done using SPSS version 20^[10]. Socio-demographic details and frequency of food intake were expressed in proportions. Univariate analysis for categorical variables (diet, smoking, alcohol, physical activity, BMI, history of diabetes, family history) were done using χ^2 test. Seven frequencies of food item intake were categorized into tertile. Tertile1 corresponds to lowest frequency of intake and tertile 3 corresponds to highest frequency of intake. OR was calculated for highest tertile of intake relative to lowest tertile by logistic regression. Factors having *P* value < 0.05 in univariate analysis were included as parameter for multivariate analysis using logistic regression. Results of multivariate analysis were given as OR with 95%CI. All *P* values were two tailed and significant when values were less than 0.05.

RESULTS

A total of 94 cases and controls were included in the study. The mean age group of cases and controls were 54.1 ± 11.5 years and 55 ± 11.8 years respectively. Age distribution of cases and controls were in the range of 17-78 years. There was almost equal distribution of males and females 48.9% and 51.1% respectively among the study subjects (Table 1). Around 39.4% cases and 35.1% of controls never attended school. In both cases and controls more than 50% of them belonged to class V socio economic status.

The distribution of subjects as per recommended cut off for consumption of food item was much skewed

Table 2 Frequency of food intake among cases and controls, *n* (%)

Table 3 Colorectal carcinoma risk associated with individual dietary item

Food item		Adjusted OR (CI)	P value
Egg	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	1.6 (0.85-3.33)	0.133
	Tertile 3 > 2-3 times a week	5.1 (2.26-11.36)	0.001
Chicken	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	0.6 (0.25-1.51)	0.297
	Tertile 3 Once a week	1.6 (0.64-4.19)	0.297
Mutton	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	1.8 (0.93-3.45)	0.070
	Tertile 3 More than 2-3 times a month	7.4 (2.93-3.45)	0.001
Fish	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	0.8 (0.44-1.60)	0.588
	Tertile 3 More than 2-3 times a month	3.2 (1.13-9.53)	0.028
Beef	Tertile 1 -	-	-
	Tertile 2 Never or hardly ever	1	
	Tertile 3 More than once a month	2.3 (0.13-4.99)	0.237
Fruits	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	1.8 (0.89-3.64)	0.099
	Tertile 3 More than 2-3 times a month	0.8 (0.39-1.68)	0.540
Vegetables	Tertile 1 2-3 times a week	1	
	Tertile 2 Once a day	0.4 (0.19-1.00)	0.050
	Tertile 3 -	-	-
Fried foods	Tertile 1 Never or hardly ever	1	
	Tertile 2 Once a month	0.61 (0.21-1.74)	0.350
	Tertile 3 2-3 times a month	2.52 (1.35-4.70)	0.004

as shown in (Table 2). Among cases 22.3% consumed egg 2-3 times a week compared to only 8.5% among the controls. In cases about one-fourth 24.5% never or hardly ever consumed mutton compared to 46.8% in controls. Beef consumption was reported to be low

among both cases and controls, 72.3% of cases and 86.2% of controls never or hardly ever consumed beef. Similarly more than 80% of cases and controls never or hardly ever consumed pork. Majority of cases 78.7% and controls 89.4% consumed vegetables once a day.

As distribution of subjects as per recommended cut off for consumption of food item was much skewed, intake of food items was categorized into tertile. The frequency cut-off into tertile is not same for all the food items. For certain food items (beef, pork, vegetables, tea, coffee) ranking into tertile was not possible due to its skewed distribution. Univariate logistic regression analysis was done considering these tertile groups as shown in (Table 3). It was observed that consumption of egg for more than 2-3 times a week increases the risk of getting CRC by five times [OR = 5.1 (2.26-11.36)] compared to those who never or hardly consume egg. Mutton consumption of more than 2-3 times a month increases the risk of CRC by 7 times [OR = 7.4 (2.935-18.732)] compared to those never or hardly consumes mutton. Consuming fish and fried foods more than 2-3 times a month increases the risk for CRC. Coffee consumption was not significantly associated with CRC [OR = 1.95 (0.76-5.43)]. Similarly Tea consumption also did not show any significant association with CRC in the present study [OR = 0.49 (0.22-1.70)].

Compared to never smokers, subjects who smoked < 10 pack years, 10-20 pack years and > 20 pack years were not at increased risk for CRC. Alcohol consumption of < 39.9 g/d, 40-59.9 g/d and > 60 g/d was not associated with increased risk for CRC compared to non-users. High (3000 METs/wk) and moderate (600-3000 METs/wk) level of physical activity was not protective for CRC. BMI greater than 25 is not associated with CRC risk. History of diabetes was not significantly

associated with CRC risk (Table 4). Multivariate logistic regression results (Table 5) for those factors found to be statistically significant in univariate analysis (mutton, egg, fish, fried foods and type of oil) showed egg and mutton as independent risk factor.

DISCUSSION

Though population based cancer registries showed a statistically significant increase in the incidence of CRC in India from 1982-2006, very few studies have been done in India to document the association of modifiable risk factors with CRC. The present study attempted to identify the modifiable risk factors so that appropriate preventive measures can be planned. Red meat consumption more than 2-3 times a month found to be an independent risk factor in multivariate regression analysis and increased the odds of developing CRC by 5.41 (1.55-19.05) times compared to those never or hardly consume. This was similar to study by Nayak *et al.*^[7] which reported beef consumption more than once a week has increased risk compared to those who do not consume beef [OR = 4.25 (2.02-8.94)]. A study from Uruguay^[9] reported a positive association between CRC and high intake of red meat with OR = 3.38 (2.37-6.20). Similarly Singh *et al.*^[11] reported red meat intake more than once a week increased the risk compared to non-

Table 5 Factors independently associated with colorectal carcinoma

Food item	Adjusted OR (CI)	P value
Mutton		
Tertile 1	Never or hardly ever	1

Palm	NA	1.6 (0.75-4.04)

consumers [RR = 1.90 (1.16-3.11)].

In the western studies red meat consumption included beef, pork and mutton. However, in present study population due to cultural practices and beliefs beef and pork consumption were minimal. Subjects who consumed egg more than 2-3 times a week had 3.6 (1.23-9.35) times higher risk compared to those who never or hardly ever consume egg. This was similar to the study^[12] which reported consumption of egg more than 2-3 times/wk is associated with increased risk of CRC compared to those who never or hardly consume egg [OR = 2.95 (1.75-5)]. In the present study fish consumption more than 2-3 times a month is associated with increased risk for CRC in univariate analysis. In contrast Nayak *et al.*^[7] from Kerala showed 20% decreased risk of CRC with consumption of fish with every meal [OR = 0.32 (0.13-0.98)]. European study reported fish consumption more than 80 g/d was inversely associated with CRC compared to those consuming < 10 g/d [OR = 0.69 (0.54-0.88)]^[13]. Discrepancy between present study finding and other studies could be due to difference in type of fish consumed, amount of fish consumed, method of cooking and method of preservation.

Fruits and vegetable consumption was not found to be protective for CRC, similar to the findings reported in studies from Western countries^[14-16]. Frequent intake of fried food a proxy variable for high fat intake was associated with CRC [OR = 2.52 (1.35-4.70)] in univariate analysis but it was not an independent risk factor. In contrast studies reported consuming deep fried foods more than once a month was not associated with increased risk^[17,18]. Coffee consumption was not significantly associated with CRC [OR = 1.95 (0.76-5.43)]. A meta-analysis by Je *et al.*^[19] in 2008 showed no significant association between coffee consumption and colorectal cancer [RR = 0.91 (0.81-1.02)], nevertheless; studies have also shown protective effect of coffee in the development of CRC. Kato *et al.*^[20] in Japan found daily coffee consumption

had protective effect on both colon and rectal carcinoma compared with the non drinkers with RR = 0.43 (0.25-0.73) and RR = 0.53 (0.27-1.03), respectively. Reasons for varying results across studies are due to difference in type of coffee, serving size, brewing method and also cutoffs for high and low exposure categories varies between studies. Tea consumption did not show any significant association with CRC in the present study [OR = 0.49 (0.22-1.70)]. Similar findings were found by Nayak *et al.*^[27] where highest quartile of tea consumption has not shown any risk difference compared to lowest quartile with OR = 1.03 (0.62-1.71). In 2005, Michels *et al.*^[14] from United States reported that tea consumption of more than 5 cups per day was not significantly associated with CRC [HR = 1.01 (0.83-1.22)].

Smoking and alcohol use was not associated with CRC in contrast to increased risk reported in few studies^[21-25]. As smoking and alcohol were considered as undesirable behavior in community people tend to under report the use due to social desirability bias^[26]. This could be the reason for no association in the present study. High level of physical activity was not associated with decreased risk for CRC compared to low level of physical activity as reported in other studies^[27,28]. BMI was not significantly associated with CRC; in contrast studies reported high BMI increased risk for CRC^[29,30]. This could be due to underlying limitation of hospital based case-control study, where cases are ill and admitted to the hospital in late stage of disease. By the time patients seek medical attention they would have lost considerable amount of weight. The weight recorded at the time of admission may not find the true association.

Selection of appropriate controls is crucial to establish the true association between exposure (diet, smoking, alcohol, physical activity) and outcome (CRC). Selection of controls remains a major concern when designing a case-control study due to the issues involved in the internal validity and cost. Scientifically there is scope for introducing bias (selection bias and information bias) while selecting hospital based controls^[31]. However there is several advantage of selecting hospital controls such as feasibility, cost, travel time and better recall among hospital controls. Validation studies conducted by Li *et al.*^[32], González *et al.*^[33], Inoue *et al.*^[34] showed that hospital based controls elicit similar information to community controls in assessment of dietary risk factors. Hospital controls are preferred in a hospital based case-control study in view of the issues of practicability. It also reduces the cost involved in the travel and decreases the time taken for face-to-face interviews at field. It has also been demonstrated that the capacity to recall and report the exposures are better in those who are actively seeking health care advise than the members randomly selected from the population^[35].

Since it measures long term, average and habitual dietary intake; FFQ as a mean of dietary assessment have been found appropriate in many nutritional and epidemiological studies^[36]. FFQ captures pattern of food consumption over a period of time ranging from months to years. Pandey *et al.*^[37] from India reported

FFQ had good correlation (0.8) with 5 d diet record and was reproducible. The quantity of food consumed is considered an important factor in estimating the dietary intake of an individual; however, the frequency rather than the serving size has been found to be a better contributor to the variance in the intake of most foods.

Primary limitation of the study was dietary items were not quantified. Though efforts were taken to minimize the recall bias, change in dietary pattern of cases after development of symptoms might have led to biased reporting of their diet.

In conclusion, this hospital based case control study showed egg consumption of 2-3 times a week and mutton consumption 2-3 times a month as independent risk factor. On other hand smoking, alcohol, physical activity, history of diabetes and family history were not associated with increased risk for CRC and no conclusive evidence to suggest fruits and vegetable consumption as protective factor. Cohort study is required to assess the risk associated with commonly consumed dietary items in a given population.

As it was found that persons consuming red meat (mutton) had an increased risk of developing CRC (OR = 5.4), the community needs to be educated to reduce the consumption of red meat such as mutton, so that they can minimize their risk for developing CRC. Similarly, egg consumption was found to increase the odds of developing CRC (OR = 3.6), people especially adults need to be advised to reduce the egg consumption.

ACKNOWLEDGMENTS

We thank the entire faculty who helped in validation and pretesting of the food frequency questionnaire. We also thank all the medical staff who helped in interviewing the patients.

COMMENTS

Background

Epidemiological studies have shown that significant proportion of colorectal cancer (CRC) incidence could be ascribed to dietary, environmental and lifestyle factors; suggesting majority of the risk factors are modifiable. Regional variation in the dietary and social habit could play a vital role in the causation of CRC and may be responsible for the geographical variations in the occurrence of CRC.

Research frontiers

For a long time, it was believed that low meat intake and high fiber vegetarian diet by Indian population is the reason for the low incidence of CRC in India. Only two studies have been reported in literature from India regarding factors associated with CRC and more research studies are require to evaluate or to confirm the risk factors. Identifying the factors associated with decreased CRC incidence among Indian population may help in the primary prevention of CRC across the globe.

Innovations and breakthrough

This study found that red meat consumption of more than 2-3 times a month egg consumption of more than 2-3 times a week are independent risk factors for the development of CRC. Contrary to common belief the study showed no association between CRC and smoking, alcohol consumption, physical activity,

body mass index or diabetes. Consumption of coffee or tea were also not associated with CRC.

Applications

As it was found that persons consuming red meat (mutton) had an increased risk of developing CRC (OR = 5.4), the community needs to be educated to reduce the consumption of red meat such as mutton, so that they can minimize their risk for developing CRC. Similarly, egg consumption was found to increase the odds of developing CRC (OR = 3.6), people especially adults need to be advised to reduce the egg consumption.

Peer-review

This is a good case control study taken a very relevant and significant problem to be studied. The article evaluated important life style and dietary factors for the possible relationship with colorectal cancer in South Indian population. The study showed significant association between red meat and egg consumption and certainly gives better insight and understandings about the other risk factors including smoking, alcohol consumption, body mass index, diabetes and physical activity, *etc.*

Abstract

AIM: To evaluate (1) the association of the *Helicobacter*

pylori (*H. pylori*) test and interleukin-8 (*IL-8*) mRNA expression alone and the severity of gastric cancer (GC); (2) the association of both tests were added to patients' characteristics to identify Thai suspected patients of gastric cancer who would receive the most benefit; and (3) diagnostic value of levels of *IL-8* mRNA expression for gastric cancer.

METHODS: A cross-sectional analytical study was completed with 220 patients with 86 GC patients who underwent endoscopy with gastric surgery divided into non-metastasis and metastasis groups, and 134 patients with benign lesions who underwent endoscopic examination, at the Gastrointestinal Surgery and Endoscopy Unit, Chiang Mai University Hospital between 2006 and 2010. Of 220 patients, 86 cases of diagnosed gastric adenocarcinoma were in an advanced stage and 134 cases were non-cancer patients.

RESULTS: The *IL-8* mRNA expression showed predominant association with advanced GC when compared to *H. pylori* infection alone [OR (95%CI); 0.86 (0.49-1.53) vs 5.44 (3.08-9.62)] when including the patients' characteristics the highest of the area under the receiver operating characteristic curves (AuROC) of the model were males older than 40 years of age [AuROC (95%CI); 0.81 (0.75-0.86)]. However, preliminary testing for diagnostic indices of four cut-off points of *IL-8* mRNA expression to predict the severity of GC cases found an increasing suboptimal trend from the likelihood ratio of positive to differentiate the severity in the GC group. The *IL-8* mRNA expression showed a predominant association with GC when compared to *H. pylori* infection, especially in males older than 40 years of age who may benefit most from this test.

CONCLUSION: The future research of *IL-8* mRNA expression to predict severity in the gastric cancer group should be warranted.

Core tip: The author reviewed updated basic research studies regarding linkages of inflammatory cytokine genetic expression level and gastric cancer (GC) risk prediction in the Thai population. The review focused on *interleukin-8 (IL-8)* mRNA expression and *Helicobacter pylori (H. pylori)* infection in which are found an increasing risk for GC and aggressive histologic types. We performed the epidemiologic data in-depth analysis, and make the various cut off points to discern which level of *IL-8* mRNA expression has remarkable predictive risk value in comparison with *H. pylori* infection to predict GC occurrence.

Chongruksut W, Limpakan (Yamada) S, Chakrabandhu B, Ruengorn C, Nanta S. Correlation of *Helicobacter pylori* and interleukin-8 mRNA expression in high risk gastric cancer population prediction. *World J Gastrointest Oncol* 2016; 8(2): 215-221 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i2/215.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i2.215>

INTRODUCTION

Gastric cancer (GC) is one of the most common cancers and continues to remain a major public health problem in the world, with a varying prevalence from 11% to 56% in different areas. The prevalence of GC in the United States was an estimated 74035 people^[1] and estimated 934000 cases, 56% of new cases from Eastern Asia, 41% from China, and 11% from Japan^[2]. In Thailand, the incidence rate of GC was 4.1:100000 for males and 2:100000 for females, especially in the northern part of Thailand which has a higher GC incidence rate with 6.6:100000 in males, and 4.5:100000 in females^[3].

GC is one of the most common causes of death from cancer worldwide, and most of the cases occur in developing countries^[4]. A gender difference of mortality of GC was reported; 14.3 per 100000 in men and 6.9 per 100000 in women worldwide^[5], as well as geographic countries; 20% mortality rate in Western countries vs up to 60% in Asia^[6].

Early diagnosis is crucial because of the possibility of early metastasis to other organs such as, liver, pancreas, omentum, esophagus, bile ducts, and lymph nodes^[7]. If GC was detected at an early stage, the five year survival was approximately 90%^[8]. Thus, in developing countries, early detection is most needed. The standard method or diagnosing GC is through the upper digestive endoscopy combined with biopsy and histopathological evaluation of the biopsy samples^[4]. This method has a high diagnostic accuracy of 95% to 99%^[9].

Helicobacter pylori (H. pylori) infection is widely regarded as the most important risk factor in the development of GC^[6] with from 0.5% to 2.0% developing

gastric adenocarcinoma^[10]. A meta-analysis of 34 cohort and case-control studied patients found that *H. pylori* carried a relative risk of GC of 3.02 (95%CI: 1.92-4.74) in high risk settings (China, Japan and Korea) and 2.56 (95%CI: 1.99-3.29) in low risk settings (Western Europe, Australia, and the United States)^[11]. Epidemiologic data indicates that GC occurs more frequently in populations with higher rates of *H. pylori* infection, and the World Health Organization has classified this bacterium as a Class 1 carcinogen for GC^[6]. *H. pylori* infection was important in the process of tissue remodeling, angiogenesis, tumor invasion and metastasis^[12] and induces a number of genes in host cells that are potential determinants of inflammation, angiogenesis, and metastasis including *interleukin-8 (IL-8)* gene expression^[13]. However, it remains unclear how *H. pylori* infection activates specific transcription factors and induces gene expression. Yamada *et al*^[14] indicated that the *H. pylori* infection in Thai GC patients was reported by combined histopathology and *H. pylori* IgG antibody test with 77.1% and 97.4% of sensitivity and specificity, respectively.

Moreover, *IL-8* mRNA expression is one of the factors that were possible influences which affect GC^[15], Yamada *et al*^[14,16] reported that GCs were detected in more than 80% of Thai patients with high levels of *IL-8* mRNA expression, while *H. pylori* infection and *IL-8* mRNA expression were relative risks for Thai GC, therefore *IL-8* mRNA expression may be a useful diagnostic and prognostic risk marker for GC. Similarly, Macri *et al*^[17] indicated that the level of serum *IL-8* mRNA expression may act as marker of GC. The high expression of *IL-8* mRNA expression was directly demonstrated with a poor prognostic histologic type in GC^[14,16].

Although, the association of *H. pylori* infection and *IL-8* mRNA expression and GC were demonstrated from several studies, most studies did not evaluate the association of these biomarkers and the GC severity, *i.e.*, no cancer, non-metastasis, and metastasis stage. There might be an increasing possibility of GC by gradient of *IL-8* mRNA expression. Moreover, some studies showed an association with independent factors such as advanced age, sex, and alcohol drinking. Therefore, this present study aimed to evaluate (1) the association of *H. pylori* test and *IL-8* mRNA expression alone and the severity of GC; (2) the association of both tests added to patients' characteristics to identify Thai suspected patient risk of GC who will receive the greatest benefit for follow up endoscopy; and (3) diagnostic value of four different levels of *IL-8* mRNA expression for GC cases.

MATERIALS AND METHODS

A cross-sectional analytical study was conducted in patients over 18 years of age. Eighty-six patients who underwent endoscopy were diagnosed with GC, and 134 patients who underwent endoscopic examination were diagnosed as non-GC, at the Gastrointestinal Surgery and Endoscopy Unit, Chiang Mai University Hospital between 2006 and 2010. All patients were comprehensively examined

by a gastrointestinal pathologist for *H. pylori* infection and combined histopathological diagnostic results. The outcomes of the study were divided into non-GC, and GC. In GC patients, those who were categorized in cancer Stages I, II, III and IV were in the GC group.

Tissue samples were taken by endoscopy with tissue *IL-8* mRNA expression conducted by real time relative quantitation polymerase chain reaction. Additionally, baseline characteristics; gender, age, alcohol drinking, smoking, stages of cancer, histological pathology were obtained by a physician and nurse, using a case record form. All enrolled patients were examined by endoscopy with a pathology result for *H. pylori* infection and received biopsy of tissues with *IL-8* mRNA expression. This study excluded all patients without results of pathology or tissue *IL-8* mRNA expression. The present study was approved by the Institutional Review Boards of the Faculty of Medicine, Chiang Mai University.

Statistical analysis

The demographic data were analyzed using χ^2 to test between groups, and the test for trend was used to test for proportion. An ordinal logistic regression, both univariable and multi-variable models, were performed to determine association of *H. pylori* and *IL-8* mRNA expression and severity of GC with or without patients' characteristics presented with crude and adjusted odds ratio with 95%CI. The area under the receiver operating characteristic curves (AuROC) was calculated and compared using a standard method. *IL-8* mRNA expression level was divided into four different cut-off points, and AuROC was compared to select the best cut-off point. Performance of each *IL-8* mRNA expression cut-off point was then evaluated for sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), positive likelihood ratio (LHR+), and negative likelihood ratio (LHR-) in only GC cases. A statistical significance level or alpha of 0.05 was selected for Type I error.

RESULTS

Of the 220 patients enrolled in this study, 86 cases were diagnosed with GC and underwent endoscopy with gastric surgery, and 134 non-cancer patients underwent endoscopic examination. Among those diagnosed with a non-GC, 45 cases were normal, 46 had benign lesions (polyps, erosion, mild superficial gastritis), and 42 cases had chronic active gastritis. When categorized by staging, 41 cases (47.67%), and 34 cases (39.53%) were in Stage III B, and Stage IV, respectively.

Two groups of patients were therefore assigned by order of severity to non-cancer, and advanced GC. Patients' characteristics found statistically significant when testing for trend were sex, age, and smoking status. The majority of GC patients were male, aged ≥ 40 years, and had a history of smoking (Table 1).

According to *H. pylori* active infection status and pathology, no statistical differences were found among

Table 1 Characteristics of gastric cancer and non-gastric cancer patients, *n* (%)

Characteristics	Gastric cancer <i>n</i> = 86	Non-gastric cancer <i>n</i> = 134	<i>P</i> value

Well differentiated	7 (8.33)	-	

the groups. While, *IL-8* mRNA expression had the highest level in the metastatic GC group (median 325) and non-cancer group (median 19.72), respectively. An *IL-8* mRNA expression was transformed to log₁₀ and divided into five cut-off points. The higher the cut-off point, the higher proportion of the severity of GC was demonstrated (Table 2).

The value of *H. pylori*, and *IL-8* mRNA expression as biomarkers, alone or combined with patients' characteristics, were determined. The results showed the predominant performance of *IL-8* mRNA expression over *H. pylori* pathology and serum IgG results (Model 1 vs Model 2). *H. pylori* pathology results in accordance with significant demographic characteristics, *i.e.*, sex and age showed lower performance compared to *IL-8* mRNA expression alone (Model 3 vs Model 2). Adding *IL-8* mRNA expression in a model with sex and age, the AuROC of probability to predict severity occurrence of GC was increased (Model 4 vs Model 2). However, adding *H. pylori* pathology in the last model did not enhance a predictability of GC severity in the last model (Model 5 vs Model 4). Therefore, *IL-8* mRNA expression is useful to differentiate severity of GC especially when combined with sex and age (Table 3). The *IL-8* mRNA expression used was the best cut-off point of two to predict the severity of GC; AuROC of cut-off-point one through four was 0.64, 0.71, 0.60, and 0.53, respectively (data not shown).

We further analyzed the prediction ability of the model containing *IL-8* mRNA expression across age group and sex. The likelihood positive ratio of all models

Table 2 Serum interleukin-8 mRNA expression and *Helicobacter pylori* infection status detection results in gastric cancer and non-gastric cancer patients, *n* (%)

Variables	Gastric cancer <i>n</i> = 86	Non-gastric cancer <i>n</i> = 134	<i>P</i> value

H. pylori: *Helicobacter pylori*.**Figure 1** Area under the receiver operating characteristic curve of *Helicobacter pylori* in prediction of gastric cancer. *H. pylori*: *Helicobacter pylori*; ROC: Receiver operating characteristic curves.

was statistically significant. The largest yield of the LHR+ was the model with all variables. Apparently, *IL-8* mRNA expression has the highest yield of the LHR+ in males who are older than 40 years old compared to the younger age or in the female group (LHR+ 14.54 vs 3.38) due to acceptable LHR+ (more than 5.0, theoretical suggested LHR+). Therefore, *IL-8* mRNA expression may be most useful in the Thai male with the age older than 40 years (Table 4).

Because the trend of prediction in the severity of GC of *IL-8* mRNA expression was observed, diagnostic indices were determined only in 86 GC patients who were categorized by metastatic status although it was still localized. Under four different cut-off points of *IL-8* mRNA expression, the sensitivity was highest in the *IL-8* mRNA expression Level one (96.8%) and continuously declined to 12.9% in the cut-off point of Level four. In the

**Figure 2** Area under the receiver operating characteristic curve of interleukin-8 mRNA Expression in prediction of gastric cancer. IL-8: Interleukin-8; ROC: Receiver operating characteristic curves.

opposite, specificity for GC metastasis increased from 8.7% in *IL-8* mRNA expression level one to 93.5% in Level four. The LHR+ increased from 1.06 to 1.98 of the Level one to Level four (Table 5). The AuROC of all of the cut-off points were not statistically significant (*P*-value of difference = 0.832) with less than a 60% range in all groups. There might have been a lack of ample sample size so the *IL-8* mRNA expression level could differentiate severity in the diagnosed GC group (Table 5).

The AuROC of *H. pylori* alone and AuROC of *IL-8* mRNA expression alone in prediction of GC occurrence is shown in Figures 1 and 2. Comparable AuROC of *IL-8* mRNA expression in an adjusted model by sex, age, and *H. pylori*, and additional AuROC of both *IL-8* mRNA expression and *H. pylori* infection in prediction of GC are shown in Figure 3.

DISCUSSION

In this study, performances of *H. pylori* infection and *IL-8* mRNA expression were determined as to whether there was an association with GC which was divided into two groups: Non-GC, and GC. The *IL-8* mRNA expression showed a predominant association with GC when compared to *H. pylori* infection, especially in males older than 40 years of age. In addition, there was a trend of the probability of GC with increasing levels of *IL-8* mRNA expression. Further, preliminary testing for diagnostic indices of four cut-off points of *IL-8* mRNA expression to predict severity of GC cases was performed. However, we found an increasing suboptimal trend from the likelihood ratio of positive (less than five times) which may be due to the small sample size to differentiate severity in GC groups.

GC has a high incidence rate in the northern part of Thailand. Epidemiological studies have shown that *H. pylori* is associated closely with the development of GC and it is widely regarded as the most important modifiable risk factor for GC^[18]. However, when categorizing GC

by severity, *H. pylori* lost its association in our findings. Unlike, *IL-8* mRNA expression, the results from our study found the superiority of prediction of GC severity over *H. pylori* infection. *IL-8* mRNA expression is one of factors that possibly affects GC^[15]. Thai people in the advanced stage of GC showed that gastric mucosal tissue *IL-8* mRNA expression has a higher level value and percentage of poorer differentiated cell type more than in favorable histology or differentiated cell type^[14]. This finding was consistent with the results of Yamada *et al.*^[14,16] which showed that a high level of *IL-8* mRNA expression was detected more than 80% in Thai advanced GC patients, of cases and they demonstrated that gastric mucosal *IL-8* mRNA expression was a relative risk for Thai GC. Thus *IL-8* mRNA expression may also be a useful diagnostic risk marker for GC. It is possible to use *IL-8* mRNA expression as a good indicator for advanced GC or aggressive types of cancer treatment selection especially in poor prognostic cell type.

Moreover, this study demonstrated the AuROC of *IL-8* mRNA expression when comparing gender with age found that males more than 40 years of age predicted the severity of GC with LHR+ 14.5 times. This may explain recent indications that men have a higher incidence rate and may have a poorer prognosis than women^[19]. The increased incidence rate of males could be due to the difference in the lifestyles and habits from females; such as smoking and alcohol consumption^[20]. A previous study on sex differences in GC incidence based on the study of etiological hypothesis indicated that the predominance of GC in men was a global phenomenon, and was related to a 10 to 15 year delay in the appearance and onset of GC of intestinal subtype in women compared with men^[21,22]. Our data showed that *IL-8* mRNA expression may be a helpful tool to identify advanced risk of GC in Thai patients especially males with an age older than 40 years.

We further investigated diagnostic performances

Figure 3 Comparable area under the receiver operating characteristic curve between interleukin-8 mRNA expression and *Helicobacter pylori* in prediction of gastric cancer. *H. pylori*: *Helicobacter pylori*; IL-8: Interleukin-8; ROC: Receiver operating characteristic curves.

of *IL-8* mRNA expression for advanced stages of GC. Although there was no statistical significance among the four cut-off points of *IL-8* mRNA expression of the AuROC, and the LHR+ values were lower than five times, there was a trend of increasing predictability of GC severity and prognosis. Future study is warranted to prove the predictive values of *IL-8* mRNA expression in GC patients with a larger clinical sample size. The limitation of this study was its retrospective nature and as a result some important available data could have been omitted due to a lack of medical records.

The *IL-8* mRNA expression showed predominant association with GC when compared to *H. pylori* infection, especially in males with age older than 40 years who may be benefit the most from this test. The preliminary testing for diagnostic indices of four cut-off points of *IL-8* mRNA expression showed a suboptimal trend to differentiate severity in the GC group.

ACKNOWLEDGMENTS

We would like to thank the study investigators and the patients in Division of Gastrointestinal Surgery and Endoscopy, Department of Surgery, Chiang Mai University. In addition, we wish to thank the Professor Bannakij Lojanapiwat, MD, the Head of Surgery Department for his support.

COMMENTS

Background

The association of *Helicobacter pylori* (*H. pylori*) infection and interleukin-8 (*IL-8*) mRNA expression and gastric cancer (GC) were demonstrated from several studies. However, there was a lack of evidence of the association of these biomarkers and GC severity.

Research frontiers

The association of *H. pylori* test and *IL-8* mRNA expression alone and the severity of GC; (1) the association of both tests added to patients' characteristics to identify Thai suspected patient risk of GC who will receive the greatest benefit for follow-up endoscopy; and (2) diagnostic value of four different levels of *IL-8* mRNA expression for GC cases.

Innovations and breakthroughs

The *IL-8* mRNA expression showed predominant association with GC when compared to *H. pylori* infection, especially in males with age older than 40 years who may be benefit the most from this test. The preliminary testing for diagnostic indices of four cut-off points of *IL-8* mRNA expression showed a suboptimal trend to differentiate severity in the GC group.

Peer-review

It might be interesting to analysis *IL-8* expression level in different stage and different histological grade, in order to demonstrate whether *IL-8* is more sensitive than *H. pylori* in different stage and grade GC.

Abstract

AIM: To investigate the prognostic role of invariant natural killer T (iNKT) cells and antibody-dependent cell-mediated cytotoxicity (ADCC) in wild type *KRAS* metastatic colorectal cancer (mCRC) patients treated with cetuximab.

METHODS: Forty-one *KRAS* wt mCRC patients, treated with cetuximab and irinotecan-based chemotherapy in II and III lines were analyzed. Genotyping of single nucleotide polymorphism (SNP)s in the *FCGR2A*, *FCGR3A* and in the 3' untranslated regions of *KRAS* and mutational analysis for *KRAS*, *BRAF* and *NRAS* genes was determined either by sequencing or allelic discrimination assays. Enriched NK cells were obtained from lymphoprep-peripheral blood mononuclear cell and iNKT cells were defined by co-expression of CD3, TCRV α 24, TCRV β 11. ADCC was evaluated as *ex vivo* NK-dependent activity, measuring lactate dehydrogenase release.

RESULTS: At basal, mCRC patients performing ADCC activity above the median level (71%) showed an improved overall survival (OS) compared to patients with ADCC

below (median 16 *vs* 8 mo; $P = 0.026$). We did not find any significant correlation of iNKT cells with OS ($P = 0.19$), albeit we observed a trend to a longer survival after 10 mo in patients with iNKT above median basal level (0.382 cells/microliter). Correlation of OS and progression-free survival (PFS) with interesting SNPs involved in ADCC ability revealed not to be significant. Patients carrying alleles both with A in FCGR2A and TT in FCGR3A presented a trend of longer PFS (median 9 *vs* 5 mo; $P = 0.064$). Chemotherapy impacted both iNKT cells and ADCC activity. Their prognostic values get lost when we analysed them after 2 and 4 mo of treatment.

CONCLUSION: Our results suggest a link between iNKT cells, basal ADCC activity, genotypes in FCGR2A and FCGR3A, and efficacy of cetuximab in *KRAS* wt mCRC patients.

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: A high number of invariant natural killer T (iNKT) cells and a high antibody-dependent cell-mediated cytotoxicity (ADCC) activity, evaluated before therapy, do correlate significantly with a longer overall survival in metastatic colorectal cancer patients treated with irinotecan-based chemotherapy and cetuximab in II and III lines. Chemotherapy impacted both iNKT cells and ADCC activity. The prognostic value of ADCC above the median basal level, get lost when we analysed those parameters after 2 and 4 mo of treatment. Correlation of overall survival and progression-free survival with interesting single nucleotide polymorphisms reported as involved in ADCC ability, either in the FCGR2A, FCGR3A or in the 3' untranslated regions of *KRAS* gene, revealed not to be significant.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer worldwide, accounting for 940000 million new cases annually and nearly 500000 deaths each year. Metastatic colorectal cancer (mCRC) previously untreated patients have demonstrated substantial improvements, with a median overall survival time now reaching more than

24 mo, by the development of systemic chemotherapy, including molecular-targeted therapy^[1].

The epidermal growth factor receptor (EGFR) signalling pathway is involved in cell differentiation, proliferation, migration, angiogenesis and apoptosis, all processes dysregulated in cancer cells.

Cetuximab is a chimeric immunoglobulin G1 (IgG1) monoclonal antibody (mAb) which binds EGFR with high affinity and inhibits ligand binding^[2].

KRAS activating mutations have been reported in 40% of mCRC showing a negative effect on response to anti-EGFR antibodies^[3,4]. Mutations in other downstream effectors of the *EGFR* signalling pathway, such as *BRAF*, *NRAS* and *PI3*kinase, might also impact the efficacy of monoclonal therapy. Thus, the absence of mutations in *RAS* appears to be a reliable marker for predicting the efficacy of cetuximab which was been restricted to mCRC patients with wild-type *RAS*^[5]. Several studies supported the biological activity of cetuximab in advanced CRC. Cetuximab enhances response rate and progression-free survival (PFS) in first-line therapy in combination with Folfiri and Folfox regimen of chemotherapy^[6,7]. However, some clinical studies have failed to show a significant correlation between EGFR expression and the response to cetuximab^[8]. The proposed working mechanism of cetuximab is thought to include antibody-dependent cell-mediated cytotoxicity (ADCC)^[9].

ADCC utilizes the response of innate immune cells to provide antitumor cytotoxicity triggered by the interaction of the Fc portion of the antibody with the Fc receptor on the immune cell. Immunotherapeutics that target natural killer (NK) cells, $\gamma\delta$ T cells, macrophages and dendritic cells can, by augmenting the function of the immune response, enhance the antitumor activity of the antibodies^[10].

Invariant CD1d-restricted natural killer T (NKT) cells are T lymphocytes characterized by an invariant T-cell antigen receptor-chain rearrangement that co-express NK cell markers^[11].

Molling *et al.*^[12] in 2007 demonstrated that a severe circulating invariant NKT (iNKT) cell deficiency was related to poor clinical outcome in head and neck squamous cell carcinoma patients, suggesting their critical contribution to antitumor immune responses. Furthermore, screening for iNKT cell levels may be useful for determining which patients can benefit from immunotherapeutic adjuvant therapies aimed at reconstitution of the circulating iNKT cell pool.

Whether ADCC is associated with EGFR expression and/or the mutational status of *RAS* and *BRAF* in CRC remains unclear. Seo *et al.*^[13] demonstrated that the ADCC activities were significantly associated with the cell surface expression levels of EGFR but not with the mutational status of *KRAS* and *BRAF*.

In this study we aimed to evaluate the prognostic and predictive value of cetuximab-mediated ADCC and circulating iNKT cells levels in mCRC and to analyse their correlation with *EGFR* level, mutational status of

MATERIALS AND METHODS

Patients and clinical samples

A total of 41 mCRC patients were enrolled in this study from March 2008 to September 2014. Characteristics of the 41 patients are described in Table 1. An informed consent for tissue collection and use for scientific purpose was obtained from each patient enrolled in this study, approved by the local Ethical Committee and carried out in the respect to Helsinki Declaration. Inclusion criteria for mCRC patients were: Suitability for combination therapy including cetuximab with irinotecan-based chemotherapy in second and third lines and *KRAS* wild type (wt) status. Patients were evaluated for PFS, OS and response at the end of treatment with CT scan according to RECIST criteria^[2]. Median follow-up was 25 mo (range 10-70).

DNA extraction, genotyping and mutational analyses

Genotyping of rs1801274 (A > G) in the *FCGR2A*, rs396991 (T > G) in *FCGR3A* and rs61764370 in the 3' untranslated regions (3' UTR) of *KRAS* gene was done on genomic DNA isolated from whole peripheral blood samples using the EZ1 DNA Blood 200 Kit (Qiagen, Germany) according to the manufacturer's instructions. Analyses were determined using the appropriate

"allelic discrimination assay" from Life Technologies (Foster city, CA, United States): c_9077561_20 for rs1801274; c_25815666_10 for rs396991 and 1350086 for rs61764370 using the ABIPRISM 7000 Sequence Detection System (Applied Biosystems Foster City, CA, United States).

Mutational analyses for *KRAS* (codons 12-13-59-61-146), *BRAF* (codon 600) and *NRAS* (codons 12-13-59-61-117-146) genes were determined on patients' DNA extracted from Formalin Fixed Paraffin Embedded (FFPE) tumor tissues archived at diagnosis in the Pathology Department of our Institution, by a standard protocol that included proteinase K treatment (EuroClone, Pero, IT).

KRAS and *BRAF* gene analyses were performed by pyrosequencing using PyroMark ID System (Biotage, Uppsala, Sweden), while a Real-Time PCR (OncoSreen *NRAS*; Relab, Jesi, Italy) was employed for *NRAS* gene using the Rotor-Gene 6000 (Corbett Research, Pty Ltd; Sydney, Australia) according to the manufacturer's protocol.

Antibody-dependent cell-mediated cytotoxicity assay

Twelve milliliter peripheral blood samples were collected at start of therapy for all the 41 patients and ADCC and NK cells were evaluated at basal level. After 2 and 4 mo of treatment a second collection of blood was done in 30 and 23 patients respectively where ADCC and NK cells were longitudinally studied.

Enriched NK cells were obtained from lymphoprep-peripheral blood mononuclear cell pellets using the human NK Cell Isolation Kit (Miltenyi Biotec, Cologne, Germany). NK cells were defined as CD56⁺/CD3⁻; T cells as CD3⁺/CD56⁻ and invariant NKT (iNKT) cells by co-expression of CD3, TCR Vα24, TCR Vβ11.

ADCC was evaluated as *ex vivo* NK-dependent activity with a standard lactate dehydrogenase (LDH) assay (Cytotox 96[®] non radioactive cytotoxicity assay, Promega, Madison, WI) as set up in our Laboratory^[14].

Statistical analysis

Statistical analyses were performed using the GraphPad Prism 5 (San Diego, CA, United States) and SPSS version 13 (SPSS, Chicago, IL) programs. The association between ADCC median levels was analyzed using the Fisher's exact test or the Pearson's test when appropriate. OS analyses were based on the time from treatment start to death or last contact in which the survivors were censored. PFS analyses were based on the time from treatment start to first event; patients without an event were censored at their last follow-up. OS was calculated using the Kaplan-Meier method with log-rank test for statistical significance. A *P*-value < 0.05 was considered statistically significant.

RESULTS

Clinical and molecular characteristics of patients

Clinical characteristics of the 41 mCRC patients are

Table 2 *FCGR2A* (rs1801274; A > G), *FCGR3A* (rs366991; T > G) and single nucleotide polymorphism rs61764370 of *KRAS* 3' untranslated region genotypes with the correspondent aminoacid change in the 41 metastatic colorectal cancer patients included in this study

Gene	SNP	Genotype	Aminoacid change	Number of subjects (%)
<i>FCGR2A</i>	rs1801274	A/A	H131H	14 (34.1%)
		A/G	H131R	20 (48.8%)
		G/G	R131R	7 (17.1%)
<i>FCGR3A</i>	rs396991	T/T	F158F	14 (34.1%)

		G/G	---	0 (0%)

SNP: Single nucleotide polymorphism; UTR: Untranslated region.

detailed in Table 1. Genotyping analyses for single nucleotide polymorphisms are reported in Table 2. All patients were wt for *KRAS* gene. Determination of *NRAS* and *BRAF* mutations failed in 1 out of the 41 patients, due to poor quality of DNA obtained from tumoral tissue. In particular we identified 6 mutations in *NRAS* gene (1 mutation in G12x-G13x; 1 in G61R; 1 in Q61K, 1 in Q61L and 2 in A59x-Q61H codons) and 1 mutation in *BRAF* gene (V600E).

Survival analysis according to iNKT cells

iNKT cells evaluated before treatment were analysed to seek correlation with OS and PFS either as number of cells/microliter or as % of T cells, since a low level of circulating iNKT cells has been reported to predict poor clinical outcome in patients with head and neck squamous cell carcinoma^[12]. iNKT cells median value at basal determination, before treatment, was 0.382 cells/microliter. We did not find any significant correlation of iNKT cells with OS ($P = 0.19$), albeit we observed a trend to a longer survival after 10 mo in the population of patients ($n = 21$) with iNKT above median level (Figure 1).

Survival analysis according to ADCC activity

Median ADCC activity before treatment for all the 41 mCRC patients was 71% (range 10%-99%). Comparison between patients with ADCC above and below median value is reported in Table 3. There were no differences in the clinical characteristics between the two groups, although *EGFR* over-expression was more common in patients with ADCC activity above the median level ($P = 0.052$; Fisher's exact test). Correlation with OS and PFS was evaluated. Median OS was 12 mo (range 3-37) and PFS was 6 mo (range 3-37). Patients performing ADCC activity above the median level showed an improved OS compared to patients with ADCC activity below this value (median 16 vs 8 mo; $P = 0.026$; Long-rank Mantel-Cox Test) (Figure 2). On the contrary, there was no difference in PFS between patients with ADCC below or above the median level (data not shown). When we

Figure 1 Overall survival in 41 metastatic colorectal cancer treated with cetuximab in II and III lines according to median basal level of invariant natural killer T cells (0.382 cells/microliter). iNKT: Invariant natural killer T.

stratified patients for both iNKT and ADCC activity at basal level, below and above the respective median level, we observed a better OS in patients having both values above the median level compared to all the other combinations (median 23 vs 10 mo; $P = 0.0075$; Long-rank Mantel-Cox Test) (Figure 3).

Survival analysis according to genotypes of *FCGR2A*, *FCGR3A* genes and in *KRAS* 3'UTR

Correlation in terms of OS and PFS with each genotype, either rs1801274 (A > G) in the *FCGR2A*, rs396991 (T > G) in *FCGR3A* or rs61764370 in the 3' UTR of *KRAS* gene reveal not to be significant (data not shown).

Patients carrying alleles both with A in *FCGR2A* (AA/AG genotypes) and TT in *FCGR3A* presented a longer PFS (median 9 vs 5 mo; $P = 0.064$; Long-rank Mantel-Cox Test) in comparison to all the other subgroups (Figure 4), although the difference was not significant.

Survival analysis according to mutational status in *RAS* family genes

Due to the limited number of patients we were not able to perform OS and PFS analyses according to all-*RAS* gene mutations. Nevertheless we observed that of ADCC activity, as median level, was not affected by the presence of a *NRAS* or a *BRAF* mutation (data not shown).

How the treatment influenced iNKT cells and ADCC activity

Both iNKT cells and ADCC activity were evaluated over time to seek for dynamic changes during treatment and to investigate the impact of therapy on patients' ability to perform ADCC and their clinical outcome. iNKT cells median number decreased from 0.382 cells/microliter at basal, before treatment, to 0.193 after 2 mo and to 0.165 after 4 mo of treatment. Likewise, ADCC activity was longitudinally evaluated up to 2 and 4 mo and its median level fell down from of 71% to 45% at two

withdrawal further analyses.

Survival analysis according to variation in ADCC activity during treatment

ADCC determination during treatment lost its prognostic value since there was no difference in OS between patients with ADCC activity above or below the median level after 2 and after 4 mo of treatment (data not shown). Variation of ADCC values was analyzed by stratifying patients on the basis of to the median values at basal level (71%, 41 patients), after 2 mo (45%, 30 patients) and after 4 mo (45%, 23 patients) of treatment. Combination of longitudinal values generated 4 groups of patients: the first included patients showing both ADCC activities above the median level [ADCCbas above/ II (or III) above, where II means on blood drawn after 2 mo and III after 4 mo], the second group a decrease from a basal above median to a II or III determination below median [ADCCbas above/ II (or III) below], the third group patients showing instead an increase from below at basal and above at II or III determination [ADCCbas below/ II (or III) above] and the fourth group patients with both ADCC activities below the median level [ADCCbas below/ II (or III) below].

Figure 2 Overall survival in 41 metastatic colorectal cancer treated with cetuximab in II and III lines according to median basal level of antibody-dependent cell-mediated cytotoxicity activity (71%). ADCC: Antibody-dependent cell-mediated cytotoxicity.

Figure 3 Overall survival in 41 metastatic colorectal cancer patients stratified for both invariant natural killer T and antibody-dependent cell-mediated cytotoxicity activity at basal level, below and above the respective median level. iNKT = 0.382 cells/microliter; ADCC = 71%. iNKT: Invariant natural killer T; ADCC: Antibody-dependent cell-mediated cytotoxicity.

We then analysed correlation with OS in the 4 groups. Patients performing ADCC activity above the median value both at basal level and either after 2 and/or 4 mo presented a trend in longer OS, albeit not significant (Figure 5).

When we focus on patients presenting ADCC values above the median levels in both determinations (basal and after 2 mo) we found that this 9 out of the 30 patients (30%) showed a higher OS compared to other patients (median 21 vs 13 mo, $P = 0.5$; Long-rank Mantel-Cox Test). After 4 mo, 8 patients out of 23 (35%) had both values above the median levels of ADCC activity, but their OS was not statistically different from that of the other patients (median 18.5 vs 15 mo; $P = 0.42$; Long-rank Mantel-Cox Test) (data not shown).

DISCUSSION

Treatment of mCRC requires a multidisciplinary approach and multiple treatment options are nowadays available^[1]. Advances in the understanding of tumor biology have led to the development of *EGFR*-targeted therapies as mAbs. In fact, the *EGFR*-signalling pathway regulates important processes involved in cell differentiation, proliferation, migration, angiogenesis and apoptosis, all of which become deregulated in cancer cells. However, the mechanisms that mediate the therapeutic effect of these mAbs are still unclear.

Cetuximab is a chimeric monoclonal antibody that specifically targets *EGFR* with high affinity and prevents the ligand-mediated activation of the *EGFR*-dependent pathway. *KRAS* mutations occur in 35%-45% of mCRC and preclude responsiveness to *EGFR*-targeted therapy with cetuximab or panitumumab. Initial response rates of about 10% were seen with cetuximab monotherapy in patients with heavily pretreated mCRC. A phase II BOND study demonstrated the ability of cetuximab to circumvent irinotecan-based chemotherapy resistance^[2]. Less than 20% patients displaying wild-type *KRAS* tumors achieve objective response. In fact, it subsequently became clear that tumors without mutations in codon 12 or 13 of the *KRAS* gene responded in 13%-17% of cases, whereas only 0.1%-2% of the *KRAS* mutant tumors did^[15].

Alterations in other effectors downstream of the *EGFR* and deregulation of the *PIK3CA/PTEN* pathway have independently been found to give rise to resistance. Moreover, the *PIK3CA* gene is mutated in approximately 20% of CRCs. *BRAF* is the principal downstream effector of *KRAS* and its oncogenic V600E mutation is mutually exclusive with *KRAS* mutations in CRCs^[4,16].

It has recently become clear that IgG1 mAb, like cetuximab, may have mechanisms of action other than the selective blockade of tumoral membrane receptors. Among them, the Fc region of the mAb may also trigger

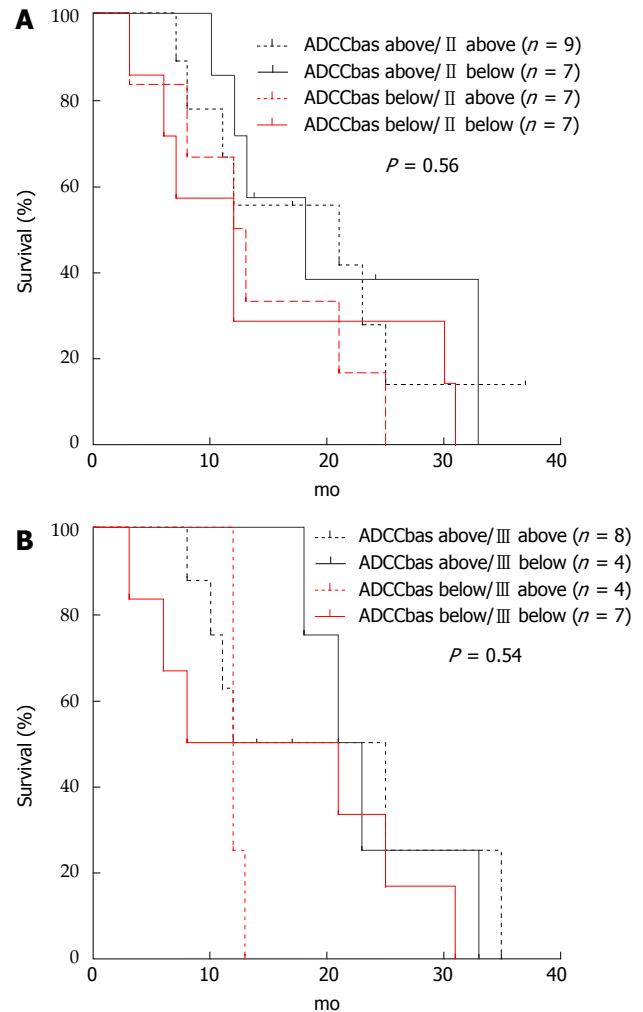

Figure 5 Overall survival in 30 metastatic colorectal cancer patients with a blood drawn after 2 mo (A) and in 23 patients with a blood drawn after 4 mo of treatment (B). Analysis was done in 4 groups of patients: The first included patients showing both ADCC activities above the median level [ADCCbas above/II (or III) above, where II means on blood drawn after 2 mo and III after 4 mo], the second group a decrease from a basal above median to a II or III determination below median [ADCCbas above/II (or III) below], the third group patients showing instead an increase from below at basal and above at II or III determination [ADCCbas below/II (or III) above] and the fourth group patients with both ADCC activities below the median level [ADCCbas below/II (or III) below]. ADCC: Antibody-dependent cell-mediated cytotoxicity.

ADCC, binding *via* Fv regions the target cell to any of the Fc- γ receptors, *i.e.*, CD16, CD32 and CD64, which are expressed, with different patterns, by cells of the innate immune system, namely monocytes, macrophages, granulocytes and NK. The contribution of the different cell types to the anti-tumor ADCC exerted *in vivo* by anti-*EGFR* mAbs is still debated. In general these cell are thought to play a relevant role controlling tumor growth and in preventing metastatic dissemination in humans^[17,18].

In particular, NK cells have been suggested to be the major mediators of the ADCC-dependent therapeutic effect of cetuximab^[19]. Moreover, invariant CD1d-restricted NKT cells has been reported to play an allegedly pivotal role in such responses *via* transactivation of immune effector cells. In particular, a severe circulating iNKT cell

deficiency was related to poor clinical outcome in head and neck squamous cell carcinoma patients^[12].

Thus, the number of iNKT and the level of ADCC activity exerted by NK cells from tumor patients in the presence of cetuximab might be useful prognostic or predictive parameters for response to treatment. With this in mind, we investigated 41 mCRC patients suitable for combination therapy including cetuximab with irinotecan-based chemotherapy in second and third lines and *KRAS* wild type.

Analyses were carried out at start of therapy for all the 41 patients and ADCC and iNKT cells were evaluated at basal level. After 2 and 4 mo of treatment additional determinations were done in 30 and 23 patients respectively where ADCC and NK cells were longitudinally studied.

Main aim of the project was to study *ex-vivo* the prognostic and predictive value of the number of iNKT cells and the level of cetuximab-mediated ADCC and to analyse their correlation with *EGFR* level, mutational status of *KRAS*, *NRAS*, *BRAF* and PFS and OS in our prospective cohort of mCRCs.

We did not find any significant correlation of iNKT cells at basal level with PFS nor with OS, albeit we observed a trend to a longer survival after 10 mo in the population of patients with iNKT above median level. Instead, patients performing, at basal determination, ADCC activity above the median level showed an improved OS compared to patients with ADCC activity below this value.

Moreover, if we combine iNKT number and ADCC basal level and we stratified patients for both determinations, as below or above the respective median level, we observed a better OS in patients having both values above the median level compared to all the other combinations. Of note, when we analysed the same parameters after 2 and 4 mo of treatment, levels of circulating T, NK, iNKT cells were significantly reduced. On the clinical side, we observed that cancer patients exhibited a lower capacity to perform ADCC as compared to the beginning of therapy; this observation has to be replaced in the global context of an immunosuppressed state of cancer patients and the immunosuppressive effect of chemotherapy and it is consistent with earlier reports^[20].

Intriguing, during treatment, neither low level of iNKT nor low ADCC activity did correlate to prognosis. In our study this could be in apparent contrast with what observed by us at the beginning of therapy and also with what reported by others, which is patients with a severe numeric iNKT cell deficiency have a strikingly poor clinical outcome in response to chemo and radiotherapy^[12].

On the other hand, we're analysing NK levels and their activity in peripheral blood; we did not have the picture of the functional properties of tumor-infiltrating T and NK cells in patients. A reduced number of NK and iNKT cells in periphery might be "the other side of the coin" and may reflect an increased activity in the tumor infiltrates^[21].

The impact of ADCC on the efficacy of cetuximab

might also be influenced by the occurrence of polymorphic forms of genes coding receptors for the antibody Fc region. The most relevant polymorphisms regulating Fc:FcR interactions are phenylalanine (F) or valine (V) expression at position 158 of the Fc fragment^[22]. In particular, differential response to therapeutic mAbs has been reported to correlate with specific polymorphisms in two of these genes: *FCGR2A* (H131R) and *FCGR3A* (V158F)^[23]. However, previous studies exploring the relation between the FCGR polymorphisms and cetuximab efficacy in mCRC have demonstrated conflicting and have been mostly low-powered studies with small sample sizes^[24].

More recently a variant allele in a let-7 microRNA complementary site within the 3'UTR of *KRAS* (rs61764370) has been correlated with clinical outcome in mCRC patients receiving cetuximab^[25].

In our cohort of mCRCs, correlation in terms of OS and PFS with each genotype, either rs1801274 (A > G) in the *FCGR2A*, rs396991 (T > G) in *FCGR3A* or rs61764370 in the 3' UTR of *KRAS* gene didn't reveal to be significant. Interestingly enough, patients carrying alleles both with A in *FCGR2A* (AA/AG genotypes) and TT in *FCGR3A* presented a longer PFS, although the difference was not significant, probably due to the low number of patients.

For the same reason, we were not able to perform OS and PFS analyses according to all-*RAS* gene mutations. It is well known, in fact, that activating *KRAS* mutations are negative predictors of the response to cetuximab therapy in patients with mCRC, since cetuximab is widely considered to be unable to block the signal initiated by oncogenic *KRAS*^[26,27].

Nevertheless we observed that of ADCC activity, as median level, was not affected by the presence of a *NRAS* or a *BRAF* mutation.

Seo *et al.*^[13] demonstrated cetuximab-mediated ADCC in human CRC cell lines and observed that ADCC activities for the tumor cells were higher in CRC patients with a high expression level of *EGFR*. Furthermore, the ADCC activity level was significantly associated with *EGFR*, but not with the *KRAS/BRAF* mutational status.

This has to be considered also in the light of the preclinical studies of nakadate and colleagues, who demonstrated that, in an ADCC assay, perforin-dependent target cell lysis was not affected by the *KRAS* mutation status. On the other hand, perforin-independent ADCC was observed only in CRC cells with wild-type *KRAS*, but not in cells with mutant *KRAS*. Their experiments also revealed that the Fas-Fas ligand (*FasL*) interaction was responsible for the induction of apoptosis and perforin-independent ADCC. Thus, their findings clearly suggested that ADCC is an important mode of action of cetuximab and that *KRAS* mutation impairs the therapeutic effect exerted by cetuximab-mediated ADCC. In our study, regrettably, the limited number of patients precluded any definitive confirmation of this in our clinical setting of mCRC patients^[27]. Therefore, all together, our results seem to suggest a link between iNKT cells, basal ADCC

activity, genotypes in *FCGR2A* and *FCGR3A*, and efficacy of cetuximab in *KRAS* wild-type mCRC patients.

The efficacy of monoclonal anti-EGFR antibodies, like cetuximab, has been proven in mCRC patients. It has been established clearly that response to anti-EGFR antibody treatment is only possible in selected patient groups. However, predictive factors for the efficacy of anti-EGFR therapy have still to be completely elucidated. A factor identified in multiple studies as essential for appropriate assessment of eligibility for cetuximab or panitumumab treatment is the absence of *KRAS* gene mutations. EGFR expression on the surface of cancer cells does not seem to have a decisive influence on the efficacy of the therapy. There are ongoing studies assessing the predictive value of the number of copies of the *EGFR* gene, mutations in the *NRAS*, *PI3KCA*, *P53* and *PTEN* genes, concentration of EGFR ligands and polymorphisms in the *EGF* and *EGFR*, and the *FCGR2A* and *FCGR3A*, genes. In our study, we observed that combining iNKT number and ADCC basal level allowed to identify a group of mCRC patients, having both determinations above the respective median level and a longer OS. This combination looks like the best prognosticator in our population of patients. However, it has not as of yet been examined in large randomized prospective studies and hence should still be better elucidated before using as a basis for mCRC patient eligibility for cetuximab treatment.

COMMENTS

Background

The efficacy of monoclonal anti-epidermal growth factor receptor (EGFR) antibodies, like cetuximab, has been proven in metastatic colorectal cancer (mCRC) patients. It has been established clearly that response to anti-EGFR antibody treatment is only possible in selected patient groups. However, predictive factors for the efficacy of anti-EGFR therapy have still to be completely elucidated. A factor identified in multiple studies as essential for appropriate assessment of eligibility for cetuximab or panitumumab treatment is the absence of mutation in *RAS* genes. EGFR expression on the surface of cancer cells does not seem to have a decisive influence on the efficacy of the therapy. There are ongoing studies assessing the predictive value of the number of copies of the *EGFR* gene, mutations in the *NRAS*, *PI3KCA*, *P53* and *PTEN* genes, concentration of EGFR ligands and polymorphisms in the *EGF* and *EGFR*, and the *FCGR2A* and *FCGR3A* genes.

Research frontiers

In this study the authors aim to evaluate the prognostic and predictive value of cetuximab-mediated antibody-dependent cell-mediated cytotoxicity (ADCC) and circulating invariant natural killer T (iNKT) cells levels in mCRC; the authors shall analyse their correlation with *EGFR* level, mutational status of *KRAS*, *NRAS*, *BRAF*, progression free survival and overall survival in a prospective cohort of mCRC patients treated with cetuximab-based therapy.

Innovations and breakthroughs

The prognostic value of circulating iNKT cell and ADCC basal level reported

here adds to previous notions and strengthens the hypothesis that human iNKT cells may also contribute to antitumor responses in cancer patients and to cetuximab efficacy. These results indicate also that the contribution of the indirect action of cetuximab may be relative high, compared with the direct anti-EGFR action, toward the clinical therapeutic effect.

Applications

In summary, the authors demonstrated here, in a prospective study, that a low level of circulating iNKT cells and a low ADCC activity before treatment in mCRC patients are significantly associated with poor survival. These data suggest that reconstitution of the iNKT cell pool (e.g., by adoptive transfer of *ex vivo* expanded autologous iNKT cells) provides a promising immunotherapeutic strategy for mCRC. Furthermore, screening for iNKT cells and ADCC levels in peripheral-blood samples might provide a noninvasive, straightforward prognostic parameter and may also be useful for determining which patients can benefit from cetuximab therapy.

Terminology

The antibody-dependent cell-mediated cytotoxicity is a mechanism of cell-mediated immune defense whereby an effector cell of the immune system actively lyses a target cell, whose membrane-surface antigens have been bound by specific antibodies. It is one of the mechanisms of the adaptive immune response through which antibodies can act to limit and contain tumors; classical antibody-dependent cell-mediated cytotoxicity is mediated by NK cells, which express CD16 which is an Fc receptor. This receptor recognizes, and binds to, the Fc portion of an antibody, such as the IgG1 anti-EGFR cetuximab; cetuximab is a recombinant chimeric mAb composed of the variable regions of a murine anti-EGFR antibody and of the constant regions of a human IgG1 kappa immunoglobulin. It is indicated for the treatment of squamous cell carcinoma of the head and neck and of *RAS* wild type mCRC.

Peer-review

This manuscript contributes to shed light to monoclonal therapy response in mCRC patients.

Abstract

Neuroendocrine tumors of the gastrointestinal tract are rare neoplasms. Rectal neuroendocrine tumors consist approximately the 5%-14% of all neuroendocrine neoplasms in Europe. These tumors are diagnosed in relatively young patients, with a mean age at diagnosis of 56 years. Distant metastases from rectal neuroendocrine tumors are not very common. Herein we describe a case of a rectal neuroendocrine tumor which metastasized to the lung, mediastinum and orbit. This case underscores the importance of early identification and optimal management to improve patient's prognosis. Therefore, the clinical significance of this case is the necessity of physicians' awareness and education regarding neuroendocrine tumors' diagnosis and management.

Key words: Rectum; Uncommon metastatic spread; Neuroendocrine tumor; Rectal neuroendocrine tumor; Rectal neuroendocrine neoplasm

INTRODUCTION

The gastrointestinal tract has the largest component of neuroendocrine cells. In spite of this, neuroendocrine tumors of the colon and rectum are rare entities, with a reported incidence ranging from 0.3% to 3.9% of all colorectal malignancies^[1]. The introduction of more sensitive diagnostic tools (*e.g.*, immunohistochemical stains) and an overall increased awareness among physicians, have largely contributed to the rising incidence of neuroendocrine tumors^[2]. Here we describe an interesting case of a rare neuroendocrine neoplasm of the rectum with an uncommon natural history.

CASE REPORT

A 54-year-old man with free medical or family history came to our hospital reporting rectal bleeding in May 2005. Colonoscopy demonstrated a rectal polypoid mass, 15 mm in diameter, located 6 cm from the anus. Biopsies were taken and histopathology evaluation showed an adenocarcinoma which invaded submucosa. An extensive work up with computed tomography (CT) scans was negative for distant metastases but there was an infiltration of pericolic fat. After that, the patient underwent low anterior resection of the rectum and the mesorectum. The histopathological examination of the dissected specimen showed a grade 2 adenocarcinoma with infiltration of pericolic fat and regional lymph nodes (stage C1 Astler-Coller). Adjuvant chemotherapy with 6 cycles of FOLFOX4 was administered without radiotherapy.

Two years later, during the scheduled follow-up, the CT scans revealed a mass in the lower left lobe of the lung, which was surgically resected and the pathology showed a neuroendocrine tumor with well differentiation. The review of both histologic specimens (paraffin tube of rectum and lung specimens, Figures 1 and 2) showed that there were medium to large tumor cells, displaying a trabecular growth pattern with nuclear pleomorphism, hyperchromasia and prominent nucleoli. Tumor cells were often spreading individually infiltrating. No lymphovascular invasion was detectable. There were a few punctate foci of necrosis. The tumor cells invaded perirectal tissues and 2 regional lymph nodes were infiltrated. Pathologic staging was pT3N1M1 and the

clinical stage IV. Moreover, the immunohistochemistry analysis revealed positivity, in both specimens, for CK18, CK20, chromogranin, synaptophysin, CD56 and Ki-67, while CK7 and TTF1 were negative. Synaptophysin and chromogranin showed a diffuse positive staining of the tumor cells. These findings led to the conclusion that the primary tumor was that in the rectum and it was a neuroendocrine neoplasm well differentiated. In particular, Ki-67 was 8%-9% and the tumour was classified as well differentiated neuroendocrine tumor, intermediate grade (G2 NET). At that time patient refused to receive any further treatment.

One year later the planned follow-up showed a mass in the mediastinum. The octreoscan that followed showed increased uptake in the same anatomic region (Figure 3). Subsequently, the patient underwent radiotherapy (44 Gy) for the mass in the mediastinum. Moreover, the patient developed a mass in the left orbit, something that was discovered after a bilateral visual impairment and was treated with stereotactic radiosurgery (Cyber-Knife 18 Gy). Despite the medical advices patient refused to receive any systemic treatment. At the same period of time new lesions in left lung, mediastinum, adrenals and scalp were found. The patient was administered chemotherapy with the regiment Cisplatin 75 mg/m² d1 plus Etoposide 100 mg/m² d1-d3. Unfortunately, patient died after 4 cycles of chemotherapy due to uncontrolled systemic infection.

DISCUSSION

Rectal neuroendocrine neoplasms are usually small; polypoid lesions located in the mid-rectum, 5 to 10 cm from the anal verge and are submucosal in location, mainly discovered incidentally on routine surveillance endoscopies. If there are any symptoms, they include rectal bleeding, pain (as happened in our case) and change in bowel habits. However, 50% of patients are asymptomatic^[3].

They belong to a heterogeneous group of tumours, which all present a common phenotype with immunoreactivity for markers such as chromogranin A and synaptophysin^[4,5]. Neuron-specific enolase (NSE) and CD56 are frequently expressed in GEP-NETs, but are not specific. At present, immunohistochemistry for Ki-67 (MIB-1) is mandatory to grade the tumor according to the 2010 World Health Organization (WHO) classification and divides the tumors into NET G1, NET G2 and poorly differentiated neuroendocrine carcinoma (NEC G3)^[4].

Prognostic factors for metastases are tumor size, depth of invasion, and lymph node involvement of the rectal NETs. These factors may be assessed by transrectal ultrasound, if feasible, and pelvic MRI. One study revealed that metastases emerged in only 2% of tumors not bigger than 2 cm, which had not infiltrated the muscularis propria, compared to 48% of those infiltrating the muscularis layer^[6]. Although neuroendocrine tumours metastasize in 50%-75% of patients with the most common sites being lymph nodes, liver, and bones, metastases to the orbits, as happened in our case, have

Figure 1 Biopsy of the rectal tumour (A) and lung tumour (B).

Figure 2 Immunohistochemical positivity for CD56 (rectum) (A) and CD56 (lung) (B).

Figure 3 Octreoscan.

only rarely been reported (about 32 cases until 2006) and are believed to occur through hematogeneous

spread^[7]. Orbital neuroendocrine tumors tend to arise from the gastrointestinal tract, whereas bronchial neuroendocrine tumors show a propensity to uveal metastasis and typically present with a mass or diplopia while visual failure is unusual^[8], characteristics that verified in our case.

Obviously, metastatic disease at diagnosis will suggest a worse prognosis despite the available treatment options. In fact, surgery may have a palliative role to the complications associated with an advanced rectal tumour mass^[9]. Adjuvant therapy for well differentiated tumours after surgery is not considered, although an argument exists for applying chemotherapy in non-differentiated tumours with incomplete resection^[3]. Well differentiated neuroendocrine tumors is an uncommon indication for systemic chemotherapy^[10]. When used for progressive disease, streptozotocin combined with 5-fluorouracil with or without doxorubicin is most often applied even though the response rate is < 25%^[4]. The effectiveness of systemic chemo-regimens is optimal in poorly-differentiated tumours and the combination of cisplatin or carboplatin and etoposide have showed satisfactory results^[4]. Newer anti-angiogenesis or mTOR inhibitors may be used as well as peptide receptor radionuclide therapy peptide in patients with advanced or metastatic disease^[4,11]. Additionally, more chemotherapy regimens such as temozolomide and capecitabine are under clinical investigation for patients with advanced or metastatic neuroendocrine neoplasms^[12].

In conclusion, rectal neuroendocrine tumors are rare and cases with distant metastases are even rarer. This case underscores the necessity of physicians' awareness and education regarding neuroendocrine tumors' diagnosis and management.

COMMENTS

Case characteristics

A 54-year-old man with rectal bleeding.

Clinical diagnosis

A rectal polypoid mass, 15 mm in diameter.

Differential diagnosis

Rectal neuroendocrine tumor; Non-neoplastic polyp; Lung neuroendocrine tumor.

Laboratory diagnosis

A well differentiated rectal neuroendocrine tumor (G2 NET) with metastases to left lung, mediastinum and left orbit.

Imaging diagnosis

Computed tomography scans revealed masses in the lower left lobe of the lung, in the mediastinum and in the left orbit.

Pathological diagnosis

The histopathological examination showed a well differentiated rectal G2 NET.

Treatment

Chemotherapy with 6 cycles of FOLFOX4 at the beginning and then regimen Cisplatin 75 mg/m² d1 plus etoposide 100 mg/m² d1-d3.

Peer-review

This is an interesting case report describing a potentially malignant behavior of a primary neuroendocrine tumor of the rectum.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, David Tougeron, MD, PhD, Professor, Department of Gastroenterology, Poitiers University Hospital, 86000 Poitiers Cedex, France

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

Since the introduction of complete mesocolic excision (CME) for colon cancer, the oncologic outcome of patients has been greatly improved, which has led to a longer survival

and a lower recurrence, just like the total mesorectum excision for rectal cancer. Despite the fact that the exact anatomy of the organ is one of the most vital things for surgeons to conduct surgery, no team has really studied the exact structure of the mesocolon and related attachments for CME, until the mesocolonic anatomy was first formally characterized in 2012. Therefore, this article mainly focuses on the anatomy development of the mesocolon and the achievement in this field. Meanwhile, we introduce the latest progress in laparoscopic surgery for colon cancer achieved by our team.

Key words: Colorectal cancer; "Page-turning" approach; Laparoscopic surgery; Complete mesocolic excision; Toldt's fascia

Core tip: Despite that complete mesocolic excision (CME) has been conducted for many years, leading to a better outcome in colon cancer patients, there are limited studies on the structure of the mesocolon or related attachments, which is of great importance for surgeons to carry out surgery, until K. Culligan first formally characterized the mesocolonic anatomy, explaining the reason why CME would have a better oncologic outcome. Meanwhile, based on the exact anatomy of mesocolon, we introduce the latest progress in laparoscopic surgery for colon cancer achieved by our team, such as "page-turning" approach, and we also list the most important structure related to the CME.

INTRODUCTION

In the past, patients with rectal cancer survived less than those with colon cancer. However, since Heald *et al.*^[1] first proposed total mesorectum excision (TME) for rectal cancer, the TME has standardized the surgical management of rectal cancer, which is based on the theory that mesorectum is composed of visceral and parietal planes covering rectum-supplying vessels and its lymphatic drainage like envelopes, leading to a lower recurrence rate as well as better 5-year cancer-related survival, which is even higher than that of colon cancer^[2-4] given that the surgery for colon cancer had not changed so much. In 2009, on the basis of the TME, Hohenberger *et al.*^[5] put forward the concept of complete mesocolic excision (CME). He stated that the mesocolon is covered by visceral and parietal planes by an envelope-style just like the mesorectum, and the "holy plane"^[6] extends to the mesocolon from the mesorectum. In his study, the patients who underwent CME had lower local recurrence and better survival, from 6.5% to 3.5% and 82.1% to 89.1% respectively. Since then, more and more studies have proven that superiority^[7,8].

Surgeons are meant to be ones who cure the disease through surgery with excellent knowledge about the organs, therefore, it is essential to stress the importance of accurately understanding mesocolic anatomy for surgeons to conduct CME. Although there have been studies on CME for years, no team really studied the exact structure of the mesocolon and related attachments, until K. Culligan *et al.*^[9] first formally characterized the mesocolonic anatomy in 2012. They made many undocumented and important discoveries, which could explain and confirm the feasibility and superiority of CME. Besides presenting the promising oncological outcome, this article mainly focuses on the anatomy of mesocolon and laparoscopic approach of CME to help peers comprehend CME better, and such improvement in anatomy-related understanding may explain why CME is a potential standardized procedure for colon cancer.

RESERACH

A systematic literature search was conducted using Pubmed and EMBASE with the terms of "complete mesocolic excision", "CME", "anatomy of CME", "laparoscopic CME" as well as "colon surgery". Many related studies were found and we summarized and presented the findings with our clinical experience.

The anatomy development of mesocolon

One of the earliest and most famous description of mesocolon was made by Sir Treves^[10] in 1885. He dissected and studied the anatomy of intestinal canal, peritoneum and mesentery with 100 cadavers and reported that mesocolon is discontinuous and fragmental. About half of the cadavers had neither an ascending nor a descending mesocolon, and 14 cadavers had them

both. The existence of mesocolon was always described as abnormal, even as "a cleft palate"^[11]. Indeed, before Sir Frederick Treves, Carl Toldt in 1879^[12], whose findings apparently differed from the above ones, studied the development of human mesentery, and noted the permanent existence of mesocolon in human being as well as a distinct fascial plane between the mesocolon and the underlying retroperitoneum. Known as Toldt's fascia, it was formed by the fusion of the visceral peritoneum of the mesocolon with the parietal peritoneum of the retroperitoneum. From today's point of view, Toldt's finding was almost true while Treves' not, but it did not work well at that time. Treves' discovery was so profound and foundational that it was spreaded and accepted extensively into surgery and teaching, even to recent days, it was still accepted widely as Rishabh Sehgal^[13,14] mentioned.

There has been no research really studying the exact structure of mesocolon for decades, until Culligan *et al.*^[9] first formally characterized the mesocolonic anatomy in detail. They chose 109 patients to undergo total abdominal colectomy, observed and recorded the anatomy of mesocolon, the related attachments and specimens, and finally noted many undocumented and meaningful findings: (1) mesocolon is continuous from the ileocaecal to rectosigmoid level; (2) Toldt's fascia is identified in the place where mesocolon is apposed to the retroperitoneum, such as ascending, descending mesocolon and non-mobile portion of mesosigmoid, while it does not show up in the transverse mesocolon and the mobile component of the mesosigmoid; and (3) the proximal rectum originates from the confluence of the mesorectum and mesosigmoid; and so on. What's more admirable, besides the important macroscopic discoveries above, Culligan's team first investigated the microscopic structures of mesocolon, Toldt's fascia and retroperitoneum before and after the colonic mobilization^[15,16]. They obtained samples from 24 cadavers, stained them with hematoxylin and eosin, Masson trichrome, and by immunohistochemistry to identify lymphatic vessels. Some samples were directly observed by scanning electron microscopy. Just like the macroscopic findings, they found consistent microscopic structures of mesocolon and associated fascia from the ileocecal to mesorectal level; in the place where mesocolon is apposed to the retroperitoneum, a connective tissue could be identified between them (*i.e.*, Toldt's fascia). Nowadays, we appreciate the excellent work done by Culligan's team. It was incredible and profound. For the first time, they described the exact anatomy of mesocolon, confirmed the continuity and surgical plane, and provided convincing proof for surgeons to conduct CME from the anatomical and histological aspects. Later, Gao *et al.*^[17] finished a similar study, also proving the continuity of mesocolon and the existence of visceral fascia. In his study he also thought the fascia to be able to block the tumor migration. Gao and Culligan used different terminologies to refer to the same thing, for example, Gao named it "visceral fascia" while Culligan called it "Toldt's fascia"^[18]. Such phenomenon is very normal, and there is also no

standardized nomenclature for CME, for instance, “right hemi-colectomy”, “enlarged right hemi-colectomy”, “Gerot’s fascia”, or “visceral fascia” and “parietal fascia”. Not being accurate and definite^[19,20] may confuse the new learners regarding explanations of the surgical procedures, which may have a bad impact on such improvement. Even though there is no “gold standard” for colon cancer, it is essential and necessary to have a unified terminology.

The laparoscopic approach of CME

Unexpectedly, despite the misconception in the textbook for centuries, surgeons have always seen mesocolon as a whole and conducted surgery based on the surgical plane between mesocolon and retroperitoneum^[19]. Back to 100 years ago, Jamieson (Jamieson and Dobson, 1909) suggested that surgery for colon cancer should resect the lesion, clean the regional lymph nodes to the vascular roots, and dissect lymph nodes of the interperitoneal colon, mesocolon and vascular roots, which was similar to the technique strategies of CME proposed by Hohenberger^[5]. Hohenberger demanded sharp separation of visceral and parietal fascia based on embryonic anatomy, ligation at the root of central supply vessels, and more radical lymph node dissection. The feasibility and promising outcome of CME have been confirmed in open surgery.

The improvement of laparoscopic techniques and further definition of equipment make it possible for surgeons to conduct colon cancer surgery. Taking the right-hemi colon cancer as an example, it is relatively more complicated and has more vessel variations. Feng *et al.*^[20] from our team first confirmed the feasibility and technical strategies of laparoscopic CME with medial access, following the dissection starting at the ileocolic vessel, proceeding along the superior mesenteric vein, and exposing the inborn surgical plane composed of Toldt’s and prerenal fascia to uncover the head of the pancreas and to mobilize the duodenum. The exposing range begins from the origin of transverse colon mesentery to the peritoneal reflection, and ligation at the origin of the central vessels to dissect the entire mesocolon was performed as a whole. Compared to the lateral access, the medial access complies more with the “no-touch” principle, since the lateral access starts with mobilizing the colon and then dissecting and ligating the central vessel. Not only is the pathological result comparable to the open surgery, but also the long-term outcome works well too^[2,4,21,22]. Based on the surgical experience through extensive surgeries, Feng *et al.*^[23] then exploited and distinguished two approaches for media access: Completely medial and hybrid medial approach (CMA and HMA). The major difference between them is the approach to dissect the inferior edge of the pancreas. The CMA uses a “bottom-to-top” fashion while the HMA uses a blending of “top-to-bottom and bottom-to-top” fashion. Compared to the HMA, the surgery time and ligation time of central vessel were significantly shorter, while the HMA induced more

vessel-related complications. Besides, our team recently found an improved surgical access based on CMA, which we named “page-turning” approach (CMAPA). It is conducted in a “bottom-to-top” and “inside-to-outside” direction, which adopted the strategy of “point-to-line” and “line-to-plane” [point: Taking the ileocolic vessels as a dissection trigger; line: Dissecting the vessels along the superior mesenteric vessel (SMV); plane: Extending the surgical plane by the “page-turning” approach, which was formed by Toldt’s fascia]. We suppose that this approach is technically feasible and complies more with the principle of tumor radical surgery.

However, CMA and HMA both emphasize the accurate recognition of the anatomical plane, especially the transverse retrocolic space which can extend to inter-mesenteric space and right retrocolic space to completely mobilize the right colon. Consequently, without a better understanding of the exact mesocolon, no surgeons can conduct perfect CME.

CONCLUSION

Just as the TME for rectal cancer, the CME follows the principle of embryology and anatomy by sharply dissecting the surgical plane between the visceral and parietal fascia to get an integrated mesocolon, ligation at the root of the central vessel and clearance of more lymph nodes, which can lead to a better survival. However, there is not an efficient evaluation system for CME except the grading system by West *et al.*^[24]: Muscularis propria plane (poor plane) if little mesocolon is excised with incision down to the muscularis propria; intramesocolic plane (moderate plane) if partial mesocolon is excised with an irregular shape but not down to the muscularis propria; mesocolic plane (good plane) if intact mesocolon is excised without defections on it and high ligation of the supply vessels. He further demonstrated a 15% increase of overall survival in the “mesocolic plane” group compared to “non-comparable” group. Even though the surgeons bear the concept in mind, there still have not been a global consensus about the accurate configuration of the mesocolon with related attachments. In addition, various words and terminologies are used in the CME, which makes people confused, especially the young. Besides, the reason why we describe CME as a better approach instead of a successful one, or why we think it has the potential to be the standard procedure for colon cancer, is that it has not been accepted universally, and there are still some debates. Some studies showed that extensive lymphadenectomy by CME failed to increase the survival^[25-28], although CME emphasizes the necessity to remove more lymph nodes, which can lead to a better survival. Besides, the operation time for CME is longer as the procedure is technically more challenging and complex, which may lead to more complications, such as bleeding, genitourinary dysfunction, or chyle leakage^[29,30]. What’s more, Culligan *et al.*^[18] first discovered abundant lymphatic vessels within Toldt’s fascia as well as mesocolon. This

means that it is possible that there are communications between them, which may cause tumor cell spread, and if that happens, there is little need to conduct CME. Further studies are needed to clarify this issue.

The majority of data we got were from single-center, retrospective studies, and not convincing enough for surgeons to accept CME as a standard procedure for colon cancer. So it is the time and it is essential for us to standardize the procedure of CME and conduct completely randomized and multi-center prospective studies to provide more proofs. At that time we will have great confidence to decide whether CME could be the standard procedure for colon cancer or not.

Abstract

Malignant biliary strictures often present late after

the window for curative resection has elapsed. In such patients, the goal of therapy is typically focused on palliation. While historically, palliative measures were performed surgically, the advent of endoscopic intervention offers minimally invasive options to provide relief of symptoms, improve quality of life, and in some cases, increase survival of these patients. Some of these therapies, such as endoscopic biliary decompression, have become mainstays of treatment for decades, whereas newer modalities, including radiofrequency ablation, and photodynamic therapy offer additional options for patients with incurable biliary malignancies.

Key words: Biliary strictures; Malignant; Endoscopic retrograde cholangiopancreatography; Photodynamic therapy; Endoscopy; Palliation; Endoscopic ultrasound; Radiofrequency ablation

Core tip: Palliative therapies for malignant biliary strictures are crucial for a disease that so often presents with surgical ineligibility. In this paper, we highlight both the established and more novel endoscopic palliative approaches for these types of strictures. Perhaps the most established of these therapies is endoscopic biliary decompression *via* endoscopic retrograde cholangiopancreatography (ERCP), which is notably approached differently in extrahepatic and intrahepatic strictures. In cases where traditional ERCP fails or is not feasible, endoscopic ultrasound-guided biliary drainage has quickly become the second-line intervention. Finally, we end by discussing the literature behind more novel therapies, namely intraductal radiofrequency ablation and photodynamic therapy.

INTRODUCTION

Biliary strictures should be considered in any patient presenting with clinical signs such as jaundice, pale stool, dark urine and pruritus. Once confirmed, a crucial step in the work-up includes differentiating between malignant and benign etiologies. Historically, this has been a challenge since as many of 15%-30% of such cases are eventually determined to be benign inflammatory processes after histologic assessment^[1,2]. Generally, the most common etiologies of malignant strictures include pancreatic adenocarcinoma (especially if located in the distal common bile duct) or cholangiocarcinoma (if in the mid- or proximal extrahepatic bile duct), although metastatic disease, ampullary neoplasia, gall bladder malignancy, hepatocellular carcinoma, and malignant periportal lymph nodes are all possibilities^[3].

Pancreatic adenocarcinoma and cholangiocarcinoma typically present late in the course of the disease, with the vast majority of patients ineligible for curative resection^[4], resulting in 5-year survival rates of under 5%^[5,6]. The role of endoscopy in these patients has expanded from a diagnostic tool to a therapeutic one, providing palliation that allows for improved quality of life at faster rates and lower cost than surgical methods^[6,7]. Endoscopic interventions for patients with malignant biliary strictures, includes endoscopic biliary drainage, intraductal radiofrequency ablation (RFA), and photodynamic therapy for cholangiocarcinoma.

A-ENDOSCOPIC BILIARY DECOMPRESSION

Extrahepatic biliary obstruction

While preoperative biliary drainage for malignant biliary strictures *via* endoscopic retrograde cholangiopancreatography (ERCP) remains controversial for surgically-eligible patients^[8], endoscopic stenting has become the gold standard for palliative biliary obstruction in non-surgical candidates. In this method, stents are placed at the site of obstruction *via* endoscope, allowing for minimally invasive relief of obstructive symptoms. Other, non-endoscopic options for palliative therapy include percutaneous transhepatic stenting of the biliary tree and surgical bypass. Early studies comparing endoscopic palliation to surgical bypass in patients with malignant strictures found that endoscopic intervention was superior to surgical bypass in terms of survival procedure-related mortality and complications^[9], survival (19 mo vs 16.5 mo^[10]), and total lifetime cost. Similarly, a randomized trial of 75 patients with malignant obstructive jaundice endoscopic palliation demonstrated that endoscopic stenting had significantly higher success in relieving jaundice while also boasting a lower 30-d mortality due to fewer liver-associated complications^[11].

A meta-analysis, which included 24 studies and over 2400 patients, found that, compared to surgical bypass, endoscopic intervention with plastic stents had similar

rates of technical and therapeutic success, as well as improvement in quality of life^[7].

Additionally, while endoscopic stenting with plastic stents had a lower risk of complications than surgical bypass, endoscopic intervention was, notably, also associated with a higher risk of recurrent biliary obstruction at 4 mo. Interestingly, given the recent increase in the use of metal (as opposed to plastic) stents in endoscopic palliation, assessing the comparative effectiveness of surgical vs endoscopic methods for palliative biliary obstruction becomes notably more difficult due to a paucity of available data. One small RCT ($n = 30$) that examined this comparison found no difference in complication rates, readmissions, or survival. However, those patients who received endoscopic therapy demonstrated better quality of life scores at roughly half the cost of surgical intervention^[12] suggesting a cost-effectiveness benefit to the utilization of endoscopic, as opposed to surgical, interventions. Nevertheless, ERCP has, over the past two decades, become the first line therapy for those ineligible for curative resection.

ERCP maintains biliary patency through stenting, options for which are continually evolving^[13]. Compared with plastic stents, self-expanding metal stents (SEMSs) have demonstrated significantly lower rates of migration and reocclusion^[7,14-17], an advantage mechanistically attributed to a wider stent diameter. However, the cost of SEMSs exceed that of plastic stents by order of magnitude^[18]. Therefore, the general consensus is that metal stents should be considered for patients with an estimated survival greater than 4-6 mo to maintain cost-effectiveness^[16,19,20].

SEMSs can be made of steel, nitinol or platinum and can be uncovered, partially covered, or fully covered. Covered stents have been manufactured with a coating designed to improve removability and prevent occlusion from tumor ingrowth or tissue hyperplasia^[21], however this theoretical advantage has not always been apparent from a clinical standpoint^[22,23] and until now the data of whether to use covered or uncovered metal stents in malignant disease is mixed among randomized controlled trials^[24-28] and even among metaanalyses^[29-31]. Underlying the inability powers those studies adequately. A recent study demonstrated longer patency of covered stent vs uncovered with the initial cost of the covered stent compensated by the benefit provide in patency.

Intrahepatic biliary obstruction

While biliary strictures commonly affect the extrahepatic biliary system, intrahepatic and hilar strictures tend to be less common, and can be asymptomatic in up to 30% of patients^[32,33]. Malignant obstruction of the biliary hilum have an exceptionally poor prognosis, with less than 10% of patients living longer than 5 years^[34]. The predominantly cause of malignant intrahepatic strictures is cholangiocarcinoma^[35], although squamous cell carcinoma, hepatocellular carcinoma, and metastatic disease are also potential etiologies^[36].

Hilar biliary strictures can be difficult diagnose. Typi-

cally presenting with ductal dilation with the absence of stones, the best available diagnostic tool is probably magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP), which not only can locate intrahepatic biliary strictures with 97% accuracy^[37], but also allows for the creation of a “road map” of the biliary tree to be used for planning endoscopic intervention (although notably, the specificity of MRCP may be more limited in the case of malignant strictures^[38]).

Therapeutic management of hilar strictures is predicated on surgical resectability. Tumors are deemed surgically unresectable in cases with (1) bilateral intrahepatic bile duct spread to secondary or segmental biliary radicals; (2) involvement of the main trunk of the portal vein; (3) bilobar involvement of hepatic arterial and/or portal venous branches; and (4) a combination of unilateral hepatic arterial involvement with cholangiographic evidence of extensive contralateral duct spread^[39].

A primary consideration in the management of hilar strictures is whether to unilaterally stent the obstructed duct or to, alternatively, place bilateral stents in both the left and right intrahepatic ducts. While unilateral stenting is less expensive than bilateral stenting^[40], a number of studies have suggested that bilateral stenting provides increased patency compared to unilateral stenting^[41,42] (although it is still debated^[43]). However, bilateral stenting is more challenging from a technical standpoint, requiring stent-within-stents or side-by-side deployment techniques^[44].

Although the use of plastic vs metal stents for intrahepatic strictures is still debated, there is growing evidence to suggest metal stents are preferable to plastic, with recent trials suggesting that SEMSs placement provides higher long-term patency, higher success rates, increased survival, and decreased costs^[14,41,45-47]. The use of metal stents is more crucial if the tumor is surgically resectable. Multiple studies examining the use of plastic stents in surgically resectable patients have noted high complication rates with no demonstrative mortality benefit^[48-50], whereas upon meta-analysis, metal stents have been found to reduce mortality up to 6%^[50], and are less likely to hinder future surgical intervention^[51].

Furthermore, the choice of using covered vs uncovered metal stents has important implications. Covered SEMS have the theoretic potential to obstruct the intrahepatic bile ducts in proximal biliary strictures, and although this limitation has been challenged in recent years^[52], most recommend placing uncovered metal stent in intrahepatic biliary obstruction. However, it warrants mention that compared to covered metal stents, uncovered stents have low migration rates, but are associated with a higher rate of stent dysfunction from tumor ingrowth and epithelial hyperplasia^[53]. For these reasons, uncovered SEMSs may be beneficial in cases of known malignant disease without eligibility for resection, but should be avoided if the diagnosis is uncertainly, or if there is any possibility of surgical resection, since covered SEMS better allows for future removal.

ENDOSCOPIC ULTRASOUND-GUIDED BILIARY DRAINAGE

In advanced disease, such as when tumor involves the second part of the duodenum, or in patients with alternated anatomy from bariatric surgeries or intestinal diversions^[54-56], endoscopic access to the biliary tree may be impaired, and ERCP not possible. Historically, upon failed ERCP, alternative therapies have included percutaneous transhepatic biliary drainage or surgical bypass. While in the past, arguments have been made in favor of these treatments^[57,58], surgical bypass is now limited to good surgical candidates, while external drainage *via* percutaneous intervention has been showed to have, negative impact on a patient's quality of life and long term failure^[59]. Furthermore, after a failed ERCP, attempting either of these interventions requires a separate intervention at a later date. Endoscopic ultrasound (EUS)-guided biliary drainage, has been offered for more than a decade in cases with (1) failed conventional ERCP; (2) altered anatomy; (3) tumor preventing access into the biliary tree; or (4) contraindication to percutaneous access (*i.e.*, ascites)^[56].

EUS-guided biliary drainage, a method first described in 1996^[60], is performed either through a transpapillary or transmural approach. The transpapillary approach consists of gaining access to bile ducts under EUS guidance, followed by placement of a guidewire across the obstruction. A conventional ERCP during a rendezvous can then be performed using the guidewire for access^[61]. Reported success rates of this procedure can vary greatly (70%-100%)^[62-65]. One of the largest study examining this procedure ($n = 58$) have reported favorable results, including success rates of over 98% with a complication rate of 6.9%^[66]. Furthermore, a recent meta-analysis demonstrated a success around 95% with adverse event of 15%^[67] related mainly to pneumoperitoneum, complication that has dramatically decreased since the use of CO₂.

In such cases where transpapillary drainage cannot be performed, transmural drainage may be taken, either through a transgastric-transhepatic (hepaticogastrostomy) approach for intrahepatic obstruction or a transenteric-transcholedochal (choledocoduodenostomy) for extrahepatic obstruction. The transgastric-transhepatic approach is typically performed through the lesser curvature of the stomach to allow for visualization and drainage of the left intrahepatic bile ducts, whereas the transenteric-transcholedochal^[68], is performed through the wall of the duodenum into the common bile duct^[56]. Similarly to traditional ERCP, plastic stents were originally placed for drainage, but SEMSs are being increasingly used^[69-71], due to their increased patency^[71,72].

The complications of EUS-guided biliary drainage include perforation, infection, and bleeding. Theoretically, EUS-guided draining may have a decreased rate of bleeding, as there is less manipulation of the papilla with this method^[73]. Furthermore, the manipulation of the wall integrity of the gastrointestinal tract could result in leakage

of bile, pneumoperitoneum, biloma, or bile peritonitis. However, the use of SEMSs should hypothetically minimize the risk of these complications by sealing the fistula created in these procedures^[74].

One single center randomized controlled trial of EUS-guided biliary drainage compared with percutaneous biliary drainage demonstrated similar levels of technical success and no difference in adverse effects or cost^[75]. Overall, EUS-guided biliary drainage in expert centers has become as a second-line therapy due to its minimal invasiveness and ability to be performed immediately after a failed ERCP.

C-INTRADUCTAL RFA

RFA is a technique in which monopolar or bipolar electrodes are inserted into tissue prior to applying an alternating electric current. The high resistance of the current in biological tissue results in the production of heat, which at sufficient levels, causes instant coagulative necrosis^[76]. RFA is used in a wide variety of palliative therapies for malignancies, including lung cancer^[77], renal cell carcinoma^[78], prostate cancer^[79], breast cancer^[80], osteoid osteomas^[81], and certain brain tumors^[82]. Among gastrointestinal tumors, RFA is an established treatment for inoperable liver neoplasm, and is increasingly being used as palliative treatment for malignancy-related biliary obstruction and advanced pancreatic tumors.

The biologic rationale of using RFA in the treatment of malignancies extends beyond its a priori destructive properties. Evidence suggests that malignant tumor cells necrosis at lower temperatures than normal cells^[83,84], indicating that cancerous cells will be disproportionately affected by thermal ablation. This effect is accentuated in areas of poor blood flow^[85], indicating that hypovascular tumors, in particular, would be ideal targets of hyperthermic treatment.

There are numerous advantages to RFA tumor therapy. Notably, it is less expensive and less invasive than surgery, carrying an eight-fold lower complication rate and a two-fold shorter hospital stay^[86,87]. For biliary obstruction, RFA is typically paired with SEMSs placement, with small trials demonstrating 100% patency at 30 d, and 85% patency at 90 d^[88], with significant improvement in stricture diameter of 3.7 mm^[89]. More impressively, in patients with malignancy-related biliary obstruction, a growing body of literature is suggesting that endoscopic RFA followed by stenting provides a significant survival benefit when compared to patients treated with stenting alone^[90-93], advocating for the use of combination endoscopic therapy. Interestingly, a 62 patients study assessing the treatment of biliary strictures related to various neoplastic etiologies found that pancreatic cancer, in particular, was a significant predictor of stricture improvement with RFA^[94], although the mechanism for this remains unknown.

D-PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) involves utilizing a specific

wavelength of light to activate a intravenously given photosensitizing agent and cause ablation by directly damaging tumor cells, interfering with microvasculature of the tumor bed, and potentiating an immune response^[95-99]. The photosensitizer-dependent wavelength light is typically delivered *via* optical fibers placed in the target tissue, with the penetrance dependent on the wavelength of light and the specific light source used^[100]. PDT causes tissue necrosis by a non-thermal cytotoxic effect, mediated by the light-induced transfer of oxygen from a photosensitizer to molecular oxygen, generating a reactive oxygen species. Unlike other ablative methods, PDT has the unique ability to trigger apoptosis in neoplastic tissue^[101] and is collagen-sparing, allowing for the maintenance of tissue architecture^[102].

There have been numerous studies examining PDT for cholangiocarcinoma, which have demonstrated that PDT provides a survival benefit^[103-106]. Further studies suggested that PDT in combination with endoscopic stenting was produced a mild survival benefit that was not matched by stenting alone^[107,108]. A randomized control trials comparing survival rates in patients treated with biliary stenting alone with those treated with combination biliary decompression and PDT was terminated early, due to the survival and quality of life benefit in the patient who received PDT^[109]. A meta-analysis of six studies found that, compared with biliary stenting, PDT was associated with improved biliary drainage, better quality of life, and longer survival with similar rates of biliary sepsis^[110]. Overall however, PDT for malignant biliary obstruction remain a strong therapy, although a large-scale randomized trial is in progress to further validate its benefits.

CONCLUSION

Palliative endoscopic therapies for malignant biliary strictures are crucial for a disease that so often presents with surgical ineligibility. Endoscopic options range from biliary decompression to more advanced therapies, such as RFA or photodynamic therapy. The potential advantages of full utilization these methods, especially in the setting of minimally invasive EUS-guided therapy, has redefined the management of patients with inoperable biliary malignancies.

Abstract

Surgery remains the only chance of cure for pancreatic cancer, but only 15%-25% of patients present with resectable disease at the time of primary diagnosis. Important goals in clinical research must therefore be to allow early detection with suitable diagnostic procedures, to further broaden operation techniques and to determine the most effective perioperative treatment of either chemotherapy and/or radiation therapy. More extensive operations involving extended pancreatectomy, portal vein resection and pancreatic resection in resectable pancreatic cancer with limited liver metastasis, performed in specialized centers seem to be the surgical procedures with a possible impact on survival. After many years of stagnation in pharmacological clinical research on advanced pancreatic ductal adenocarcinomas (PDAC) - since the approval of gemcitabine in 1997 - more effective cytotoxic substances (nab-paclitaxel) and combinations (FOLFIRINOX) are now available for perioperative treatment. Additionally, therapies with a broader mechanism of action are emerging (stroma depletion, immunotherapy, anti-inflammation), raising hopes for more effective adjuvant and neoadjuvant treatment concepts, especially in the context of "borderline resectability". Only multidisciplinary approaches including radiology, surgery, medical and radiation oncology as the backbones of the treatment of potentially resectable PDAC may be able to further improve the rate of cure in the future.

Core tip: Pancreatic cancer remains one of the most challenging tumor entities and is predicted to become the second leading cause of cancer deaths. More effective chemotherapeutic concepts in combination with early and exact imaging and more extensive surgical approaches may improve the rate of cure.

Perioperative treatment options in resectable pancreatic cancer - how to improve long-term survival. *World J Gastrointest Oncol* 2016; 8(3): 248-257 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i3/248.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i3.248>

INTRODUCTION

Pancreatic ductal adenocarcinomas (PDAC) are predicted to become the second largest cause of cancer related death in the United States by 2030^[1]. This is mainly due to the lack of therapeutic options, making PDAC one of the few types of cancer with a still increasing mortality rate^[2]. Surgery remains the only chance of cure for this devastating disease, but only 15%-25% of patients present with resectable disease at the time of primary diagnosis^[3]. Important goals in clinical research must therefore be early detection with suitable diagnostic procedures, further broadening operation techniques, and determining whether chemotherapy or radiation therapy is the most effective perioperative treatment. Only multidisciplinary approaches including surgery, radiology, medical and radiation oncology and gastroenterology may be able to further improve the rate of cure in the future^[4].

This review of the treatment options of potentially resectable PDAC will focus on the 3 backbones - radiological assessment, surgical procedures and perioperative regimen (chemotherapy/radiochemotherapy) - and their potential impact on long-term survival. Current standards will be discussed as well as ongoing or recently completed clinical trials.

ROLE OF RADIOLOGY

Although explorative laparotomy is considered the gold standard for resectability assessment, radiological imaging plays a key role in planning surgical procedures. Until the recent refinement of national management guidelines for PDAC, the main concern on radiological assessment of patients with suspected PDAC was the determination of resectability^[5]. In view of the high mortality rate, it is necessary to offer curative resection, as this is the only chance for long-term survival. On the

other hand, this chance is rather small, with only about 20% 5-year survival rate in case of curative resection, and the procedure is not free of risk for mortality, which depends on the medical centers' experience and ranges from 3.8% to 16.3%^[6,7]. Furthermore, morbidity after resection can limit the use of adjuvant chemotherapy. Thus, the preoperative imaging must be used to determine whether a patient has a good chance of curative resection and should have explorative laparotomy or should rather undergo conservative treatment with chemotherapy without further delay. This decision is always accompanied by the double risk of either denying a patient a potentially lifesaving resection or performing unnecessary surgery in patients with unresectable tumors.

The achievement of an R0-resection is one of the most significant parameters for survival^[6]. Therefore, the first goal of radiological assessment is to confirm the probability of R0-resection without the necessity of arterial reconstruction^[8]. Both computed tomography (CT) and magnetic resonance imaging (MRI) have been shown to be effective to this end. The assessment accuracy of local resectability by CT was as high as 93% in a representative study conducted in a high volume center^[9]. The criteria have been extensively reviewed elsewhere and are summarized in current guidelines^[10-12]. Basically, arterial encasement of the celiac trunk, the common hepatic artery, the proper hepatic artery or the superior mesenteric artery is deemed unresectable, as survival remains poor even after technically successful tumor removal and arterial reconstruction (Figure 1)^[8]. Similarly, survival is impaired for those patients requiring resection of the mesentericoportal venous axis; however, long-term survival can be observed in some of these cases^[8]. Therefore, venous involvement of the tumor is not a criterion for unresectability if reconstruction of the mesentericoportal flow by vessel resection and reanastomosis, patch plastic or graft interposition is technically feasible (Figure 1). CT can predict clear infiltration by encasement of arteries and clear non-infiltration by non-contact to adjacent arteries (surrounding preserved fat plain) with acceptably high accuracy; however, once tumor contact to the vessels is present, the ability to decide whether the tumor can be surgically removed from the artery without resection and reconstruction of the artery decreases^[13,14]. In such cases, the accuracy of prediction of local resectability by radiological imaging is limited and repeatedly results in unexpected abortion of surgical exploration. Or - vice versa - could cause preclusion of a patient from resection if no exploratory attempt was undertaken because the disease was found to be too advanced on imaging. Even though these cases are becoming rare thanks to improvements in imaging in terms of spatial resolution and speed of image acquisition, with better vessel enhancement and tumor delineation as well as minimization of image artifacts^[9], it would be desirable to offer the remaining patients inside this grey zone of locally advanced tumors an approach to safely decide

Figure 1 Examples of resectability assessment in untreated pancreatic ductal adenocarcinoma by means of computed tomography. A: Unresectability due to encasement of the common hepatic artery reaching to the celiac trunc (arrows); B: Borderline resectability with infiltration of the portal vein and one-sided contact to the common hepatic artery without extension to the celiac trunc. Neoadjuvant treatment and/or pancreatic left resection with *en-bloc* resection of the celiac trunc (after embolization) can be considered; C: Unresectability due to encasement of the superior mesenteric artery by more than 180°; D: Infiltration of the superior mesenteric vein and venous confluence with stenosis and multiple separated mesenteric venous branches unsuitable for surgical reconstruction.

whether it is worth undergoing the R0-resection or continuing with conservative treatment.

Preoperative treatment could serve as “problem solver” in such cases, termed “borderline resectable” cancers. They are characterized by intense tumor contact to the arterial mesenteric (up to 180° encasement) and celiac axes (up to short encasement of the common hepatic artery without extension to the celiac trunk) or infiltration of the mesentericoportal venous axis (if technically manageable) (Figure 1)^[5]. This concept could help increase the rate of R0-resection in this group *via* tumor shrinkage and aid in selection of patients for resection by filtering out those with aggressive tumors nonresponsive to chemotherapy. Observational cohort studies of this concept have been promising, but as yet no prospective controlled studies have been performed. Arguments against this approach could be that shrinkage of initially radiologically invisible micrometastases (*e.g.*, to the peritoneum and liver), will lead to false negative M0-assessments intraoperatively despite residual viable tumor cells in these remote lesions. In order to appropriately select patients for this new approach, the actually most accurate imaging strategy for detection of small metastases, MRI of the liver with diffusion weighted imaging (DWI) and hepatocyte specific contrast agents^[15-17] would be justified.

Finding the optimal imaging strategy is also desirable for the local assessment of tumor extent. On the other hand, introduction of a third type of assessment complicates the work of the radiologists and should not be used to avoid definite statements by calling tumors borderline resectable in case of any doubt. In consequence, diagnostic imaging should consist of state of the art imaging

under optimal conditions such as hardware and contrast agents used, as well as imaging protocols including dynamic high resolution contrast imaging in order to optimize delineability of the peripancreatic vasculature. One of the most important factors to be considered is how recent the imaging studies are, as it is known that regardless of the imaging quality, images older than 4 wk do not reflect the extent of tumors found on surgery^[18], making repeated imaging necessary before a decision can be made.

Another problem of preoperative therapy is the necessity of histological confirmation and grading of the tumor. It therefore becomes even more important to characterize the tumor by means of radiological imaging and to exclude other tumors such as neuroendocrine tumors, sarcomas, lymphomas, as well as non-malignant diseases (*e.g.*, mass forming pancreatitis, autoimmune related pancreatitis). This aids decision making regarding pretherapeutic biopsy strategies.

The reassessment of tumors after neoadjuvant treatment poses new challenges for diagnostic imaging. After initial reports showing results almost as good as in patients without preoperative therapy, more recent studies have increasingly shown that local tumor extent tends to be overestimated by imaging procedures after chemotherapy, and even more so after radiation^[19-21]. The reliability of a preoperative radiological statement is diminished and can only be compensated for by thorough surgical exploration. This again - knowing of the “point of no return” of the resection of a pancreatic head carcinoma, beyond which R0-resection may still be found to be impossible in some cases - can be a drawback of the preoperative concept, potentially resulting in R2-

resected patients. In this context new parameters are needed to identify response and shrinkage of viable tumors. DWI, perfusion measurement by MRI and CT (including dual energy CT), and positron emission tomography are currently under investigation to fill this gap with results pending. Alternative surgical strategies are also included, such as the very promising distal pancreatectomy with en-bloc resection of the celiac trunk for cases where pancreatic tail carcinoma has reached the celiac axis. This requires very precise planning based on radiologic imaging and a preoperative radiological intervention in order to train collateralization (see "surgical procedures" below)^[22,23].

In conclusion, with the advent of new management options in preoperative therapy of pancreatic cancer, radiological imaging - for planning of biopsy and surgery as well as pre-surgical reassessment and preconditioning - has moved to the frontline of treatment decision making and become the basis of measures to achieve the treatment goal: Prolonged survival of the patients.

SURGICAL PROCEDURES

Much progress has been made in the field of pancreatic resection in recent years and importantly, as the quality of surgery is considered a key factor in long-term survival, consensus has been reached on a number of surgical principles. An analysis of our own patient cohorts ($n = 428$) suggests that postoperative complications deteriorate long-term outcome after pancreatic resection in pancreatic cancer patients. We found that severe postoperative complications had a strong negative impact on long-term survival. This effect was significant and even comparable to that of the most relevant tumor characteristics such as lymph node involvement, grading or resection margin^[24]. An analysis by Birkmeyer *et al.*^[7] showed absolute differences in 5-year survival probabilities rates between low-volume hospitals (LVH) and high-volume hospitals (HVH): The absolute difference in 5-year survival in patients with pancreatic cancer between LVH and HVH was 5%. These findings underline the importance of centralization of pancreatic surgery for pancreatic cancer; in other words, patients should be transferred to specialized centers to further improve the results of surgical procedures^[7].

Perioperative medical management

Several studies have suggested that blood transfusion is associated with impaired long-term survival. A recent systematic review including 23 studies with 4339 patients confirmed this assumption. Patients receiving perioperative blood transfusion had a significantly lower 5-year survival rates after pancreatic resection in 13 of 19 studies in univariate and multivariate analyses^[25].

Extended pancreatectomy

The goal of any pancreatic resection for pancreatic adenocarcinoma should be the complete removal of

the tumor (R0-situation). To this end, more radical or "extended" surgical techniques have been established in the last decades, whereat "extended" in this context means a more aggressive marginal clearance^[26-28].

This may include total duodenopancreatectomy, resection of the portal-mesenteric axis, and extended lymph node dissection. Extended pancreatectomy is defined as standard pancreatoduodenectomy and includes the resection of the head of the pancreas and uncinate process, duodenum and first segment of the jejunum, common bile duct and gallbladder, lymphadenectomy, sometimes pylorus and/or antrum of the stomach and sometimes elements of the transverse mesocolon. Relevant vascular structures and any of the following organs involved in continuity are excluded: More than the antrum or distal half of the stomach; colon and/or mesocolon with relevant vascular structures of the transverse mesocolon (ileocolic, right, or middle colic vessels); the small intestine beyond the first segment of the jejunum; portal vein, superior mesenteric, and/or inferior mesenteric vein; hepatic artery, celiac trunk, and/or superior mesenteric artery; the inferior vena cava, right adrenal gland, right kidney and/or its vasculature; and last but not least the resection of liver and diaphragmatic crura.

The standard distal pancreatectomy is defined as the resection of the body and/or tail of the pancreas; the spleen with the splenic vessels combined with a standard lymphadenectomy; the resection of the fascia of Gerota if necessary; and potentially also elements of the transverse mesocolon apart from relevant vessels.

In contrast, an extended distal pancreatectomy refers to the standard distal pancreatectomy plus any type of gastric resection, colon and/or relevant vascular structures of the transverse mesocolon, small intestine; portal vein, superior mesenteric, and/or inferior mesenteric artery; inferior vena cava, left adrenal gland, left kidney, liver and diaphragmatic crura.

The extended resection approach may have problematic consequences: Operating time and blood loss; in addition the length of stay in the intensive care unit and hospital may be increased after extended surgery. Furthermore, surgical morbidity is increased after extended pancreatectomy. Perioperative mortality seems to be similar to that of standard pancreatectomies. Data regarding survival suggested no difference between patients after standard resection compared to those who underwent extended resection^[29]. However, recent long term follow-up findings suggest an inferior prognosis after extended pancreatic resection compared to those who underwent standard resection (11.7% 5-year survival vs 21% 5-year survival)^[30].

Extended lymph node dissection

The resection of the regional lymph nodes around the duodenum and the pancreas plus the lymph nodes on the right side of the hepatoduodenal ligament, the right side of the superior mesenteric artery and the

anterior and posterior pancreatoduodenal lymph nodes is defined as standard lymphadenectomy. Lymph node dissection beyond this area is considered extended. However, a prospective comparison of the surgical results of extended lymph node dissection and standard lymph node resection did not show any significant difference in survival between the two strategies^[31]. Extended lymph node dissection is therefore not considered to improve long-term survival.

Portal vein resection

A recent publication showed that resection of the portal vein was significantly associated with the four following factors: Larger and poorly differentiated tumors, higher numbers of positive lymph nodes and positive resection margins^[32]. Debate is currently ongoing as to whether routine portal vein resection during pancreatoduodenectomy for PDAC is reasonable. In this context, a French retrospective analysis has been published showing that patients (without microscopic venous tumor involvement of the portal vein) who underwent pancreatic resection combined with portal vein resection had a significantly longer overall survival than patients in a matched control group after pancreatic head resection without venous resection^[33]. These data may indicate that a “*per se*” portal vein resection results in a more radical local tumor elimination and may improve long-term survival.

Infiltration of the celiac trunk

As a particular situation in the context of locally advanced PDAC, tumor manifestation in the pancreatic body with involvement of the celiac trunk and/or the common hepatic artery needs mentioning. Normally such a situation is considered unresectable^[34]. However, a radical distal pancreatectomy with splenectomy and *en-bloc* resection of the celiac trunk without reconstruction of the celiac axis is a potential curative approach for these cases^[35]. The weak point of this concept is the interruption of the direct arterial blood supply to the liver, bile ducts and stomach. This may lead to acute liver failure, bile duct necrosis or ischemic necrosis of the stomach. A multidisciplinary approach is therefore needed to avoid such severe complications. Preoperative digital subtraction angiography is necessary to provide information about the perfusion of the crucial vessels^[23]. In cases where there is a pre-existing stenosis of the celiac trunk, spontaneous collateral blood flow from the superior mesenteric artery directly to the gastroduodenal artery *via* pancreaticoduodenal arcades and therefore to the hepatic artery can be seen. In such a situation, the tumor can be resected immediately including the celiac trunk. If there is no pre-existent celiac trunk stenosis, embolization of the celiac trunk is needed to enhance collateral blood flow before the operation. Important requirements for this multi-step approach are the existence of sufficient collateral arteries and no tumor invasion of the superior mesenteric artery. Sperti *et al*^[22] reported on similar survival rates to regular R0-resections after this sophisticated intervention.

Is there a role for pancreatic resection in resectable pancreatic cancer with limited liver metastasis?

A recent retrospective analysis conducted by our institution showed that even patients with advanced pancreatic cancer (locally advanced or locally resectable with hepatic oligometastasis) seem to benefit from pancreatoduodenectomy followed by gemcitabine-based chemotherapy. Forty-five patients who had undergone palliative intended pancreatic resection followed by chemotherapy were therefore matched with 45 patients after upfront gemcitabine-based palliative chemotherapy. A subgroup of patients with locally resectable tumor and limited liver metastasis (R0/M1) showed a significant improvement in overall survival compared to patients who had not had surgery (14.4 mo vs 7.2 mo), suggesting a potential role for pancreatic resections in patients with limited liver metastasis if the primary tumor is completely removable^[36].

ADJUVANT AND NEOADJUVANT CONCEPTS

Current standards

In the ongoing discussion about the role of perioperative treatment options in PDAC, ideal timing (neoadjuvant/adjuvant) and the ideal modality (chemotherapy, radio-chemotherapy) remain controversial^[11,37]. The most convincing contemporary data based on a high level of evidence are available for the effectiveness of adjuvant chemotherapy alone, based firstly on the results of the CONKO-001 trial. This randomized multi-center phase III trial included 368 patients and compared 6 cycles of adjuvant gemcitabine (Gemcitabine 1000 mg/m² d1, 8, 15, q29) to observation only^[38]. Median disease-free survival was significantly improved (13.4 mo for the gemcitabine group compared to 6.7 mo for the observation only group; $P < 0.001$) and led to a significant but numerically small advantage in overall survival (22.4 mo gemcitabine vs 20.2 mo observation only; $P = 0.01$). Indeed, the most important and clinically relevant result of the CONKO-001 remains that 5-year survival (an established surrogate marker for long-term survival) and rate of cure were doubled by adjuvant gemcitabine: 20.7% in the Gem group compared to 10.4% in the observation group. These data are based on long-term follow-up over more than 11 years^[39] and were confirmed to a large extent by the ESPAC-3 trial. This large randomized, multicenter phase III trial included 1088 patients and compared 6 cycles of gemcitabine to 6 cycles of 5-FU (425 mg/m² d1-5 bolus *i.v.*, q d29) and folinic acid (20 mg/m² d1-5 *i.v.*, q29). Median DFS (Gem 14.3 mo vs 14.1 mo; $P = 0.53$) and OS (Gem 23.2 mo vs 5-FU 23.0 mo; $P = 0.32$) were similar in both treatment groups (and to the CONKO-001 gemcitabine group), but more relevant toxicities were observed in the 5-FU group^[40]. In conclusion, both chemotherapeutic regimens are considered standard care in the adjuvant

Table 1 Standard adjuvant therapy

Gemcitabine 1000 mg/m ² <i>i.v.</i> 30 min	d1, 8, 15, q29
	6 cycles
5-fluorouracil 425 mg/m ² <i>i.v.</i> Bolus	d1-5, q29
Folinic acid 20 mg/m ² <i>i.v.</i> Bolus	6 cycles

setting^[41], but the better toxicity profile of gemcitabine should be taken into consideration^[34]. More recently, the Japanese JASPAC-01 trial compared gemcitabine to the 5-FU prodrug S1 (80/100/120 mg/d based on body surface area, p.o., d1-28, q6w, for 4 courses). S1 is known for its specific effectiveness in Asians and is widely used, especially in the treatment of gastric cancer^[42]. 385 patients were included in this randomized phase III trial which showed impressive results, with a significantly improved 2-year survival of 70% in the S1 group compared to 53% in the gemcitabine group (HR 0.56, $P < 0.001$). The data were presented at the annual ASCO-GI meeting in 2013^[43], but full publication and a confirmatory trial, especially in non-Asian patients, must be awaited (Table 1).

Therapeutic concepts combining chemotherapy with targeted therapy have been so far unsuccessful at further improving survival in resectable PDAC - a well-known phenomenon for unresectable PDAC as well^[44]. CONKO-005, designed as a follow-up randomized phase III trial of CONKO-001, investigated the additional effect of the EGFR-tyrosine-kinase inhibitor Erlotinib (100 mg daily p.o. d1-28, q29) in combination with gemcitabine (standard dosage) for 6 cycles in 436 patients after R0 resection. No improvement could be demonstrated for the primary endpoint DFS, but a trend was described for improved long-term survival in the erlotinib + gemcitabine group^[45]. Longer follow-up and ongoing molecular analyses will clarify whether it is possible to identify a subgroup which could benefit from erlotinib in the future. The parallel trial CONKO-006 for R1 resected patients investigated the concept of prolonged additive chemotherapy in this high risk patient cohort, as well as the role of the multikinase inhibitor sorafenib. All patients ($n = 122$) received 12 cycles of adjuvant gemcitabine and were randomized for gemcitabine alone or in combination with sorafenib (400 mg bid, p.o., d1-28, q29). No improvement in DFS or OS could be demonstrated for the overall study population by prolonging postoperative chemotherapy or using sorafenib^[46].

Several trials which investigated the role of adjuvant radiochemotherapy in PDAC also failed to show a clear survival advantage in the use of intensified treatment modalities. The CAPRI trial^[47] may be presented as a disappointing endpoint of this concept. In this phase III trial, 132 patients were randomized to receive either 5-FU as standard of care or an aggressive postoperative regimen of 5-FU (200 mg/m² daily), Cisplatin (30 mg/m² weekly) and Interferon alpha-2b (3 Mio IU 3 × weekly) in combination with radiation therapy (50.4

Table 2 Completed adjuvant phase III trials

	Gem	26.5	33%	19%

5-FU: 5-fluorouracil; OS: Overall survival.

Gray), followed by 2 cycles of continuous 5-FU. No difference was found for the primary endpoint OS (26.5 mo vs 28.5 mo, $P = 0.99$) or DFS (15.2 mo vs 11.5 mo); instead a massive increase of grade 3/4 toxicities (85% vs 16%) was seen.

An overview of the completed and clinically relevant adjuvant phase III trials is given in Table 2.

Ongoing adjuvant trials

Several adjuvant phase III studies with different concepts are ongoing, such as the combination of two or more cytostatic substances, or chemotherapy in combination with immunotherapy or radiochemotherapy (Table 3).

The ESPAC-4 trial is investigating the role of a more intense chemotherapeutic regimen combining gemcitabine (standard dosage) with capecitabine (d1-14, q22) for 6 cycles in a randomized phase III trial. Recruitment for the pancreatic cohort (732 patients) has been completed and initial results can be expected soon.

More recently, the chemotherapeutic regimens which are more effective for the palliative situation, namely FOLFIRINOX^[48] and nab-paclitaxel in combination with gemcitabine^[49], are also available for adjuvant treatment. The actively recruiting APACT (adjuvant therapy for pancreatic cancer trial) will provide information about whether the combination therapy of nab-paclitaxel (125 mg/m² d1, 8, 15, q29) and gemcitabine is feasible in resected PDAC patients ($n = 800$) and also whether it is more effective than gemcitabine alone. The French ACCORD/PRODIGE study group will investigate a similar concept in a randomized phase III trial of 480 patients comparing 6 cycles of modified FOLFIRINOX (Irinotecan 150 mg/m², oxaliplatin 85 mg/m², folinic acid 400 mg/m², 5-FU 2400 mg/m² per 46 h d1, q 15) to gemcitabine monotherapy. As both trials are based on the current most effective and evidence-based chemotherapies for advanced PDAC with a clear advantage in comparison to gemcitabine monotherapy, they have the potential to further improve current standard therapy. The question remains as to whether these more aggressive concepts

Table 3 Ongoing adjuvant trials

Trial	Registration No.	Treatment groups	Patients planned
ESPAC-4	ISRCTN96397434	Gem + capecitabine	732
APACT	NCT01964430	Gem Gem + nab-paclitaxel	800
ACCORD24	NCT01526135	FOLFIRINOX Gem	490
ROG-0848	NCT01013649	Gem + RCT (capecitabine or 5-FU)	950

5-FU: 5-fluorouracil; RCT: Randomized controlled trial.

will be feasible in PDAC patients with a partially reduced performance state and after extended abdominal surgery. Accrual of the trials and (long-term) follow up data must be awaited.

With regard to radiochemotherapy, the RTOG-0848 trial is planned to investigate an additional effect of postoperative radiochemotherapy to standard chemotherapy. All patients are to receive 6 cycles of gemcitabine as standard of care and if without signs of disease recurrence will then be randomized to either receive additive radiochemotherapy or not 950 patients are planned. The protocol was amended and the initial randomization to gemcitabine ± erlotinib was terminated.

Immunotherapy is one of the most fascinating recent innovations in the treatment of oncological disease, but most clinical research to date has had disappointing results in PDAC, which is considered to be non-immunogenic^[50]. Seven hundred and twenty-two patients have been recruited for a phase III study of chemotherapy and chemoradiotherapy with or without Algenpantucel-L (HyperAcute®-Pancreas), a new immunotherapeutic concept. Algenpantucel is a vaccine derived from 2 pancreatic cell lines which showed promising results in a single-arm phase II trial^[51]. Results of the phase III trial are pending.

Neoadjuvant concepts

Chemotherapies with response rates (in terms of tumor shrinkage) of about 30% - compared to formerly < 10% for gemcitabine monotherapy - have become available^[52,53] in the treatment of PDAC for the first time due to the introduction of FOLFIRINOX and gemcitabine/nab-paclitaxel. This is of special relevance for the further development of neoadjuvant and perioperative treatment strategies, as pancreatic cancer must be considered a systemic disease. Many patients experience early recurrence postoperatively, which in the majority of cases may in fact be metastatic spread which was undetected at the time of primary diagnosis. Analogue to the ongoing discussion on the role of induction chemotherapy in locally advanced unresectable PDAC^[11], the question as

to whether patients with resectable PDAC and disease progression under neoadjuvant therapies would really profit from primary resection must be posed (Table 4).

Two trials are ongoing to investigate these questions in clearly defined study protocols: The German NEONAX is investigating the role of perioperative gemcitabine/nab-paclitaxel and perioperative modified FOLFIRINOX is being investigated in the United States in a phase II trial by the University of Yale.

Treatment strategies for borderline resectable PDAC

In addition to the aim of improving the rate of cure in terms of hindering recurrence of disease after curatively intended surgery, a further aim must be to render more patients resectable after intensified induction treatment. In this context, the term "borderline resectable" PDAC is relevant and relatively recent but different definitions are currently in use^[4] (Table 4).

Katz *et al.*^[54] presented data at the Annual ASCO meeting in 2015 of a small phase II trial which may be the starting point for a new era in borderline resectable PDAC. Twenty-two patients with ECOG 0 and 1 were included and prospectively analyzed. Participants were centrally reviewed to assess borderline criteria [tumor-vessel interface (TVI) with superior mesenteric/portal vein (SMV) $\geq 180^\circ$, TVI with superior mesenteric artery (SMA) $< 180^\circ$, TVI with any degree of hepatic artery]. All patients were intended to be treated with neoadjuvant modified FOLFIRINOX (oxaliplatin 85 mg/m², irinotecan 180 mg/m², leucovorin 400 mg/m² on day 1 followed by 5-FU 2400 mg/m² × 48 h for 4 cycles) and CRT (50.4 Gray in 28 fractions) with capecitabine (825 mg/m² BID) prior to pancreatectomy and postoperative gemcitabine (1000 mg/m² d1, 8, 15 for 2 cycles). Of the 15 (68%) patients who underwent pancreatectomy, 14 (93%) of the operations were R0, suggesting efficacy for this therapeutic concept.

The German NEOLAP trial includes borderline resectable and non-resectable PDAC and focuses in particular on the fact that the effectiveness of neoadjuvant treatment may not be reflected by a radiologically measurable response^[21]. After an induction treatment with gemcitabine + nab-paclitaxel for 2 cycles, participants will be randomized for 2 further cycles of gemcitabine + nab-paclitaxel or 2 cycles of FOLFIRINOX. In the case of stable disease an obligatory explorative laparotomy/laparoscopy will be performed to answer the question of a possible discrepancy between radiological assessment and intraoperative evaluation of resectability.

CONCLUSION

Although the progress in the last decades in pancreatic surgery has been clinically relevant, as demonstrated by a clinically relevant decrease of mortality in specialized centers, more extensive operations will be needed to further improve long-term survival. Extended pancreatectomy, portal vein resection and pancreatic resection in resectable pancreatic cancer with limited liver metastasis seem to be

Table 4 Ongoing neoadjuvant/borderline resectable trials

Trial	Registration No.	Treatment groups	Primary endpoint	Patients planned
NEONAX	NCT02047513	2 cycles Gem + nab-paclitaxel neoadjuvant 4 cycles Gem + nab-paclitaxel adjuvant 6 cycles Gem + nab-paclitaxel adjuvant	DFS	166
Perioperative mFOLFIRINOX	NCT02047474	3 cycles FOLFIRINOX Neoadjuvant + adjuvant	DFS	46
NEOLAP	NCT02125136	2 cycles Gem + nab-paclitaxel + 2 × FOLFIRINOX + adjuvant 3 × Gem + nab-paclitaxel 4 cycles Gem + nab-paclitaxel + adjuvant 3 × Gem + nab-paclitaxel	Conversion rate	168 (including locally advanced PDAC)

DFS: Disease-free survival; PDAC: Pancreatic ductal adenocarcinomas.

the surgical procedures with the highest impact in this field.

In this context, the concept of borderline resectability appears very promising. Although this concept has already been adopted to some extent in some national guidelines, it is still evolving. Criteria for imaging are defined quite strictly and pragmatically, as they do not only reflect technical resectability but must be considered prognostic parameters indicating more advanced extent of tumors. Furthermore, variability of the vasculature of the individual patient is not reflected by the criteria, leaving the individual decision dependent on the experience of the treating medical institution. This includes alternative surgical strategies such as the promising distal pancreatectomy with *en-bloc* resection of the celiac trunk in case of pancreatic tail carcinoma reaching the celiac axis, which requires very precise planning based on radiologic imaging and a preoperative radiological intervention in order to train collateralization. The timing of imaging studies is another important factor, as it is known that regardless of imaging quality, images older than 4 wk rarely represent the tumor spread found upon surgery. In such cases imaging has to be repeated before the decision is made.

Adjuvant chemotherapy for PDAC can double the rate of cure, as demonstrated by the clinical trials outlined in this review. Although this is comparable to results for other cancers, further improvements are urgently needed, as the starting point is catastrophically unfavorable, with rates of recurrence of disease of about 90% without perioperative treatment. Since the approval of gemcitabine in 1997 more effective cytotoxic substances (nab-paclitaxel) and combinations (FOLFIRINOX) are now available for advanced PDAC, raising hopes for more effective adjuvant and neoadjuvant treatment concepts for potentially resectable tumours. The fact that therapies with a broader mechanism of action will become available for research projects in the near future is equally important. In addition to the omnipresent immunotherapy, stromal depletion, e.g., with hyaluronidase^[55] and anti-inflammatory concepts^[56], appear most promising.

The only hope for improving long-term survival in this still challenging disease is a multidisciplinary approach, ideally with the close collaboration of radiologists, surgeons and oncologists in specialized tumor centers.

Abstract

Venous thromboembolism event (VTE) is a common and morbid complication in cancer patients. Patients with gastrointestinal cancers often suffer from symptomatic or incidental splanchnic vein thrombosis, impaired liver function and/or thrombocytopenia. These characteristics require a thorough risk/benefit evaluation for individual patients. Considering the risk factors for the development of VTE and bleeding events in addition to recent study results may be helpful for correct initiation of primary pharmacological prevention and treatment of cancer-associated thrombosis (CAT), preferably with low molecular weight heparins (LMWH). Whereas thromboprophylaxis is most often recommended in hospitalized surgical and non-surgical patients with malignancy, there is less agreement as to its duration. With regard to ambulatory cancer patients, the lack of robust data results in low grade recommendations against routine use of anticoagulant drugs. Anticoagulation with LMWH for the first months is the evidence-based treatment for acute CAT, but duration of secondary prevention and the drug of choice are unclear. Based on published guidelines and literature, this review will focus on prevention and treatment strategies of VTE in patients with gastrointestinal cancers.

Key words: Thromboembolism; Gastrointestinal cancer; Prophylaxis; Treatment; Anticoagulation

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The risk for venous thrombosis and pulmonary

embolism is clearly elevated in patients with gastrointestinal cancers. This risk is highest for patients with pancreatic, gastric or colorectal cancer and those receiving anti-cancer therapies. Available guidelines usually refer to thromboembolism in cancer patients without differentiating between types of cancer. Those patients with gastrointestinal cancers are more likely to present with additional problems such as hepatopathy-associated low platelet counts and/or prolonged prothrombin times. Furthermore, symptomatic or incidental thromboembolism of the visceral veins may occur more often. Identifying the risk factors for the development of venous thromboembolism and bleeding events may be helpful for correct initiation of primary pharmacological prevention and treatment of cancer-associated thromboembolism. Based on published guidelines and literature, this review will focus on prevention and treatment strategies of venous thromboembolism in patients with gastrointestinal cancers.

Primary prevention and treatment of venous thromboembolic events in patients with gastrointestinal cancers - Review. *World J Gastrointest Oncol* 2016; 8(3): 258-270 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i3/258.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i3.258>

INTRODUCTION

Venous thromboembolism (VTE) commonly presents as deep vein thrombosis (DVT) or pulmonary embolism (PE), occasionally as thrombosis of the hepatic, portal, or splanchnic veins. Patients with cancer are at increased risk for VTE^[1-4]. In addition to prothrombogenic cancer-related factors, the risk for symptomatic VTE is modulated by patient-specific and treatment-related factors (Table 1). Among the different subtypes of malignancy, some gastrointestinal cancers have a clinically relevant VTE incidence of more than 5% in the first year after cancer diagnosis (Figure 1), such as pancreatic (16%-22%), gastric (12%-17%) and colorectal (8%-12%) cancers^[2,5-8]. Symptomatic VTE is not only associated with substantial morbidity and complications in clinical management, but has been shown to have a detrimental effect on cancer survival^[9-11]. Acute and follow-up complications such as intestinal necrosis and esophageal bleeding due to portal hypertension may be life threatening if intra-abdominal veins are involved^[12-15].

Furthermore, anticoagulation with a vitamin K antagonist (VKA), such as warfarin, is complicated by drug interactions and variable drug absorption due to the changing nutritional status of cancer patients^[16]. In fact, therapeutic anticoagulation with VKA does not prevent VTE recurrences as effectively as in non-cancer patients, and major bleeding complications are also more than twice as common^[17]. Acute anticoagulation and secondary prevention with low molecular weight heparin (LMWH) has been established as an effective treatment

of VTE in cancer patients^[18], but daily subcutaneous application may result in local complications such as hematoma or infections, thus negatively influencing quality of life.

Most research into the primary prevention and treatment of VTE included both cancer and non-cancer patients. Recommendations for patients with malignancies are therefore based on the sparse available evidence and the guidelines differ only marginally (Table 2)^[19-27]. Most clinical studies focusing on VTE in cancer patients do not differentiate between different kinds of cancer, resulting in a lack of specific data concerning VTE in gastrointestinal cancers.

PERIOPERATIVE PROPHYLAXIS OF VTE IN CANCER PATIENTS UNDERGOING SURGERY

The risk for VTE is higher in cancer patients undergoing surgery without prophylaxis in comparison to non-cancer surgical patients^[27,28]. Administration of LMWH or fondaparinux (FPX) in these patients significantly reduces the rate of VTE^[29,30]. Dosages of LMWH in the range of 3000-5000 anti-FXa units per day are more effective than and as safe as lower doses. Patients undergoing major abdominal or pelvic surgery for malignancy remain at risk for VTE for up to five weeks after surgery. Thus, a prolonged pharmacologic thromboprophylaxis (LMWH or FPX once daily) should be considered, unless contraindicated because of high bleeding risk or active bleeding^[31,32]. Prophylactic regimens begin 12-24 h pre- or 6-24 h postoperatively^[29-32]. Based on these studies^[31-33], and according to the different guidelines (Table 2), antithrombotic prophylaxis is recommended for a minimum of 7 d and up to 35 d postoperatively. FPX (2.5 mg/d) was found to be as effective and safe in preventing VTE after abdominal surgery as the LMWH dalteparin (5000 antiFXa units/d). A post-hoc analysis of 1407 (out of 2048) patients with cancer demonstrated a significant (39%) risk reduction of VTE^[29]. Accordingly, the European (ESMO) guideline^[20] recommends extended prophylaxis for all patients undergoing elective cancer surgery. In the American guidelines (ASCO, NCCN)^[19,34], extended prophylaxis is only recommended in the presence of high thromboembolic risk factors such as residual or advanced cancer, aged 60 or older, obesity, previous history of VTE, duration of surgery longer than 2 h or prolonged postoperative immobilization. In patients with contraindications to pharmacological anticoagulant prevention strategies (e.g., increased risk of hemorrhage), the use of intermittent pneumatic compression devices or compression stockings is advised^[19-27].

The recommendations for patients undergoing minimally invasive or laparoscopic surgery are even less evidence-based. In a recently published randomized study evaluating postoperative antithrombotic prophylaxis with LMWH for one vs four weeks in patients undergoing

Figure 1 Venous thromboembolic event-risk according to different cancer entities (modified from Wun *et al.*^[8] 2009). VTE-Incidence in the first year after cancer diagnosis (all stages) California Cancer Registry 1993-1999 (Patient Hospital Discharge Dataset). VTE: Venous thromboembolism event.

Table 1 Some venous thromboembolic event risk factors in cancer patients

Cancer-related	Patient-related	Treatment-related
Reduced mobility		
Primary cancer (e.g., pancreatic cancer > colo-rectal cancer)	Age	Operation
Stage (IV > III)	History of VTE	Chemotherapy
Histology (e.g., adeno- > squamous cell-carcinoma)	Infection/fever	Central line/port-catheter
Grade (3 > 2)		Parenteral nutrition
Thrombocytosis		Radiation therapy
Leukocytosis		
Acute phase (elevated CRP)		
Elevated D-dimer		

CRP: C-reactive protein; VTE: Venous thromboembolic event.

laparoscopic surgery for colorectal cancer, extended antithrombotic prophylaxis was safe and reduced the 3-mo risk of VTE by more than 90%, and that of proximal DVT by 50%, as compared to the one week regimen^[35]. These data are consistent with the suggestion to follow the same recommendations regardless of whether a cancer patient is to undergo an open or laparoscopic surgical intervention^[36,37].

Prevention of portal vein thrombosis

Splanchnic vein thromboses (SVT), including portal vein thrombosis (PVT), mesenteric vein thrombosis, splenic vein thrombosis and the Budd Chiari syndrome are frequent events in patients with hepato-biliary-pancreatic cancers, with cancer-associated PVT responsible for 21% of all cases^[14]. The risk of VTE and SVT is increased in patients with cirrhosis^[38,39], and PVT is a relevant complication of hepato-biliary-pancreatic surgery^[40], reported to occur in 9% of patients after liver resections^[41]. In this context, thromboprophylaxis with LMWH was demonstrated to be effective and safe in a retrospective comparative cohort study of 201 patients undergoing liver resections for liver cancers, with a reduction in PVT from 10% to 2%^[42]. These data suggest that prophylactic anticoagulation with

LMWH - as recommended in patients undergoing major abdominal cancer surgery - is also effective in cancer patients undergoing liver resection.

PROPHYLAXIS OF VTE IN HOSPITALIZED MEDICAL PATIENTS WITH CANCER

Hospitalized patients with active cancer - a term not uniformly defined - were included in all published randomized clinical trials investigating the role of unfractionated heparin (UFH), LMWH or FPX for the prevention of VTE. Treatment of hospitalized patients for 6-14 d with low-dose enoxaparin (20 mg/d s.c.) was ineffective^[43], whereas higher prophylactic doses of LMWH (enoxaparin 40 mg/d, or dalteparin 5000 anti FXa units/d)^[43,44] or FPX (2.5 mg/d)^[45] demonstrated superiority compared to placebo in the prevention of VTE with minimal or no increase in major bleeding events. Subgroup analyses failed to identify a subgroup which did not benefit from pharmacological thromboprophylaxis^[46]. This was also true for a small subgroup (5%-15% of the study population) of cancer patients.

Subgroup analysis of 274 patients with active cancer from the CERTIFY study comparing UFH (3 × 5000 IU/d) with LMWH (certoparin 3000 anti FXa units/d) demonstrated a similar VTE risk (5.3% vs 4.1%) and similar rates of any (4.0 vs 3.9) or major (0.7% vs 0.5%) bleeding compared to the 2965 patients without cancer^[47,48].

Based on three studies, extended prophylaxis with the anticoagulant drugs LMWH^[49] or non-vitamin K oral anticoagulant drugs (NOACs)^[50,51] cannot be recommended in medical patients. In the MAGELLAN trial^[51], cancer patients ($n = 592$; 7.3%) had higher rates of VTE when prophylaxis with rivaroxaban was extended from 10 to 35 d.

Discussion is ongoing as to whether all cancer patients hospitalized for reasons such as infectious complications or complex chemotherapy regimens should generally receive medical thromboprophylaxis unless contraindicated by active bleeding or high bleeding risk^[52-55]. According to the

Table 2 Comprehensive outline of some guidelines focusing on the prevention and treatment of cancer associated venous thromboembolism

	Primary prophylaxis/prevention of VTE in cancer patients			Treatment of cancer-associated VTE	
	Surgical patients	In-patients (non surgical)	Out-patients	Acute/initial	Long-term/secondary prevention
ASCO Guidelines 2013 ^[15]	UFH, LMWH (Dalteparin, Enoxaparin), Fondaparinux A combined regimen of pharmacologic and mechanical prophylaxis may improve efficacy, especially in the highest risk patients. Patients undergoing major cancer surgery should receive prophylaxis starting before surgery and continuing for at least 7 to 10 d and it should be considered an extension up to 4 wk in patients undergoing abdominal and pelvic surgery	UFH, LMWH (Dalteparin, Enoxaparin), Fondaparinux	Not recommended routinely ¹ LMWH may be considered	UFH, LMWH (Dalteparin, Enoxaparin, Tinzaparin), Fondaparinux VKA not recommended	LMWH (Dalteparin, Enoxaparin, Tinzaparin) VKA (INR 2-3) acceptable if LMWH is not available Use of NOACs is not recommended Treatment of splanchnic or visceral vein thrombi diagnosed incidentally should be considered on a case-by-case basis, considering potential benefits and risks of anticoagulation
ESMO Guidelines 2011 ^[16]	LMWH (Dalteparin, Enoxaparin), UFH Fondaparinux not recommended Cancer patients undergoing elective major abdominal or pelvic surgery should receive in hospital and post-discharge prophylaxis with s.c. LMWH for up to 1 mo after surgery	LMWH (Dalteparin, Enoxaparin), Fondaparinux, UFH	Not recommended routinely May be considered in high risk patients	LMWH (Enoxaparin, Dalteparin), UFH	Treatment for a total of 6 mo. Initial dose of LMWH 100% for 1 mo, thereafter 5 mo with 75%-80% of the initial dose of LMWH
International Consensus Groupe 2013 ^[17]	LMWH (Dalteparin, Enoxaparin, Nadroparin, Tinzaparin), Fondaparinux, UFH For 10 ± 2 d or 25-31 d (28 d) extended use (Bemiparin sodium 3500 IU per day for 28 d)	LMWH (Dalteparin, Enoxaparin, Nadroparin, Tinzaparin), Fondaparinux, UFH	Not recommended routinely To be considered/recommended: Patients with locally advanced or metastatic lung or pancreatic cancer treated with chemotherapy and having a low bleeding risk	LMWH (Dalteparin, Enoxaparin), UFH	LMWH (Dalteparin, Enoxaparin) for 3 to 6 mo
British Committee for Standards in Haematology 2015 ^[18]	Patients undergoing abdominal and pelvic surgery for cancer should be considered for extended thromboprophylaxis	Patients with active or recent cancer should receive thromboprophylaxis throughout their admission unless contraindicated Patients without a history of venous thromboembolism receiving adjuvant hormonal therapies for cancer should not routinely receive thromboprophylaxis	Patients should be assessed for thrombosis risk and although most do not routinely require thromboprophylaxis, it should be considered for high risk patients	Initial treatment should be with LMWH for six months Cancer patients with incidental pulmonary embolus or deep vein thrombosis should be therapeutically anticoagulated as for symptomatic disease	Warfarin and other oral anticoagulants are acceptable alternatives if LMWH is impractical and anticoagulation is indicated Anticoagulation should be continued, taking pt status and wishes and bleeding risk into consideration. There is a rationale but little direct evidence for preferring to continue to use LMWH

Australian Governments National Health and Medical Research Council 2009 ^[19]	LMWH, continue for at least 7 to 10 d following major general surgery Consider using extended thromboprophylaxis with LMWH for up to 28 d after major abdominal or pelvic surgery for cancer, especially in patients who are obese, slow to mobilise or have a past history of VTE	LMWH, UFH	-	-	
MAYO CLINIC VTE Prevention and Management Guidelines 2014 ^[20]	UFH, LMWH (Enoxaparin, Dalteparin), Fondaparinux Cancer patients undergoing pelvic or abdominal surgery should receive 4 wk of LMWH	UFH, LMWH (Enoxaparin, Dalteparin), Fondaparinux	UFH, LMWH (Enoxaparin, Dalteparin), Fondaparinux VKA (INR2-3)	Anticoagulants are continued until there is no evidence of active malignant disease defined as any evidence of cancer on cross-sectional imaging or any cancer-related treatment (surgery, radiation, or chemotherapy) within the past 6 mo	
ASH Guidelines 2013 ^[21]	UFH, LMWH, Fondaparinux in all patients undergoing major surgical intervention for malignant disease Prolonged prophylaxis for up to 4 wk may be considered in patients undergoing major abdominal or pelvic surgery for cancer with high-risk features such as residual malignant disease, obesity, and prior history of VTE	UFH, LMWH, Fondaparinux	Routine VTE prophylaxis in ambulatory patients receiving chemotherapy is not recommended	LMWH	LMWH Continue treatment with LMWH is preferred for at least the initial 6 mo of treatment
German Guidelines ^[22,23]	LMWH, Fondaparinux, (UFH) Patients undergoing abdominal and pelvic surgery for cancer are recommended to get extended thromboprophylaxis (28 to 35 d)	LMWH, Fondaparinux, (UFH)	LMWH, Patients should be assessed for thrombosis risk and thromboprophylaxis should be considered for high risk patients	LMWH, Fondaparinux, UFH	LMWH for 3 to 6 mo If cancer persists extended secondary prophylaxis (with LMWH, VKA, or NOAC) is useful (till death)

¹For highly selected high-risk patients (*e.g.*, such as those with pancreatic cancer) preventive anticoagulation may be considered to be applied routinely. VTE: Venous thromboembolic event; LMWH: Low molecular weight heparins; UFH: Unfractionated heparin; VKA: Vitamin K antagonist; INR: International normalized ratios; NOAC: New oral anticoagulants.

available guidelines (Table 2), routine thromboprophylaxis should at least be considered. Italian investigators assessing the risk of VTE in hospitalized medical patients confirmed cancer to be a major predisposing factor for VTE (PADUA prediction score), without differentiating between cancers^[56]. However, the existence of active cancer on its own does not classify as a high VTE risk unless additional risk factors are present (Table 1).

VTE PROPHYLAXIS IN OUTPATIENTS WITH CANCER

Prevention of catheter-related VTE

Patients who have been recently diagnosed with cancer are at high risk for VTE^[57,58]. Nowadays these patients usually receive non-surgical therapies such as

radiation, chemotherapy or radiochemotherapy in an outpatient setting. Long-term central venous catheters (*e.g.*, port or picc line catheters) are used to facilitate drug administration in many of these patients. There is an increased risk of DVT in the subclavian or jugularis interna veins after insertion of a central line, with an estimated incidence of asymptomatic catheter-related DVT of about 20%, although less than 5% develop clinical symptoms, which very rarely result in symptomatic PE or relevant post-thrombotic sequelae^[59-64]. Multicenter randomized double blind placebo-controlled studies to assess the efficacy and safety of LMWH or VKA demonstrated a significant reduction in asymptomatic catheter-related thrombi, but failed to show significant benefit with regard to clinically symptomatic DVT^[59]. International guidelines therefore recommend against routine prophylaxis for this

Table 3 Primary prevention of cancer-associated venous thromboembolic event in gastrointestinal cancers

indication.

Antithrombotic prophylaxis in cancer outpatients receiving chemotherapy

The risk of VTE in cancer patients is especially high during the first weeks or months of specific therapy^[4,62,65]. Several clinical trials have evaluated the role of primary prevention in outpatients with selected or unselected malignancies. An early study on patients receiving chemotherapy for advanced breast cancer found low dose warfarin to be safe and efficacious, with 85% relative reduction in VTE compared to placebo^[66]. Two other randomized trials in patients with breast or lung cancers using prophylactic dosages of LMWH failed to show a benefit^[67]. The PROTECHT study, however, showed a statistically significant relative risk reduction of 50% for symptomatic VTE in cancer outpatients receiving chemotherapy for different types of malignancy (including gastrointestinal cancers) in favor of prophylactic dosages of the LMWH nadroparin (Table 3)^[68]. Moreover, despite a relatively low event rate of less than 3% in the placebo group, prophylactic dosages of semuloparin, an ultralow molecular weight heparin (not further developed), demonstrated a highly significant reduction (65%) of VTE in patients with metastatic or locally advanced solid cancers (1590 of 3212 with pancreatic, gastric or colorectal cancers) receiving chemotherapy^[69] (Table 3), without an increase in the incidence of clinically relevant or major bleeding complications. Whereas these trials investigated the effect of prophylactic dosages of antithrombotic drugs, two randomized open-label studies in patients with advanced pancreatic cancer undergoing chemotherapy investigated primary prophylaxis with higher doses of LMWH (Table 3). The phase II FRAGEM-trial^[70] examined the therapeutic dose of dalteparin (200 anti FXa units/kg per day), and the phase III CONKO-004 trial^[71] used half the therapeutic dosage of the LMWH enoxaparin (1 mg/kg per day). Despite differences in study design and primary endpoint of effectiveness, both trials found this intensity of anticoagulation to be safe and reported a more than 80% relative risk reduction of thromboembolic events compared to observation (Table 3).

Nevertheless, available international guidelines do

not recommend routine prophylaxis in all ambulatory cancer patients receiving anti-cancer chemotherapy (Table 2). ACCP and ASCO guidelines^[19,62] suggest considering antithrombotic prophylaxis in outpatients receiving chemotherapy with unspecified solid tumors and additional risk factors, whereas others recommend considering primary prevention, especially in patients with lung or pancreatic cancer^[21] in accordance with a recent meta-analysis^[72].

A number of attempts have been made to classify individual cancer outpatients receiving chemotherapy more precisely according to VTE risk. In this context, the scoring system developed by Khorana *et al*^[73] (Table 4), which associates pancreatic and stomach cancer with a very high VTE risk, demonstrated potential for the identification of cancer outpatients at risk for VTE prior to the start of chemotherapy with simple and commonly available criteria. A prospective randomized trial investigating the benefit of primary antithrombotic prophylaxis in high risk patients according to this score is ongoing. Until results from this study become available, the initiation of pharmacological prophylaxis in high risk patients is suggested by the standardization subcommittee of the ISTH^[74]. Supplementing the Khorana score with lab parameters such as D-dimer and soluble P-selectine^[75] or chemotherapy components such as gemcitabine and cis- or carboplatin^[76] may further categorize patients according to their VTE risk.

With the exception of patients suffering from pancreatic cancer, for whom primary prophylaxis with LMWH is highly warranted unless contraindicated by increased bleeding risk, insufficient evidence is available regarding other gastrointestinal cancers to recommend routine primary prevention with anticoagulant drugs. Until further evidence has accumulated, the Khorana score is helpful for classification of patients with gastrointestinal cancer according to their VTE risk and as an aid in decision-making regarding initiation of pharmacologic prophylaxis. While prophylactic dosages of LMWH may be effective in most gastrointestinal cancers, half-therapeutic dosages of LMWH should be considered for patients with advanced pancreatic cancer in the first three months of chemotherapy.

Table 4 Assessment scores for prediction of the venous thromboembolic event-risk in cancer out-patients receiving chemotherapy, according to Khorana *et al.*^[73], Pabinger *et al.*^[75] and Verso *et al.*^[76]

Khorana score criteria ^[73]	Score
Primary cancer	
With very high risk (pancreas, stomach) (high grade glioma ¹)	2
With high risk (lung, lymphoma, gynecologic, bladder, testicular)	1
Platelet count prior to chemotherapy > 350000/ μ L	1
Hb < 10 g/dL or ESA-application	1
Leukocyte count prior to chemotherapy > 11000/ μ L	1
Body mass index > 35 kg/m ²	1
High risk	> 3
Vienna prediction score (additional parameters to Khorana score) ^[75]	
D-dimer > 1.44 μ g/mL	1
Soluble P-selectin > 153.1 μ g/mL	1
High risk	> 4
Protecht prediction score (additional parameters to Khorana score) ^[76]	
Cisplatin or carboplatin	1
Gemcitabine	1
High risk	> 3

¹High grade glioma are considered very high risk site of cancer in the Vienna prediction score only. ESA: Erythropoiesis stimulating agents.

VTE risk and new drugs

The introduction of new drugs which target angiogenesis, tumor stroma or immunity in gastrointestinal cancer medicine led to the realization that individual VTE risk may be strongly influenced by the drugs. For example, the introduction of bevacizumab for the treatment of advanced colorectal cancer not only resulted in a clinically relevant increase in bleeding, but in thromboembolic complications as well^[75,77,78].

Moreover, drug-associated VTE may become an important factor limiting further cancer therapy development. At the ASCO meeting in May 2015, Hingorani *et al.*^[79] presented a phase II trial in pancreatic cancer patients treated with gemcitabine, nab-paclitaxel and recombinant pegylated hyaluronidase - an experimental drug - which had to be stopped due to high numbers of VTEs. A prophylactic dose of LMWH (40 mg enoxaparin/d) was not effective, but the use of half therapeutic doses of enoxaparin (1 mg enoxaparin/kg per day) allowed the continuation of the study.

TREATMENT OF ACUTE VTE IN CANCER PATIENTS

The treatment of patients with active cancer and acute VTE with the standard treatment for non-cancer VTE patients (LMWH or FPX plus concurrent introduction of anticoagulation with VKA) resulted in a two- to three-fold increase of both re-thrombosis and bleeding^[17,18]. Several randomized controlled trials compared prolonged application of LMWH to oral anticoagulation with VKA in patients with cancer-associated thrombosis (CAT) and demonstrated superior efficacy of LMWH with no increase

in bleeding complications (Table 5), results confirmed by meta-analysis^[18,19,80,81]. Based on these results, guidelines recommend a standard treatment of three to six months of weight-adjusted LMWH regardless of whether the patient suffers from gastrointestinal or another type of cancer (Table 2). The underlying malignancy, probably representing the most important risk factor for VTE, continues beyond six months after the initial VTE in most of these patients. Therefore, anticoagulation beyond this period may be warranted and is recommended in most guidelines (Table 2). Nevertheless, evidence for this recommendation is clearly weaker, as prospective randomized trials investigating type of anticoagulation, dosage of anticoagulant drugs or duration of prolonged anticoagulation have not been reported. Available data suggest that the pro-thrombotic risk correlates with disease progression due to increasing tumor load, decreasing performance status, progressive mobility reduction and increased use of palliative chemotherapy^[82-84]. On the other hand, an increased bleeding risk, associated with progression of cancer, prolonged anticoagulation and prolonged chemotherapy needs to be considered in order to balance the benefit of preventing recurrent VTE against the risk of bleeding^[83,84]. Furthermore, the impact of prolonged anticoagulation on the quality of life of cancer patients needs to be considered.

Although clinical guidelines (Table 2) currently recommend considering indefinite anticoagulation in patients with advanced malignancy, they do not recommend a specific anticoagulant drug due to the limited evidence available.

Treatment of acute PVT

Acute thrombosis of splanchnic veins - PVT in particular - is a frequent complication in patients with cancers of the hepato-biliary-pancreatic system^[23,85]. PVT results in portal hypertension and impairment of liver perfusion. Spread of thrombosis to splenic or mesenteric veins can result in fatal complications such as splenic or intestinal infarction. Anticoagulation is the therapy of choice in non-cirrhotic, non-cancer patients, with successful recanalization in about half of acute PVT cases^[86,87]. Anticoagulation is considered in patients with cirrhosis and PVT with a small increase in bleeding complications^[86], and can safely be combined with placement of transjugular intrahepatic portosystemic shunts^[87]. Unfortunately cancer patients, e.g., those with gastrointestinal cancers, were excluded from these trials^[86,87].

Treatment of cancer-associated PVT is therefore based on evidence from non-cancer patients with or without cirrhosis. Despite the fact that prophylactic and therapeutic anticoagulation seems to be effective and safe for cirrhotic patients^[86-88], an individual risk/benefit evaluation which takes prognosis, anticancer treatment options and acute anticoagulation-associated bleeding risk, as well as future complications with the associated consequences for surgical interventions and the risk of variceal hemorrhage into consideration is challenging.

Table 5 The CLOT and CATCH studies^[80,81]: Study-population characteristics and study outcomes

	CLOT	CATCH	VKA	Dalteparin	P	VKA	Tinzaparin	P
Study-population characteristics								
n	676	900						
Women	52%	59%						
Median age (yr)	63	59						
ECOG 0-1	63%	77%						
Metastasized cancer	67%	55%						
Brest cancer	17.6%	9%						
Colo-rectal cancer	17.8%	13%						
Lung cancer	14.8%	12%						
Gynecological cancer	11.2%	23%						
Pancreatic cancer	4.8%							
Urogenital cancers	14.2%							
Brain cancers	5.5%							
Hematological cancers	10%	10%						
Study outcomes								
VTE			15.8%	8.0%	0.002	10.0%	6.9%	0.07
DVT			11.0%	4.2%		5.3	2.7	0.04
Fatal PE			2.1%	1.7%		3.8%	3.8%	
Non-fatal PE			2.7%	2.7%		0.7%	0.4%	
Major bleeding			4%	6%	0.25	2.7%	2.9%	
CRNM-bleeding						16%	11%	0.03
Any bleeding			19%	14%	0.09			
6-mo mortality			41%	39%		41%	40%	
INR < 2			30%			26%		
INR 2-3			46%			47%		

VKA: Vitamin K antagonist; VTE: Venous thromboembolic event; DVT: Deep vein thrombosis; PE: Pulmonary embolism; INR: International normalized ratios.

Treatment of CAT in particular situations

Thrombocytopenia is a well-known effect of chemotherapy in cancer patients and higher degrees of thrombocytopenia increase the risk of hemorrhage. Anticoagulation should therefore be administered to thrombocytopenic patients after thorough evaluation of the risks and benefits. The risk of recurrent VTE is high in the month following the initial diagnosis on beginning cancer therapy^[1,4]. Full therapeutic anticoagulation with LMWH is considered appropriate in these situations when the platelet count is above 50000/ μ L, and a reduction of anticoagulation intensity to 75% or even 50% may be reasonable later in the course of treatment. When platelets are below 50000/ μ L but above 20000/ μ L, a half-therapeutic to prophylactic dose should be considered^[89].

It should be recognized that increased prothrombin times and elevated international normalized ratios (INR) as a result of hepatic dysfunction only reflect reduced synthesis of coagulation factors. In fact coagulation inhibitors are also decreased, resulting in a well-balanced but more labile equilibrium with normal thrombin generation capacity^[90,91]. For this reason patients with reduced hepatic capability are not protected against VTE, despite an increased INR, but patients with cancer and hepatic dysfunction have an increased VTE risk^[90,92]. Again, higher grade evidence in favor of or against full-dose anticoagulation in patients with CAT and reduced liver function due to pre-existing cirrhosis or advanced hepatic metastasis resulting in increased INR is lacking. Clinical experience suggests a cautiously balanced approach of 75% to 100% of the therapeutic LMWH

anticoagulation dose for acute VTE.

VTE recurrences are to be expected in more than 5% of patients within the first months despite CAT therapy according to guidelines with LMWH (Table 5). Again, there is sparse evidence on treatment of these patients. Based on a report from Carrier *et al.*^[93], a 20% increase in LMWH dose - without adjustment to laboratory parameters - is a practical, safe and effective approach.

NON-VITAMIN-K ANTAGONIST ORAL ANTICOAGULANTS IN THE PREVENTION OR TREATMENT OF CAT

A number of new oral anticoagulants (NOAC) have been introduced and licensed for prevention and treatment of VTE in recent years^[94]. These drugs work by direct inhibition of active coagulation factors direct oral anti-coagulants (DOAC), namely factor IIa/thrombin (dabigatran) or factor Xa (apixaban, edoxaban, rivaroxaban). The term non-vitamin K oral anticoagulant was created in order to maintain the acronym NOAC. Although these drugs have been successfully tested and licensed in trials investigating NOACs in the post-operative setting of elective hip or knee replacement, drug development for other surgical patients was never initiated and the programs for medical patients were stopped early^[50,51]. A placebo-controlled dose-finding phase II trial for primary prophylaxis of VTE in ambulatory cancer patients undergoing chemotherapy showed relevant activity^[95], but this indication has not yet been further developed. There

Table 6 Take home messages

Patients with gastrointestinal cancers are among those with the highest cancer-associated VTE risk (<i>e.g.</i> , pancreatic cancer, gastric cancer)
Primary prevention of VTE should be considered according to an individual risk-benefit estimation
Scoring systems help to identify patients at high VTE risk. These patients may benefit from prophylactic anticoagulation
Usual prophylactic dosages of LMWH may not be effective enough in patients with the highest risk (<i>e.g.</i> , pancreatic cancer)
Gastrointestinal cancer patients with VTE should have medical anticoagulation therapy with LMWH for at least three to six months
In patients with gastrointestinal cancers splanchnic vein thrombosis, portal hypertension, hepatopathy-associated coagulation defects (<i>e.g.</i> , decreased prothrombin time) and thrombocytopenia may complicate anticoagulation strategies

VTE: Venous thromboembolic event; LMWH: Low molecular weight heparins.

is therefore no evidence for the use of NOACs for primary prevention in hospitalized or ambulatory cancer patients undergoing surgery or any other kind of anticancer therapy.

The four drugs mentioned above have all been compared to VKA (warfarin) in randomized phase III trials for the treatment of DVT, PE and atrial fibrillation^[96-101]. All of these trials demonstrated that NOACs are at least as effective and safe as VKA. As confirmed by meta-analysis, the study data for these NOACs showed a clinically relevant reduction in bleeding, most pronounced for intracerebral bleeding events^[102]. Depending on the inclusion and exclusion criteria of the individual studies and on the definition of "patients with active cancer", all six trials included cancer patients, a subgroup adding up to 2.5% of more than 25000 patients^[102]. Meta-analysis of these patients suggests a potential role for NOACs in patients with CAT, with a similar risk/benefit relationship as demonstrated in non-cancer patients^[76]. There are major drawbacks to the use of NOACs for this indication, however. First of all, standard therapy of CAT is LMWH for several months and not LMWH followed by VKA - the standard treatment arm in the VTE trials. Secondly, "patients with active cancer" included in the phase III trials demonstrate a three-month-mortality of less than 15%^[103-105], whereas those included in the two pivotal CAT trials (CLOT, CATCH) recruiting cancer patients ten years apart, have a six-month-mortality of 40%^[80,81] (Table 5). Obviously these patient groups differ to a great extent. Thirdly, despite having less interactions with other drugs compared to VKA, NOAC still bear a largely unclear risk of interactions with cytotoxic or targeted drugs. A CLOT- or CATCH-like head to head comparison of NOACs vs LMWH, the current standard of care, is eagerly awaited, especially as the oral application of NOACs might provide an improvement in quality of life compared to s.c. administered LMWH. Unless study data are available, NOACs are not to be considered the first choice in patients with acute CAT. As an alternative to LMWH or VKA (Table 2), anticoagulant treatment with NOACs beyond six months may be reasonable in many CAT patients, as there are no studies defining the optimal drug in this period.

CONCLUSION

The risk for VTE is clearly elevated in patients with (gastrointestinal) cancer. This risk is highest for patients

with pancreatic cancer and those receiving anti-cancer therapies. VTE is the second leading cause of death in patients with cancer, and mortality is increased among patients with CAT^[10,106]. Whereas available guidelines usually refer to VTE in cancer patients without differentiating between types of cancer, those with gastrointestinal cancers are more likely to present with additional problems such as hepatopathy-associated low platelet counts and/or prolonged prothrombin times. Furthermore, symptomatic or incidental VTEs of the visceral veins may occur more often. Despite limited data, prophylactic anticoagulation must be endorsed in most hospitalized patients with malignancies. In ambulatory patients undergoing chemotherapy, an assessment of individual prothrombotic and prohemorrhagic factors may help transfer the beneficial effect of pharmacologic prophylaxis demonstrated in a number of trials to those patients with the highest VTE risk, in particular those suffering from pancreatic cancer. Treatment recommendations for CAT with LMWH have been reconfirmed by recent evidence. Further progress will help clarify the risk/benefit relationship of NOACs in this field, identifying economic and quality of life aspects as well (Table 6).

Abstract

Gastric cancer (GC) develops as a result of inflammation-associated carcinogenesis due to *Helicobacter pylori* (*H. pylori*) infection and subsequent defects in genetic/epigenetic events. Although the indication for eradication therapy has become widespread, clinical studies have revealed its limited effects in decreasing the incidence of

GC. Moreover, research on biopsy specimens obtained by conventional endoscopy has demonstrated the feasibility of the restoration of some genetic/epigenetic alterations in the gastric mucosa. Practically, the number of sporadic cases of primary/metachronous GC that emerge after successful eradication has increased, while on-going guidelines recommend eradication therapy for patients with chronic gastritis and those with background mucosa after endoscopic resection for GC. Accordingly, regular surveillance of numerous individuals who have received eradication therapy is recommended despite the lack of biomarkers. Recently, the focus has been on functional reversibility after successful eradication as another cue to elucidate the mechanisms of restoration as well as those of carcinogenesis in the gastric mucosa after *H. pylori* eradication. We demonstrated that Congo-red chromoendoscopy enabled the identification of the multi-focal distribution of functionally irreversible mucosa compared with that of restored mucosa after successful eradication in individuals at extremely high risk for GC. Further research that uses functional imaging may provide new insights into the mechanisms of regeneration and carcinogenesis in the gastric mucosa post-eradication and may allow for the development of useful biomarkers.

Core tip: Since the indication for eradication therapy for *Helicobacter pylori* became widespread, the number of gastric cancer (GC) cases that emerge after eradication has continued to increase. However, the underlying mechanism of restoration/carcinogenesis in the gastric mucosa after eradication therapy has not been fully elucidated. We previously demonstrated that, instead of conventional endoscopy, Congo-red chromoendoscopy might be more precise in its ability to identify the multi-focal distribution of functionally irreversible mucosa that

may be present in individuals with high risk for GC even after successful eradication. Further research using functional imaging may provide new insights to address the mechanism of gastric regeneration/carcinogenesis, and subsequently, may allow for the development of biomarkers for GC in high risk individuals during post-eradication surveillance.

INTRODUCTION

Gastric cancer (GC) is considered a major cause of cancer-related deaths worldwide^[1], and cancer prevention based on the knowledge of gastric carcinogenesis has been considered the most useful strategy. It has been shown that GC is closely associated with chronic inflammation due to persistent infection with *Helicobacter pylori* (*H. pylori*), a class I gastric carcinogen. The development of GC occurs through a multi-step sequence from chronic gastritis, chronic atrophic gastritis, intestinal metaplasia (IM), dysplasia, and finally, GC after an extended period of time^[2-4]. In a cohort study of 4655 healthy asymptomatic individuals with a 7.7 ± 0.9-year surveillance, the risk of GC was increased in a stepwise fashion from patients with *H. pylori*-positive chronic gastritis to those with *H. pylori*-positive chronic atrophic gastritis, and finally, to those with atrophic metaplastic gastritis (HR = 7.1; 95%CI: 1-53.3 vs HR = 14.9; 95%CI: 2-107.7 vs HR = 61.9; 95%CI: 5.6-682.6, respectively)^[5].

In fact, clinical outcomes are determined by a complex interaction of multiple factors, such as *H. pylori* virulence factors, genetic susceptibility of the host, and environmental factors^[6,7]. The bacterial virulence factors, such as cytotoxin-associated gene A antigen (CagA) and vacuolating cytotoxin, play an important role in *H. pylori*-associated gastric disorders^[8,9]. Notably, the *CagA* gene, which is part of the *cag* pathogenicity island, produces one of the most pivotal virulence factors of many carcinogenic signaling pathways^[10,11]. Moreover, the epithelial cells and inflammatory cells in the gastric mucosa are in direct contact with the outer environment. Therefore, the immune receptors on these cells, such as toll-like receptors and nucleotide-binding oligomerization domain-containing protein, recognize bacterial components of *H. pylori* and other oral microbes that reach the gut^[12,13]. Actually, the long-term colonization by *H. pylori* was reported to cause an environment of chronic inflammation together with reductions in acidity and in the level of antioxidant enzymes in the gastric juice. This results in the synergistic overgrowth of ingested outer bacteria in the intra-gastric environment, which sustains the inflammation^[12,14]. As a result, these reactions can produce large amounts of

inflammatory mediators, such as reactive oxygen/nitrogen species and inflammatory cytokines, which may facilitate the aberrant methylation of the cytosine ring preceding guanine (*i.e.*, CpG dinucleotide) islands in the promoters of DNA or microRNAs (miRNAs)^[15,16]. A theory of the field effect of carcinogenesis, which states that pathologically non-cancerous tissue that surrounds the tumor may also have genetic/epigenetic alterations, is currently accepted as a reliable mechanism of gastric carcinogenesis^[17]. For example, aberrant genetic methylation was reported to accumulate during the sequential development of GC^[18,19], and further quantitative methylation analyses of both driver and passenger genes showed that patients with GC had higher methylation levels in the background normal-appearing tissues than those without GC; additionally, patients with multiple gastric tumors had significantly higher methylation levels than those with a single gastric tumor^[20-22]. Thereafter, some epigenetic alterations were shown to be restored by the elimination of *H. pylori*^[23-31].

Accordingly, it is strongly believed that successful eradication of *H. pylori* may be an effective approach for the prevention of GC, and the numbers of subjects in whom *H. pylori* has been eradicated have continued to increase. However, it was also demonstrated that eradication therapy had only limited effects on the inhibition of GC development. Sporadic cases of GC that emerge after successful eradication have been observed in a clinical setting. These cases strongly suggest two possibilities for the development of sequential carcinogenesis after eradication: A point-of-no-return, where irreversible alterations have already occurred in spite of the eradication or another cause of carcinogenesis such as bile reflux or other microorganisms. Here, we review the results of clinical and laboratory studies on the preventive effect of *H. pylori* eradication on gastric carcinogenesis to establish future surveillance strategies.

CLINICAL EFFECTIVENESS OF ERADICATION THERAPY FOR THE PREVENTION OF GC OCCURRENCE

Eradication for patients with non-dysplastic gastritis

Although some studies have found that the *H. pylori* eradication gradually led to regression or complete resolution of chronic gastritis^[32-34], it is still unclear whether eradication therapy might truly prevent the development of premalignant lesions/GC in patients with chronic gastritis and several grades of inflammation, atrophy and metaplasia.

In a randomized control trial (RCT) that included a total of 435 *H. pylori*-infected subjects with/without eradication followed by an endoscopic biopsy after 5 years of surveillance, Leung *et al*^[35] showed that eradication was protective against the progression of premalignant gastric lesions in 52.9% of *H. pylori*-positive subjects. On the contrary, in a population-based RCT of 1630 healthy *H. pylori*-carriers in China, Wong *et al*^[36] showed that the incidence of GC was similar between participants who had

received eradication treatment and those who received placebo during an observation period of 7.5 years (7/817 vs 11/813, $P = 0.33$, respectively). However, eradication therapy significantly decreased the incidence of GC only in a limited group of 988 *H. pylori*-carriers who did not have premalignant lesions when they entered the study. A well-designed meta-analysis of 6 RCTs that were conducted primarily in Japan and China, demonstrated a significant decline of 1.6% (51/3294) in the occurrence of GC in patients who had received eradication therapy compared with 2.4% (76/3203) of all patients who did not receive eradication therapy during a period longer than 4 years [relative risk (RR) = 0.66; 95%CI: 0.46-0.95]. However, eradication therapy did not demonstrate a significant benefit in terms of the prevention of GC incidence in any of the subjects with or without premalignant lesions at base-line^[37,38]. These data not only provided evidence that successful eradication might reduce the incidence of GC in asymptomatic *H. pylori*-infected Asian individuals but also suggested the possibility of a point-of-no-return, beyond which eradication may be of no use for cancer prevention. Actually, some discrepancies exist about whether eradication therapy can reduce the risk of GC occurrence in subjects with pathologically defined premalignant changes. Such discrepancies may be caused by several factors, as follows: Selection of the study population, including age, dietary habits, smoking, alcohol abuse, and genetic factors that may influence the susceptibilities of the host; *H. pylori* strain; intra-gastric conditions with/without premalignant lesions at the time of eradication therapy; and methodological differences during surveillance, including biopsy protocols and the interval/duration of surveillance. A more recent study identified several risk factors for the failure of eradication therapy to prevent GC in a Chinese community-based randomized trial, and thus the sequential data from the long-term surveillance of these patients should provide promising data on the preventive effect of eradication on the incidence of GC^[39].

Eradication therapy for patients after endoscopic resection

Previous studies have demonstrated that eradication did not completely eliminate the risk of secondary cancer occurrence after curative endoscopic resection (ER) of the primary GC, although it was found that eradication might suppress or delay the development of cancer^[40]. Based on the theory of field cancerization, the remaining gastric mucosa after ER is thought to harbor endoscopically invisible micro-lesions with malignant potential^[41,42].

Uemura *et al.*^[43] first reported that eradication after ER significantly decreased the occurrence of metachronous GC^[44]. Similarly, an RCT in Japan also showed that eradication after ER had a protective effect with respect to the development of secondary GC during a 3-year follow-up period. In contrast, a RCT in South Korea revealed that eradication after ER for gastric neoplasms, including GC and low- or high-grade dysplasia, did not

reduce the incidence of metachronous GC^[45]. A Japanese retrospective study used longer-term follow-up data of 1.1 to 11.1 years (median 3.0 years) for 268 *H. pylori*-positive patients who had undergone ER for GC, which may or may not have been followed by successful eradication. This study showed that eradication did not reduce the incidence of metachronous GC more than 5 years after ER (8.5% vs 14.3%, respectively, $P = 0.262$, log-rank test) and that the existence of mucosal atrophy at the time of entry into the study, and not *H. pylori*-infection status, was an independent risk factor for the incidence of metachronous GC^[46]. Accordingly, the preventive effect of successful eradication on metachronous GC remains controversial, possibly because of selection bias, underpowered numbers and residual confounding factors that may have been present in the studies. However, in an up-to-date meta-analysis of 13 relevant studies including 3 prospective trials, Yoon SB *et al.*^[47] demonstrated a preventive effect of eradication on the incidence of metachronous GC after ER. In detail, compared with the patients who did not receive eradication therapy, the pooled odds ratio in those who received eradication therapy was 0.42 (95%CI: 0.32-0.56). The pooled analysis of 6237 patients in all 13 studies demonstrated a significantly lower incidence of metachronous GC in the patients who received eradication therapy compared with those who did not [4.7% (111/2382) vs 6.8% (263/3855, 6.8%), respectively]. From now on, it will be difficult to conduct further well-designed and practical studies with long-term surveillance due to the ethical considerations that result from the fact that Japanese and Korean clinical guidelines have already recommended *H. pylori* eradication in cases of chronic gastritis as well as in cases of post-ER gastric background mucosa^[48,49]. Instead, regular surveillance endoscopy after eradication is recommended as the most practical method because GC occurrence may be uninterrupted even after successful eradication. Therefore, the development of useful biomarkers for GC that emerges after successful eradication will be urgently needed to detect high risk groups among such a large number of individuals who have received eradication therapy.

THE EFFECT OF ERADICATION ON HISTOLOGY AND BIOLOGICAL MARKERS

The effect of eradication on histological alterations

Previous systematic reviews and meta-analyses have demonstrated the impact of *H. pylori* eradication on the gastric histology of precancerous lesions (e.g., atrophy and IM) according to the (updated) Sydney System, during a surveillance period of less than 10 years^[50-52]. Through an examination of one RCT and seven observational studies, Rokkas *et al.*^[50] found that eradication had beneficial effects on gastric atrophy, but not on IM, in both the antrum and corpus. After the inclusion of three RCTs and nine

observational studies, Wang *et al.*^[51] showed that gastric atrophy in the corpus only recovered after eradication, but atrophy in the antrum and IM of the corpus and antrum did not recover. On the contrary, some studies incorporated longer-term follow-up of the histological changes after successful eradication based on the updated Sydney System. These previous studies revealed that, after atrophy of any site within the gastric mucosa and IM in the lesser curvature of the corpus were gradually restored, scores at both 5 and 10 years after eradication were significantly decreased compared with those at baseline^[52-54].

Accordingly, controversial results have been obtained from limited surveillance periods and studies with various methodological flaws, and therefore, additional RCTs with a longer observational period are required.

The effect of eradication on genetic/epigenetic alterations

Genetic and epigenetic alterations have been implicated mainly in the activation of oncogenes and/or the inactivation of tumor suppressor genes that are involved in cell-cycle regulation, cell-cell adhesion, DNA repair, and telomerase activation during gastric carcinogenesis.

The effect of eradication on genetic alterations

The effect of eradication treatment on genetic abnormalities remains unclear. Ohara *et al.*^[55] showed that eradication might not have led to changes in chromosomal structures, such as loss of heterozygosity and microsatellite instability, in 13 patients with *H. pylori*-positive GC, 12 patients with *H. pylori*-negative GC and 8 patients with GC detected after eradication. On the contrary, Zhu *et al.*^[56] revealed that increased expression of human telomerase, including ribonucleoprotein/human telomerase reverse transcriptase and human telomerase RNA, in the *H. pylori*-infected mucosa was significantly diminished after successful eradication.

The effect of eradication on epigenetic abnormalities

Recent interest in oncology research has shifted from genetics toward epigenetics. Actually, 90% of heritable alterations in cancer cells have been reported to be epigenetic in nature^[57,58]. Additionally, the most important difference between genetic and epigenetic alterations is that epigenetic changes are reversible by therapeutic interventions. Previous studies demonstrated that the medical elimination of *H. pylori* infection might reverse the epigenetic alterations and thus restore the histological phenotype of the gastric mucosal tissue, in spite of some discrepancies.

Gene promoter methylation: Gene promoter methylation is one of the major epigenetic alterations that is responsible for gene silencing^[19]. In particular, the hypermethylation of CpG-dinucleotide islands within promoter regions of genes, such as CDH1, APC, COX2, CHFR, DAPK, DCC, GSTP1, MAGE, MLH1, p16, PTEN, p14,

RASSF1A, RUNX3, SNCG, THBS1, TIMP-3, and TSLC1, have been reported to be associated with aberrant transcriptional gene silencing and consequent loss of protein expression during the multistep development of gastric carcinogenesis. It is well-known that dense methylation of CpG islands through the accumulation of "non-core" and "scattered" DNA methylation causes permanent overall deregulation of carcinogenic signal transduction^[59-68]. These phenomena are strongly supported by the epigenetic field defect hypothesis, but previous studies have shown complex changes in DNA methylation in non-cancerous mucosa after eradication; these changes are possibly due to the complicated results of reversible and irreversible changes of aberrant methylation in the gastric mucosa with various grades of inflammation/atrophy/metaplasia.

Originally, two studies from groups in Hong-Kong found that eradication reversed CDH1 promoter methylation and caused a reduction of inflammatory cell infiltration in the non-cancerous gastric mucosa^[25,26]. The first RCT involved 81 patients with biopsy-proven *H. pylori*-positive chronic active gastritis who were treated with/without eradication therapy. In this study, Chan *et al.*^[25] demonstrated that the methylation status of CDH1 as well as inflammatory cell infiltration at 6 wk after eradication therapy were significantly reversed only in patients without IM. In the second RCT, Leung *et al.*^[26] showed that eradication significantly reduced the methylation density of the CDH1 promoter in biopsy specimens that were obtained from the antrum and corpus of 28 middle-aged *H. pylori*-infected subjects without GC.

Thereafter, interest in other target genes has increased. Perri *et al.*^[27] suggested that gene-specific alterations in the gastric mucosa after successful eradication resulted from promoter methylation of CDH1, APC, COX2, MLH1, and p16. This conclusion was based on an examination of three paired gastric biopsy specimens obtained from the antrum, angles, and corpus of 57 *H. pylori*-positive dyspeptic outpatients before and 1 year after eradication. Significant differences were observed in the mean numbers of methylated genes, which were 0, 1.1 ± 0.9 , and 1.6 ± 0.9 among the 12 *H. pylori*-/IM- patients, 28 *H. pylori*+/IM- patients, and 17 *H. pylori*+/IM+ patients, respectively. In the 17 patients who received eradication therapy out of 45 total *H. pylori*-positive patients, a significant reversal of DNA methylation in both CDH1 and p16, and to a lesser extent, in APC and COX2, was observed after eradication. Sepulveda *et al.*^[28] revealed that hyper-methylation of CpG islands within the promoter of the gene that encodes the DNA repair protein MGMT was significantly reduced at 6-8 wk after successful eradication in 19 patients with *H. pylori*-gastritis (from 70% to 48% of cases, $P < 0.039$); an increase in the expression of MGMT protein was only seen on the mucosal surface. Using data from real-time methylation-specific PCR for FLNc and THBD and the updated Sydney System, Nakajima *et al.*^[29] examined specimens from 35 post-ER patients and 11 *H. pylori*-

negative healthy volunteers who underwent successful eradication. They showed that the methylation levels were gradually decreased together with a decrease in inflammatory cell infiltration throughout the 1 year after eradication, but that the methylation levels in post-ER patients were persistently higher than those in healthy individuals. Shin *et al.*^[30] investigated DNA methylation of the tumor-suppressor genes *LOX*, *APC* and *MOS* over a time course of 26.0 mo in non-cancerous gastric mucosa after eradication in 221 subjects. They showed that successful eradication significantly decreased the methylation levels within the *LOX* promoter, but not in *APC*, while a reduction in the *MOS* methylation level after eradication was significant only in subjects without IM at base-line. In addition, hypo-methylation of CpG islands is also considered to be another major mechanism of DNA methylation at an early phase during *H. pylori*-associated gastric carcinogenesis, because many genes that are susceptible to aberrant hyper-methylation were reported to overlap with the target genes of global hypo-methylation^[69-71]. Using an immunohistochemical evaluation of 5-methylcytosine, a marker of global hypo-methylation, as well as Ki67 and p53, Compare *et al.*^[31] assessed the changes in global hypo-methylation during a 10-year follow-up period after successful eradication in 10 patients with pre-neoplastic gastric lesions (*i.e.*, atrophy and IM). They demonstrated that global DNA methylation was negatively correlated with a gradual decrease in proliferative/apoptotic markers, depending on the histological grade of the multi-step transformation into GC, but independently of the Cag-A status and treatment response to eradication therapy.

miRNA: MiRNAs, which are non-coding RNA sequences that are 18- to 25-nucleotides in length, are transcribed without translation into proteins and are involved in post-transcriptional gene silencing^[72,73]. Tissue-specific expression of miRNAs has been shown to be associated with apoptosis, proliferation, differentiation, metastasis, angiogenesis, and immune responses in inflammatory-associated carcinogenesis^[74,75]. With regard to gastric carcinogenesis, several studies have reported different phenotypes of miRNA expression in the normal mucosa, *H. pylori*-induced precancerous lesions and GC^[76-80], but the changes in miRNA expression after successful eradication are still not completely understood.

Matsushima *et al.*^[79] revealed that the down-regulation of 14 miRNAs in 4 *H. pylori*-positive individuals was increased at 4 wk after successful eradication, although the expression of oncogenic miRNAs was significantly diminished only in non-metaplastic mucosa, but not in cases of IM, at 1 year after the eradication. Specifically, hsa-miR-21, hsa-miR-25, hsa-miR-93, hsa-miR-194 and hsa-miR-196 were found to be overexpressed in GC in comparison with non-cancerous gastric tissues, and eradication therapy decreased the expression levels of these miRNAs only in cases of atrophic gastritis without metaplastic changes. Moreover, in a case-control study using endoscopic biopsy specimens from 20 patients

who were treated with ER for GC and 14 sex- and age-matched non-cancer controls, Shiotani *et al.*^[81] revealed that, although the expression of oncogenic miRNAs (miR-17/92 and the miR-106b-93-25 cluster, miR-21, miR-194, and miR-196) was significantly higher in the gastric mucosa of the post-ER group than in the controls, none of these miRNAs that were expressed in cases of IM were significantly changed after eradication in any of the groups. This indicated that eradication therapy might be effective in the restoration of the expression of oncogenic miRNAs only in patients with atrophic gastritis and not in those with IM. On the contrary, in a more recent multicenter prospective cohort study of 782 patients who were treated with ER for GC followed by eradication, Asada *et al.*^[82] demonstrated that the risk of metachronous GC after ER might be predicted *via* an assessment of epigenetic field defects using the methylation levels of three genes (*miR-124a-3*, *EMX1* and *NKX6-1*) by quantitative methylation-specific PCR. In the post-ER background gastric mucosa, which might be highly associated with metaplastic changes, the highest quartile of the miR-124a-3 methylation level had a significant univariate (HR = 2.2; 95%CI: 1.1-4.4; *P* = 0.03) and a multivariate-adjusted (HR = 2.3; 95%CI: 1.0-5.1; *P* = 0.04) for the incidence of metachronous GC^[82]. However, questions remain about whether those parameters are simultaneously expressed in the metaplastic lesions as well as in the non-metaplastic mucosa, both of which are categorized as background gastric mucosa with malignant potential; questions also remain as to whether some uniform phenotypes of IM with those parameters might develop into GC after eradication. Considering that the metaplastic mucosa is already regarded as a clinically malignant predictor, future biological predictors will provide valuable ways to overcome these clinical issues.

Furthermore, miRNAs have been reported to exist in cell-free stable forms in the plasma and serum, and therefore, serum miRNAs may serve as novel biomarkers during non-invasive surveillance for large numbers of individuals.

Summary of the histological and biological studies

Clinical and laboratory studies have found only limited usefulness of *H. pylori* eradication in the regression of DNA methylation and miRNA expression in the non-cancerous gastric mucosa, which seems to be dependent on the gene type and histological grade of the atrophy and metaplasia. In other words, successful eradication might reverse the malignant potential of pathologically non-cancerous gastric mucosa prior to the point-of-no-return.

The first limitation of the aforementioned studies is gene-specific restoration after eradication. Instead of genome-wide studies, the investigators targeted only a single gene or a few genes, whose role in gastric carcinogenesis had not yet been clarified^[17,30]. The second limitation may have originated from differences in the sensitivities of the histology and molecular biology techniques, such as methylation-specific PCR,

that were used to detect the abnormalities. In addition, the distribution of metaplastic/dysplastic lesions is uneven throughout the entire gastric mucosa, which results in sampling error by targeted biopsy, although the distribution as well as the phenotype of the IM were suggested to provide a higher predictive value of the cancer risk. Cassaro *et al.*^[83] showed that IM on the lesser curvature from the cardia to the pylorus, or throughout the entire stomach, was associated with a higher risk of GC than focal/antrum-predominant IM. Among the three phenotypes of IM [*i.e.*, complete IM (type I) or incomplete IM (types II, type III)], type III IM was reported to harbor more genetic/epigenetic changes, which are similar to those that were found in cases of gastric dysplasia^[84,85]. However, the distribution of molecular and morphological alterations in the gastric mucosal tissue after successful eradication are likely to be more complex than those that were present prior to eradication, where the multi-focal distribution of epigenetic events is related to the severity of inflammation or metaplastic changes. As previous studies have demonstrated the gradual and irregular occurrence of areas of gastric-acid secretion up to 2 years after successful eradication, the areas that are restored after eradication might be irregular/atypical^[86-88]. These phenomena may result in increased sampling errors by random biopsies under a conventional endoscopic inspection, especially those in the post-eradicated gastric mucosa. Since the updated Sydney System was originally established to assist pathologists in the formal recording of their findings in a clinical setting, but not in a research setting, a suitable scoring system to guide targeted biopsies of the gastric mucosa after successful eradication is needed^[89].

FUNCTIONAL IMPROVEMENT OF THE GASTRIC MUCOSA BY *H. PYLORI* ERADICATION THERAPY

Functional reversibility of the gastric mucosa after successful eradication will provide another important clue, similar to what was provided by the reversibility of the macroscopic/microscopic morphology. The reversibility might be caused by the reduced production of inflammatory cytokines that have inhibitory effects on gastric acid secretion or by the increased expression of H⁺/K⁺-ATPase, intrinsic factor, and M3 muscarinic receptor mRNA in the gastric mucosa, but is likely not caused by the numbers of parietal cells^[90,91].

Ji *et al.*^[92] used *in vivo* functional imaging as well as tissue morphological imaging by confocal laser endomicroscopy (CLE) and fluorescein tracers to investigate the reversibility of mucosal barrier defects after eradication in 42 *H. pylori*-positive patients. They demonstrated that gastric IM was associated with an impaired para-cellular barrier, which did not recover after eradication. Essentially, the para-cellular permeability in the setting of IM, despite *H. pylori* infection, was significantly higher than that in non-

IM tissue with *H. pylori* infection, which was in turn higher than that in non-IM tissue without *H. pylori* infection. Six months after successful eradication in 14 patients, the para-cellular barrier dysfunction of the non-IM mucosa was significantly improved, as shown by electron microscopy and CLE, in spite of a lack of significant changes in IM. The irreversible mucosal barrier dysfunction of IM may cause constant trans-epithelial penetration of various intra-gastric substances, which may promote an immune response and the further development of cancer. Accordingly, the CLE findings may be useful for the depiction of the functional and morphological irreversibility of the disrupted para-cellular barrier of IM as a reasonable cause of carcinogenesis in patients with IM, although CLE has point-sampling characteristics.

ROLE OF CONGO-RED CHROMOENDOSCOPY IN THIS RESEARCH FIELD AND FUTURE PERSPECTIVES

Congo-red chromoendoscopy is another functional test that is used to visualize the gastric areas that are capable of gastric acid secretion; this technique involves a pH-dependent color reaction, which may be performed during a conventional endoscopic inspection (Figure 1)^[93,94]. Instead of CLE and an endoscopic biopsy, this method provides a comprehensive view that distinguishes endoscopically normal-appearing gastric mucosa based on functional characteristics. Additionally, its reproducibility may be ideal for the measurement of functional and morphological changes in the mucosa during long-term surveillance after eradication.

Based on findings by Congo-red chromoendoscopy, Iijima *et al.*^[88] found an expansion of the acid-secreting mucosa during a mean follow-up of 62 mo after eradication in 24 *H. pylori*-positive patients. Subsequently, after an investigation of the histological features using a Ki67 labeling index in the biopsy samples that were obtained from both acid-secreting and non-acid-secreting areas, they showed that functionally irreversible gastric mucosa after eradication was associated with extensive IM and sustained hyper-proliferation. This indicates the importance of increased malignant potential in the genesis of GC. Specifically, during the surveillance periods, the entire area of the greater curvature became occupied exclusively by acid-secreting mucosa, whereas the expansion of the acid-secreting area in the lesser curvature was limited. With the exception of the score for neutrophil infiltration, the mean inflammation score in the non-acid-secreting area was significantly higher than in the acid-secreting area (1.3 ± 0.5 vs 0.8 ± 0.5 , respectively). Marked atrophic/metaplastic changes with high numbers of Ki67-positive cells were observed in non-acid-secreting areas, whereas none to mild atrophic/metaplastic changes with a low number of Ki67-positive cells were found in acid-secreting areas. Accordingly, this study showed that

Figure 1 Representative photos of Congo-red chromoendoscopy in a 66-year-old female patient with gastric cancer that emerged after successful eradication of *Helicobacter pylori* infection. A: A lesion of well-differentiated adenocarcinoma located on the lesser curvature in the lower part of the stomach [FQ260Z (Olympus, Tokyo)]; B: Congo-red imaging showed GC in a non-acid secreting area (Red); C and D: Post-eradicated gastric background mucosa (Red: Non-acid secreting area; Black: Acid secreting area). GC: Gastric cancer.

even long after successful eradication, the histological degrees of residual inflammation infiltration, atrophy, IM, and epithelial proliferation in the functionally irreversible non-acid-secreting areas were significantly higher than those in the functionally recovered area. Another study that used Congo-red chromoendoscopy in a total of 19 GC lesions that emerged after more than 2 years post-successful eradication in 14 consecutive patients demonstrated that GCs were observed exclusively in non-acid-secreting areas with sustained hyper-proliferation and accumulation of p53 protein^[95]. Accordingly, the non-acid secreting areas that were observed by Congo-red chromoendoscopy might truly be at a high risk for gastric carcinogenesis after eradication. Surprisingly, these studies also demonstrated that histological evaluation of targeted biopsy specimens from both acid-secreting and non-acid-secreting areas based on Congo-red chromoendoscopic findings revealed striking differences in their histological manifestations, even if these areas were separated by only a few centimeters. Therefore, Congo-red chromoendoscopy enables us to identify high-risk areas in a site-specific manner and to determine the distribution of functionally and morphologically irreversible mucosa after successful eradication. With careful consideration of the balance between the risks and benefits, Congo-red chromoendoscopy can provide important clues to gastric carcinogenesis that occurs after successful eradication^[96]. Further research on biopsy specimens guided by functional imaging, such as Congo-red chromoendoscopy, may be a promising approach in the clarification of molecular-biological events in the functional and morphological restoration and carcinogenesis after successful eradication.

SUMMARY

In conclusion, we reviewed the limited effect of the *H. pylori* eradication on the reduction of GC incidence, although the indication for eradication therapy is clinically widespread. No useful biomarkers for individuals who are at a high risk for GC that emerges after successful eradication have been identified because previous studies by conventional methods have not yet fully elucidated the underlying mechanisms of mucosal restoration as well as of gastric carcinogenesis after eradication. In accordance with a proof-of-concept of the epigenetic field defect of gastric cancerization, we propose the usefulness of Congo-red chromoendoscopy to differentiate functionally irreversible mucosal areas that are at an extremely high risk for gastric carcinogenesis. In addition, another study that used CLE with tracers identified the functional irreversibility of the metaplastic mucosa in the setting of post-eradication carcinogenesis. Therefore, future research that focuses on functional aspects may provide new insights that address both the mechanisms of mucosal regeneration and cancer development after successful eradication.

Abstract

Cystic fibrosis transmembrane conductance regulator (CFTR), a glycoprotein with 1480 amino acids, has been well established as a chloride channel mainly expressed in the epithelial cells of various tissues and organs such as lungs, sweat glands, gastrointestinal system, and reproductive organs. Although defective CFTR leads to cystic fibrosis, a common genetic disorder in the Caucasian population, there is accumulating evidence that suggests a novel role of CFTR in various cancers, especially in gastroenterological cancers, such as pancreatic cancer and colon cancer. In this review, we summarize the emerging findings that link CFTR with various cancers, with focus on the association between CFTR defects and gastrointestinal cancers as well as the underlying mechanisms. Further study of CFTR in cancer biology may help pave a new way for the diagnosis and treatment of gastrointestinal cancers.

Key words: Gastrointestinal cancer; Protein interaction; Cystic fibrosis transmembrane conductance regulator; Nuclear factor κ B; Signaling molecule

INTRODUCTION

Cystic fibrosis transmembrane conductance regulator (CFTR), a glycoprotein with 1480 amino acids, is a cAMP activated anion channel expressed in the epithelial cells of a wide variety of tissues including lung, pancreas, liver, sweat gland, reproductive system, and intestine^[1,2]. Mutations or dysregulation of CFTR will cause several pathological conditions such as cystic fibrosis (CF), a common life threatening autosomal recessive disease in the Caucasian population^[3]. The *CFTR* gene, identified in 1989, is approximately 230kb containing 27 exons^[4]. CFTR protein contains 12 hydrophobic membrane-spanning regions, 2 cytoplasmic nucleotide binding domains (NBD) involved in ATP binding and hydrolysis, and one cytosolic regulatory domain which can be phosphorylated by PKA and PKC^[5,6]. Even though it was identified initially as a chloride channel, other functions of CFTR have also been characterized over the past decades. CFTR performs as a modulator of other ion channels and transporters^[7-10], and it can also cooperate with other proteins by forming macromolecular complexes to regulate important cellular processes^[11-14]. Recently, it has been reported that CFTR is likely to interfere with the expression of proteins involved in the signaling pathways of inflammation^[15,16]. Additionally, it has been reported that CFTR is associated with apoptosis in proximal renal failure^[17]. Therefore, the defect in CFTR function results in multi-system disorders affecting airways, pancreatic ducts, bile ducts, intestines^[18,19].

Accumulating research has demonstrated that aberrant expression or function of CFTR may lead to various pathological conditions, especially inflammatory diseases and inflammation-associated cancers^[20-22]. Recently, a large cohort study which recruited 41188 cases of CF patients conducted in the United States revealed an elevated risk of digestive tract cancers among CF patients^[23]. In addition, another group also reported an increased risk of malignancies for the kidney, thyroid, endocrine, lymphoma, skin and prostate in CF patients^[23]. Moreover, some groups showed that the *CFTR* gene is hypermethylated in several cancer cell lines and resected tumors^[22,24-26], which indicates that defects in the expression or function of CFTR may have a pivotal role in the pathogenesis of various cancers. It has also been well established that CFTR is critical in maintaining epithelial cell polarity and integrity^[27]. Consequently, the observed association between cancer risk and CFTR, as well as the connection between CFTR and cell junction molecules, has led to the hypothesis that CFTR plays important roles in cancer progression^[28,29]. In this review, we focus on the recent findings that associate CFTR with various cancers, especially gastrointestinal cancers.

CFTR AND GASTROINTESTINAL CANCER

Focus has been placed on the association between pancreatic cancer risk and CFTR deficiency since the early 1990s^[30] when cohort studies were performed to investigate how CFTR variants affect the risk of pancreatic cancer^[31,32]. CF patients suffer from chronic pancreatic damage and inflammation, which may predispose them to malignancy^[33]. Even though the overall cancer risk in CF patients is similar to that of the general population, CF patients are at elevated risk (6.5 fold) of developing gastrointestinal cancers including pancreatic cancer^[32]. The results from the cohort studies indicate an increased risk for pancreatic cancer among CF patients, which is supported by two recent reports^[33,34], in which multiple CFTR mutations were analyzed. These studies also found that patients who are CFTR mutant carriers develop pancreatic cancer earlier than those who carry normal CFTR. While there are reports that do not support the view that CFTR mutations increase the risk of pancreatic cancer^[35,36], Maisonneuve *et al.*^[23] concluded that there is a consistent increased risk of pancreatic cancer in CF patients, which is supported by retrospective studies that recruited a large amount of cases and screened multiple CFTR mutations^[33,34]. The difference between the reported associations of pancreatic risk and CFTR variation could be due to multiple reasons such as limited case number, different parameters regarding selection of the control population, mutations investigated in the study, and environmental factors including smoking and alcohol consumption. This requires regional or even global collaboration to adjust the possible biases that could occur as a result of the mentioned parameters^[37].

Different interpretations have been presented by investigators based on the observations of epidemiological studies and laboratory research to reveal the underlying mechanism of the association between CFTR and cancer. One mechanism is that CFTR dysfunction in the exocrine pancreas results in an ion transport defect, giving rise to obstruction of the pancreatic duct and consequently chronic inflammation, which is closely related with cancer initiation^[34]. It has been reported that wild-type CFTR suppresses tumor progression by negatively regulating MUC4, a protein involved in tumor growth and metastasis, providing a potential mechanism for CFTR inhibiting pancreatic cancer progression^[38]. Another group reported that increased PKC activity is associated with degradation of CFTR in pancreatic ductal cells^[39]. Altogether, these studies indicate that the microenvironment and cell signaling change in tumor cells could be implicated in the down-regulation of CFTR expression and the up-regulation of certain cancer promoting proteins in pancreatic cancer.

There is an increased risk of gastrointestinal cancers in CF patients, of which colon cancer is the most prevalent^[32]. Case reports have described CF patients developing colon cancer at relatively young ages^[40-42]; meanwhile, the mechanism behind this phenomenon has also been investigated, and several speculations have been

proposed. According to reports from different groups, Ras, PKC and interferon-gamma (IFN- γ) are involved in the down-regulation of CFTR in colonic ductal cells^[39,43-45]. More interestingly, the down-regulation of CFTR is correlated with drug resistance in colon cancer^[46]. When HT-29 cells, a human colorectal adenocarcinoma cell line, were treated with an increasing amount of colchicine, an alkaloid with anti-cancer activity^[47], the down-regulation of CFTR was accompanied by the acquisition of a drug resistant phenotype, and the restored expression of CFTR was observed when the drug was removed^[46]. Although the mechanism is not fully understood, it is possible that CFTR may transport certain unidentified metabolites or factors other than ions. Recently, Sun *et al.*^[48] demonstrated that the interaction between CFTR and AF-6/afadin, an adherens junction molecule, is important in the process of colon cancer migration and metastasis. In their study, the expression of CFTR and the interaction between CFTR and afadin were linked to epithelial-mesenchymal transition (EMT), an important process during tumor metastasis, indicating that functional CFTR may act as a tumor suppressor, while the deficiency of CFTR would facilitate tumor progression in colon cancer^[48].

The involvement of CFTR deficiency was also studied in other gastrointestinal malignancies such as gastric cancer^[49]. It is reported that serum CFTR is significantly associated with a cancer biomarker, carbohydrate antigen 199 (CA199), and it is significantly associated with gastric cancer staging. In addition, the combination of CFTR and CA199 yields a higher receiver operating characteristic (ROC) curve, which is used in the diagnosis of gastric cancer^[49]. Although this research did not discuss the association between CFTR and gastric cancer, it has provided a potential biomarker for the diagnosis of not only gastric cancer but also other types of cancer.

CFTR AND OTHER CANCERS

A large cohort study conducted by Neglia *et al.*^[32] demonstrated that the genetic variation of the CFTR gene is associated with a moderate increase (1.4 fold) in the risk of lung cancer, and CFTR gene mutation has been reported in lung cancer patients^[50,51]. Epigenetic modifications such as DNA methylation regulate gene expression to maintain cell growth and development. However, aberrant DNA methylation of the cytosine preceding guanosine (CpG) sites of the promoter regions of many genes plays a critical role in cancer by silencing the tumor suppressor genes, which is one of the earliest alternations in cancer^[52,53]. Hypermethylation of the CFTR promoter gene has been reported, and corresponding clinical data also indicates that CFTR promoter gene hypermethylation is associated with significantly poorer survival among younger lung cancer patients^[22]. On the other hand, CFTR gene expression was restored when A549 cells, a human lung adenocarcinoma epithelial cell line, were treated with demethylation reagents^[22]. Similarly, the results of a retrospective study from another group demonstrated that low CFTR expression is correlated with advanced stage

and metastasis as well as poor prognosis in non-small cell lung cancer^[54]. Similar to the findings in colon cancer^[48], investigators linked the expression of CFTR to EMT in lung cancer and demonstrated that CFTR suppresses EMT *via* inhibiting the uPA/uPAR-mediated signaling pathway^[54]. These findings indicate that functional CFTR may play an inhibitory role in the initiation and progression of lung cancer.

Based on the results obtained from different groups, the protective role of CFTR on tumor progression is reflected by the inhibitory effect on tumor metastasis, which seems unrelated to its ion transportation activity. It has been reported that CFTR physically interacts with multiple proteins including ZO-1^[55], E-cadherin^[56], multidrug resistance protein-2 (MRP2)^[14], MRP4^[13], and afadin^[48]. These protein-protein interactions may be important in the inhibition of tumorigenesis. On the other hand, functional CFTR has been shown to down-regulate tumor promoting proteins such as NF- κ B, which plays a pivotal role in inflammation and cancer progression^[57].

The role of CFTR has also been examined in the pathogenesis of other cancers such as prostate cancer^[24,58], hepatocellular cancer^[26,59] as well as bladder^[25] cancer with the focus mainly on DNA methylation. CFTR promoters are hypermethylated in these cancers compared with normal tissues. Moreover, researchers proposed that it is possible that methylation of the CFTR promoter may be an early event in the process of tumorigenesis^[26]. Additionally, it is also important to point out that more frequent hypermethylation of CFTR promoter was observed in prostate cancer patients with a high Gleason score and Ki-67 index^[24], indicating that CFTR hypermethylation could be used to predict prognosis in prostate cancer. Based on the study of CFTR hypermethylation in lung cancer, it is possible that CFTR may function as a tumor suppressor in these cancers as well, which is partly supported by the findings in prostate cancer^[28] that the CFTR knockdown promoted cancer cell proliferation, invasion and migration.

The role of CFTR in breast cancer has been investigated since the 1990s, but the findings are controversial. According to the cohort study conducted by Neglia *et al.*^[32] breast cancer is less common in CF patients. In 1996, Abraham *et al.*^[60] reported that the CF phenotype with elevated blood ATP concentration yielded decreased tumor growth and implantation in mice. The authors believed that dysfunctional CFTR in the digestive duct failed to excrete ATP into gut lumen resulting in elevated blood ATP, which is cancer suppressive. However, recently Zhang *et al.*^[29] reported that the down-regulation of CFTR promoted cell migration and invasion *in vitro* as well as metastasis *in vivo* while over-expressing CFTR reversed these activities. Although this seems controversial, the findings indicate that the role of CFTR in cancer depends, at least partially, on the pathological conditions of the individuals. Under the CF condition, in which the CFTR and other CFTR-regulated ion channels/transporters are dysfunctional, the de-regulated transport activity due to dysfunctional CFTR may

be the main factor that contributes to the pathogenesis of cancer. When the CFTR is functional, it is possible ion transportation activities do not account for the main aspect of the tumorigenesis.

CFTR has also recently been related to cervical cancer^[61-63]. A series of studies from Peng *et al.*^[61] demonstrated that the expression of CFTR is gradually increased from normal to pre-cancerous cervical tissue and cervical cancer tissues, and it is also positively correlated to histological grades, tumor stage, and metastatic grades. In addition, further investigation by the Peng *et al.*^[61] indicated that the upregulated CFTR in pre-cancerous and cervical cancer tissues resulted from aberrantly increased NF- κ B p65 translocation^[62]. RNA sequencing results obtained from samples co-existing with pre-cancerous lesions and adjacent normal cervical tissue demonstrated that CFTR was also significantly up-regulated in cervical cancer^[63], which is in agreement with the findings from Peng *et al.*^[61] and Wu *et al.*^[62]. These findings are opposite of those from other types of cancers which demonstrated the tumor suppressive roles of CFTR, indicating that the role of CFTR in cancer is organ/system specific. Although CFTR has been originally identified as a chloride channel, accumulating evidence has demonstrated it has different functions in different models, suggesting that the function of CFTR is organ/system dependent, and consequently the role of CFTR in different cancers may also be organ/system specific.

MOLECULAR MECHANISMS LINKING DYSFUNCTIONAL CFTR AND CANCERS

Investigations have been performed to propose molecular mechanisms to link defect found in CFTR to cancer, the underlying mechanism of which can be divided into two major subgroups depending on the different aspects of the CFTR function.

One subgroup is based on the transporter feature of CFTR. As a transporter located on the epithelial membrane, CFTR is able to transport ATP across the membrane^[64]. On the other hand, it is demonstrated that extracellular ATP processes an inhibitory effect on tumor growth both *in vitro* and *in vivo*^[65,66]. In gastrointestinal cancers, CFTR dysfunction or dysregulation leads to decreased luminal ATP, which may account for the elevated cancer incidence. However, as a result of decreased ATP secretion into gut lumen, the blood concentration of ATP increased, probably resulting in decreased malignancy such as breast cancer^[60]. This explains, to some degree, why CFTR dysfunction promotes the risk of certain types of cancer while suppresses the risk in others. In addition, the transporting property of CFTR is also linked to the apoptosis and survival of cells. CFTR is reported to be able to transport glutathione (GSH), an important antioxidant protecting cells from excessive oxidative stress, out of cells during apoptosis^[67]. This activity is hampered when CFTR is dysfunctional or the expression of CFTR is too low, which are common in several types of cancers. In addition, metabolites such

as CO₂ and lactate are generated by fast tumor growth, resulting in an acidic and hypoxic microenvironment around cancer cells. Functional CFTR facilitates the survival of cancer cells *via* transporting bicarbonate out of the cells^[68]. Therefore, CFTR seems to possess both cancer promoting and suppressing properties, but the exact role it plays in a particular cancer may depend on the cancer type and tumor microenvironment.

The other subgroup, which is more complicated and independent of the transporter feature of CFTR, is based on the signaling and protein-protein interactions that CFTR is involved in. It is well established that NF- κ B pathway, an important player in cancer proliferation and cell survival^[69,70], is negatively regulated by functional CFTR^[57,71]. Meanwhile, decreased NF- κ B activity was also observed in CFTR over-expressed lung cancer cells^[72]. Recently, CFTR was found to be associated with tumor metastasis in multiple cancers in which uPA/uPAR pathway is involved^[28,54]. Although the mechanisms are not fully understood, these investigations have shed light on the importance of the NF- κ B related signaling. Moreover, Ras, PKC, IL-1 β , and IFN- γ are involved in the down-regulation of CFTR in cancer cells^[43-45,73]. In addition, CFTR has been shown to physically interact with other proteins such as ZO-1, afadin, and E-cadherin contributing to various cellular activities^[48,55,56], and the disruption of these interactions leads to enhanced cell invasion and migration, indicating that CFTR plays more complicated roles than previously thought. Further, CFTR promoter hypermethylation is also observed in multiple types of cancer including hepatocellular cancer, lung cancer, bladder cancer, and prostate cancer^[22,24-26,58]. It is still not clear whether this epigenetic modification occurs at early stages or is a result of tumorigenesis, although a study in hepatocellular cancer suggests that the methylation may be an early event of cancer progression^[26]. Conclusively, CFTR functions not only as an ion channel/transporter but also as a signaling hub involved in multiple signaling pathways and macromolecular complexes, contributing to seemingly opposite cellular functions: Either promoting or suppressing cancer progression.

CONCLUSION

CFTR, a glycoprotein with 1480 amino acids, was originally identified as a chloride channel that transports chloride ions in and out of cells. Emerging evidence suggests that CFTR possesses both tumor promoting and tumor suppressing properties as shown in Table 1. However, the exact role it plays in cancer depends on the cancer type and the microenvironment of the cancer cells. Since the expression of CFTR differs from one organ to another, it is possible that the functions of CFTR in different organs are also different. For instance, in the pancreas CFTR is mainly responsible for excretion^[74] while in macrophages it contributes to controlling cytokine production^[75]. In addition, the microenvironment of cancer cells also dictates the role of CFTR. There is variation in proteins expressed in different cancer cells as well as cytokines

Table 1 Summary of impact of cystic fibrosis transmembrane regulator on the malignancies of different organs

Organs	Impact	Ref.
Pancreas	Wildtype CFTR suppresses tumor progression	[23,32-34,38,39]
	CFTR dysfunction my results in obstruction of pancreatic duct and chronic inflammation	
Colon	CFTR dysfunction increases the risk of colon cancer	[40-46,48,73]
	Wildtype CFTR may act as a tumor suppressor in colon cancer	
Stomach	Serum CFTR is associated with gastric cancer staging	[49]
Lung	CFTR mutation is associated with increased risk of lung cancer	[22,32,50,51,54]
	CFTR expression is also associated with tumor progression and poor prognosis	
Prostate	CFTR gene was hypermethylated in prostate cancer cells	[24,58]
Liver	CFTR gene was hypermethylated in hepatocellular cancer cells	[26,59]
Bladder	CFTR gene was hypermethylated in bladder cancer cells	[25]
Breast	Suppresses breast cancer by elevating blood ATP but promotes cancer metastasis by enhancing EMT	[29,32,60]
Cervix	Promotes cancer progression	[61-63]

CFTR: Cystic fibrosis transmembrane regulator; EMT: Epithelial-mesenchymal transition.

or chemokines produced in different types of cancers, generating different microenvironment around the cells. Consequently, CFTR may react differently according to environmental stimulants. For example, IFN- γ and TNF- α down-regulate the expression of CFTR, while cAMP up-regulates the expression of CFTR in cancer cells^[76,77]. Even though the biology of CFTR has been investigated for decades, its function is still not fully understood, especially in cancer cells. Based on the literature to date, it will be helpful to study the protein interactome and the signaling pathways associated with CFTR in cancer cells. In addition, previous studies of CFTR dysfunction were largely based on CF related CFTR gene variations, and most of the studies usually only covered very small amounts of mutations, though over 1900 CFTR mutations have been documented so far. This may limit the findings and/or conclusions from these studies. In order to obtain a more comprehensive knowledge of CFTR biology and its role in cancer, interdisciplinary collaborations using system biology and integrative approaches are encouraged.

Abstract

The most frequent cause of treatment failure following surgery for gastric cancer is peritoneal dissemination, mainly caused by the seeding of free cancer cells from the primary gastric cancer, which is the most common

type of spread. Unfortunately, there is no standard modality of intraperitoneal free cancer cells detection to predict peritoneal metastasis until now. We reviewed English literature in PubMed was done using the MeSH terms for gastric cancer, peritoneal wash, and reverse transcriptase polymerase chain reaction. All the articles were reviewed and core information was tabulated for reference. After a comprehensive review of all articles, the data was evaluated by clinical implication and predictive value of each marker for peritoneal recurrence. There are still many limitations to overcome before the genetic diagnosis for free cancer cells detection can be considered as routine assay. To make it a reliable diagnostic tool for detecting free cancer cells, the process and method of genetic detection with peritoneal washes should be standardized, and the development of simple diagnostic devices and easily available kits are necessary. Herein, we reviewed the past, present and future perspectives of the peritoneal lavage for the detection of intraperitoneal free cancer cells in patients with gastric cancer.

Key words: Gastric cancer; Peritoneal metastasis; Free cancer cells; Reverse transcriptase polymerase chain reaction; Genetic detection

Core tip: The most common cause of treatment failure after gastric cancer surgery is peritoneal metastasis, mainly caused by free cancer cells from primary cancer. Genetic detection using reverse transcriptase polymerase chain reaction analysis has been used for the detection of free cancer cells. The process and method of genetic detection with peritoneal washes should be standardized, and the development of simple diagnostic devices and easily available kits are necessary in the future. In this article, we summarize the current evidence of genetic detection in peritoneal washes from gastric cancer patient.

INTRODUCTION

Although the incidence of gastric cancer has been declining in western countries, gastric cancer is still the fourth most common cancer and the second leading cause of cancer deaths worldwide^[1]. Peritoneal dissemination of gastric cancer, which is caused by free cancer cell seeding from the primary tumor, is the most common cause of treatment failure after surgery. In general, the frequency of peritoneal dissemination is increased with depth of invasion of the gastric wall^[2]. Intraperitoneal free cancer cells detected in peritoneal washes from gastric cancer patients have been reported to be significant and independent prognostic factor for recurrence and survival after surgery.

To predict peritoneal metastasis, several methods have been used for many studies, which are conventional cytology^[3,4], ThinPrep^[5], and molecular markers^[4,6-8]. Conventional cytology had been regarded as the gold standard for detecting cancer cells in peritoneal washes. However, the usefulness of conventional cytology for prediction of peritoneal metastasis has controversy because of its low sensitivity^[3,4,7,9].

Recently, reverse transcriptase polymerase chain reaction (RT-PCR) analysis has been used for the genetic detection of free cancer cells^[10-12]. Several target genes have been used, which are carcinoembryonic antigen (CEA), heparanase, matrix metalloproteinase-7 (MMP-7), cytokeratin 20 (CK-20), telomerase, and melanoma-associated gene (*MAGE*)^[2,13]. The sensitivity of RT-PCR is higher than that of conventional cytology^[14-16]. Several studies reported that the results of RT-PCR analysis from peritoneal washes correlate strongly with peritoneal recurrence and prognosis after curative surgery in patients with advanced gastric cancer^[6,14-20].

In this reason, we reviewed the present status and future perspectives of peritoneal lavage for the detection of intraperitoneal free cancer cells in patients with gastric cancer (Figure 1).

DETECTION OF INTRAPERITONEAL FREE CANCER CELL WITH GASTRIC CARCINOMA

The past

Conventional cytology from the peritoneal washes had been widely used to detect free cancer cells and to predict peritoneal metastasis^[3,9], based on several studies reporting a correlation between peritoneal recurrence and presence of intraperitoneal free cancer cells^[21-24].

In patients with serosal involvement, 50% of patients develop peritoneal recurrence even if curative resection is performed^[25,26]. Bando *et al*^[3] reported that 24% of positive cytology from 1297 gastric cancer patients. This result presented higher positive rate than other studies, probably because many patients with advanced stage of gastric cancer were included in the study (296 patients had peritoneal metastasis). Ribeiro *et al*^[27] reported much higher incidence of positive cytology (41%) from their study from 49 patients with advanced gastric cancer including metastatic disease. Other studies that evaluated patients with gastric cancer underwent curative resection showed approximately 5% of positive rate from peritoneal washes cytology^[3,8-10,25,27,28].

In many past studies, intraperitoneal free cancer cells detected in peritoneal washing cytology have been demonstrated as significant and independent prognostic factor, influencing both recurrence free survival and overall survival of patients with gastric cancer. Therefore, peritoneal wash cytology is recommended in the Japanese Classification of Gastric Carcinoma from 1998^[29]. Recently, the American Joint Committee on Cancer tumor node metastasis staging system classified the positive peritoneal cytology in gastric cancer as metastatic disease (M1) in the 7th edition^[1].

However, the conventional cytology is often criticized for its relatively low sensitivity to detect intraperitoneal free cancer cells and to predict peritoneal metastasis^[3,4,7,9]. Furthermore, previous studies reported that the conventional cytology in patient without any macroscopic peritoneal metastasis (P0) after curative resection had very low sensitivity (5%-15%)^[3,4,7]. Although obtaining peritoneal cytology has been advocated by Japanese and Dutch investigators^[30,31], this is not a uniform practice in other Western centers. Immunocytochemical methods that used a panel of monoclonal antibodies, directed to gastric cancer-associated antigens had improved detection of peritoneal cytology by providing more sensitive and may have a higher specificity than conventional cytology^[32].

The present

General principles: The high sensitivity of RT-PCR analysis has made it possible to detect micrometastasis on the cancer tissue specific messenger RNA (mRNA) expression in peripheral vein, bone marrow, lymph nodes, and peritoneal cavity^[19,33-35]. Although RT-PCR analysis of peritoneal washes is a more sensitive than conventional cytology, the result variations in RT-PCR between different laboratories have been reported. Therefore standardization and quality control of the process of RT-PCR is very important.

For the detection of gastric cancer micrometastases in peritoneal washes, RT-PCR technique has been used from the twenty-first century^[10-12]. The primer sequences, which are used in previous studies, for RT-PCR of peritoneal lavage in patients with gastric cancer are summarized in Table 1. The sensitivity of RT-PCR is higher than that of conventional cytology^[10-12]. Based on several studies, There is strong correlation between

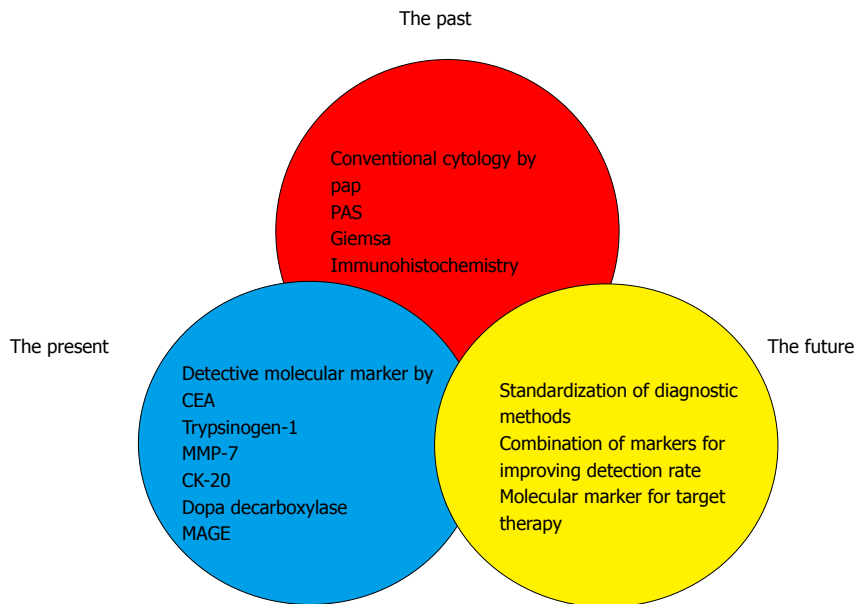

Figure 1 Detection of free cancer cell in peritoneal washes of gastric cancer patients: The past, present and future. CEA: Carcinoembryonic antigen; MMP-7: Matrix metalloproteinase-7; CK-20: Cytokeratin-20; MAGE: Melanoma associated gene.

the results of RT-PCR analysis from peritoneal washes and prognosis, including peritoneal recurrence rate, after curative resection in patients with advanced gastric cancer^[6,14,16-20] (Table 2).

Although many investigators have demonstrated that molecular techniques using RT-PCR may serve as a useful method for the detection of free cancer cells, there are still several problems. These are time-consuming, expensive, relatively laborious compared with conventional cytology, and the accuracy is widely variable between laboratories and the methods of processing the peritoneal washes is not yet standardized. Current experimental studies which aim to identify a rapid, accurate, and cost-effective detection method are proposed. The transcription-reverse transcription concerted reaction system and the LightCycler system have shown promise in intraperitoneal free cancer cell detection.

Molecular markers: (1) CEA: CEA is the most commonly studied tumor marker and is predominantly used clinically in patients with gastrointestinal cancer. Structurally, it is a glycoprotein with a molecular weight of 200 kd and is a component of the glycocalyx, located on the luminal side of the cell membrane of normal epithelial intestinal cells. Although its exact function is unknown, CEA has been shown to be involved in cell adhesion and is able to inhibit apoptosis induced by loss of anchorage to the extracellular membrane.

In 1997, Nakanishi *et al*^[16] had proposed the first study that more sensitive detection of free cancer cells could be achieved through amplification of CEA mRNA by means of the RT-PCR, and reported a high sensitivity of the CEA RT-PCR assay for the detection of peritoneal micrometastasis and a 20% improvement in the positive rate, as compared with that of cytology alone. CEA is presented in all of gastric cancer cell lines examined irrespective of the differentiation degree,

and it is absent in blood and mesothelium. That is indicating the specificity of CEA RT-PCR for detection of carcinoma cells in peritoneal lavage fluid.

Since this report, many investigators have been used CEA as the target gene of RT-PCR for the patients with gastric cancer. From 2001, many other studies have reported that quantitative CEA mRNA detection using RT-PCR is an accurate method for predicting the risk of peritoneal recurrence in patients with gastric cancer^[36-42].

Many studies reported that the detection of CEA mRNA using RT-PCR of peritoneal washes was the most reliable prognostic marker for recurrence and peritoneal carcinomatosis in patient with gastric cancer, and more sensitive than conventional cytology^[8,17]. Kodera *et al*^[43] found that the use of RT PCR for CEA mRNA resulted in a detection rate of free cancer cells of 28% (41 of 148), with a 14% higher detection rate than for peritoneal wash cytology. However, the sensitivity of the CEA RT-PCR assay for the detection of peritoneal micrometastasis still remains low. Furthermore, false-positive results, caused by expression of CEA in non-cancer cells like mesothelial cells and lymphocytes, is remained as main problem of this technique^[20].

(2) Trypsinogen-1: Trypsin is a member of the serine protease family composed of three trypsinogen genes (*trypsinogen 1, 2 and 4*) with a potential role in cancer invasion^[44,45]. These family members are sharing same nucleotide structures above 90% with each other.

Trypsin has potent proteolytic activity, and its inappropriate activation may lead to peritoneal dissemination of infiltrative gastric cancer by defoliation of cancer cells from the surface of advanced primary tumor, attachment and invasion to extracellular matrix under the mesothelium^[46].

(3) MMP-7: Recently, MMPs are gaining attention and attracted by many investigators who are interested in new biomarkers for cancer spread and metastasis^[47].

Table 1 Primer sequences used for reverse transcriptase polymerase chain reaction

Gene	Sequence of primer pair (5'→3')	Tm (°C)	Amplicon length (bp)
CEA	F: TCTGGAAGTCTCTCTCTCTCAGCTGG R: TGTAGCTGTGCAAAATGCTTTAAGGAAGAAGC	69	160

Tm: Melting temperature; F: Forward; R: Reverse; CEA: Carcinoembryonic antigen; CK-20: Cytokeratin-20; MMP-7: Matrix metalloproteinase-7; DDC: Dopa decarboxylase; L3PP: L-3 phosphoserine phosphatase heparanase; MAGE: Melanoma associated gene.

Table 2 Reports on molecular marker with peritoneal washes in gastric cancer

Ref.	Year	Method	Molecular marker	Outcome
Nakanishi <i>et al</i> ^[17]	1997	RT-PCR	CEA	
Fujimura <i>et al</i> ^[46]	1998	RT-PCR	Trypsinogen	
Kodera <i>et al</i> ^[20]	2002	RT-PCR	CEA	Peritoneal recurrence, survival
Nakanishi <i>et al</i> ^[17]	2000	Q-RT-PCR	CEA	Peritoneal recurrence, survival
Yonemura <i>et al</i> ^[6]	2001	RT-PCR	MMP-7	
Sugita <i>et al</i> ^[14]	2003	Q-RT-PCR	CEA and CK-20	Peritoneal recurrence, survival
Sakakura <i>et al</i> ^[62]	2002	Q-RT-PCR	Dopa decarboxylase	
Shimomura <i>et al</i> ^[66]	2004	Q-RT-PCR	L3-PP	
Kodera <i>et al</i> ^[7]	2006	RT-PCR	CEA	Overall survival
Jeon <i>et al</i> ^[13]	2010	RT-PCR	MAGE	Overall survival
Jeon <i>et al</i> ^[71]	2014	RT-PCR	MAGE and CEA	3-yr survival

CEA: Carcinoembryonic antigen; CK-20: Cytokeratin-20; MMP-7: Matrix metalloproteinase-7; L3-PP: L-3 phosphoserine phosphatase heparanase; MAGE: Melanoma associated gene.

MMPs have key role in degrading extracellular matrix by proteolytic activity, as well as regulating other enzymes, chemokines and cell receptors^[48,49]. MMP-7, also called Matrilysin, is a distinct family member in MMPs family because its highest proteolytic activity for wide range of molecules and pivotal role in activating other MMPs for cell degradation^[50-53]. Another specific characteristic of matrilysin in contrast to other MMPs is that it is mainly expressed by tumor cells and not by stromal cells^[54-56].

Yonemura *et al*^[6] reported that MMP-7 mRNA was not expressed by fibroblasts, peripheral blood, mesothelial cells, normal gastric mucosa, or the peritoneal lavage fluid of patients with benign disease. In contrast, it was expressed by all of the examined specimens of peritoneal dissemination in gastric cancer. By combining cytology and MMP-7 RT-PCR, the sensitivity rate for the prediction of peritoneal dissemination was improved to 11% over the prediction by routine cytology.

(4) CK-20: The keratins are intermediate filament proteins responsible for the structural integrity of epithelial cells. Recently, many investigators identified CK-20 as

one of the potential cancer-related biomarkers used for detecting peritoneal free cancer cells in gastric cancer^[57].

CEA had been reported that there are strong positivity of mRNA expression in differentiated gastric carcinoma, but relatively weak or undetectable in poorly differentiated type^[57]. Thus, CK-20 has been the use as option for multiple marker assay with CEA for the detection of nodal metastasis^[58]. Also for the peritoneal recurrence, many studies reported the usefulness of multi-marker assay, employing both CEA and CK-20 RT-PCR^[14,15,59,60].

(5) Dopa decarboxylase (DDC): DDC is an enzyme for the metabolism of dopamine, and also has a role for the synthesis of important neurotransmitters including serotonin. Although DCC is investigated as cancer-related marker with its high expression in lung cancer and neuroblastoma^[61], the role of this marker in gastric cancer is still unclear.

Sakakura *et al*^[62] have analyzed in their studies for the global gene expression of a gastric cancer cell line, and approximately 21168 genes were established from the tumor and metastatic site of gastric cancer patients.

Among them, they found that 24 genes were upregulated and 17 genes downregulated, and DCC was one of these upregulated genes. DCC-specific RT-PCR is potentially a novel marker for peritoneal dissemination of gastric cancer and reliable and efficient for the prediction of peritoneal recurrence of gastric cancer.

(6) L-3 phosphoserine phosphatase heparanase (L3-PP): L3PP is one of the up-regulated genes and hundreds of protein phosphatases are known. It is an intermediary enzyme in both amino acid biosynthesis and gluconeogenesis, and is an enzyme that acts specifically in the synthesis of serine from 3-phosphoserine^[63,64]. It has been reported that activity of the enzyme L3-PP increases when cell multiplication and frequency of mitosis increases^[65].

Shimomura *et al*^[66] had reported that L3-PP over-expression in gastric cancer cells from peritoneal metastasis by cDNA microarray as well as RT-PCR suggest that overexpression of L3-PP is probably involved in peritoneal metastasis of gastric cancers. When they had used combination RT-PCR of CEA and L3-PP to reduce false-negative result of CEA mRNA, the sensitivity of peritoneal dissemination was improved from 71.4% to 85.7%.

(7) Melanoma associated gene (*MAGE*): *MAGE* has been shown to be a cancer-specific marker that suppresses apoptosis and plays an important role in carcinogenesis^[67]. *MAGE* gene expression in RT-PCR of gastric cancer is relatively higher than that of other markers^[68,69]. Although the rate of expression is different according to their subtype, expression of *MAGE-4*, *MAGE-6*, *MAGE-8*, *MAGE-9*, *MAGE-10*, and *MAGE-12* genes was very high as 82% in gastric cancer tissue^[70]. Furthermore, previous studies reported that *MAGE* showed no expression in normal gastric tissue^[69,70]. In this reason, *MAGE* has been attracted for the new target gene for predicting prognosis of gastric cancer, and expected as a marker for target therapy because of its specific expression^[69,70].

Jeon *et al*^[71] had reported, in their trial on the comparison of the 2 markers (CEA and *MAGE*) after long-term follow-up, that *MAGE* RT-PCR showed better specificity and more significant associations with peritoneal recurrence than CEA RT-PCR, and *MAGE* RT-PCR results was proved to be the most important prognostic factor for recurrence in patients with gastric cancer after curative resection.

The future

Genetic detection in peritoneal washes with gastric carcinoma can be performed only at university hospitals and large volume cancer centers. Furthermore, there is no standard for processing of peritoneal fluid and the method of genetic detection. To make it a reliable diagnostic tool for detecting free cancer cells, the process and method of genetic detection with peritoneal washes should be standardized, and the development of simple diagnostic devices and easily available kits are necessary.

Also, effective modality of treatment for the patient with a positive peritoneal molecular diagnosis should be needed. If the molecular marker for peritoneal free cancer cell is used not only for the diagnosis but also for the therapeutic modality with the development of target therapy, it might be one of useful method for the treatment of advanced gastric cancer and the prevention of peritoneal recurrence.

CONCLUSION

The methods of detecting intraperitoneal free cancer cells represent are still area of evolution. In past, conventional cytology was regarded as the only method for detecting peritoneal free cancer cells from gastric cancer. However low sensitivity of this method had been criticized, and many studies about various method with peritoneal washes were performed for better prediction of peritoneal metastasis. In present, genetic detection using RT-PCR analysis has been used for improving the detection rate. It has been suggested that these tools have better sensitivity in detecting intraperitoneal free cancer cells with better correlation to peritoneal recurrence. But it can be performed only at university hospitals and large volume cancer centers. Furthermore, there is no standard for processing of peritoneal fluid and the method of genetic detection and effective modality of treatment for the patient with a positive peritoneal molecular diagnosis. In near future, standardization of diagnostic methods, combination of markers for improving detection rate, and development of molecular marker for target therapy could provide us with being relevant in clinical decision-making, detection methods need to be accurate, reliable, cost-effective and effective modality of treatment for the patient with a positive peritoneal diagnosis.

Abstract

Metastatic pancreatic cancer (MPC) is one of the most aggressive malignancies, known to be chemo-resistant and have been recently considered resistant to some targeted therapies (TT). Erlotinib combined to gemcitabine is the

only targeted therapy that showed an overall survival benefit in MPC. New targets and therapeutic approaches, based on new-TT, are actually being evaluated in MPC going from immunotherapy, epigenetics, tumor suppressor gene and oncogenes to stromal matrix regulators. We aim in this paper to present the major causes rendering MPC an untargetable malignancy and to focus on the new therapeutic modalities based on TT in MPC.

Key words: Pancreatic cancer; Tumor suppressor genes; Targeted therapies; Immunotherapy; Epigenetics

INTRODUCTION

Pancreatic cancer (PC) is one of the most aggressive and devastating solid tumors, with less than 5% of patients still alive at 5 years^[1]. Its poor prognosis is also due to the late diagnosis of PC and the absence of early detection tools or markers.

The incidence of this cancer is increasing worldwide; it represents actually the seventh most diagnosed cancer in Europe and the fifth leading cause of cancer mortality^[2]. More than 80% of these cancers are locally advanced

or metastatic at diagnosis. The only curative treatment remains surgery, possible in less than 20% of the patients with PC, diagnosed at an early stage^[1].

Adenocarcinomas represent the majority of PC, less than 5% are neuroendocrine tumors. Pancreatic neuroendocrine tumors have specific features and different treatment modalities^[3]. In this paper, we will focus only on metastatic pancreatic adenocarcinomas.

Many risk factors and inherited syndromes are incriminated in the development of this cancer. PC represents a genetically complex and heterogeneous tumor; it results from successive accumulation of gene mutations. PC tumor cells harbor more than 60 genetic alterations that affect more than twelve signaling pathways^[4].

According to the national cancer institute dictionary, targeted therapies (TT) are defined as a type of treatment that uses drugs or other substances to identify and attack specific types of cancer cells with less harm to normal cells^[5]. Till the end of the last century, hormonal therapies were considered one of the rare routinely used drugs respecting the definition of TT in oncology. After hormonal therapies, monoclonal antibodies and tyrosine kinase inhibitors (TKIs) were widely being tested and approved in the management of different cancers during the last 15 years.

TT can be divided into two major groups: Therapies targeting the cancer cell itself and therapies targeting the tumor microenvironment. The first group includes hormonal therapies, small molecules (TKIs) and monoclonal antibodies; antibody drug conjugates and oncolytic viruses were recently added to this category. The second group includes mainly angiogenesis inhibitors and immunotherapy.

In the emerging era of TT, this new concept was widely introduced in the management of different tumors; however, PC remains resistant to available TT. Is metastatic pancreatic cancer (MPC) an untreatable malignancy? This review focuses on the major clinical trials evaluating TT in MPC and the potential new targets and new approaches in MPC.

APPROVED TREATMENTS IN MPC

Before Gemcitabine era in PC, 5-FU was the most frequently used chemotherapy in the treatment of MPC. In 1997, gemcitabine, as monotherapy, was approved by the Food and Drug Administration (FDA) as the first line treatment in MPC after a trial comparing gemcitabine to 5-FU in untreated MPC; less than two months of difference in overall survival were good enough for the approval of gemcitabine as a first line therapy in MPC^[6]. During 14 years, two new combinations associating gemcitabine with either erlotinib or cisplatin were considered potential regimens in the treatment of MPC. The first was approved based on a minimal overall survival benefit when added to gemcitabine compared to gemcitabine alone, knowing that this regimen is only beneficial to the subgroup of patients that develop rash^[7], while the approval of the second regimen was based on

two meta-analyses^[8,9].

The turning point in the natural history of MPC was in 2011 with the approval of the FOLFIRINOX regimen. FOLFIRINOX was the first chemotherapeutic regimen that surpasses the barrier of one year of survival in MPC. It became the standard of care in patients having MPC with good performance status. The major side effects of this regimen are neutropenia, fatigue diarrhea and sensory neuropathy^[10]. Another regimen, associating gemcitabine with nab-paclitaxel, showed a better overall survival when compared to gemcitabine alone, and was therefore approved in the treatment of MPC. Its toxicity profile was different compared to FOLFIRINOX: Less febrile neutropenia and fatigue and more peripheral neuropathy^[11].

TT IN MPC

After the approval of gemcitabine as standard of care in MPC in 1997 and the emergence of TT during the same period, many trials tried to associate gemcitabine to one of the TT. All these trials had negative results; only Gemcitabine-erlotinib combination demonstrates statistically significantly improved survival in advanced PC^[7]. Although the practical implication and benefit of the use of this drug remains debatable, erlotinib is currently the only FDA approved targeted therapy drug for pancreatic adenocarcinoma.

The results phase III trials associating TT to gemcitabine were disappointing. Thus, cetuximab^[12], bevacizumab^[13], aflibercept^[14], axitinib^[15], sorafenib^[16] and ganitumab^[17] failed to show any benefit when added to gemcitabine and compared to gemcitabine alone in the treatment of MPC. The results of these studies (PFS-OS) and mechanisms of action of TT are summarized in the Table 1.

Associating two TT with gemcitabine also failed to show any positive results, the association of erlotinib and bevacizumab to gemcitabine was not superior to erlotinib-gemcitabine^[18]. Another phase I trial evaluated the combination of gemcitabine-erlotinib-cixitumumab, but without any promising results^[19]. Associating two chemotherapies (gemcitabine and capecitabine) and two TT (bevacizumab and erlotinib) showed promising results with an overall survival exceeding one year in a phase I / II trial^[20]. Clinical trials in MPC associating two TT to chemotherapeutic agents are summarized in the Table 2. Many TT are tested as single agent in second line treatment of MPC; selumetinib (anti-MEK) and everolimus (mTOR inhibitor) are two examples^[21,22]. Combining two TT without chemotherapy is also being tested actually in new ongoing trial in a second line treatment of MPC with afatinib and selumetinib compared to capecitabine (NCT02450656) and sorafenib plus everolimus (NCT 00981162).

MECHANISMS OF RESISTANCE OF PC TO CHEMOTHERAPY AND TT

PC was known to be resistant to chemotherapy before

the era of FOLFIRINOX; many hypotheses tried to elucidate this chemo-resistance. Thus, alterations in key pathways involved in cell cycle control, namely apoptosis, were largely incriminated. NF κ B, pro-inflammatory and anti-apoptotic factor, seemed to be a key link between inflammation and cancer chemo-resistance in PC. The genetic complexity and heterogeneity of PC is also a challenge in the treatment of this cancer, since more than 60 genetic alterations affecting more than twelve signaling pathways are involved in its pathogenesis. The most commonly affected signaling pathways in PC are apoptosis, DNA damage repair, G1/S transition (CDKN2A/p16, CyclinD), cell-cell adhesion, regulation of invasion, embryonic signaling (Notch pathway, Hedgehog pathway and Wnt pathway) and MAPK signaling [c-Jun N-terminal kinase, ERK and transforming growth factor beta (TGF- β) signaling]^[23].

Actually, recent data revealed that tumor stroma is a major extrinsic mechanism of resistance to chemotherapy and targeted therapy of PC. The tumor stroma of PC is limiting the drug delivery to pancreatic tumor cells at therapeutically relevant concentrations^[24].

Next to intrinsic resistance to TT due to the multitude of pathways incriminated in the pathogenesis of PC, extrinsic resistance seems to be as important in the mechanism of non-response to TT. This extrinsic resistance seems to be particular to PC, rendering it a hardly targetable malignancy.

NEW TREATMENT APPROACHES AND TARGETS IN MPC

PC represents one of the least targetable malignancies with the present available drugs. Despite the huge efforts in research and promising results in some phase I and II trials, TT have not been approved yet in this

indication, neither influenced the natural history and the evolution of PC. New approaches and modalities are necessary to counteract the resistance to treatment of this malignancy, from immunotherapy and epigenetics to oncogenes and tumor suppressor genes regulation (Table 3).

Immunotherapy

Several immunotherapy approaches for PC have shown promising results in early clinical trials. Checkpoint inhibitors represent actually the most expanding and booming novel therapeutic approach in oncology; many new agents were recently approved in melanomas^[25-27] and lung cancer^[28]. Adoptive T cell transfers are also being largely evaluated and studied with encouraging results in some cancers including PC.

Many trials are testing different checkpoint inhibitors in advanced solid tumors including MPC. Check point inhibitors are new immunologic agents, that block inhibitory receptors of immune system elements, such as cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), programmed cell death protein -1 (PD-1) and its ligand PD-L1, leading to the activation of tumor-specific T cells with effector function against tumor cells^[29]. An ongoing phase I trial is evaluating a checkpoint inhibitor exclusively in advanced PC by combining gemcitabine and ipilimumab (anti-CTLA4).

Adoptive cell therapy is a new therapeutic approach based on the modification and selection of autologous T cells *in vitro* from the patient's tumor in order to have more potent and efficient T-cells, either by collecting tumor infiltrating lymphocytes (TILs) or by developing genetically engineered cells. These modified and selected T cells are re-infused to the patient. Two different mechanisms are implicated in the concretization of the concept of genetically engineered cells, the first by modifying genetically a T-cell receptor for cancer antigen (transgenic TCR) and the second by adding a chimeric antigen receptor (CAR), which recognizes a specific cancer antigen^[30]. Two specific phase I / II trials for PC are adopting this new approach. The first one is a phase I clinical trial exploring the potential of CAR T cells modified to recognize mesothelin, which is expressed in all PCs but not in healthy pancreatic cells (NCT01897415,

Tumor suppressor genes regulation	miRNA inhibitors	TP53-SMAD4- CDKN2A
	Anti-PARP	BRCA1-BRCA2

CTLA4: Cytotoxic T-lymphocyte-associated antigen 4; TP53-SMAD4-CDKN2A: Tumor protein p53 - cyclin-dependent kinase inhibitor 2A; BRCA: Breast cancer; PARP: PolyADP ribose polymerase.

NCT02159716). The second one is a phase I /II trial also testing CAR T cells modified to recognize mesothelin in patients with PC at the National Cancer Institute (NCT01583686). Many other trials including patients with solid tumors (including PC) are evaluating the effect of reinfusing TILs (NCT01174121) and genetically reengineered T cells to target the NY-ESO-1 antigen in patients with NY-ESO-1-positive cancers (NCT01967823).

Toll-like receptors (TLRs) recognize distinct pathogen-associated molecular patterns and play a critical role in innate immune responses. They participate in the first line of defense against invading pathogens and play a significant role in inflammation, immune cell regulation, survival, and proliferation. Likewise, TLRs can start immunological reactions against endogenous molecules released into the extracellular compartment under due to stress or tissue damage^[31]. TLRs are expressed in the PC tissue, whereas they are not expressed in the normal pancreas^[32,33]. Thus, they appear to play a role in the pathophysiology of PC and may thereby also represent targets for intervention. Many ongoing phase I /II trials combining TLRs with chemotherapy or radiation therapy are being evaluated in breast cancer, sarcomas and melanomas are being evaluated and some preclinical trials in PC showed promising results^[34].

Epigenetics

Epigenetic modifications are independent from the changes in the DNA sequence. They are due to variations in DNA methylation and histone acetylation. Many new drugs, targeting methylation of DNA and acetylation of histones have been mainly approved in hematology. This new approach is also being evaluated in PC. Ongoing phase I and II trials in PC are associating vorinostat, gemcitabine, bortezomib (anti-proteasome) and radiation therapy (Clinical Trial.gov. NCT00983268, NCT00243100).

Targeting tumor suppressor genes and oncogenes

As mentioned before, PC is caused by multiple genetic sequential changes. This subtype of cancer is associated also with chromosomal instability, since more than 90% of PC is aneuploidy: Presence of losses and gains of large portions of chromosomes or whole chromosomes

leading to abnormal karyotype. The accumulation of genetic instability mainly higher number of mutations of oncogenes and tumor suppressor genes is a part of the early event of the development of PC. More than 80% of ductal PCs exhibit KRAS mutations. Furthermore, 90% of the tumors exhibit deletions, mutations or epigenetic alterations in the *CDKN2A* gene. Nearly 50% have mutations in the tumor suppressor p53 and also approximately 50% exhibit mutations or homozygous deletions in the *SMAD4* gene^[2]. Ten percent of sporadic PCs present one of these mutations present BRCA1 or BRCA2 mutations^[35].

MicroRNAs, single-stranded chains of non-coding RNA of small number of nucleotides, that inhibit gene expression at the post-transcriptional level, regulate CDK2NA, TP53 and SMAD4 tumor suppressor genes^[36]. For example, CDK2NA or p16 inhibits cycline -dependant kinase 1, 4 and 6 and also help to stabilize p53; CDKN2A itself is regulated by a microRNA, miR-10b^[37]. TGFβ is a potent tumor suppressor that signals *via* the SMAD pathway and intersects with the WNT beta-catenine signaling pathway; it regulates the cell cycle by inhibiting cyclin-dependant kinases, E2F and histone deacetylase during the G1 phase of the cell cycle. TGFβ itself is regulated by different miRNA including mi-RNA 15/16 and mi-RNA 224^[38,39].

Some of these microRNAs inhibiting these tumor suppressor genes are in relation with the resistance to chemotherapy (gemcitabine), the poor prognosis of PC and the higher potential to rapid progression and metastasis development; inhibiting these microRNAs can be a promising strategy in TT. Other microRNAs are in relation with radio-resistance of PC; in a recent study evaluating a radio-resistant pancreatic cell line, miRNA-216a was significantly down regulated, whereas the autophagy activity was controlled. Using bioinformatics analysis, it was concluded that forced expression of microRNA-216a enhances the radio-sensitivity of pancreatic cells by inhibiting beclin-1 mediated autophagy^[40].

BRCA1 and *BRCA2* are two genes implicated in the DNA repair process. A mutation in one of these genes can cause breast, ovarian, and PCs. Recently another gene of the same family, the *PALB2*, was incriminated in the development of PC^[41]. Many studies are evaluating anti-PARP drugs in patients carrying BRCA1 and BRCA2 diagnosed with breast and ovarian cancers with promising results. Anti-PARP drugs cause multiple double strand breaks in the DNA and in tumors carrying one of these three mutations, these DNA breaks cannot be efficiently repaired, leading to the death of the cells. The FDA has recently approved Olaparib (anti-PARP) in BRCA-mutated ovarian cancers^[42]. Thus, the presence of one of these mutations can be a predictive biomarker of the use of these new drugs alone or in combination with gemcitabine in patients with PC. Many ongoing trials are studying this treatment options. NCT00515866 trial is evaluating the safety and tolerability of a PARP inhibitor in combination with gemcitabine in PC. Another randomized, phase II trial (NCT01585805) is testing the veliparib (anti-PARP) in

combination with gemcitabine hydrochloride and cisplatin compared to gemcitabine hydrochloride and cisplatin alone in patients with pancreatic adenocarcinoma having a known BRCA/PALB2 mutation.

Targeting stromal extracellular matrix

One of the important reasons of resistance to treatment in PC is the difficulty to deliver drug to tumor cells, because of the extensive deposition of extracellular matrix components and low vascularization of tumor environment. Targeting stromal extracellular matrix components seems to be an interesting approach to counteract this mechanism of resistance. Many trials targeting matrix metalloproteinases failed to show any benefit^[43,44], actually new targets are being tested using Hyaluronidase next to gemcitabine with promising results^[45]. Hyaluronidase acts by depleting pancreatic tumors of their high hyaluronan content in preclinical trials; hyaluronan being a glycosaminoglycan, one of the major components of extracellular matrix throughout the pancreatic tumor.

Targeting oxidative stress, chronic inflammation and targeting programmed cell death pathway

Oxidative stress has been shown to participate in the process of PC. Evidences supporting the role of reactive oxygen species and cytokines, as factors in the development of PC have been proposed. The concept of antioxidant supplementation as a preventive approach for PC has been evaluated^[46]. Curcumin, resveratrol, and genistein have antioxidant activities and demonstrated anti-cancer effects against PC *in vitro* and *in vivo* experiments^[47-49].

Chronic inflammation seems also to be incriminated in the development of PC. Many studies showed an increased incidence of pancreatic in patients with chronic pancreatitis. Prolonged inflammation may precede the onset of frank malignancy by a significant interval, and that once malignancy is established, the resulting inflammation occurred may act as a continued driving force in accelerating further malignant change. Targeting this chronic inflammation may prevent or postpone the process of PC. NFκB, cyclooxygenase 2 (COX2), lipoxygenase and inducible nitric oxid (NO) are the main targetable components of the chronic inflammation in PC^[50]. A study of 28283 participants, over a 7-year period, found that women who took regular aspirin had a 43% lower risk of PC than women who did not use aspirin^[51].

PC is characterized by an important resistance to apoptosis, which is associated by high expression levels of multiple prosurvival proteins of the extrinsic and intrinsic apoptosis signaling cascades and/or reduced expression or function of pro-apoptotic proteins. Many components of programmed cell death signaling pathways are being studied as targets for cancer therapies, for example the TRAIL system, IAP proteins or anti-apoptotic Bcl-2 proteins^[52].

DISCUSSION

The molecular and genetic complexity of MPC is one

of the major barriers causing the failure of TT in this indication; more than 60 genetic alterations that affect more than twelve signaling pathways are involved in the development of PC rendering this tumor resistance to TT. Inhibiting one pathway by a specific targeted therapy is not sufficient to block to the cellular proliferation and will probably induce the activation of another pathway. Many other factors make MPC difficult to treat: The aggressive molecular and cellular features, the late diagnosis and absence of tools of early detection the stromal proliferation forming a drug's barrier, the reduced vascular density and the immune suppression.

Detecting PC at an early stage remains the most rationale and solid perspective in the future management of this disease. At present, serum CA-19-9 (carbohydrate antigen 19-9) is the only FDA-approved biomarker for PDA, and it has utility marker of disease recurrence and surveillance. There has been a recent explosion in the PC biomarker field with more than 2000 biomarker studies implicating thousands of informative genes as candidate biomarkers^[53].

Many markers of early detection of PC are being evaluated in blood, pancreatic cyst fluid, pancreatic juice and stool based on the new advances in technology for whole genome, methylome, ribonucleome and proteasome interrogation. Many promising results are being reported for different markers of early detection of PC^[54]. Circulating tumor cells are one of the promising markers in blood used to the early detection of PC; the detection of a mutation, as KRAS for example, in the cells of pancreatic juice can help the early diagnosis of the PC^[55,56]. Glycpan-1 circulating exosomes were detected in the serum of patients with PC with absolute specificity and sensitivity; this new diagnostic and screening marker may serve as a potential non-invasive tool to detect early stages of PC and consequently, to facilitate possible curative surgical therapy^[57]. Recently, a new non-invasive urinary biomarker, based on a set of three urinary proteins (LYVE-1, REG1A, and TFF1) was identified, able to distinguish patients with early-stage PDAC from healthy individuals^[58].

To conclude, associating many TT, based on well-defined molecular biomarkers leading to a specific profile, can surpass some of those obstacles aiming to offer the best treatment to the appropriate patient. Combining different approaches in the same patient according to his molecular profile can be the best treatment option.

Abstract

AIM: To investigate the dynamic expression of p-signal transducer and activator of transcription 3 (STAT3) and vascular endothelial growth factor (VEGF) in the formation of gastric tumors induced by drinking water containing N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) in Wistar rats.

METHODS: One hundred and twenty Wistar rats were randomly divided into two groups (60 in each group): Control group and Model group. The rats in each group were then randomly divided into three groups (20 in each group): C/M15, C/M25 and C/M40 (15, 25 and 40 represent the number of feeding weeks from termination). Rats in the control group received normal drinking water and rats in the model group received drinking water containing 100 µg/mL MNNG. Stomach tissues were collected at the end of the 15th, 25th and 40th week, respectively, for microscopic measurement using hematoxylin and eosin staining. The expression of p-STAT3 and VEGF in different pathological types of gastric tissue, including normal, inflammation, atrophy, hyperplasia and gastric stromal tumor, was observed by immunohistochemistry and Western blot, and the correlation between p-STAT3 and VEGF was analyzed.

RESULTS: (1) The expression of p-STAT3 in tissue with gastritis, atrophy, dysplasia and gastric stromal tumor were significantly increased in the model group compared with the control group (2.5 ± 1.0 , $2.75 \pm$

0.36, 6.2 ± 0.45 , 5.67 ± 0.55 vs 0.75 ± 0.36 , $P = 0.026$, 0.035, 0.001, 0.002, respectively); the expression of p-STAT3 in tissue with dysplasia was higher than that in samples with gastritis or atrophy (6.2 ± 0.45 vs 2.5 ± 1.0 , $P = 0.006$; 6.2 ± 0.45 vs 2.75 ± 0.36 , $P = 0.005$, respectively); however, the expression of p-STAT3 in gastritis and atrophy was not significantly different ($P > 0.05$); (2) the expression of VEGF in tissue with gastritis, atrophy, dysplasia and gastric stromal tumor was significantly increased in the model group compared with normal gastric mucosa; and the expression of VEGF in tissue with dysplasia was higher than that in tissue with inflammation and atrophy (10.8 ± 1.96 vs 7.62 ± 0.25 , $P = 0.029$; 10.8 ± 1.96 vs 6.26 ± 0.76 , $P = 0.033$, respectively); similarly, the expression of VEGF in tissue with gastritis and atrophy was not significantly different ($P > 0.05$); and (3) the expression of VEGF was positively correlated with p-STAT3.

CONCLUSION: p-STAT3 plays an important role in gastric cancer formation by regulating the expression of VEGF to promote the progression of gastric tumor from gastritis.

Core tip: The results show that signal transducer and activator of transcription 3 (STAT3) is partially responsible for the progression from chronic gastritis to gastric carcinoma induced by N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) and is significantly related to the expression of vascular endothelial growth factor (VEGF) during this process. It is considered that STAT3 induces an abnormal level of VEGF expression to promote the formation of gastric carcinoma. To the best of our knowledge, this is the first report to show that p-STAT3 is persistently activated during the progression of chronic gastritis to gastritis carcinoma induced by the administration of MNNG in rats, and was positively associated with the expression of VEGF.

Expression of p-STAT3 and vascular endothelial growth factor in MNNG-induced precancerous lesions and gastric tumors in rats. *World J Gastrointest Oncol* 2016; 8(3): 305-313 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i3/305.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i3.305>

INTRODUCTION

Gastric cancer is the second leading cause of cancer-related death worldwide, its prevalence rate and mortality are very high, especially in some developing

countries, and the high incidence of gastric cancer is a major public health problem worldwide^[1]. The formation and development of gastric cancer are complex and are associated with a multifactorial etiology^[2]. *Helicobacter pylori*, high-salt diet, smoking, obesity and Epstein-Barr virus are factors which increase gastric cancer risk^[3-7]. In addition, environmental factors significantly contribute to the etiology of cancer^[2]. N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) is commonly used to induce gastric tumors in basic research^[8,9], therefore we chose MNNG to induce gastric precancerous lesions and gastric tumors in this study. Consistent with other tumors, the pathogenesis of gastric tumors is still unclear.

Signal transducer and activator of transcription 3 (STAT3), a key transcription factor^[10] was shown to play a vital role in human gastric cancer angiogenesis^[11]. It was reported that activation of STAT3 and the microbial environment were important for gastric tumor initiation and development in the gp130 (757F/F) mouse^[11], and it is believed by some investigators that STAT is directly involved in gastric tumorigenesis^[12].

Vascular endothelial growth factor (VEGF) plays a very critical role in cancer metastasis due to its function in the generation of vascular tissue^[13,14]. Recently, VEGF was reported to be closely associated with gastric cancer, which may provide additional prognostic information for the preoperative evaluation of gastric cancer invasion and tumor type^[15], thus anti-VEGF may be a targeted therapy for the treatment of gastric cancer^[16]. Several researchers demonstrated that the expression of STAT3 was potentially associated with the expression of VEGF-C in various malignant diseases^[17,18], and Judd *et al.*^[11] reported that constitutive STAT3 activation promoted VEGF expression and stimulated tumor angiogenesis. However, to our knowledge, the roles of STAT3 and VEGF in the formation of gastric precancerous lesions and gastric cancer induced by MNNG are still unknown.

The aim of this study was to investigate the dynamic expression of p-STAT3 and VEGF as well as the relationship between them in the formation of gastric tumors from gastritis induced by MNNG in male Wistar rats.

MATERIALS AND METHODS

Animal preparation

One hundred and twenty male Sprague-Dawley (SD) rats aged 4 wk and weighing 125-150 g were provided by the Animal Center of Zhejiang Chinese Medical University. The animals were housed in groups of five per cage under controlled illumination (12:12 h light/dark cycle, lights on/off: 6 h/18 h), humidity (60%) and temperature ($22^{\circ}\text{C} \pm 2^{\circ}\text{C}$) for one week to acclimatize to the environment. The animals were then randomly divided into two groups (60 in each group): Control group (the rats were able to eat regular food and drinking water) and the model group (the rats were able to eat regular food and drinking water containing 100

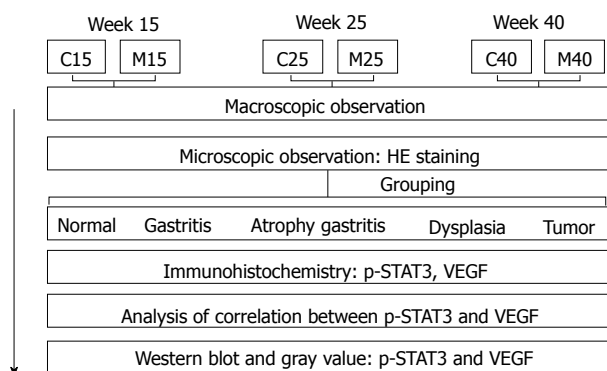

Figure 1 The experimental protocol. VEGF: Vascular endothelial growth factor; STAT3: Signal transducer and activator of transcription 3.

μg/mL MNNG); each group was then randomly divided into three groups (20 rats in each group): C/M15, C/M25 and C/M40 (15, 25 and 40 represent the number of feeding weeks). The Animal Care and Use Committee of the Zhejiang Chinese Medical University approved the protocol.

Experimental protocols

Rats were fed normal food and drinking water or drinking water with MNNG. Rats in C/M15 were sacrificed at the end of the 15th week in both the control group (C15) and the model group (M15) and the gastric tissue was collected immediately and stored at -80 °C or was perfused with cold PBS on ice and then placed in a tube with 4% paraformaldehyde to obtain various measurements as follows. Similarly, rats in C/M25 or C/M40 were sacrificed at the end of the 25th week or 40th week and gastric tissue was collected. The experimental protocol is described in Figure 1.

Measurement of morphological changes

The rats were killed at the end of the 15th week, 25th week and 40th week respectively. The stomachs were separated immediately and were opened along the long axis on ice to record the following conditions: Edema, hyperemia, erosion, ulcer or mass, and photographs were taken by two pathologists who were unaware of the treatment groups. The stomach tissue was then divided into two parts, one was stored at -80 °C and the other was placed in tubes with 4% paraformaldehyde (PFA).

Histology measurements

Gastric tissue was perfused with PBS followed by 4% PFA in 0.1 mol/L phosphate buffer and cryoprotected in 30% sucrose in PBS overnight at 4 °C. Samples were embedded in paraffin wax, and 5 μm specimens were stained with hematoxylin and eosin. The results of histology were divided into four types according to the following histological features: Chronic superficial gastritis, chronic atrophic gastritis, dysplasia and tumor.

Gastritis was defined as inflammation of the stomach lining associated with mucosal injury. Atrophic gastritis was characterized by chronic inflammatory processes

of gastric mucosa leading to the loss of appropriate glands^[19] and gastric dysplasia was diagnosed according to the classification of gastrointestinal tract epithelial neoplasia by the World Congress of Gastroenterology in Vienna in 1998^[20]; gastric tumor was diagnosed by the presence of tumor cells.

Tissue collection and immunohistochemical processing

The expression of p-STAT3 and VEGF in gastric mucosa in the different groups was evaluated using immunohistochemistry. Specimens were cut into 1-cm blocks transversely oriented to the hippocampal long axis. Blocks were placed in buffered PFA (Sigma, St Louis, MO, United States). After 48 h, the specimens were paraffin-embedded for immunohistochemistry as described by Jung *et al.*^[21] and Meng *et al.*^[22]. Briefly, endogenous peroxidase activity was blocked using 3% H₂O₂ in methanol for 15 min. The sections were washed, and stained with a rabbit polyclonal antibody against p-STAT3 and VEGF (Santa Cruz Biotechnology, TX, United States) diluted 1:50. Primary antibody binding was detected using the Bond Polymer Refine Detection Kit (Leica, Wetzlar, Germany). The sections were counterstained with hematoxylin, dehydrated and mounted.

Evaluation of immunohistochemical staining

Scoring of immunohistochemical results was performed according to the semi-quantitative method as described by Meng *et al.*^[22]. Briefly, the percentage of immunopositive cells was scored using a four-point system: 0 points, < 5% of positive cells; 1 point, 5%-25% of positive cells; 2 points, 26%-50% of positive cells; 3 points, 51%-75% of positive cells; 4 points, > 75% of positive cells. The staining intensity was scored similarly, with 0 points for negative staining, 1 point for weak staining (light yellow), 2 points for moderate staining (brown), and 3 points for strong staining (dark brown). The immunoreactivity score for each lesion was calculated as (the score for the percentage of immunopositive cells + the score for the staining intensity)/2. Based on the immunoreactivity scores, immunohistochemical staining was considered negative (< 0.5), weakly positive (0.5-1.5), or strongly positive (> 1.5).

Extraction of proteins for Western blot analysis

Frozen gastric tissue samples (whole layer) were homogenized in homogenization buffer (50 mmol/L Tris-HCl, pH 7.2) containing Na₃VO₄ and a protease inhibitor cocktail (Sigma-Aldrich) using an OmniTH homogenizer (Omni International, Marietta, GA, United States). After sonication, the homogenate was centrifuged at 2000 rpm for 5 min. The resulting supernatants were collected as total proteins and protein concentrations were measured using the Bio-Rad Protein Assay (Bio-Rad Inc., Hercules, CA, United States)^[23].

SDS-PAGE and Western blot analysis

Western blots were performed as previously described by Li *et al.*^[24] with minor modifications. Briefly, the proteins were separated on 12.5% SDS polyacrylamide gels and

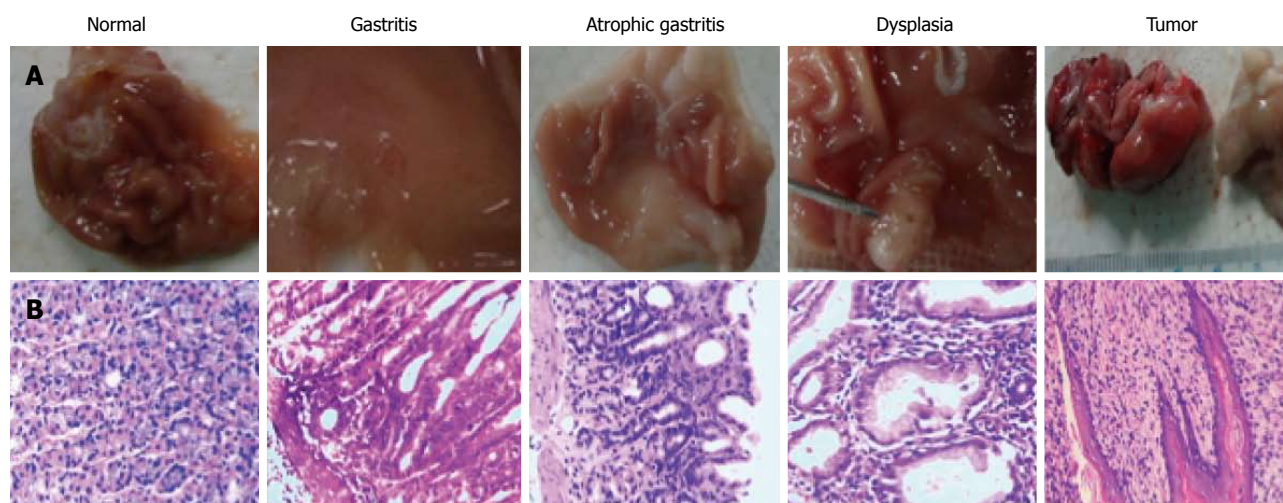

Figure 2 Administration of N-methyl-N'-nitro-N-nitrosoguanidine induced macroscopic changes: Gastritis, atrophic gastritis, dysplasia and gastric tumor in rats (A) and respective microscopic changes were observed by hematoxylin and eosin staining (B).

blotted onto nitrocellulose membranes. These membranes were incubated in PBST-milk (0.1% Tween-20 and 5% milk), followed by primary antibodies (2 h) for p-STAT3 and VEGF and β -actin (Santa Cruz Biotechnology Inc., TX, United States). The blots were then washed with PBST 3 times, and subsequently incubated for 1 h with corresponding fluorescently labeled secondary antibodies (Rockland Immunochemicals, Inc., Gilbertsville, PA, United States) diluted in PBST-milk. The blots were washed 3 times and the fluorescence intensity of the detected protein bands was quantified using the Quantity One system (Bio-Rad Inc., Hercules, CA, United States).

Statistical analysis

Statistical analyses were performed using SigmaStat 17.0 (SPSS, Chicago, IL, United States). Data are reported as means \pm SE. The Student's *t*-test was used to analyze the difference in measurements between the ES group and sham-ES group. Analysis of variance (ANOVA) was used for multiple comparisons. A *P* value of < 0.05 was considered statistically significant.

RESULTS

Macroscopic and microscopic changes in the different groups

Administration of MNNG induced significant changes in macroscopy and microscopy in the model group compared with the control group. Little hyperemia and sporadic erosion were observed in gastric tissue at the end of the 15th week (A15 group); and ulcer, reduction in mucosal folds, gray mucosa and even some mucosal hyperplasia in addition to hyperemia and erosion were observed at the end of the 25th week (A25 group); obvious masses were observed at the end of the 40th week (A40 group) (Figure 2A). Respective changes in microscopy were observed in these treatment groups. Inflammatory cells were observed in gastritis samples in the A15 group, loss of appropriate glands in some samples in the A25 group and

A40 group and tumour cells were noted in some samples in the A40 group (Figure 2B). These changes were not observed in the control group.

Histological changes in the different groups

Only 20% of rats had gastritis (4/20) in the C15 group, while 42.1% of rats had gastritis (8/19), 10.53% of rats had atrophic gastritis (2/19) and 5.3% of rats had dysplasia (1/19) in the M15 group (Table 1). In the C25 group, 30% of rats had gastritis (6/20), 10% of rats had atrophic gastritis (2/20) and none of the rats had dysplasia or tumour; however, in the M25 group, 31.58% of rats had gastritis (6/19), 26.32% of rats had atrophic gastritis (5/19) and 15.79% of rats had dysplasia (3/19) although no rats had tumours (Table 1). At the end of the study, 16.67% of rats had gastritis (3/18) in the M40 group (vs 35% in the C40 group, 7/20), 27.78% of rats had atrophic gastritis (5/18) (vs 20% in the C40 group, 4/20) and 27.78% of rats had dysplasia (5/18) (vs 5% in the C40 group, 1/20). It was observed that 27.78% of rats had tumours (5/18) in the M40 group (vs 0% in the C40 group, 0/20) (Table 1).

Expression of p-STAT3 and VEGF in different pathological types of stomach tissues measured by immunohistochemistry

The expression of p-STAT3 and VEGF in the model groups measured by immunohistochemistry increased significantly compared with the control groups. The expression of p-STAT3 in gastric tissue was mainly in the nucleus (Figure 3A), and the immunochemical score for p-STAT3 in tissues with gastritis, tissues with atrophy and tissues with dysplasia were significantly higher than those in the control groups (all *P* values < 0.05), and the expression of p-STAT3 in tissues with dysplasia was higher than that in tissues with gastritis and tissues with atrophy ($P < 0.001$, $P < 0.001$, respectively). The expression of p-STAT3 in tissues with tumor was

Table 1 Histological findings

Group	n	Pathological type				
		Normal	Gastritis	Atrophic gastritis	Dysplasia	Tumour
A15 group						
Control	20	80.00% (16/20)	20.00% (4/20)	0	0	0
A15 group	19	42.11% (8/19)	42.11% (8/19)	10.53% (2/19)	5.26% (1/19)	0
A25 group

Figure 3 Expression of p-signal transducer and activator of transcription 3 and vascular endothelial growth factor in the model groups. A: The expression of p-signal transducer and activator of transcription 3 (STAT3) measured by immunohistochemistry. From a normal sample to samples with tumor induced by the administration of N-methyl-N'-nitro-N-nitrosoguanidine, the expression of p-STAT3 was more obvious; B: Similar results for the expression of vascular endothelial growth factor were observed.

substantially higher than that in tissues in the control group ($P < 0.001$); however, the difference in expression of p-STAT3 between tissues with gastritis and tissues with atrophy was not significant ($P > 0.05$) (Figure 4A).

Similarly, the expression of VEGF, mainly in the cytoplasm (Figure 3B), was higher in precancerous lesions than in the control group ($P < 0.05$) (Figure 4B). Consistent with p-STAT3, the expression of VEGF in tissue with dysplasia was higher than that in tissue with gastritis, tissue with atrophy and the control group ($P < 0.001$, $P < 0.001$, respectively); the expression of VEGF in tissue with stromal tumor was substantially higher than tissue in the control group ($P < 0.001$) (Figure 4B), however, the difference between the tissue with gastritis and tissue with atrophy was not significant ($P > 0.05$).

Expression of p-STAT3 and VEGF in different pathological types of stomach tissue measured by Western blot

To further determine whether the observed p-STAT3 and VEGF changes were consistent with the changes shown by immunohistochemistry, proteins were extracted from scraped freshly excised stomach tissue, and the samples

were analyzed by SDS-PAGE and Western-blot using primary antibodies for p-STAT3 and VEGF. As shown in Figure 5: (A) both p-STAT3 and VEGF protein expression were significantly higher in tissue with gastritis, atrophy, dysplasia or tumor than in the control group ($P < 0.05$); (B) both p-STAT3 and VEGF protein expression were significantly higher in tissue with dysplasia or tumor compared with that in tissue with gastritis or atrophy ($P < 0.05$); and (C) there was no significant difference in p-STAT3 and VEGF protein expression between tissue with dysplasia and tumor ($P > 0.05$).

The relationship between the expression of p-STAT3 and VEGF

A strong correlation was observed between the expression of p-STAT3 and VEGF both in the immunohistochemistry and Western Blot results. In order to further examine the relationship between the expression of p-STAT3 and VEGF, we performed a relativity analysis and found that there was a strong positive correlation in the immunohistochemical score between the expression of p-STAT3 and VEGF ($R^2 = 0.86$, $P < 0.001$) as well as protein expression measured by Western Blot ($R^2 = 0.90$,

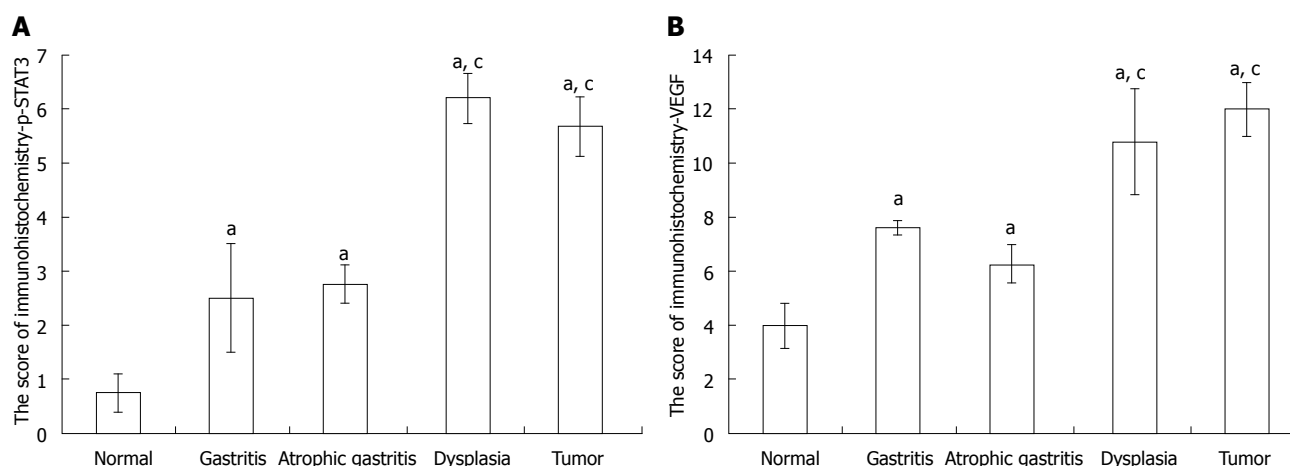

Figure 4 Immunohistochemical score of p-signal transducer and activator of transcription 3 and vascular endothelial growth factor. A: The immunohistochemical score of p-signal transducer and activator of transcription 3 (STAT3) was significantly increased by N-methyl-N'-nitro-N-nitrosoguanidine during the progression from gastritis to gastric tumor. The p-STAT3 score in precancerous lesions and tumor samples was significantly higher than that in the normal sample; and the p-STAT3 score in dysplasia samples was significantly higher than that in gastritis and atrophic gastritis, which was comparable to that in tumor samples; B: Similar results were observed for the vascular endothelial growth factor score (^a $P < 0.05$ vs normal group; ^c $P < 0.05$ vs gastritis or atrophic gastritis).

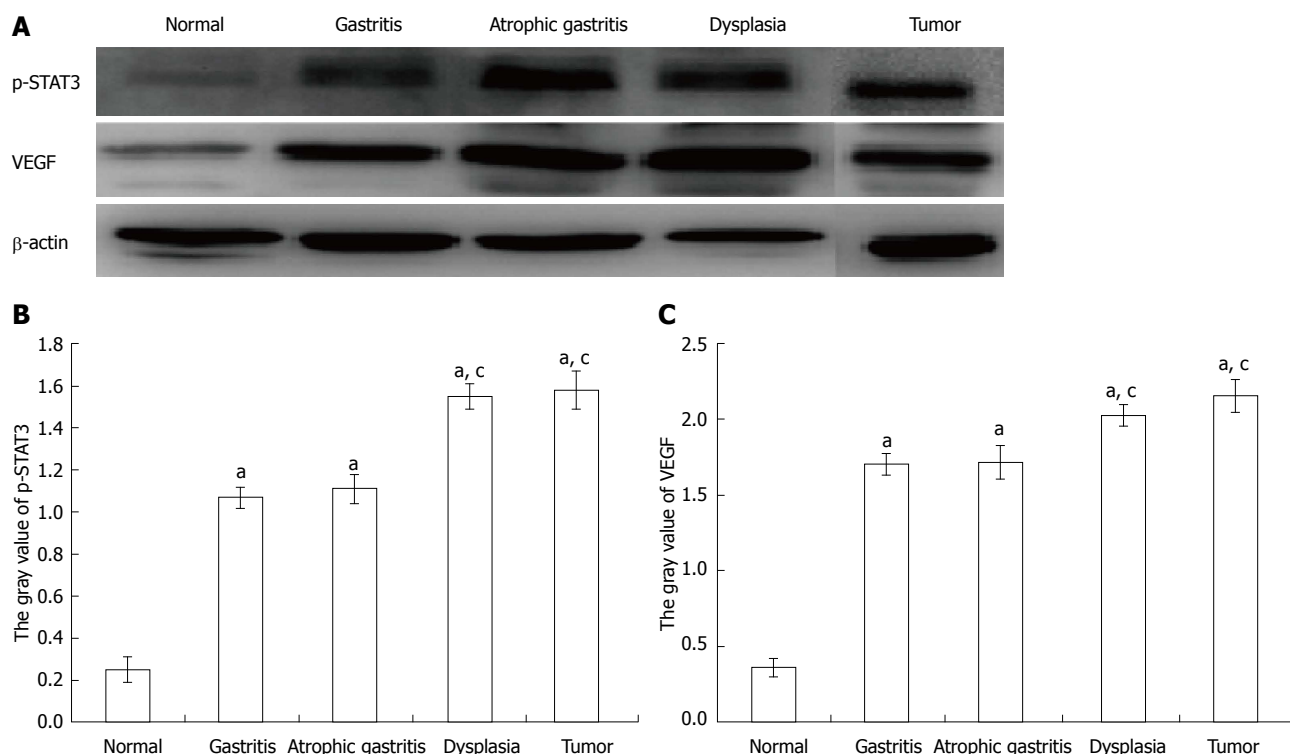

Figure 5 Protein expression of p-signal transducer and activator of transcription 3 and vascular endothelial growth factor. A: The protein expression of p-signal transducer and activator of transcription (STAT3) in dysplasia and tumor samples was more obvious than that in the other samples; B: The protein expression of p-STAT3 in dysplasia and tumor samples was significantly higher than that in gastritis and atrophic gastritis samples, but the difference between the dysplasia and tumor samples was not significant. The same results were observed for gastritis and atrophic gastritis samples; C: Consistent results were found for the protein expression of vascular endothelial growth factor in samples (^a $P < 0.05$ vs normal group; ^c $P < 0.05$ vs gastritis or atrophic gastritis).

$P < 0.001$), suggesting that p-STAT3 may regulate VEGF to promote the formation and development of gastric cancer (Figure 6).

DISCUSSION

In this study, we examined the significance of p-STAT3 and VEGF expression in the development of gastric

cancer from gastritis, atrophic gastritis and dysplasia induced by the administration of MNNG in rats. The results showed that STAT3 is partially responsible for the development of gastric carcinoma from chronic gastritis induced by MNNG and was significantly related to the expression of VEGF during this process. Although overexpression of p-STAT3 in primary tumor sites has been recognized as a predictor of poor survival in many

Figure 6 Correlation of immunochemical score between p-signal transducer and activator of transcription 3 and vascular endothelial growth factor. A: There was a strong correlation in immunochemical score between p-signal transducer and activator of transcription (STAT3) and vascular endothelial growth factor (VEGF). The immunochemical score of p-STAT3 was positively related to that of VEGF ($R^2 = 0.86$, $P < 0.001$); B: Similar results were observed for the protein expression of p-STAT3 and VEGF ($R^2 = 0.90$, $P < 0.001$).

malignancies, including gastric cancer^[25,26], to the best of our knowledge, this is the first report to show that p-STAT3 is also persistently activated in the progression of chronic gastritis to gastric carcinoma induced by MNNG in rats, and was positively associated with the expression of VEGF.

STAT3, plays important roles in the development of inflammation and carcinogenesis as well as tumor metastasis^[27,28]. Normally, STAT3 is activated for a short time and then is deactivated to maintain homeostasis; however, under abnormal conditions, STAT3 activation continues, which triggers oncogene transcription^[29]. Only a few studies have reported the difference in expression of p-STAT3 between normal gastric mucosa and precancerous lesions. In a clinical study^[30], it was reported that p-STAT3 expression was significantly higher in chronic atrophic gastritis (60.0%), intestinal metaplasia (77.1%), dysplasia (68%) and gastric cancer (60.1%) than in normal gastric mucosa (41.1%, $P < 0.05$). Consistent with these findings, we found that p-STAT3 expression in samples with chronic gastritis or atrophic gastritis was significantly higher than that in normal mucosa and was substantially increased in samples with dysplasia or tumor compared with normal mucosa, and even higher than that in samples of chronic gastritis or atrophic gastritis, further indicating the potential role of p-STAT3 not only in the invasion and metastasis of gastric cancer, but also in the development of gastric cancer from chronic gastritis. However, there was no significant difference in the expression of p-STAT3 between chronic gastritis and atrophic gastritis samples. Similar results were observed between dysplasia and tumor samples, indicating the important effect of p-STAT3 on the progression from atrophic gastritis to gastric carcinoma.

VEGFs are glycoproteins secreted by tumor cells and are the most important factors in angiogenesis and tumor metastasis^[31]. The VEGF family includes VEGF-A to F and placental growth factor. It has been reported

that VEGF-A and B play a key role in blood vessel growth, whereas VEGF-C and D are important for the growth of lymphatic vessels^[32,33]. VEGFs, particularly VEGF-A, C, and D promote angiogenesis and metastasis of many cancers including gastric cancer^[34].

Some clinical studies have shown the potential effects of VEGF inhibitors in the treatment of multiple cancers including gastric cancer^[35]. Raica *et al.*^[36] investigated the immunohistochemical expression of VEGF on 80 patients with intestinal-type gastric carcinoma and found that VEGF was positive in 52 of 80 cases (70%), indicating that the expression of VEGF could signify an early angiogenic switch during tumorigenesis. Consistent with this finding, we also found that the expression of VEGF in dysplasia and tumor samples was higher than that in chronic gastritis and atrophic gastritis samples. However, consistent with the expression of p-STAT3, both the difference in expression of VEGF between chronic gastritis and atrophic gastritis samples and the difference between dysplasia and tumor samples were not significant. According to these results, we analyzed the correlation between the expression of p-STAT3 and VEGF and found that the expression of VEGF was significantly and positively related to p-STAT3. To the best of our knowledge, this is the first report on the positive relationship between p-STAT3 and VEGF in precancerous lesions of gastric cancer induced by MNNG.

Some published papers support the findings in our study regarding the relationship between the expression of p-STAT3 and VEGF in gastric cancer. Deng *et al.*^[37] reported that STAT3, p-STAT3, and VEGF-D expression in gastric cancer tissue was significantly higher than those in adjacent non-tumor tissue, and both STAT3 and VEGF-D mRNA expression was much higher in many gastric cancer cell lines than in the GES-1 cell line. Using STAT3 siRNA transfection, these authors found that VEGF-D expression significantly decreased in HGC-27 cells, representing the potential STAT3 regulation of VEGF-D expression^[37]. Similar results were observed

by Zhu *et al.*^[38] who found that (-)-epigallocatechin-3-gallate inhibited IL-6-induced VEGF expression and angiogenesis by suppressing STAT3 activity in human gastric cancer cells. However, the relationship between p-STAT3 and VEGF in precancerous lesions of gastric cancer is still unclear. In the current study, we found that even in chronic gastritis and atrophic gastritis samples, the expression of both p-STAT3 and VEGF were higher than that in normal mucosa and showed a positive relationship, suggesting that VEGF may be activated on initial damage of gastric mucosa induced by MNNG via the p-STAT3 pathway and contributes to the development and progression of gastric cancer, highlighting the potential for anti-p-STAT3 as a therapeutic target for the prevention of gastric cancer.

In conclusion, STAT3 activation plays an important role in the changes in gastric mucosa from chronic gastritis to gastric tumor via the STAT/VEGF pathway, confirming the potential value of targeted therapy focusing on STAT/VEGF in protecting against gastric cancer in clinical applications.

COMMENTS

Background

Signal transducer and activator of transcription 3 (STAT3) has been shown to play a vital role in human gastric cancer angiogenesis. Vascular endothelial growth factor (VEGF) plays a very critical role in cancer metastasis due to its function in vascular formation. Several researchers have demonstrated that the expression of STAT3 is potentially associated with the expression of VEGF-C in various malignant diseases; Judd *et al* reported that constitutive STAT3 activation promoted VEGF expression and stimulated tumor angiogenesis. However, to the best of our knowledge, the role of STAT3 and VEGF in the formation of gastric precancerous lesions and gastric cancer induced by "N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) is still unknown.

Research frontiers

The effects of STAT3 and VEGF on gastric cancer have been reported. The present study showed that STAT3 activation plays an important role in the changes in gastric mucosa from chronic gastritis to gastric tumor via the STAT/VEGF pathway.

Innovations and breakthroughs

To the best of our knowledge, this is the first report to show that p-STAT3 is also persistently activated during the progression from chronic gastritis to gastric carcinoma induced by the administration of MNNG in rats, and was positively associated with the expression of VEGF.

Applications

It was shown in this study that STAT3 is partially responsible for the progression from chronic gastritis to gastric carcinoma induced by MNNG and was significantly related to the expression of VEGF during this process. It is considered that STAT3 can induce an abnormal level of VEGF expression to promote the formation of gastric carcinoma.

Peer-review

Previous studies have established that STAT3 has close relationship with VEGF in cancers. However, this is the first time to report that p-STAT3 is also persistently activated during chronic gastritis to gastritis carcinoma induced by administration of MNNG in rats, which is positively associated with the expression of VEGF.

Abstract

AIM: To estimate the incidence of esophageal cancer (EC) in Kilimanjaro in comparison to other regions in Tanzania.

METHODS: We also examined the clinical, epidemiologic, and geographic distribution of the 1332 EC patients diagnosed and/or treated at Ocean Road Cancer Institute (ORCI) during the period 2006-2013. Medical records were used to abstract patient information on age, sex, residence, smoking status, alcohol consumption, tumor site, histopathologic type of tumor, date and place of diagnosis, and type and date of treatment at ORCI. Regional variation of EC patients was investigated at the level of the 26 administrative regions of Tanzania. Total, age- and sex-specific incidence rates were calculated.

RESULTS: Male patients 55 years and older had higher incidence of EC than female and younger patients. Of histopathologically-confirmed cases, squamous-cell carcinoma represented 90.9% of histopathologic types of tumors. The administrative regions in the central and

eastern parts of Tanzania had higher incidence rates than western regions, specifically administrative regions of Kilimanjaro, Dar es Salaam, and Tanga had the highest rates.

CONCLUSION: Further research should focus on investigating possible etiologic factors for EC in regions with high incidence in Tanzania.

Key words: Esophagus; Cancer; Tanzania; Epidemiology; Distribution

Core tip: In the manuscript "Clinical and epidemiologic variations of esophageal cancer in Tanzania", the authors describe the geographic distribution of esophageal cancer in Tanzania. The regions of Dar es Salaam and Kilimanjaro have higher incidences of esophageal cancer in comparison to other regions of Tanzania. There were also higher incidences found in the eastern and central parts of Tanzania compared to Western Tanzania. The authors did not find any differences in the age, sex, and histopathologic distribution of esophageal cancer when grouping the regions based on incidence rates.

INTRODUCTION

Globally, esophageal cancer (EC) is the 8th most common incident cancer and the cancer with the 6th highest mortality^[1,2]. There are two histologic types of EC that are commonly diagnosed, squamous cell carcinoma (SCC) and adenocarcinoma (AC). SCC has been linked to tobacco and alcohol use while AC has been linked to diet and esophageal reflux; both are associated with older age^[3-5]. The incidence of esophageal AC is often significantly higher in developed than developing countries while the incidence of SCC is usually higher in developing countries, including Africa, than developed countries^[6,7]. In certain developed countries in East Asia, such as China and Japan, the incidence of SCC is much higher than AC incidence^[8].

Approximately 80% of all EC occur in developing countries^[2]. Africa specifically has a much higher incidence of EC in the Eastern and Southern regions^[6]. The highest risk populations in Africa tend to be poorer, malnourished, and consume alcohol and tobacco^[6,7,9,10]. There is also a large variation of risk for EC based on geographic region in Africa. Specifically, West Kenya and the Rift Valley Province of Kenya have shown high

rates^[6,11-15]. These regional differences may reflect risk and etiologic factors other than tobacco and alcohol^[6,11].

Tanzania, located on the southern border of Kenya, is one of the poorest countries in the world, and a location where EC is commonly found^[6]. Globocan estimates show an age-standardized rate of EC incidence in Tanzania for both sexes of 9.2 per 100000, which is the second highest cancer in Tanzania^[16]. This rate is similarly high among other East African countries^[16].

The Ocean Road Cancer Institute (ORCI), located in Dar es Salaam is the only specialized cancer treatment center in Tanzania, and the only facility in the country where radiation therapy is available^[17]. The majority of EC patients in Tanzania are diagnosed at advanced disease stages (stage III and IV) and the main lines of treatment for such advanced stages include chemotherapy and radiation therapy^[18]. It is also important to note that although AC and SCC develop from different cell types in the esophagus, they have similar treatment options^[19]. Therefore, the majority of EC patients in Tanzania are treated at ORCI because of its radiation therapy facility^[17].

Oncologists at ORCI have noted a higher number of EC patients referred from the Kilimanjaro region than other regions of Tanzania, despite similarities of population between regions, distance between the consultant hospital in the region and ORCI, and quality of roads between the consultant hospital and ORCI. This study aimed to estimate the incidence of EC in Kilimanjaro in comparison to other regions in Tanzania. The study also aimed to examine the demographic, clinical, and geographic distribution of EC patients in Tanzania during the period 2006-2013.

MATERIALS AND METHODS

Study population and data collection

This study was conducted at ORCI, the only specialized cancer treatment center in Tanzania. The majority of EC patients treated at ORCI are referred from a few major hospitals in Tanzania after initial histopathologic confirmation or clinical diagnosis. ORCI keeps medical records for all patients treated by chemotherapy and/or radiotherapy, including EC. These medical records and patient logbooks were utilized for this study, for the period 2006-2013. Logbooks were used as the original source for identifying medical record numbers of EC patients. Logbooks contain the names, medical record numbers, and type of cancer for each patient and were used to identify all patients with EC. Logbooks for 2007 were not available so manual search was performed to identify the EC medical records of 2007 without the initial list from the logbooks.

Abstracted information from the medical records included age, sex, residence, smoking status, alcohol consumption, tumor site, histopathologic type of tumor, treatment received, date and place of diagnosis, and date of beginning treatment at ORCI were abstracted from the medical records. This procedure was used for all EC patient records treated at ORCI during the period

2006-2013. There were a total of 1277 patient records collected and recorded. There were a total of 112 records of EC patients that were found in ORCI logbooks, but no medical record could be recovered (8.1%). Of the 1277 patients, 15 were removed because they were from a country other than Tanzania ($n = 13$) or had no recorded place of residence ($n = 2$), leaving a total of 1262 patients from ORCI records.

Surgical resection of EC is a major procedure that is mainly done at Muhimbili National Hospital (MNH) and the Kilimanjaro Christian Medical Centre (KCMC), and these hospitals are among the only in the country that provide histopathology diagnosis. Medical records for patients referred from MNH are included in the medical records of patients when they receive treatment at ORCI. For EC patients referred from KCMC, we created a list of their names and year of diagnosis and cross-referenced this information with all EC patients diagnosed and/or treated at KCMC during the period of 2006-2013. Additional information of patients from KCMC who were not included in the ORCI records were added to the final study dataset that included 1332 EC patients.

Statistical analysis

Regional variation in geographic distribution was investigated at the level of the 26 administrative regions of Tanzania. For calculating incidence rates, the total, age-, sex-specific population data of each region was obtained from the 2002 and 2012 Census of Tanzania^[20,21]. The annual projected growth rate for each region was used to estimate the annual population for years 2006-2013^[20,21].

Based on the incidence rates that were calculated, the 26 administrative regions and Zanzibar were grouped into 5 groups. This was done to compare risk factors between different incidence groups. The very high incident group, with a rate of over 1.00 cases per 100000 person-years, was made up of the Dar es Salaam and Kilimanjaro regions. The high incident group, with an incidence of 0.75-0.99 cases per 100000 person-years was comprised of the region Tanga. The mid-range group ranged from 0.50-0.74 cases per 100000 person-years was made up of the administrative districts of Morogoro, Pwani, and Iringa. The regions of Ruvuma, and Dodoma represented the group with low incidence range, 0.25-0.49 cases per 100000 person-years. All other regions, Lindi, Mtwara, Njombe, Mbeya, Rukwa, Katavi, Tabora, Singida, Tabora, Kigoma, Manyara, Arusha, Mara, Simiyu, Kagera, Geita, Shinyanga, Zanzibar, and Mwanza, had an incidence of less than 0.25 cases per 100000 person-years and made up the very low incidence group. These groups will now be referred to as Group 1, Group 2, Group 3, Group 4, and Group 5, respectively.

Data were analyzed using χ^2 tests to examine differences in the distribution of patient characteristics between the 5 incidence groups. These included differences based on demographic, clinical, and histopathologic variation of EC by age and sex groups and possible sex, age, and treatment differences among the two histologic

types. The analysis for this paper was generated using SAS software, Version 9.3 of the SAS System. Copyright © 2011 SAS Institute Inc^[22].

The study was approved by the University of Nebraska Medical Center IRB and the ORCI Academic, Research, Publications and Ethics Committee.

RESULTS

Figure 1 categorizes all of the administrative regions in Tanzania based on the incidence rate per 100000 person-years. The administrative regions of Kilimanjaro and Dar es Salaam were found to have the highest incidence rates for EC in Tanzania for years 2006-2013, at 1.20 and 1.65 cases per 100000, respectively.

Table 1 illustrates the age, sex, year of treatment, histopathologic type, and smoking and alcohol history of the study population. Male patients comprised slightly over 2/3 of the study population (68%) and over half (60%) of the EC patients were aged 55 years and older. Over 50% of the EC patients smoked tobacco or consumed alcohol, however this rate may be much higher as over 20% had unknown alcohol and tobacco status. Over 90% of histopathologically-confirmed EC cases were SCC (Table 1).

Table 2 displays the sex, age, and treatment distribution of both histopathologic types. The distribution of age group, sex, and treatment was not significantly different among SCC and AC patients. Males comprised nearly 2/3 of both SCC (67.1%) and AC (64.9%) patients. Sex distribution was not significantly different among SCC and AC patients ($P = 0.73$). Patients aged 55 and older were the majority of both SCC (63.2%) and AC (75.4%) patients. The distribution of age groups did not differ significantly between SCC and AC patients ($P = 0.1702$). The treatment received among SCC and AC patients also was not significantly different ($P = 0.13$).

Table 3 illustrates the distribution of histopathologic type, sex, and age group among the different incident groups. Males comprised the majority of patients in every incident group (64.7%-73.6%). The distribution of sex was not significantly different among the different incident groups ($P = 0.12$). SCC was the majority histopathologic type among all groups (86.6%-98.2%). The histopathologic type composition did not differ significantly among incident groups ($P = 0.13$). Those aged 55 and older comprised over half of all incident groups (52.3%-70.5%). The age group distribution among the incident groups was not significantly different ($P = 0.14$).

DISCUSSION

In this study, the eastern and central parts of Tanzania had higher incidence rates compared to western parts of the country. This can be observed for all age groups and sexes. This is an interesting observation, as the Western part of Kenya has been noted to have a higher incidence

Figure 1 Geographic distribution of overall esophageal cancer incidence in Tanzania, 2006-2013.

compared to other areas in Kenya^[6,10-14]. Because our study hospital (ORCI) is on the eastern side of Tanzania, the higher rates of the disease from eastern Tanzania might be related to more accessibility to care. It is worth noting that some regions with the lowest incidence rates are not a significantly farther distance than some of the regions with a higher incidence. For example, Manyara, a region in the lowest incidence group, is not significantly farther from ORCI than Kilimanjaro, a region in the highest incidence group.

Males had a higher incidence in all administrative regions, and in total comprised 68% of the EC patients included in this study. The male-to-female ratio reported in this study is consistent with other studies on EC from developed and developing countries^[3,23,24].

SCC represented over 88% of all histopathologically confirmed patients in every age and sex group. SCC also made up the majority of confirmed patients who received treatment. This finding is not surprising, as SCC has been noted to be the more prominent histopathologic type in developing countries^[6,7,23]. The proportion of SCC and AC did not change significantly among administrative regions when grouped by incidence.

In this study, patients 55 years and older constituted over 64% of all EC patients in the study population. Older age was also found to be a risk factor for EC in a variety of studies from developing and developed countries^[3,23,24]. The age distribution of patients did not change significantly among administrative regions when grouped by incidence.

The etiology of EC is important when considering factors that may contribute to a higher incidence in different regions of Tanzania. Some known risk factors for EC include age, sex, tobacco smoking, alcohol intake, obesity, and reflux^[3-5]. No significant differences between regions with respect to age and sex exist. There is no available information detailing possible regional differences in lifestyle factors related to EC such as tobacco smoking, alcohol intake, viral infections, or customs.

It is worth noting that over 20% of SCC and AC patients who identified from the medical records, had no treatment information recorded. Lack of availability of treatment information in the medical records could be due to death of patients before starting treatment or seeking alternative medicine outside ORCI.

Table 1 Descriptive information of the study population of 1332 esophageal cancer patients at Ocean Road Cancer Institute, Tanzania 2006-2013

	<i>n</i> (%)
Age group (<i>n</i> = 1329)	
15-34 yr	78 (5.9)
35-44 yr	141 (10.6)
45-54 yr	246 (18.5)
55-64 yr	374 (28.1)
65+ yr	489 (36.8)
Sex (<i>n</i> = 1332)	
Male	906 (68.0)
Female	426 (32.0)
Year starting treatment at Ocean Road Cancer Institute (<i>n</i> = 1332)	
2006	135 (10.1)
2007	140 (10.5)
2008	174 (13.1)
2009	202 (15.2)
2010	211 (15.8)
2011	171 (12.8)
2012	139 (10.4)
2013	160 (12.0)
Histopathologic diagnosis (<i>n</i> = 626)	
Squamous cell carcinoma	569 (90.9)
Adenocarcinoma	57 (9.1)
Smoking and alcohol history (<i>n</i> = 1332)	
Status	
Alcohol and smoking	396 (29.7)
Alcohol only	150 (11.3)
Smoking only	137 (10.3)
Neither alcohol nor smoking	371 (27.9)
Unknown	278 (20.9)

This study has several strengths. First, the large number of cases and several years of study population were assets for this study. Second, availability of reliable census data for Tanzania allowed us to calculate the incidence rates. Third, the limited number of treatment facilities in Tanzania also contributed to capturing most patients that had EC in Tanzania, who are usually diagnosed at advanced disease stages. Fourth, the availability of clinical information within ORCI and MNH records also contributed to our ability to accurately abstract information and cross-reference patients between the two hospitals.

The study also has a few limitations. While we included all the patients who were seen at ORCI for treatment, it is still a possibility that some patients might have died before reaching ORCI, and therefore contributed to possible underestimation of the incidence. There may also be additional missing cases due to difficulty in journey because of roads, climate, and terrain, patients not believing that treatments in the hospital can treat cancer, or because traveling to the hospital is too expensive. It is also possible that certain geographic areas of Tanzania experience these barriers to treatment and other lifestyle factors related to EC more strongly than others leading to a greater underestimation in those areas, however this information is not available and is a limitation of the study. Patients wishing to escape enumeration due to the large amount of people seeking treatment at ORCI also have the potential to seek treatment outside of Tanzania and contribute to

Table 2 Characteristics of esophageal cancer patients at Ocean Road Cancer Institute, Tanzania by histopathologic types *n* (%)

	Squamous cell carcinoma (<i>n</i> = 569)	Adenocarcinoma (<i>n</i> = 57)	<i>P</i> value
Sex			0.7338
Male	382 (67.1)	37 (64.9)	
Female	187 (32.9)	20 (35.1)

None	123 (21.6)	15 (26.3)	

Unknown histology and histology reports categorized as "other" were removed for this analysis.

possible underestimation of the incidence; however, this is unlikely because these patients would no longer receive the free universal medical care that is provided to citizens of Tanzania. Cross-referencing KCMC helped identifying patients not included in the ORCI records. However, this opportunity of utilizing the large hospital of KCMC with histopathologic resources was not available at small hospitals in Tanzania. The country has the goal of establishing more cancer centers in the future to avoid patients missing treatment. Finally, missing data was another limitation for this study^[25,26]. HIV status is not commonly recorded for EC patients in Tanzania, as they receive the same treatment regardless of HIV condition. Other studies have reported that HIV is a risk factor for EC^[27,28]. The missing data for tobacco smoking, alcohol intake, non-HIV viral infections, and other lifestyle factors, which are risk factors for EC, was also a limitation of this study^[3-5].

This study confirmed the clinical impressions of physicians at ORCI of a higher proportion of EC patients from the Kilimanjaro region. The study also revealed higher incidence in patients from the Central and Eastern regions compared to Western Tanzania. This study confirmed previous findings about higher rates among older patients, higher male-to-female ratio, and higher SCC compared to AC on EC in East Africa^[4,5].

Future studies should further address the difference in geographic distribution of EC in Tanzania. The studies should examine the etiological factors that may contribute to the higher incidence in Kilimanjaro and the Central and Eastern regions. Also, future studies should examine the possibility of underestimation of EC in Tanzania.

COMMENTS

Background

Esophageal cancers (ECs) are a top ten cancer both for incidence and

Table 3 Difference in proportion of histopathologic type, sex, and age group between different incident groups in Tanzania *n* (%)

	Group 1	Group 2	Group 3	Group 4	Group 5	P value
Histology						0.1269
Squamous cell carcinoma	276 (92.0)	54 (98.2)	90 (89.1)	39 (90.7)	110 (86.6)	
Adenocarcinoma	24 (8.0)	1 (1.8)	11 (10.9)	4 (9.3)	17 (13.4)

65+ yr	235 (36.3)	47 (40.9)	72 (33.3)	36 (33.6)	99 (40.6)	

Group 1-Group 5 reflect decreasing incidence of EC by region, *i.e.*, Group 1 were regions with highest incidence and Group 5 were regions with lowest incidence. Unknown histology and histology reports categorized as "other" were removed for histology analyses, unknown sex were removed for sex analyses, and unknown age were removed for age group analyses.

mortality, globally. ECs are very common in developing countries. Previous studies have observed high rates of EC in western Kenya and in the Rift Valley. Oncologists at the Ocean Road Cancer Institute in Dar es Salaam, Tanzania noted what they believed to be a large number of patients being referred from the Kilimanjaro region in Tanzania for EC compared to other regions. Because of this, medical records were used to determine the geographic distribution of EC in Tanzania for 2013-2006.

Research frontiers

This study brings to light the possibility of geographic differences in EC in Tanzania. This could lead to additional investigations to determine what etiologic factors may contribute to these differences. Additionally, the possibility of underestimation of EC in Tanzania should be further explored.

Innovations and breakthroughs

This is the first study to our knowledge to look at the distribution of EC in Tanzania. This study found that the regions of Dar es Salaam and Kilimanjaro had the highest incidences of EC in Tanzania. There were also generally higher incidences in the Eastern and Central parts of Tanzania compared to Western Tanzania.

Applications

This study brings to light differences in geographic distribution and potential access to care and underestimation of cancer patients in Tanzania.

Terminology

The histology of the cancer is determined in a laboratory and is based on which cell type the cancer derives from.

Peer-review

Peer-reviewers noted that the incidence of EC in Tanzania was estimated in this study and clinical, epidemiologic, and geographic distribution from medical record information was described. Previous findings on EC were confirmed in this study and a difference in geographic distribution was revealed. There is potential for underestimation of EC in this study and the information is limited to Tanzania.

Abstract

Myeloid sarcoma, also known as granulocytic sarcoma or chloroma is an unusual accumulation of malignant myeloid precursor cells in an extramedullary site, which disrupts the normal architecture of the involved tissue. It is known to occur more commonly in patients with acute myelogenous leukemia and less commonly in those with myelodysplastic syndrome and myeloproliferative neoplasm, such as chronic myelogenous leukemia. The most common sites of involvement include bone, skin and lymph nodes. However, rare cases have been reported in the gastrointestinal tract, genitourinary tract, or breast. Most commonly, a neoplastic extramedullary proliferation of myeloid precursors in a patient would have systemic involvement of a myeloid neoplasm, including in the bone marrow and peripheral blood. Infrequently, extramedullary disease may be the only site of involvement. It may also occur as a localized antecedent to more generalized disease or as a site of recurrence. Herein, we present the first case in the English literature of a patient presenting with an isolated site of myeloid sarcoma arising in the form of a colonic polyp which, after subsequent bone marrow biopsy, was found to be a harbinger of chronic myelogenous leukemia.

Key words: Myeloid sarcoma; Granulocytic sarcoma; Chloroma; Chronic myelogenous leukemia

Core tip: Myeloid sarcoma rarely presents in the gastrointestinal tract. Rarer still, does myeloid sarcoma manifest in the gastrointestinal tract without systemic involvement

by a myeloid neoplasm. This case report documents the first instance in the English literature wherein an isolated extramedullary site of myeloid sarcoma adopting the form of a colonic polyp was found to be a harbinger of chronic myelogenous leukemia.

Rogers R, Ettl M, Cho M, Chan A, Wu XJ, Neto AG. Myeloid sarcoma presenting as a colon polyp and harbinger of chronic myelogenous leukemia. *World J Gastrointest Oncol* 2016; 8(3): 321-325 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i3/321.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i3.321>

INTRODUCTION

Myeloid sarcoma (MS) is defined as an extramedullary tumor composed of myeloid precursors which efface the normal architecture of the involved tissue^[1-3]. There is a predilection for males and the median age at diagnosis is 56 years^[1-3]. MS occurring *de novo* is considered the equivalent of a diagnosis of acute myelogenous leukemia (AML)^[1-3]. It may precede or coincide with AML, signify a relapse in AML or constitute an acute blastic transformation of myelodysplastic syndrome or myeloproliferative neoplasms, such as chronic myelogenous leukemia (CML) (663, 742)^[1-3]. In this case report, we illustrate a novel presentation of this lesion, discuss its histologic appearance and hematopathologic workup, and review the pertinent literature.

CASE REPORT

A 55-year-old man with hematochezia for an unknown period of time underwent colonoscopy. A polyp (< 1 cm) was seen in the colon, 20 cm from the anal verge, and was retrieved. No other endoscopic findings were identified. HE slides and accompanying immunostained slides from the colon polyp were evaluated at our institution after referral from the outside institution. HE sections showed polypoid colonic mucosa markedly expanded by an infiltrate of sheets of large neoplastic cells exhibiting fine chromatin, prominent nucleoli and moderately irregular nuclear contour (Figure 1). The background stroma was expanded by a mixed cellular infiltrate. Immunohistochemistry revealed that the large, immature appearing neoplastic cells were diffusely positive for myeloperoxidase, lysozyme, CD43, CD15, and CD33 (Figure 2), while negative for B-cell markers (CD20, CD79a, Pax5), T/NK-cell markers (CD3, CD56, granzyme), and plasma cell marker (CD138). Few scattered neoplastic cells were positive for CD34 and CD117 (Figure 2). In addition, the neoplastic cells were negative for CD30, CD61 and glycophorin. The findings support the diagnosis of myeloid sarcoma (MS). The neoplastic cells were limited to the polyp with adjacent fragments of colonic mucosa in the biopsy showing unremarkable findings. During subsequent workup, the patient was noted to have a leukocytosis with a white blood cell count of 221 k/ μ L, Hgb 11.7 g/dL, MCV 89.1 fL,

and platelets 366 k/ μ L. The bone marrow biopsy showed hypercellular marrow with myeloid hyperplasia (Figure 3). There was no evidence of increased blasts (Figure 3). Cytogenetics reported a t(9;22) translocation in the bone marrow. A diagnosis of chronic myeloid leukemia, Ph+ was rendered. A retrospective FISH analysis for t(9;22) performed on the colonic polyp was negative. Because Ph chromosome + CML with MS in the colon is considered equivalent to a blast crisis, the patient received systemic chemotherapy, with protein kinase inhibitors (PKIs) and Dasatinib. Repeat colonoscopies two and three years later showed no residual or recurrent disease. Follow up bone marrow biopsies over a five-year period demonstrated a cytogenetic and morphologic complete response with minimal residual CML by molecular analysis. A bone marrow biopsy in 2014 showed that the number of cells carrying the t(9;22) translocation had risen from < 1% previously to 13%. The most recent bone marrow biopsy in March 2015 was stable with the prior biopsy. The patient did not receive bone marrow transplantation.

DISCUSSION

MS has been referred to as chloroma because of the green hue imparted to the cut surface of the tumor due to the presence of myeloperoxidase, an enzyme present in granulocytic cells. MS is known to occur in patients with various myeloid neoplasms. It occurs predominantly in four clinicopathological situations: (1) as a harbinger of AML in the non-leukemic patient; (2) as a sign of impending blast crisis in CML or leukemic transformation in myelodysplastic disorders; (3) as an additional manifestation in patients with known AML; and (4) as an isolated event, preceding the onset in the marrow by months to years^[4-9].

Our case showed an unusual presentation of hematochezia resulting from an isolated colonic polyp which subsequently revealed Ph+ CML upon workup. This unexpected diagnosis of MS, an AML equivalent, prompted the systemic chemotherapy and evaluation for potential bone marrow transplant as a future therapy modality. Recognition of MS is clinically critical for the choice of treatment modality. However, the majority of MS do not produce clinical signs and symptoms, hence the difficulty in making the diagnosis either clinically or histologically; it is most often discovered at autopsy^[4]. Soft tissue, bone/spine, skin, lymph nodes and the periosteum are the commonest sites of involvement. MS infrequently involves the gastrointestinal tract^[7-12]. Neiman *et al.*^[13] reported 61 such tumors and found gastrointestinal involvement in only 4 (7%) of the tumors^[3]. Choi *et al.*^[7] reported 8 cases where the small bowel and large intestine were affected. It has been reported that the ileum is the most affected area in the intestine^[14]. Isolated primary involvement of the colon and rectum is exceedingly rare with secondary extension from the peritoneum being more common^[7]. Several reported cases of MS presented as an intraluminal polypoid mass, diffuse polyposis^[7], or rarely, coexisting

Figure 1 Fragments of polypoid colonic mucosa (A) markedly expanded by a hypercellular infiltrate (B) composed of large immature-appearing neoplastic cells with prominent nucleoli (C) (HE stain; 4 ×, 10 ×, 40 ×).

Figure 2 Immunohistochemical studies demonstrate diffuse positivity for CD33 signifying myeloid origin (A), weak, granular CD34 staining highlighting immature cells (B) (strong CD34 staining highlights endothelial cells), and CD117 highlighting scattered large, immature cells (C) (immunohistochemistry; 10 ×, 20 ×, 10 ×).

Figure 3 Bone marrow biopsy shows a hypercellular marrow (A) with myeloid hyperplasia (B) without an increased number of blasts by CD117 (C) (HE; 10 ×, 40 ×; immunohistochemistry; 20 ×).

with adenoma^[12]. Our case is one of the few cases that presented as polyp in the large intestine without any other manifestation of a leukemic process and the first case to reveal Ph+ CML upon subsequent workup.

When present in the gastrointestinal tract, particularly in the intestine, the most common complication of leukemic involvement is massive hemorrhage, perforation, necrosis, acute or intermittent abdominal pain from partial to complete bowel obstruction and intussusceptions^[4,15,16]. Nevertheless, MS of the gastrointestinal tract can be also an isolated manifestation in the absence of any hematologic disorder, thereby precluding an overt diagnosis of MS^[4,7,9,17,18]. The diagnosis of MS can be challenging and confused with other malignant tumors by

histomorphologic evaluation. The morphologic features of the tumors can be poorly differentiated or that of nondistinct hematolymphoid neoplasms with little or no evidence of myeloid differentiation by morphology. To that end, a significant proportion of tumors (47%-56%) are initially misdiagnosed as malignant lymphoproliferative disorders including Hodgkin lymphoma, lymphoblastic lymphoma, Burkitt's lymphoma, large cell non-Hodgkin lymphomas, small round blue cell tumors (Ewing sarcoma, rhabdomyosarcoma, neuroblastoma, medulloblastoma), or poorly differentiated carcinoma^[14,19]. An accurate diagnosis of MS is of great clinical importance in the ongoing management of hematologic malignancies, and must be distinguished from extranodal lymphoma

and other entities aforementioned, in order to achieve optimal therapeutic benefit and avoid detrimental outcome^[12,19]. If left untreated, the majority (88%) of MS patients progress to AML within 11 mo whereas a much longer disease free interval is noted in patients receiving upfront treatment with AML chemotherapy^[12]. Of note, patients with isolated MS of the GI tract who are treated with standard induction chemotherapy appear to have a substantially lower probability of subsequent development of leukemic form of AML^[7,20].

The current World Health Organization classification system states that MS most commonly consists of myeloblasts with or without maturation that partially or totally efface the tissue architecture in an extramedullary site^[1]. Tumors with other hematopoietic elements such as erythroid precursors or megakaryocytes are rare and may occur in conjunction with transformation of myeloproliferative neoplasms^[1,3]. In a significant proportion of cases, MS displays myelomonocytic or pure monoblastic phenotypes^[1-3]. The common cytogenetics abnormalities include trisomy 8, t(8;21), inv(16), and rearrangement involving MLL^[1]. Of note, it bears mentioning that extramedullary hematopoietic tumor (EMT) is not considered the same tumor, has a different prognosis, warrants different treatment strategy and is not covered here.

In our patient with Ph+ CML, myeloid sarcoma in the colon polyp failed to demonstrate the presence of t(9;22) translocation by FISH analysis. There have been reported cases of development of clonal unrelated AML or myeloid sarcoma in CML patients. These patients usually had a prolonged history of CML with interferon and busulphan treatment or tyrosine kinase inhibitor (TKI) treatment^[21,22], which was not the case with our patient. The possibility of a false negative result exists with FISH analysis. However, given the limited material, further confirmatory testing by cytogenetic analysis or molecular sequencing studies could not be performed.

As a general rule, systemic chemotherapy is recommended, given that MS has a dismal prognosis with a median survival of 9 mo from the time of diagnosis^[23,24]. Because most cases of MS progress to AML, the majority of investigators recommend the treatment for AML^[4,7,25]. Most of the tumors respond to chemotherapy or external radiation. Patients with MS should also be considered as high risk AML with a poor outcome and an early and intensive therapy according to AML protocols, possibly including allogenic/autologous bone marrow transplantation in the first remission, is strongly suggested in order to avoid systemic involvement which could occur with the use of only local surgical or radiation therapies^[4,26]. The clinical behavior and response to therapy seem not to be influenced by any of the following factors: Age, sex, anatomical site(s) involved, *de novo* presentation, histological features, immunophenotype, cytogenetic findings or clinical history related to AML, myelodysplastic syndrome, and myeloproliferative neoplasms^[1,3]. Patients who undergo allogenic or autologous bone marrow

transplantation seem to have a higher probability of prolonged survival or cure^[1,3,27]. Our patient is still living at the time of this report, six years from his initial presentation.

In summary, MS presenting as a colonic polyp is infrequent. We describe an unusual presentation and emphasize the need to be aware of granulocytic sarcomas presenting in the GI tract, as they may precede or occur concurrently with acute myeloid leukemia, or reveal blastic transformation of chronic myeloproliferative disorders or myelodysplastic syndromes. MS can be easily misdiagnosed in this site, especially without a previous history of such disease. Indeed, experienced pathologists encounter difficulty with this lesion as incorrect initial diagnosis occurs in up to 50% of cases, most of which are diagnosed as high grade non-Hodgkin's lymphoma. Therefore careful evaluation of morphology for evidence of myeloid differentiation, use of an immunohistochemistry panel, and high index of suspicion when confronted with a less differentiated neoplasm are required to avoid diagnostic pitfalls. Awareness and prompt recognition of this disease entity is of great clinical importance given that an early start of anti-leukemic therapy could lead to a longer survival for these patients. The prognosis is in general poor and comparable to that of other acute leukemias^[4].

COMMENTS

Case characteristics

A 55-year-old man with no significant medical history presented with hematochezia.

Clinical diagnosis

Colonoscopy revealed a subcentimeter colon polyp located 20 cm from the anal verge.

Differential diagnosis

Hyperplastic polyp, adenomatous polyp, malignant polyp.

Laboratory diagnosis

White blood cell count was elevated (221 k/ μ L).

Pathological diagnosis

Myeloid sarcoma forming a colon polyp with subsequent cytogenetic studies of a bone marrow biopsy revealing chronic myelogenous leukemia (CML).

Treatment

The patient received systemic chemotherapy including protein kinase inhibitors and a tyrosine inhibitor, Dasatinib.

Related reports

There are infrequent reports of isolated primary involvement of the colon and rectum by myeloid sarcoma. This case is one of a few documented instances of myeloid sarcoma presenting as a colon polyp without any manifestations of a leukemic process and the first to reveal Ph+ CML upon subsequent workup.

Term explanation

Myeloid sarcoma is an extramedullary tumor composed of myeloid blasts with or without maturation which effaces the normal architecture of the involved

tissue.

Experiences and lessons

This case report serves to illustrate a unique manifestation of myeloid sarcoma. CML with myeloid sarcoma is considered equivalent to a blast crisis, and should be treated accordingly.

Peer-review

The paper is well-written. This is an interesting case.

INTRODUCTION

Primary cardiac liposarcoma is exceedingly rare and its metastatic potential varies based on the actual tumor subclass. Intestinal intussusception is also an uncommon cause of abdominal pain and bowel obstruction in adults and it usually generates at a malignant lead point in this age group. We report a case of a primary cardiac dedifferentiated liposarcoma in a pregnant woman causing small bowel seeding leading to bowel intussusception.

CASE REPORT

A 29-year-old female with recent history of surgically resected intra-cardiac liposarcoma presents to the hospital at 27 wk of gestational age with complains of sudden onset of abdominal pain associated with intractable nausea and vomiting.

Three months prior to this presentation, the patient was admitted with severe shortness of breath and dyspnea on exertion. She was found to have a left intra-atrial mass on a transthoracic echocardiogram involving a large portion of the left atrium, anterior leaflet of the mitral valve and pulmonary venous system causing complete occlusion of the right inferior pulmonary vein. Cardiac magnetic resonance imaging confirmed the lesion (Figure 1). The patient underwent resection of the mass and porcine mitral valve replacement. In addition, she also had pulmonary venous endarterectomy. Due to the size of the mass with significant extension into the pulmonary venous vasculature, a complete en-block resection could not be performed. Postoperative course was complicated by a transient 3rd degree atrio-ventricular block. She was discharged on post-operative day 14. Outpatient tumor staging included non-contrast MRIs of the brain, abdomen and pelvis that were negative for any metastatic disease.

On this presentation to the hospital, an magnetic resonance imaging (MRI) of the abdomen and pelvis was performed for severe abdominal pain, which revealed an entero-enteric left upper quadrant intestinal intussusception with proximal small bowel dilation suggestive of a mechanical small bowel obstruction (Figures 2 and 3). After an unsuccessful trial of conservative management with nil per os and naso-gastric tube decompression, she developed acute cardiopulmonary decline associated with significant fetal cardiac distress. A multi-disciplinary meeting was held and she had an emergency caesarian section, exploratory laparotomy and placement of a transcutaneous cardiac pacemaker prior to the surgical interventions. A healthy, viable 950 g female infant was delivered. At exploratory laparotomy, a 10 cm long intussuscepted small bowel segment without evidence of ischemia, beginning at 50 cm from the ligament of Treitz was identified. After several and unsuccessful manual attempts at reducing this bowel segment, partial small bowel resection of the affected area with end-to-end anastomosis was performed.

The surgically resected specimen showed two polypoid

Figure 1 Cardiac magnetic resonance imaging showing a large mass in the left atrium.

Figure 3 Magnetic resonance imaging of the abdomen showing an entero-enteric intussusception in the left upper quadrant.

lesions, which were 5 cm and 1 cm in their greatest dimension. Pathology was consistent with pleomorphic neoplasm with spindle cells, giant cells, vesicular nuclei with macro nuclei and occasional intra nuclear inclusions (Figures 4 and 5). Immunohistochemical staining was positive for Murine Double Minute (MDM) 2 and CDK 4. The histological features were identical to the original neoplasm seen in the heart 3 mo earlier (Figure 6). Post operatively the patient developed respiratory failure and was not able to be weaned off the ventilator. On post-operative day 8, the family decided to withdraw care.

Figure 4 Normal small bowel mucosa (left hand corner) in contrast to infiltrative area of increased cellularity (right lower hand corner).

Figure 6 Poorly differentiated malignant neoplasm composed of variably spindled polygonal or histiocytoid cells and irregular vesicular nuclei consistent with a dedifferentiated liposarcoma.

Figure 5 High power: Population of poorly differentiated malignant cells that are high grade (pleomorphic, hyperchromatic and contain increased mitotic activity) and are similar to the intracardiac dedifferentiated liposarcoma.

Unfortunately, the patient passed away the same day.

DISCUSSION

Primary cardiac neoplasms are exceedingly rare. Secondary (metastatic) cardiac lesions are 20-40 times more common than primary tumors^[1,2]. Malignant cardiac neoplasms constitute between 15%-25% of these primary lesions and sarcomas are found to be the most common malignancy^[3,4]. Liposarcoma accounts for about 13% of primary malignant tumors of the heart^[5]. There are five histological subtypes of these adipocyte precursor tumors including well differentiated, dedifferentiated, myxoid or round cell type, pleomorphic and mixed variant. Dedifferentiated liposarcoma commonly arises from the retroperitoneum and extremities and carries a lower incidence of distal seeding compared to the pleomorphic variant^[6-8]. Most common sites of metastasis include the lung, liver, bone, brain and soft tissues. Metastasis to the small bowel is rare with only few previously reported cases in the medical literature.

Surgical management is the preferred approach for cardiac liposarcoma, given its metastatic potential and the significant associated cardiorespiratory morbidity.

Intestinal intussusception is a rare cause of intestinal

obstruction in adults accounting for 1%-5% of the cases^[9]. It is defined as telescoping or prolapsing of a proximal intestinal segment into the adjacent more distal bowel segment secondary to peristaltic movements. Depending on the location of intestinal segment involved, intussusceptions are classified as enteroenteric, ileocolic, ileocecal or colocolonic. Majority of cases in adults are related to pathologic conditions that serve as a lead point for initiation of the prolapsing process. Intestinal diverticulum, luminal strictures and benign or malignant neoplasm are some of the more common causes^[9,10]. Enteroenteric intussusceptions due to malignant conditions accounts for up to 30% of all cases^[11]. Metastatic disease, adenocarcinoma and small bowel lymphomas are some of the leading metastatic causes^[12].

Clinical presentation varies depending of the degree of obstruction and ranges from chronic abdominal pain to intractable nausea, vomit and frank hematochezia in cases of complete obstruction associated with intestinal ischemia. Computer tomography scan of the abdomen and pelvis is the preferred imaging modality, with reported accuracy rates from 30%-100%^[12]. Abdominal Ultrasound and abdominal MRI are two other alternatives and can be used in pregnancy to minimize radiation exposure to the fetus.

Surgical resection of the intussuscepted area is the treatment of choice in the adult population^[9]. Although surgical resection was performed in our patient, with appropriate treatment of intestinal obstruction, her simultaneous pregnancy, heart block and respiratory condition increased her overall risks for mortality.

There have been few reported cases of liposarcoma causing metastasis to the small bowel. To the best of our knowledge, this is the first reported case of a primary cardiac dedifferentiated liposarcoma causing metastasis to the small bowel with associated intussusception.

COMMENTS

Background

Primary cardiac liposarcoma is exceedingly rare and its metastatic potential

varies based on the actual tumor subclass.

Research frontiers

Intestinal intussusception is also an uncommon cause of abdominal pain and bowel obstruction in adults and it usually generates at a malignant lead point in this age group.

Innovations and breakthroughs

The authors report a case of a primary cardiac dedifferentiated liposarcoma in a pregnant woman causing small bowel seeding leading to bowel intussusception.

Applications

On this presentation to the hospital, a magnetic resonance imaging of the abdomen and pelvis was performed for severe abdominal pain, which revealed an entero-enteric left upper quadrant intestinal intussusception with proximal small bowel dilation suggestive of a mechanical small bowel obstruction.

Peer-review

The case is interesting, well written and easy to read. References are new and adequate.

World Journal of Gastrointestinal Oncology
Volume 8 Number 4 April 15, 2016

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Oncology*, Karl-Friedrich Becker, PhD, Professor, Institute of Pathology, Technical University of Munich, D-81675 Munich, Germany

AIM AND SCOPE

World Journal of Gastrointestinal Oncology (*World J Gastrointest Oncol*, *WJGO*, online ISSN 1948-5204, DOI: 10.4251) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGO covers topics concerning carcinogenesis, tumorigenesis, metastasis, diagnosis, prevention, prognosis, clinical manifestations, nutritional support, molecular mechanisms, and therapy of benign and malignant tumors of the digestive tract. The current columns of *WJGO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Oncology is now indexed in PubMed, PubMed Central.

Abstract

MicroRNAs (miRNAs) are key regulators involved in various tumors. They regulate cell cycle, apoptosis and cancer stemness, metastasis and chemoresistance by controlling their target gene expressions. Here, we mainly discuss the potential uses of miRNAs in colorectal cancer (CRC) diagnosis. We also shed light on the important corresponding miRNA targets and on the major regulators of miRNAs. Furthermore, we discuss miRNA activity in assessing the prognosis and recurrence of CRC as well as in modulating responsiveness to chemotherapy. Based on the various pro-oncogenic/anti-oncogenic roles of miRNAs, the advantages of a therapeutic strategy based on the delivery of miRNA mimics are also mentioned. Together, miRNA seems to be an excellent tool for effectively monitoring and targeting CRC.

Core tip: MicroRNAs (miRNAs) regulate oncogenesis, metastasis and chemotherapy by controlling corresponding target gene expressions. Here, we shed light on the diagnostic and prognostic value of some miRNAs in colorectal cancer and potential miRNA-based therapy was also discussed. We hope that this review will offer useful information for researchers who work in a related field.

INTRODUCTION

MicroRNAs (miRNAs) are endogenous short non-coding RNAs that downregulate target gene expressions by binding to their 3'-UTR^[1]. MiRNAs function as regulators in a broad biological process. Dysregulation of miRNAs exerts a strong influence in disease progression by changing target gene expressions in various tumors^[2,3]. More and more data have suggested that miRNAs could be potential biomarkers of early-stage colorectal cancer (CRC) since they are unable to be degraded easily and their expression levels in colorectal polyps, blood and stool may give a hint of the occurrence of the disease. CRC accounts for 10% of new cancer cases and is one of the leading causes of death worldwide (over 1.23 million deaths per year)^[4]. To date, the common methods for CRC early diagnosis are computed tomography (CT), colonoscopy and fecal occult blood test (FOBT)^[5]. However, CT has a low sensitivity for the diagnosis of early CRC and could result in a large radiation exposure^[6]. Colonoscopy is also expensive and increases the risk of morbidity or mortality due to perforation of the gut^[7], although it can effectively detect neoplastic occurrence and allow for the removal of polyps when found. FOBT is commonly used but other digestive diseases such as ulcerative colitis and hemorrhoids may also cause blood in stool^[8] so the detection of FOBT is not a sensitive test for an early diagnosis. Taken together, current methodologies for early detection are neither sensitive nor specific. Differential miRNA expression in CRC individuals vs normal individuals is a common event and may be pivotal for tumor onset and progression. What's more, some dysregulated miRNAs are associated with progression and grade malignancy of CRC. Multiple studies have identified the values of miRNAs in CRC diagnosis. Some reports indicated that changed expression levels of miRNAs correlate closely with cancer progression and prognosis^[9-11]. Here, we review the literature to summarize the association of some important miRNAs with early-stage diagnosis, prognosis and recurrence of CRC and to discuss some miRNAs that might give a hint to guide treatment decisions (Table 1).

MiR-21

MiR-21 is one of the most extensively investigated oncogenic miRNAs whose expression is frequently upregulated in CRC^[12-14]. Overexpression of miR-21 is closely correlated with CRC cell proliferation, invasion, lymph node metastases and advanced clinical stage, all of which are the main prognostic factors for CRC. MiR-21 can downregulate several tumor suppressor genes, including PTEN and RECK. The tumor suppressor protein PTEN acts as a lipid phosphatase to dephosphorylate phosphatidylinositol 3,4,5-trisphosphate (PIP3), antagonizing the PI3K/Akt pathway^[15]. This pathway has an important effect on numerous biological functions, such as cell proliferation, adhesion, angiogenesis, migration, invasion, metabolism and anti-apoptosis^[16]. Besides, the key action of RECK (reversion-inducing cysteine rich protein with kazal motifs) is to suppress the cell metastasis by

inhibiting matrix metalloproteinases (MMPs) involved in the breakdown of the extracellular matrix (ECM)^[17]. All of these suggest the oncogenic role of miR-21 in CRC.

CRC tissue has been extensively reported on, as discussed in head and neck squamous cell carcinoma (HNSCC), non-small-cell lung cancer (NSCLC) and carcinomas of the digestion system^[18,19]. Moreover, some but not all polyps end up as malignant tumors through a string of increased genetic events. Therefore, it is important for early diagnosis to determine which polyp has the potential to become invasive carcinoma and then to remove it early. Accumulating studies show that miR-21 is correlated with the malignant progression of polyps and is highly expressed in CRC^[20-22]. Yamamichi *et al.*^[23] evaluated the expression of miR-21 during CRC progress in 39 surgically excised colorectal tumors and 34 CRC endoscopically resected colorectal polyps using nucleic acid *in situ* hybridization and found that miR-21 keeps increasing from precancerous polyps to early cancer, further increasing from the early to advanced stage of CRC. MiR-21 from CRC tissues may also be used to identify prognosis. Oue *et al.*^[12] used formalin-fixed, paraffin-embedded (FFPE) tumor tissues from 301 CRC patients at different TNM stages to discuss the relationship between miR-21 and prognosis and found that high miR-21 expression is significantly associated with poor survival. Furthermore, a meta-analysis of miR-21 expression level in 1174 CRC tissues suggested that increased miR-21 can be predictive of poor survival; however, CEA level shows no correlation with miR-21 expression^[24]. The relationship between Pdc4 (programmed cell death 4) and miR-21 is of great interest as well because miR-21 posttranscriptionally regulates Pdc4 and Pdc4 suppresses invasion and intravasation by suppressing the expression of the invasion-related urokinase receptor (*u-PAR*) gene *via* the transcription factors Sp1/Sp3^[25]. More importantly, Pdc4 was revealed by Asangani *et al.*^[26] to be a novel and independent prognostic factor in CRC. All of these suggested that miR-21 may be a poor prognostic biomarker. Consistently, the expression of miR-21 in a Japanese cohort ($n = 156$) and a German cohort ($n = 145$) was measured and analyzed by Harris's group. Elevated expression of miR-21 is correlated with poor prognosis in both stage II/III Japanese and stage II German cohorts^[12]. Similar results were also observed in another Japanese cohort^[11], American^[13], Hong Kong^[13], Czech^[27] and Danish^[28,29] cohorts of CRC patients.

In addition, the prognostic significance of miR-21 level was investigated in 306 patients with CRC at each Dukes' stage. However, a significant prognostic impact is not demonstrated in the analysis of Dukes' stage A patients, which may be due to the low rate of recurrence and death. This study showed that high miR-21 expression indicates poor overall survival (OS) and disease-free survival (DFS) in patients of Dukes' stage B, C and D^[30]. The prognostic value of miR-21 was also assessed for TNM stage. The TNM system describes a degree to which the tumor has invaded the

Table 1 Overview of functions of microRNAs in colorectal cancer

MiRNA	Disease progression	Biomarker	Treatment
MiR-21	Increased miR-21 correlated with CRC cell proliferation, invasion, lymph node metastases and advanced clinical stage ^[11,23,24] MiR-21 keeps increasing during the process from precancerous polyps to early cancer ^[20] High expression of miR-21 associated with poor progress in the stage II / III Japanese ^[11,21] and stage II German cohorts ^[21] , Hong Kong ^[25] , Czech ^[26] and Danish ^[27,28] cohorts of CRC patients	Increased miR-21 as an indicator for poor OS and DFS in patients of Duke stage ^[29] Elevated miR-21 as a marker for lymph metastasis in patients of TNM stage ^[30] MiR-21 in serum ^[33] as a noninvasive marker to detect early stage of CRC	Decreased miR-21 sensitizes CRC cells to 5-FU-treatment ^[21]
MiR-29	Elevated miR-29a is significantly correlated with metastasis, especially liver metastasis ^[38,39,42] Upregulation of miR-29a associated with a better outcome at 12 mo ^[43,44] High miR-29b expression associated with higher 5-yr DFS and OS ^[48]	MiR-29a as a biomarker for early detection of CRC and prediction of survival ^[38,43,44] MiR-29b as a biomarker for 5-yr DFS and OS (stage III CRC) ^[48]

MiR-124a	High frequency of methylation of miR-124a in chronic inflammation and CRC ^[65,66] Methylation of miR-124a is emerging during oncogenesis in UC patients and could be used to estimate individual risk for cancer ^[71]	The methylation level of miR-124a as a factor for evaluating the risk of carcinogenesis in UC patients ^[71]	
MiR-130b	High level of miR-130b in advanced tumor stages (III-IV), miR-130b-PPAR γ axis plays a novel role in progressing towards more invasive CRC ^[77] MiR-130b inhibits CRC cells migration ^[75]	Increased miR-130b in advanced tumor stages ^[77]	
MiR-139-3p	Decreased miR-139-3p in CRC tissues ^[82,83] Downregulation of miR-139-3p associated with poor survival, especially in patients with TNM stages I and II ^[82]	MiR-139-3p as a marker for poor survival ^[82] MiR-139-3p in plasma used for predicting occurrence of CRC ^[84]	
MiR-155	High expression correlated with an advanced TNM stage and metastasis ^[85] Increased expression of postoperative miR-155 correlated with recurrence and metastasis of CRC ^[87]	MiR-155 as a prognostic maker for OS and DFS of CRC patients ^[11,86]	
MiR-224	Increased expression of miR-224 associate with tumor growth and metastasis of CRC ^[90] MiR-224 inhibits CRC cells migration ^[95]	MiR-224 as a predictor for the short-time relapse and shorter metastasis-free survival ^[90-93]	Suppression of miR-224 sensitizes CRC to chemoradiotherapy ^[94]
MiR-378	MiR-378 is up-regulated in CRC samples ^[96,97] and promotes cell survival, invasion, and angiogenesis ^[98,99] Expression of miR-378 is increased in plasma of CRC patient, and rapidly goes down within 4-6 mo after surgery ^[103] Decreased miR-378 in CRC tissues and cell lines is associated with increased the size of tumor, metastasis and short OS ^[104,105]	MiR-378 in plasma used to predict the occurrence of CRC ^[103] Reduction of miR-378 in CRC tissues as a predictor for short OS ^[104]	

UC: Ulcerative colitis; CRC: Colorectal cancer; OS: Overall survival; DFS: Disease-free survival.

intestinal wall and spread to the regional lymph nodes as well as distant organs. Compared to T1, T2 and T3 cases, Harris's group found that miR-21 expression level is significantly elevated in T4 cases. A similar result was also observed in the comparison of N1 to N0^[12]. Besides, patients with a high level of miR-21 expression are insensitive to 5-FU therapy, while decreasing miR-21 enables patients to achieve a better response to 5-FU. Recently, anti-miRNA based therapies have achieved primary progress in treatment of patients with chronic hepatitis C infection^[31]. Hence, anti-miR-21 based therapies seem to be promising for the future.

More importantly, the prognostic value of miR-21 in serum and stool of CRC patients has also been extensively investigated. Due to the ineffectiveness of a

direct amplification method, the importance of circulating miR-21 was vague^[32]. Recently, TaqMan assays as an effective approach was used by Kanaan *et al.*^[33] and they found dramatically upregulated plasma miR-21 in patients with CRC. Toiyama *et al.*^[14] systematically investigated the expression of miR-21 in medium collected from 2 CRC cell lines and serum from 12 CRC patients and 12 healthy volunteers and concluded that miR-21 is a secretory miRNA. They further expanded verification of circulating miR-21 expression in 246 CRC cases, 53 controls and 43 patients with polyps. They also tested whether serum miR-21 reflects that of CRC tissues in 166 matched CRC specimens. MiR-21 significantly increases in serum from patients with precancerous polyps and CRCs. Notably, its expression decreases in patients' serum after surgery.

Moreover, serum miR-21 expression shows an apparent difference between patients with precancerous polyps and controls. Accumulated miR-21 level is correlated with tumor size, metastasis and poor survival. Thus, miR-21 in serum could be an ideal noninvasive biomarker to detect CRC early and evaluate the prognosis. Additionally, the expression of miR-21 in stool samples is different in healthy individuals compared to CRC individuals. Link *et al.*^[34] found higher expression of miR-21 in stool from 29 patients with CRC compared to 8 healthy individuals. A similar result was also revealed by Wu *et al.*^[35] from 88 patients with CRC and 101 healthy controls. Furthermore, miR-21 in later TNM carcinoma stages was reported to exhibit a more pronounced expression^[36]. To sum up, miR-21 expression could be a promising biomarker to predict the outcome of CRC patients.

MiR-29 family

MiR-29 family consists of three members: MiR-29a, miR-29b and miR-29c. Members of this family have been shown to be dysregulated in many different types of cancers. MiR-29 family members exert function by targeting genes involved in cell proliferation, senescence and metastasis at genetic and epigenetic levels, which makes them effective regulators of tumorigenesis and cancer progression^[37].

MiR-29a: Huang *et al.*^[38] analyzed 100 CRC samples and 59 controls and found that the expression levels of miR-29a in plasma are significantly upregulated. The authors further investigated the diagnostic significance of plasma miR-29a in 37 early lesions of CRC and found an obvious increase in miR-29a expression compared to that of the control, suggesting the plasma miR-29a appears to be a novel biomarker for early detection of CRC^[38]. In addition to serving as a noninvasive tool to detect the CRC earlier, the prognostic value of miR-29a can also be applied to the early detection of CRC metastasis. Tang *et al.*^[39] analyzed the expression levels of miR-29a and KLF4 mRNA in 85 cases using quantitative real-time polymerase chain reaction (qRT-PCR). Because KLF4 has been identified as a novel target of miR-29a, KLF4 inhibits metastasis through inhibition of MMP2 and upregulation of E-cadherin^[40,41]. Tang *et al.*^[39] found that low KLF4 mRNA expression is correlated with metastasis. More importantly, a correlation between miR-29a expression and metastasis was observed in this study, with elevated miR-29a indicating metastasis and worse survival of CRC patients. Wang *et al.*^[42] recruited a total of 114 participants, including 58 liver metastatic patients and 56 non-metastatic CRC patients, into their study since colorectal liver metastasis is most common. They discovered that the expression of miR-29a in the serum is significantly elevated in colorectal liver metastatic patients. Besides, the significantly elevated expression of miR-29a was found in CRC patients with advanced tumor T stage, while miR-29a shows a non-significant elevation in patients with advanced tumor N stage. Consequently,

they discovered that miR-29a can serve as a promising non-invasive, economic screening tool for early detection of colorectal liver metastasis^[42]. In conclusion, high expression of miR-29a is associated with poor prognosis and metastasis.

With regards to the prediction of CRC early recurrence, Kuo *et al.*^[43] found that both miR-29a and miR-29c show significantly decreased expression levels in 43 patients with early recurrence compared to 35 patients of non-early recurrence. Increased miR-29a or increased miR-29c suggests a better outcome at 12 mo. However, only miR-29a can be used as a predictor of the early recurrence. That miR-29c fails to predict the early recurrence may be due to a short follow-up or a small sample size^[43]. Furthermore, the prognostic value of miR-29a was also found in stage II CRC. Weissmann-Brenner *et al.*^[44] examined the microRNA array expression profile in 51 stage I and 59 stage II CRC samples and then 903 miRNA expressions were verified by qRT-PCR. The authors defined poor prognosis as recurrence within 3 years after surgery. Their data revealed that in stage II, miR-29a solely shows an obvious difference between patients with good prognosis and those with poor prognosis. However, in stage I, there are no miRNA with different expressions between the two groups. The result showed the prognostic value of miR-29a on the recurrence in patients with stage II. They also concluded that higher expression of miR-29a is associated with a longer DFS^[44].

MiR-29b: As a member of the miR-29 family, miR-29b is the most highly expressed in the miR-29 family and is found at two genomic loci^[45]. MiR-29b can inhibit proliferation and induce apoptosis in CRC cells and mediate the inhibition of epithelial-mesenchymal transition (EMT), which is closely related to the prognosis of CRC. Moreover, Yuan *et al.*^[46] performed qRT-PCR to test miR-29b in 41 matched-paired CRC samples and reported that miR-29b is significantly decreased in CRC, suggesting that miR-29b is associated with tumor size, advanced clinical stage and lymph node metastasis of CRC^[46,47]. Furthermore, Inoue *et al.*^[48] analyzed miR-29b expression in 245 patients with CRC. The patients were divided into two groups: Those under the median (low) and those above the median (high) of miR-29b expression. Their analysis revealed that high miR-29b expression is significantly associated with higher 5-year DFS and OS. In sub-analyses by each stage, they found that miR-29b expression has a prognostic impact on 5-year DFS solely in patients with stage III CRC, which showed that low miR-29b expression is an independent predictor of a reduced 5-year DFS. In addition, low miR-29b expression is predictive of lymph node metastasis and a pathological T classification, indicating the prognostic value of miR-29b in stage III CRC^[48]. Hence, the dysregulation of miR-29a and miR-29b can serve as a biomarker to predict early recurrence and shorter DFS in CRC.

MiR-34

The miRNA-34 family (miR-34a, miR-34b and miR-34c) has been reported to be a tumor suppressor regulated by the TP53 and DNA hypermethylation. The miR-34 family influences a series of cancer cell activities, such as stemness, metastasis and chemoresistance^[49]. It is well known that miR-34 is directly regulated by p53 at transcriptional level and miR-34 exerts p53 downstream effects through targeting c-MET, CDK6 and c-MYC to regulate proliferation arrest and to induce apoptosis^[50]. MiR-34a treatment results in downregulation of NOTCH1 and induction of apoptosis^[51]. The expression level of miR-34a is crucial for CRC cells to self-renew or divide. In addition, the NOTCH signaling regulates asymmetric division of stem cells. High miR-34a levels downregulate NOTCH signaling and suppress symmetric division, thus reducing the production of colon cancer stem cells (CCSC)^[52,53].

Proteinase activated receptor 2 (PAR2) is positively correlated with tumor progression in CRC. Ma *et al.*^[54] described that miR-34a is inhibited by PAR2, resulting in the upregulation of Cyclin D1 and TGF- β in CRC cells. MiR-34a promoter methylation in CRC tissues is associated with metastasis. Consistently, in 101 of 111 CRC tissues and in 9 of 9 cell lines, the miR-34 family is epigenetically silenced; hence, the authors pointed out that the methylation of miR-34a promotes motility and metastasis^[55,56]. In another study, the downregulation of miR-34a was noticed in some CRC patients, indicating the role of miR-34a in CRC development^[57].

The potential treatment value of miR-34a was also tested. In 5-FU-resistant CRC DLD-1 cells, low levels of miR-34a were observed. The restoration of miR-34a significantly sensitizes cells to 5-FU treatment and inhibits cell growth^[58]. Furthermore, miR-34a as a recurrence biomarker has been investigated. In two independent cohorts of 268 CRC patients, miR-34a expression is positively associated with DFS survival and can serve as a prognostic factor for recurrence of CRC. In addition, compared to patients with p53-negative expression, miR-34a is much higher in those with p53-positive expression. The authors concluded that miR-34a inhibits cell growth and invasion of CRC in a p53-dependent manner and predicts recurrence in stage II and III CRC patients^[59].

Most recently, the effects of the miR-34 family on prognosis was also systematically surveyed in CRC and an increased miR-34b/c predominantly expressed in stromal tissues was revealed to be associated with poor prognosis in CRC^[60]. The relationship between miR-34b/c and the development of disease was investigated in CRC samples from 159 American and 113 Chinese by qRT-PCR. They found that miR-34b/c was accumulated in advanced tumors and associated with poor cancer-specific mortality in two independent cohorts. TP53 regulates the expression of miR-34b/c at transcriptional level. Moreover, compared with epithelial tissue, miR-34b/c is enhanced greatly in cancer stroma. Collectively, miR-34 b/c may contribute to cancer-stromal interaction associated with CRC progression. All data presented

above revealed that the miR-34 family might be an ideal tool to predict the prognosis and recurrence in CRC.

MiR-124a

MiR-124a is known as a tumor suppressor gene, which has been shown to downregulate oncogenic cyclin-dependent kinase 6 (CDK6) involved in carcinogenesis, resulting in cell-cycle arrest at the G1-S checkpoint^[61,62]. MiR-124a was reported to be expressed at low levels in CRC due to the methylation^[63]. On one hand, miR-124a is the most frequently methylated in CRC compared to other tumor types, indicating the methylation status of miR-124a may be a specific marker for CRC. As mentioned by Deng *et al.*^[64], the lower expression of miR-124a is associated with the methylation of it and the treatment with 5-aza-2'-deoxycytidine can induce the expression of miR-124a. Among CRC, cancer of the pancreas, stomach, liver, lung, breast, kidney and prostate and melanoma, they found that CRC shows the highest frequency of methylation of miR-124a and a high frequency of methylation of miR-124a was also observed in polyps^[65,66]. Together, the methylation of miR-124a may be an early event in all pathways of colorectal carcinogenesis. On the other hand, the transcription of miR-124a is controlled by DNA methylation of the promoter regions of three miR-124a isoforms (miR-124a-1, 2 and 3) in CRC^[61,62,67,68]. It was known that aberrant methylation of miR-124a is induced in chronic inflammation^[69]. In the colorectal mucosa of pediatric patients with ulcerative colitis (UC), miR-124a was reported to positively regulate the expression of signal transducer and activator of transcription 3 (STAT3), which is a major factor in inflammatory response^[70], indicating that silencing of miR-124a is related to the promotion of inflammation in colorectal mucosa through the STAT3 signaling pathway. Ueda *et al.*^[71] tested the miR-124a level in 40 UC patients without CRC, 4 patients with CRC or dysplasia, 8 sporadic CRC patients and 12 normal controls. They found that miR-124a-1, 2 and 3 genes are all methylated and cyclin-dependent CDK6, as the target of miR-124a, is elevated in neoplastic samples. The methylation level of miR-124a-3 is significantly higher in pancolitis than in HV and methylation levels in long-standing UC are higher than in short-term UC. Moreover, in contrast to patients without long-standing UC and pancolitis, the methylation level of patients with these risk factors shows a 7.4-fold increase. Collectively, methylation of miR-124a-3 is emerging during oncogenesis in UC patients and could be used to estimate individual risk for cancer.

MiR-130b

Previous studies demonstrated that miR-130b is significantly dysregulated in some tumors, such as CRC, clear cell renal cell cancer (ccRCC), liver cancer, osteosarcomas and pancreatic cancer, and contribute to the tumorigenesis^[72-76]. In 52 pairs of pancreatic cancer tissues, Zhao *et al.*^[72] showed that miR-130b is significantly downregulated, which is correlated with a worse prognosis, increased tumor size, late TNM stage,

lymphatic invasion and distant metastasis of pancreatic cancer. Wu *et al.*^[74] used the microarray technology to profile miRNA expression of 28 localized and metastatic ccRCC specimens and 78 benign tissues and samples from ccRCC patients who had at least 5 years follow-up if no metastasis developed. They speculated that miR-130b is associated with ccRCC metastasis and prognosis. However, in CRC, Colangelo *et al.*^[77] identified that miR-130b directly targets peroxisome proliferator-activated receptor γ (PPAR γ). Furthermore, they provided data that miR-130b exerts biological functions mostly through suppression of PPAR γ , leading to deregulation of E-cadherin, Snail, PTEN and VEGF. As the enhanced miR-130b was found in III-IV tumor stages of CRC, they proposed that the miR-130b-PPAR γ axis plays a novel role in progressing towards more invasive tumors. Thus, miR-130b-PPAR γ may be a promising biomarker to predict prognosis. On the other hand, we previously reported the inhibitory function of miR-130b in migration and invasion of CRC because it downregulates the expression of integrin β 1^[75], which mediates cell migration in a wide variety of human cancers. Blocking integrin β 1 can inhibit the transformation of human breast cancer cells^[78,79]. All of the above gave us a hint that miR-130b may have potential value in the prognosis of CRC.

MiR-139-3p

Previous studies reported the abnormal expression of miR-139-3p in some types of human cancers, such as adrenocortical cancer, clusters in bladder carcinoma and CRC^[80-82]. Accumulating evidence suggested the potent role of miR-139-3p as a molecular biomarker for CRC. Chen *et al.*^[83] screened the difference of miR-139-3p expression among CRC tissues, matched normal samples and celecoxib-treated HT-29 CRC cells through miRNA microarray, then verified the readout by qRT-PCR. They found that miR-139-3p is downregulated in CRC tissues and that the expression of miR-139-3p is different from the early to advanced stage. Similar data were also reported by Kanaan *et al.*^[84] in that miR-139-3p in plasma may be used to distinguish CRC patients and normal individuals by examining 12 healthy controls and 20 CRC patients. Therefore, miR-139-3p may have a potential role in CRC early diagnosis. In addition, miR-139-3p may be related to poor prognosis of CRC. Liu *et al.*^[82] examined the expression level of miR-139-3p in 63 pairs of CRC and adjacent tissues. Compared with the adjacent normal controls, miR-139-3p expression levels in CRC tissues are notably decreased and decreased miR-139-3p is significantly associated with poor OS, especially in patients with TNM stages I and II. In conclusion, miR-139-3p has potential as an early diagnostic and prognostic biomarker for CRC.

MiR-155

MiR-155 is encoded by the non-protein-coding transcript of the B-cell integration cluster gene (*BIC* gene). Altered expression of miR-155 has been described in multiple

tumors, reflecting staging, progress and treatment outcomes. Zhang *et al.*^[85] found a significant increase in miR-155 in cancer tissues compared to the matched normal samples after analyzing 76 clinical samples of patients with CRC. MiR-155 can suppress E-cadherin and upregulate ZEB-1 through promoting expression of claudin-1, leading to increased cell migration and metastasis. Furthermore, there is a correlation between miR-155 expression and lymph node metastasis, advanced TNM stage and distant metastasis. Together, all of these results indicated that miR-155 plays an important role in CRC development and metastasis^[85]. In another study, Shibuya *et al.*^[11] revealed that patients with increased miR-155 show poorer OS and DFS than those with decreased miR-155, suggesting that miR-155 has independent prognostic values for OS and DFS of CRC patients. The link of miR-155 with the poor prognosis in CRC was also proved by Lv *et al.*^[86] by multivariate analysis. Consistent with the data above, Hongliang *et al.*^[87] assessed the levels of serum carcinoembryonic antigen (CEA) and miR-155 in 84 matched-pairs specimens from patients with CRC before and after surgery. It is well known that the CEA is mainly used for prognosis, observation of curative effect and monitoring recurrence and metastasis in CRC. The authors found that miR-155 expression is significantly increased in CRC tissues and is notably associated with tumor relapse and metastasis. Before surgery, miR-155 expression in patients correlates positively with the serum CEA levels and the high postoperative miR-155 expression level is associated with the short duration before the serum CEA level increases again^[87]. Moreover, Lv *et al.*^[86] discovered that there is no change in serum miR-155 expression level between controls and stage I CRC patients after measuring the serum of 146 CRC patients and 60 healthy controls. However, there is a great elevation of miR-155 expression in stages II-IV patients. Thus, miR-155 in serum cannot be used as a biomarker for early diagnosis^[86]. Taken together, miR-155 in tissues combined with serum CEA could provide concrete clues for the diagnosis of CRC and prediction of recurrence.

MiR-224

MiR-224 is consistently reported to be upregulated in CRC and it can potentially affect many cellular processes associated with cancer, including cell proliferation, growth, differentiation and cell death^[88]. High expression of miR-224 was observed in CRC tissues. The clinicopathological significance of miR-224 in CRC was recently evaluated in 110 CRC patients by Liao *et al.*^[89] who found that increased expression of miR-224 is significantly associated with an aggressive phenotype and poor prognosis of CRC. They also pointed out that miR-224 accelerates the G₁/S-phase transition through activation of Akt/FOXO3a signaling by targeting PHLPP1 and PHLPP2, antagonists of PI3K/Akt. MiR-224 also downregulates p21Cip1 and p27Kip1 and upregulates

cyclin-D1. Therefore, miR-224 promotes CRC tumor growth^[89]. The study by Nicoloso's group^[90] supported that miR-224 is an activator for CRC metastasis *via* targeting SMAD4 and miR-224, alone or combination with SMAD4, may be an independent prognostic marker for survival of patients with CRC. Clinical outcomes correlated with miR-224 status were analyzed in 6 sets of 449 CRC cases in order to assess the difference in survival between patients with low or high levels of miR-224 expression. Their data indicated that miR-224 expression increases consistently with tumor burden and microsatellite stability status and enhances CRC metastasis through targeting SMAD4. Patients with high miR-224 levels display shorter OS in multiple CRC cohorts and shorter metastasis-free survival^[90,91]. Consistent with the data from Nicoloso's lab, Zhang *et al.*^[92] also pointed out that SMAD4 is regulated by miR-224, suggesting miR-224 as a new biomarker for recurrence of CRC. They collected a total of 108 stage I - II colorectal patients who received radical resection and evaluated clinicopathological information of 40 patients with tumor relapse and 68 without relapse within 3 years after surgery. Their data suggested that miR-224 is notably increased in CRC tissues and this upregulation is associated with recurrence and poor DFS. By analyzing precancerous polyps, a similar conclusion was also achieved by Adamopoulos *et al.*^[93]. In addition, miR-224 also has some links with the treatment of CRC. Preoperative chemoradiotherapy (CRT) is the standard treatment for locally advanced rectal cancer and miR-224 was found to result in an increased resistance to CRT in CRC cell lines^[94]. In another study, when the expression of miR-224 was investigated in 79 specimens from CRC patients and 18 healthy controls, miR-224 in CRC tissues was greatly downregulated. Moreover, miR-224 suppresses the migratory ability of the CRC cell line through targeting Cdc42. In a word, this research indicated the vital role of miR-224 in suppressing cell migration of CRC. They concluded that miR-224 might be used as a promising biomarker to predict CRC development. The high expression of miR-224 predicts the short-time relapse and shorter metastasis-free survival and besides, miR-224 can increase the resistance to CRT^[95]. Collectively, miR-224 may be a prognostic biomarker predicting the patients' survival outlook.

MiR-378

MiR-378 is expected to participate in the process of multiple tumorigenesis and play an important role in CRC. Previous studies demonstrated that miR-378 is upregulated in CRC samples^[96,97], targets the tumor suppressor genes Sufu and Fus-1 and regulates cancer progression by promoting cell survival, invasion and angiogenesis^[98,99]. The difference of miR-378 expression level between cancer individuals and healthy individuals in blood and tumor tissues was reported. For example, Hauser *et al.*^[100] reported that miR-378 in serum is significantly increased in 25 cCRC patients compared with 25 healthy individuals. Liu *et al.*^[101] showed that

serum miR-378 could serve as a novel noninvasive biomarker in gastric cancer detection. All of the above suggested that miR-378 might be a possible tumor biomarker. Moreover, miR-378 in plasma may have the highest predictive capability in CRC^[102]. The authors further investigated miRNA expression in the plasma of 65 CRC patients and 70 healthy individuals and found that miR-378 significantly increases in plasma from CRC patients once the level of miR-378 goes down notably after surgery. In addition, they also found that miR-378 expression decreases in patients who have no relapse within 4-6 mo after surgery, which further explained that plasma levels of miR-378 may be used to discriminate CRC patients from normal individuals^[102].

However, in another study, Zhang *et al.*^[103] pointed out the downregulation of miR-378 in 84 matched pairs CRC samples and cell lines. MiR-378 was considered a tumor inhibitor since it can suppress tumor cell growth in a nude mice model^[103,104]. In addition, there is a strong association between the reduction of miR-378 and increased tumor volume, metastasis and short OS of CRC patients. Consistently, miR-378 as a tumor suppressor was also observed by Wang *et al.*^[105] after analyzing the expression of miR-378 in 47 pairs of CRC samples. All of the above suggested that miR-378 plays a vital role in carcinogenesis and could serve as a biomarker to predict the outcome of CRC.

In a word, miR-378 may predict the presence of CRC and serve as a potential and reasonable biomarker for the early diagnosis of CRC.

CONCLUSION

MiRNA might be a powerful tool in diagnosis and treatment of CRC through modulating various crosstalks of oncogenic signaling pathways. MiRNAs we discussed here are, to date, the most extensively investigated tumor suppressor/enhancer miRNAs in CRC. Through *in vivo* and *in vitro* experiments, related miRNAs have been proved to be dysregulated in CRC and to be possible ideal diagnostic, prognostic and therapeutic tools (Table 1). However, some obstacles in miRNA-based therapies need to be overcome, such as degradation by nucleases, inefficient delivery to cells, fast blood clearance, renal toxicity and hemodynamic toxicity. Currently, much more efficient intracellular delivery systems are being developed to benefit miRNA-based clinical treatments, such as nanoparticle and the combination of miRNA in combination with other anticancer agents. In our review, contradictory findings regarding some miRNAs are introduced since we consider that the phenomenon could be explained by less informative clinical data, especially the lack of the definition of "healthy" control subjects, which will very likely affect the miRNA quality. Secondly, population ethnicity may be a potential confounding variable. Lastly, we hope that further studies concerning diagnosis and therapy will be done by more groups in the future in order to finally optimize the uses of miRNAs for

subsequent translation in the clinical setting.

Abstract

Helicobacter pylori (*H. pylori*) is one of the most widespread infections in humans worldwide that chronically infects up to 50% of the world's population. The infection is involved in the pathogenesis of chronic active gastritis, peptic ulcer, mucosa-associated lymphoid tissue lymphoma and gastric cancer, therefore, it has been

classified as class I definite carcinogen by the World Health Organization. Despite the established etiological role of *H. pylori*, its actual distribution and association with related diseases is controversial and there is a large intercountry variation especially among Asian countries. *H. pylori* infection is more frequent in developing countries like India, Pakistan, and Bangladesh as compared to developed Asian countries like Japan, China and South Korea. However, the frequency of gastric cancer is comparatively lower in India, Pakistan, and Bangladesh with that of Japan, China and South Korea. Such phenomenon of clinical diversity, defined as enigma, is judged by genetic variability of the infecting *H. pylori* strains, differences in the host genetic background in various ethnic groups, and environmental factors such as dietary habits. Most of the studies have so far focused on the bacterial factor while environmental issues, including dietary components, were not given due attention as one of the factors related with *H. pylori* associated gastric carcinogenesis. The dietary factor has been suggested to play an important role in *H. pylori* related carcinogenesis, and in this respect several studies have corroborated the intake of various dietary components as modulatory factors for gastric cancer risk. In this review, such studies, from *in vitro* experiments to clinical trials, are being focused in detail with respect to enigma associated with *H. pylori*. It may be conceivably concluded from the available evidence that dietary factor can be a game changer in the scenario of Asian enigma, particularly in high risk population infected with virulent *H. pylori* strains, however further affirmation studies are desperately needed to achieve conclusive outcomes.

Key words: *Helicobacter pylori*; Asian enigma; Gastric cancer; Dietary factor; Salt; Fermented food; Spices

Core tip: Despite the established etiological role of *Helicobacter pylori* (*H. pylori*), its actual distribution and association with related diseases is controversial,

especially among Asian countries, a phenomenon termed as Asian enigma. This is judged by genetic variability of the infecting *H. pylori* strains, diversity in the host genetic background, and environmental factors such as diet. Amongst these, the dietary factor was not given much attention. In this review, dietary components are focused in detail with respect to *H. pylori*-associated enigma with a specific emphasis and comparison of dietary ingredients between Asian countries in order to critically evaluate its role in Asian enigma.

INTRODUCTION

Helicobacter pylori (*H. pylori*) have been found in the stomachs of humans in all parts of the world. It is one of the most common bacterial infections worldwide, infecting more than half of the world's population^[1]. *H. pylori* infection in the stomach induces mucosal inflammatory response and oxidative stress that leads to diverse clinical outcomes in humans such as gastritis, peptic ulcer and gastric cancer^[2]. There is a strong correlation between prevalence of infection and socioeconomic status^[3]. In some developing countries 70%-90% of the population is infected with *H. pylori*, whereas in high-income countries the prevalence is 25%-50%. Most infections are acquired in childhood^[4,5]. However, the incidence of *H. pylori* infection is declining, and today only 10% of children in high income countries are infected^[6,7]. Regardless of the established etiological role of *H. pylori*, its actual distribution and association with related diseases is controversial especially in Asian countries. *H. pylori* infection is more frequent in developing Asian countries like Thailand, Malaysia, India, Pakistan, and Bangladesh, whereas, the occurrence of gastric cancer is comparatively lower than in developed Asian countries like Japan, China, and South Korea^[8-10]. Such phenomenon of clinical diversity, defined as Enigma, is judged by genetic variability of the infecting *H. pylori* strains with respect to virulence factors, difference in the host genetic makeup, and environmental factors such as dietary habits (Figure 1)^[11].

PREVALENCE OF *H. PYLORI* INFECTION IN ASIAN COUNTRIES

Epidemiological studies indicate that Asian countries have a high prevalence of *H. pylori* infection as compared to Western countries, with a correspondingly high incidence of severe gastroduodenal (GD) diseases, especially gastric neoplasia^[8]. However, the frequency of *H. pylori* infection differs markedly between and within populations

of different Asian countries. In developing countries like India, Pakistan, Bangladesh and Thailand, infection with *H. pylori* is more frequent among the general population^[9]. In contrast, in more industrialized and developed regions of Asia like Japan, China, and South Korea, frequency of *H. pylori* infection has been reported to be somewhat lower^[8]. Singapore is also in the same category and the prevalence of *H. pylori* infection is quite low compared to developing countries^[10].

FREQUENCY OF GASTRIC CANCER IN ASIAN COUNTRIES

Although the overall incidence of gastric cancer is declining, it is still the world's second most widespread malignancy, having been overtaken by lung cancer^[12]. There is a marked variation internationally in gastric cancer incidence with highest rates reported from Japan^[8,13]. It is noteworthy that despite Japan being a developed country with a lower prevalence of *H. pylori* infection, it has the highest frequency of gastric cancer. The annual incidence of gastric cancer in Japan is around 100 times higher than those in India. Similarly, the frequency of gastric cancer is quite high in China despite a lower frequency of *H. pylori* infection^[8]. Contrary, people living in underdeveloped countries of Asia with high frequency of *H. pylori* infection have a lower incidence of gastric cancer^[8,14]. Some studies from India revealed no correlation between *H. pylori* infection and gastric cancer, while studies from China and Japan are consistent with previous findings, affirming association between *H. pylori* infection and gastric cancer^[15-17]. It has also been observed that frequency of gastric cancer varies within regions of a particular country; for example, in Japan and India^[16,18]. These corroborations support a potential role of other factors in the diverse and contradictory presentation of gastric diseases in different regions and populations.

The above mentioned evidences point out the fact that only *H. pylori* infection is solely not enough to cause life threatening conditions like gastric cancer, highlighting the importance of factors behind enigma, like genetic variability of the infecting strain and infected individual, along with life style habits.

As much has been focused on the genetic differences of host and agent, therefore, in this review the basics of these factors will be covered, while more emphasis will be on environmental factors including life style and dietary components, to critically evaluate their plausible role in *H. pylori* associated enigma.

REASONS BEHIND ENIGMA

Bacterial factors

H. pylori is a micro-aerophil gram-negative bacterium with several flagella required for bacterial motility^[19]. Numerous biochemical factors are produced by *H. pylori* that are

Figure 1 Three main factors behind *Helicobacter pylori* associated enigma namely: (1) Bacterial virulence factors; (2) Host genetic factors; and (3) Environmental factors. *H. pylori*: *Helicobacter pylori*; cagA: Cytotoxin associated gene-A; VacA: Vacuolating cytotoxin A; IL-1: Interleukin-1.

important to the organism's survival, virulence and initiation of pathophysiological effects in the infected host. Multiple pathways are modulated after *H. pylori* infection either through direct interaction or *via* virulent factors injected in the host cell which leads to the pathological outcome. Some of the important virulence factors are mentioned below that are responsible for bacterial colonization and pathogenesis, which are postulated to play some role in enigmatic diversity of clinical outcomes.

It is postulated that all strains of *H. pylori* are not pathogenic and the genetic diversity of *H. pylori* virulence factors has been linked with clinical outcome. The most pathogenic and well-established cluster of virulence in *H. pylori* is the *cytotoxin associated pathogenicity island (cag PAI)*; this being a 27-gene locus that is present in a majority of the clinical strains found in Europe, United States and Japan. *H. pylori* strains with the cag PAI have been shown to be more virulent, with an increased risk of development of GD disorders like duodenal ulcers and gastric adenocarcinoma, than strains lacking the gene complex^[20]. The *cytotoxin associated gene A (cagA)* is located in the cag PAI, and encodes for the cagA protein. Inside the host cell the cagA interferes with cell signaling pathways and induces cytoskeletal rearrangements^[21,22]. It has been suggested that cag PAI positive strains are involved in the activation of transcription factor nuclear factor-kappa B (NF- κ B), resulting in production of inflammatory or carcinogenic molecules such as interleukin-8 (IL-8) or activation-induced cytidine

deaminase (AID)^[21-23]. The *in vitro* observation of large vacuoles in the cytoplasm of cells incubated with *H. pylori* lead to the discovery of the *Vacuolating cytotoxin A (VacA)*^[24]. VacA induces apoptosis in epithelial cells, but it is still not clarified why vacuolation is required for this type of apoptosis. The VacA protein inserts itself into the epithelial cell membrane and forms a channel through which bicarbonate and organic anions can be released^[25]. Several studies have documented the genetic polymorphism in VacA gene and have concluded that the presence of both cagA and VacA genotype s1/m1 is more associated with severe disease outcomes^[26-28]. The gene *babA2* encodes for the protein BabA, which is an outer-membrane protein. *H. pylori* strains that possess the *bab2* gene are associated with an increased incidence of gastric adenocarcinoma. BabA-expressing strains adhere more tightly to epithelial cells, which might promote pathogenesis^[29]. Another virulence factor, *iceA*, has been linked with peptic ulceration and increased mucosal IL-8 secretion^[30,31]. Although the above mentioned studies provide evidence for the linkage of genetic variation in *H. pylori* with the disease outcomes, it is still not always conclusive due to controversial results. Genotyping analysis of *H. pylori* from an Indian population showed high prevalence of pathogenic strains in both adults and children with GD diseases as well as in control subjects^[9,32]. However, the incidence of gastric cancer is quite low in India as discussed above. Hence other factors behind enigma play simultaneous role in producing the

final outcome of *H. pylori* infection.

HOSTS GENETIC FACTORS

As discussed above, the basis for the diverse clinical outcomes of enigmatic scenario particularly in Asian countries cannot be entirely explained on the strain genetic diversity, as most patients are infected by more virulent strains than in Western countries^[8]. Another reason behind enigma is the host genetic makeup or ethnicity. Infection with any microorganism results in immune response leading to expression of inflammatory cytokines. Polymorphism in the genes of these cytokines may affect the dynamics of response to any infection, including that of *H. pylori*. Few studies have reported such polymorphism in the gene cluster of IL-1, a proinflammatory cytokine with a potent acid inhibitory effect, and its association with gastric cancer risk^[33,34]. Polymorphisms in other candidate cytokine genes, such as tumor necrosis factor- α and IL-10, may enhance or suppress inflammation of the gastrointestinal (GI) mucosa resulting in different disease outcomes^[35,36]. Besides inflammatory cytokines, gastric atrophy associated with reduced acid secretion is also documented to be linked with the ethnic background. For example, the Japanese population has much lower acid secretion as compared to the western population^[37]. As reported, gastric atrophy occurs more readily in subjects with lower acid secretion than in those with high acid secretion^[38]. It was further confirmed by Kuipers *et al*^[39] that the use of proton pump inhibitors, drugs that reduce gastric acid secretion, in the patients of reflux esophagitis aggravated the severity of *H. pylori*-associated gastritis. This may be one of the reasons that the Japanese have high incidence of gastric cancer, as gastric atrophy is a precancerous lesion. In short, the above findings support the role of genetic makeup or ethnicity in *H. pylori*-associated enigmatic disease outcome but still further studies are required from other Asian countries like Malaysia, India or Pakistan to conclude the precise role of polymorphisms in specific genes or combinations of genes for disturbances in acid secretory output and gastric cancer risks in Asian countries.

DIETARY AND ENVIRONMENTAL FACTORS

Stomach and intestines are among the parts in our body that are exposed at maximum to our daily diet and of course environmental factors like personal hygiene can equally affect them. Hence, it is postulated that diet may play a critical role in GD disorders like peptic ulcer or gastric carcinoma. When talking about enigma associated with *H. pylori* under the light of recent scientific and molecular studies, dietary components can modulate the pathogenic processes by simple anti-oxidant to complex anti-carcinogenic activities. The paradoxical clinical outcomes after *H. pylori* infection might be crucially regulated by dietary habits of the

population, especially when talking about the Asian population under Asian enigma. It has been known since ancient times that healthy diet prevents digestive problems and avoid chronic malaise, but it was not long ago when the dietary factor was brought into focus with respect to *H. pylori* associated pathogenesis. It was first reported by Holcombe^[40] back in 1992 in his leading article on African enigma that environmental factors including dietary habits can influence the outcome of *H. pylori* infection. Several studies from various countries thereafter followed Holcombe's hypothesis and documented the plausible role of dietary components in disease outcome.

East Asian population and dietary habits

So as to discuss about Asian enigma, two sets of populations can be broadly classified as mentioned above; one with low incidence of gastric cancer and high prevalence of *H. pylori* such as the South Asian population including India, Pakistan, and Bangladesh and the second with high incidence of gastric cancer and low prevalence of *H. pylori* such as the East Asian population including Japan, China and Korea. Among the latter, Japanese researchers initiated the focus on the dietary factor in their population to uncover the plausible role of diet in Asian enigma not only by comparing it with western dietary habit but also within different regions of Japan^[8]. Both aggravating (negative) and alleviating (positive) effects of diet have been documented with respect to *H. pylori* associated pathogenesis but majority of the studies from Japan linked dietary components as a negative regulator. This may be due to the fact that the Japanese population is well recognized for high prevalence and mortality due to gastric cancer and the diet therein might be a negative regulator. However, it is interesting to note that different regions of Japan have a variable incidence of gastric cancer. For example, northern regions in Japan such as Akita prefecture have a higher prevalence of gastric cancer than the Southern region of Okinawa prefecture^[41]. While looking at the dietary pattern in Akita, it was found that salt has been highly consumed in this region almost double to that of Okinawa^[42]. This may further provide the convincing evidence that in a population of similar host genetic makeup and *H. pylori* strains, it may be due to different dietary habits, like high salt intake in that region that can lead to enigmatic outcomes.

High salt consumption is one of the most extensively investigated dietary component which is well known to increase the risk of gastric cancer^[43,44]. Furthermore, interesting data was published in a prospective study of a Japanese population which demonstrated the aggravating effect of high-salt diet in *H. pylori* infected subjects with an increase in gastric cancer risk, when compared with infected subjects with lower consumption of salt^[45]. This may be one of the leading clues for the potential role of diet in *H. pylori* associated enigma. *In vivo* studies have also shown that high salt not only

Figure 2 Multiple roles of salt in augmenting *Helicobacter pylori*-associated diseases. Salt can not only cause direct mucosal damage but also increase the colonization as well as virulent *Helicobacter pylori* strains. *H. pylori*: *Helicobacter pylori*.

directly damages the gastric mucosa but also increases the colonization of *H. pylori* in stomach resulting in loss of parietal cells, atrophy, and intestinal metaplasia^[46-48]. A recent study conducted in Mongolian gerbils provided the evidence that both *cagA*⁺ *H. pylori* strains and a high salt diet are synergistically significant risk factors for gastric adenocarcinoma compared with mutant *cagA* strain and a regular diet^[49]. An interesting finding was revealed by Loh *et al*^[49] that changes in salt concentration altered the gene expression in *H. pylori* especially *cagA* which was later observed in *H. pylori* infected gerbils as well^[50]. These findings provide evidence that salt can aggravate gastric mucosal damage in multiple ways, shown in Figure 2, which might form the basis of different disease outcomes in a genetically similar population like in Japan. It may be intriguing to evaluate the effect of high salt intake in different populations infected with *H. pylori* in a single study along with the genetic status of *H. pylori*. This may help in identifying the role of host genetic makeup in the presence of high salt intake and *H. pylori* infection in the process of gastric carcinogenesis.

Other than salt, high consumption of pickled, preserved, and smoked food in the Japanese population has also been postulated as a risk factor for gastric cancer^[43]. Pickled vegetables are also very much common in the East Asian region such as Japan, China, and Korea and are almost a part of daily cuisine. Nitrosamines are dietary carcinogens found in pickled and smoked food and their intake increased the risk of gastric cancer^[51,52]. It has been documented that nitrosamine can augment *H. pylori* associated gastric carcinogenesis not only in gerbils but in rhesus monkeys as well^[53,54]. A recent study in *H. pylori*-infected Chinese population documented the similar finding; that high intake of sodium, heme iron, and red meat increase the risk of gastric cancer while abundant consumption of fresh fruits decrease the risk^[55]. Another important source of carcinogens in the East Asian population is fermented products such as soybean pastes and kimchi, a traditional Korean dish made of fermented cabbage^[51,56]. Nan *et al*^[57] documented

the increase in gastric cancer risk in Korean subjects consuming kimchi and soybean pastes. This may again be due to the presence of nitrosated compounds in high quantity in such fermented products which have been reported to augment *H. pylori* associated carcinogenesis^[51,58]. In short, it can be retrieved from the above mentioned studies that the continuous intake of these salty, pickled, and fermented foods in the East Asian population might be a crucial factor in *H. pylori*-associated enigma of gastric cancer.

South Asian population and dietary habits

When it comes to the South Asian region, including India, Pakistan, and Bangladesh, dietary habits are quite different from those in East Asian population. It is due to this difference in dietary pattern that many researchers have postulated dietary habits as one of the important factors behind *H. pylori*-associated disease outcome and Asian enigma^[8,9,59]. One of the reasons behind this speculation is the low incidence of gastric cancer despite high prevalence of virulent *H. pylori* strains in South Asia^[60]. Although host genetic factors may also interplay in pathogenesis, diet can be quite crucial when comparing East with South Asian countries. As discussed above, some ingredients in the East Asian population diet are negative (aggravating) regulator in *H. pylori* associated pathogenesis, while in the case of the South Asian region, one can hypothesize that diet might be functioning as a positive regulator in alleviating *H. pylori*-linked diseases. This seems to be true to some extent under the light of available evidence. Consumption of salty, pickled, and fermented food is comparatively low in the South Asian region than in East Asian countries. Furthermore, the use of spices in daily cuisine and frequent over the counter use of herbal or traditional medicines can be a hallmark in different disease outcomes^[61]. It is interesting to note that the daily cuisine and dietary patterns in South Asian countries like India, Pakistan, and Bangladesh are quite alike, which to some extent, is a true copy of the

similarity in dietary habits between East Asian nations such as Japan, China, and South Korea.

Several studies from India have documented the plausible role of diet on the incidence of gastric cancer in different regions^[8,9]. Although the overall prevalence of gastric cancer in India is quite low when compared with Japan, it is worth to note that the frequency of gastric cancer differs in different regions of India, most probably due to differences in dietary habits of these regions; a pattern similar to that in Japan, as discussed above. Southern and eastern parts of India have high frequency of gastric cancer compared to the northern region. This is attributed to be due to frequent consumption of non-vegetarian food, like fish with excess spices and high salt. Contrarily, northern regions have a wheat-based vegetarian diet^[9]. A similar pattern is seen in the Kashmir region of India where esophageal and gastric cancer frequency is higher than other districts^[62]. This is again supposed to be due to high intake of dietary amines and nitrate in the Kashmir district^[63]. Another study by Mathew *et al*^[64] from south India documented the increase risk of gastric cancer with a high intake of rice, spicy, and high-temperature food. One of the limitations in these studies is the lack of consideration of *H. pylori* co-infection in the study subjects. However, one study by Phukan *et al*^[65] from South Indian region of Mizoram demonstrated the association of dietary components (fermented and smoked meat) with *H. pylori* infection with an increased risk of gastric cancer. These facts further ascertain the role of diet in the diverse prevalence of gastric cancer in the Indian population, thus highlighting its importance in enigma.

Several studies have shown protective effects of spices and medicinal plants against numerous diseases including *H. pylori* and GI disorders^[66-70]. It is worth mentioning here that in South Asian countries like India, Pakistan, Nepal, and Bangladesh, spices are also used as medicinal herbs as they possess medicinal values in the traditional system of medicine of these countries. In addition, many of these dietary spices are prescribed for the treatment of GI diseases^[67,71]. O'Mahony *et al*^[70] first reported the bactericidal and anti-adhesive activities of culinary herbs from Malaysia against *H. pylori*. Later, we reported in a series of studies the potential effect of commonly used spices and medicinal plants from Pakistan on *H. pylori* and its associated pathogenesis^[71-76]. All of the medicinal plants/spices used in these studies are also prescribed for the treatment of GI disorders. The results of these studies are very convincing, which reveals not only bactericidal (anti-*H. pylori*) activities of these plants but also anti-inflammatory effects against *H. pylori*-initiated pathological events. Spices like turmeric, nutmeg, mace, cardamom, black caraway, cumin, *etc.* which are part of daily cuisine in South Asian countries exhibited promising anti-*H. pylori* activities^[71]. We further documented that the plants, not having anti-*H. pylori* activity, can inhibit *H. pylori*-induced IL-8 secretion or reactive oxygen species (ROS) generation in gastric

epithelial cells. Both IL-8 and ROS are reported to play an important role in *H. pylori*-linked pathological sequel^[74]. Among the spices that inhibit IL-8 secretion, cinnamon showed most strong activity, and cinnamaldehyde was found to be the major reason for this effect^[76]. The major limitation with these studies was the use of only *in vitro* assays, which points out the dire need of *in vivo* or clinical trials with these herbs.

Some of the dietary components and spices have not only been examined against *H. pylori* in *in vitro/in vivo* assays but also in clinical trials. The most promising effects were demonstrated by the spice named turmeric or curcuma and its active ingredient curcumin. In *in vitro* assays, both turmeric and curcumin showed significant anti-*H. pylori* activity^[71,77]. Curcumin has also been documented to eradicate *H. pylori* in C57BL/6 infected mice and also reduced the level of gastric damage^[78]. Anti-inflammatory activity of curcumin was also documented by Foryst-Ludwig *et al*^[79] by decreasing *H. pylori*-induced NF- κ B activation and the subsequent release of IL-8. We also demonstrated that curcumin not only blocked NF- κ B activation but also suppressed the anomalous expression of AID, an enzyme highly linked with *H. pylori*-induced gastric carcinogenesis^[23]. Sintara *et al*^[80] reported the role of curcumin in Sprague-Dawley rats by reducing the gastric inflammation by inhibiting NF- κ B. Later, a clinical study demonstrated that curcumin based triple therapy significantly improved dyspeptic symptoms and reduced serologic signs of gastric inflammation even after 2 mo of the therapy^[81]. Hence, it can be postulated that the use of spices like turmeric/ cinnamon can, not only suppress *H. pylori* colonization, but also halt the inflammatory cascade initiated by *H. pylori*, ultimately preventing carcinogenesis.

Another commonly consumed cuisine ingredient in South Asian countries is garlic. Garlic or allium has revealed promising activities against *H. pylori*-induced gastritis model of Mongolian gerbils by decreasing the degree of gastritis^[82]. However, it has been described in the same study that *H. pylori* was not eradicated by the garlic extract treatment. A clinical trial was also conducted using garlic in *H. pylori* infected subjects revealing no effect on eradication of the bacteria^[83]. This suggests that garlic might only be helpful in attenuating *H. pylori*-induced pathological pathways while not killing the bacteria itself in *in vivo* and clinical settings. Overall these studies signify the potential role of dietary ingredients including spices in South Asian countries in modulating *H. pylori* associated pathological processes. However, it cannot be overlooked that the excessive and continued use of a spicy diet may act as an aggravating factor in *H. pylori*-infected individuals, a question still needed to be affirmed in the region of South Asia. Last but not the least, it is important to note that high amount of spices are always accompanied with high amount of salt to give proper taste. So it might be the salt as the main offender in these spicy diets rather than spices itself. It will be interesting to see the effect of a high intake of spices with or without excessive

Figure 3 Dual impact of diet in either aggravating or alleviating *Helicobacter pylori* linked diverse disease outcome. Dietary ingredients can equally increase or decrease the inflammatory cascade by modulating the expression of various molecules ultimately modifying the outcome of *H. pylori* infection. *H. pylori*: *Helicobacter pylori*; ROS: Reactive oxygen species.

salt either by *in vivo* experiments or clinical trials in *H. pylori*-infected subjects.

CONCLUSION

H. pylori associated pathological outcome is a result of chronic inflammation from years to decades, and as *H. pylori* alone is not enough to cause associated diseases, several factors can play an important role in the final outcome. Each of the factors discussed above behind enigma is plausibly exerting some influence in the variable incidence of gastric cancer in Asian countries. Along with genetic status of both *H. pylori* and host, diet can also modulate the clinical outcome by aggravating or alleviating *H. pylori*-linked pathogenic processes (Figure 3). In this review, plausible mechanisms by which diet can manipulate the enigmatic consequences of *H. pylori* infection are discussed. As evident from the high prevalence of *H. pylori* infection among South Asian countries in the studies mentioned earlier, these dietary ingredients can barely eradicate *H. pylori* in the doses that are consumed on a daily basis. However, it is quite evident from the discussion that the dietary factor can modulate *H. pylori*-linked pathogenesis either by decreasing the colonization of *H. pylori* or *via* hampering the production of inflammatory/carcinogenic mediators released after *H. pylori* infection. This can end up in perplexing clinical outcomes leading to enigma. Besides the negative or aggravating role of salt among daily dietary components, it may be too earlier to firmly pose any other ingredient as a positive or negative regulator in the scenario of Asian enigma. There is no doubt concerning the role of *H. pylori* as a significant and intriguing factor in causing chronic gastritis that may later predispose the infected host to develop gastric cancer, but the nature of our daily diet can undeniably define the future course of disease outcome.

Further large scale comparative studies are required on a national and international level, not only to identify perpetrators in our dietary habits but also to develop effective ways for preventing this cancer in high risk

populations, as chemoprevention seems to be the most practical way of controlling this deadly disease. It is needless to mention that while designing clinical trials or *in vivo* models, the triad of causing factors, *i.e.*, virulence of *H. pylori*, host genetic make up, and dietary habits should be considered, otherwise exhaustive efforts will again end up with no conclusive results.

Abstract

Surgical therapy for ulcerative colitis (UC) depends on the medical therapy administered for the patient's condition. UC is a benign disease. However, it has been reported that the rare cases of cancer in UC patients are increasing, and such cases have a worse prognosis. Recently, surgical therapy has greatly changed, there has been quite an increase in the number of UC patients with high-grade

dysplasia and/or cancer. These lesions are known as colitis-associated cancer (CAC). The relationship between inflammation and tumorigenesis is well-established, and in the last decade, a great deal of supporting evidence has been obtained from genetic, pharmacological, and epidemiological studies. Inflammatory bowel disease, especially UC, is an important risk factor for the development of colon cancer. We should determine the risk factors for UC patients with cancer based on a large body of data, and we should attempt to prevent the increase in the number of such patients using these newly identified risk factors in the near future. Actively introducing the surgical treatment in addition to medical treatment should be considered. Several physicians should analyze UC from their unique perspectives in order to establish new clinically relevant diagnostic and treatment methods in the future. This article discusses CAC, including its etiology, mechanism, diagnosis, and treatment in UC patients.

Key words: Inflammatory bowel disease; Ulcerative colitis; Colitis-associated cancer; Surgical therapy; Colorectal cancer surveillance

Core tip: Inflammatory bowel disease, especially ulcerative colitis, is an important risk factor for development of colon cancer. There has been quite increased in the number of patients who had high-grade dysplasia and/or cancer. The relationship between inflammation and tumorigenesis is well-established and in the last decade has received a great deal of supporting evidence from genetic, pharmacological, and epidemiological data. To avoid such a problem, there is a need for appropriate diagnosis and treatment. It should be considered that actively introduce the surgical treatment in addition to medical treatment.

Kinugasa T, Akagi Y. Status of colitis-associated cancer in ulcerative colitis. *World J Gastrointest Oncol* 2016; 8(4): 351-357 Available from: URL: <http://www.wjgnet.com/1948-5204/full/v8/i4/351.htm> DOI: <http://dx.doi.org/10.4251/wjgo.v8.i4.351>

INTRODUCTION

Ulcerative colitis (UC) is of unknown cause inflammatory bowel disease (IBD) associated with inflammation of the large intestine mucosa. UC number of the patients that have been recorded in Japan in 2014 at 166110 people, this number is increasing every year. As a recent problem, in patients with UC, it has been reported that it is easy to develop colorectal cancer (CRC). The longer the period of UC, the higher is the risk of developing UC-associated CRC. The mechanism of IBD-related colon cancer is different from sporadic CRC. The former is an inflammation-dysplasia-carcinoma sequence^[1] and the latter is from the adenoma-carcinoma sequence in sporadic CRC (Figure 1).

Therefore the UC patient becomes the indication of the operation when the pathological findings are demonstrated high-grade or multifocal low-grade dysplasia in colonic mucosal which means that the entire mucosal lining of the colon exposed to chronic inflammation is at increased risk of cancer^[1,2].

IBD

Crohn's disease (CD) and UC, which include IBD, is a chronic, relapsing inflammatory condition of the gastrointestinal tract. IBD has a clear pathological and clinical characteristic. Though many studies were performed about this cause of IBD for the past several decades, the cause is not yet clear. The only consensus was obtained about IBD which was deregulated the mucosal immune response in the host. Some various components, which including environmental intestinal epithelial cells, and microbial factors, genetic susceptibility, and components of the innate and adaptive immune system, are implicated in the pathogenesis of IBD.

Mechanism of colitis-associated cancer in UC patients

The connection between inflammation and tumorigenesis is well established, and in the last decade, a great deal of supporting evidence has been obtained through genetic, pharmacological, and epidemiological studies. IBD is an important risk factor for the development of colon cancer.

As a result has high mortality, it is difficult to treat colitis-associated cancer (CAC), which is the CRC subtype that is associated with IBD^[3]. When the patients with IBD are the higher the probability within 30 years disease duration, and > 50% of these patients will die from CAC^[4]. Some of the essential stages of cancer development, including the formation of aberrant crypt foci, polyps, adenomas, and carcinomas, are similar in noninflammatory CRC and CAC. However, several different pathogenic sequences CAC, has been reported including a well-defined inflammation and damage dysplasia cancer that occurs without the formation of the gland. Nevertheless, both of in the CRC and CAC had changed same genetic and signaling pathways which involving Wnt, β -catenin, K-ras, p53, and transforming growth factor (TGF)- β . However, the difference activation timing between

CRC and CAC were reported about p53, adenomatous polyposis coli (APC) and K-ras^[4,5]. A > 2-fold higher risk for colon cancer development with a family history of CRC have than without in IBD patients, suggesting an overlap in the mechanisms driving CRC and CAC^[6]. Kinugasa *et al.*^[7] also showed that high-grade dysplasia (HGD) and CAC in patients with UC results in an increase in β -catenin transcriptional activity that may contribute to increased claudin (CL)-1 expression. According to above things, the expression of CL-1 was increased in CAC and dysplasia than normal mucosa is likely to be involved in neoplastic progression in UC patients. Thus, I propose that there is a possibility that increased CL-1 expression may contribute to carcinogenesis in UC. CL-1 is a tight junction specific protein that was first described by Furuse *et al.*^[8] in 1998. The signaling pathways, including TGF- β /SMAD and β -catenin^[9,10] were interacted with the CL protein that is separate from their effects on the barrier function. We reported that CL-1 is regulated by β -catenin/TCF/lymphocyte-enhancer factor signaling^[11,12] suggests that the expression of CL-1 is concerned in β -catenin activation (Figure 2).

These mechanisms are the basis for the current discussion about CAC as well as for new approaches to prevention and therapy.

Is the frequency of colorectal cancer in UC patients higher than in the normal population?

Patients with IBD are at an increased risk of developing colorectal advanced neoplasia, including colorectal HGD and CRC^[13-16]. Chronic intestinal inflammation is considered to be a promoter of carcinogenesis^[17]. The two major drivers of the excess risk of CRC in IBD are disease extension^[18] and duration^[13]. Concomitant primary sclerosing cholangitis^[19], family history of CRC^[6], and active intestinal inflammation^[20-23] are the other established risk factors.
