Treatment of perianal fistula requires a multidisciplinary approach between surgery, gastroenterology, and radiology. Initial management begins with assessment of the extent and complexity of disease^[45]. Endoscopy evaluates the presence of proctitis, which is predictive of a non-healing fistula tract. Rectal examination under anesthesia helps identify and classify fistulas and enables control of the infection through drainage of the abscess and insertion of a seton. Magnetic resonance imaging (MRI) is considered the gold standard for imaging of PCD with higher specificity compared to transrectal ultrasound. It enables evaluation of the abscess volume and maximum fistula length and can be used to restage and assess response to treatment^[46].

Once the extent and nature of the PCD is characterized combination treatment consisting of surgical and medical therapy (TNF- α with or without immunomodulator) results in improved rates of fistula healing compared with surgery or medical therapy alone^[46-50]. Depending on the study, the endpoint may be fistula healing, usually defined as absence of fistula or drainage by medical examination, or clinical improvement, defined as reduction of symptoms or drainage.

Initially, the role of surgery is to control sepsis and define the anatomy of the fistula track after which definitive treatment can be planned. Surgical options for the treatment of perirectal abscesses or fistulas in patients with CD favor conservative approaches including incision and drainage and placement of non-cutting setons. Non-cutting setons preserve the integrity of the anal sphincter, drain fistula tracts and limit abscess formation and recurrences^[45]. More aggressive procedures including fistulotomy or advancement flap may be appropriate in certain circumstances but are generally avoided because they are associated with increased morbidity and risk of fecal incontinence.

According to recent literature the most effective approach for PCD consists of seton placement prior to starting medical treatment with anti-TNF- α agents or anti-TNF- α agents plus thiopurine^[50-53]. El-Gazzaz *et al*^[50] showed complete healing in 36.6% of patients treated with biologic agents plus surgery vs 26.5% for patients treated with surgery alone with a median follow-up of over 3 years but this was not statistically significant ($P = 0.1$). Bouguen *et al*^[51] reported a study of 156 patients with PCD treated with IFX. Sixty-two percent of patients also underwent seton placement and 56% were on concomitant immunomodulators. At a median follow-up of 57 mo, 46% of total patients and 69% of patients treated with IFX and seton placement for a

median of 8 mo had sustained complete fistula closure. Haennig *et al*^[52] reported data on 81 IBD patients with perianal fistula, 62 (80.5%) underwent drainage with loose seton plus IFX therapy and 73 (90%) received treatment with immunomodulators (either Azathioprine or Methotrexate) in addition to anti-TNF- α . At a median follow-up of 64 mo fistula closure was achieved in 75% of patients.

The need and timing of seton removal and the appropriate duration of anti-TNF therapy remain debated topics^[53]. Bouguen *et al*^[51] found improved outcomes when the seton was removed within 34 wk of starting biologic therapy. Haennig *et al*^[52] hypothesize that the optimal time for seton removal should be determined by the surgeon based on clinical characteristics and recommend that it be left *in situ* between 2 and 8.5 mo. Most series evaluate the status of the fistula by clinical examination, however there is increasing data that MRI may be the more accurate instrument to guide decisions regarding timing of seton removal. MRI often shows residual inflammation and disease activity even when the external tract is closed, which is the basis for recurrence^[45,46]. In terms of how long biologic therapy should be maintained, no consensus can be found in literature but there is a suggestion that long-term anti-TNF- α therapy is associated with better long-term results.

UC

Anti-TNF- α agents are approved to treat moderate to severe UC as second line treatment in patients refractory to corticosteroids and immunomodulators^[54-56]. IFX was approved for UC refractory to standard medications in 2006^[7], adalimumab was approved in 2012^[57,58] and recently, golimumab received approval in Europe and the United States^[59,60].

A recent meta-analysis^[8] demonstrated that anti-TNF- α therapy is more effective than placebo in reducing UC-related hospitalizations. The study analyzed results of IFX^[54], ADA^[55,56] and golimumab^[7,57] trials and found that IFX and ADA achieve long-term mucosal healing at 52-54 wk in 35.6% of patients compare to 16.8% in the placebo group. In addition IFX and ADA were able to reduce UC-related hospitalizations^[61-64] and IFX alone was superior to placebo in reducing the need for colectomy.

Postoperative complications

Unlike CD, in UC a proctocolectomy is curative and removes the risk of developing colorectal cancer. In the era of conservative management, the timing of surgery vs medical therapy with biologics or other medications is challenging^[65]. A colectomy for UC may be done as an emergent/urgent or elective procedure depending on the clinical scenario. An emergent/urgent colectomy is indicated for significant hemorrhage, perforation, megacolon, and severe colitis refractory to medical management. Elective colectomies may be performed in patients with UC that experience chronic symptoms

refractory to medical therapy, those who can't tolerate the adverse effects of medication^[66] and patients with high-grade dysplasia, multifocal low-grade dysplasia or cancer^[53]. There is increasing evidence that in current practice the threshold for surgery is too high and that it is important to consider surgery an alternative therapy rather than a failure of medical therapy^[65,67,68]. Roberts *et al*^[67] compared 3 years mortality for patients who had urgent or elective surgery vs medical management in over 28000 patients hospitalized with UC. The elective colectomy group had the lowest mortality rate (3.7%), while the medical management and urgent colectomy groups had similar mortality rates (13.6% and 13.2% respectively, $P = 0.001$).

In terms of the postoperative effects of anti-TNF therapy on surgery in UC patients, studies of IFX have shown differing results^[20,29,69-76]. The Cleveland Clinic group reported that patients undergoing restorative proctocolectomy with ileoanal pouch anastomosis (IPAA) who were treated pre-operatively with IFX had a 3.54 times greater risk of developing early complications ($P = 0.004$), with the rate of sepsis increased by 13.8 fold ($P = 0.011$), even though the majority of cases were done in 3 stages^[72]. However, Gainsbury *et al*^[69] demonstrated that preoperative IFX use was not associated with an increased risk of short-term postoperative complications after IPAA performed in 2 or 3 stages. They evaluated 81 patients, 29 treated with IFX within 12 wk of surgery and 52 not exposed to IFX. Overall short-term postoperative complications were similar between the IFX and NIFX groups (44.8% vs 44.2%, $P = 0.960$). Infections complications, defined as pelvic/intra-abdominal abscess or wound infection, were similar between the IFX and NIFX groups (17.2% vs 26.9%, $P = 0.32$). In multivariate analysis the risk of wound infection while correlated with a higher body mass index (odds ratio = 0.88, 95%CI: 0.78-0.9, $P = 0.049$) was not related with biologic treatment. Similar results were found by Ferrante *et al*^[70] who analyzed 119 patients undergoing restorative proctocolectomy with IPAA in 1 or 2 stages with 22 of the patients having received IFX 12 wk before surgery. Short-term post-operative complications were not significantly different between the two groups. The two predictors of short-term postoperative complications were use of moderate to high dose corticosteroids (> 20 mg of methylprednisolone for > 2 mo) and absence of a diverting ileostomy.

A recent meta-analysis^[73] of 5 studies including 132 patients on IFX who underwent a restorative proctocolectomy with IPAA in either 2 or 3 stages demonstrated an increase in total postoperative complications (OR = 1.80, 95%CI: 1.12-2.87), but not short-term infectious complications (OR = 2.24, 95%CI: 0.63-7.95) or non-infectious complications (OR = 0.85, 95%CI: 0.50-1.45) in the IFX group.

In our experience^[29], we found no correlations between exposure to IFX within 12 wk of surgery and the rate of postoperative adverse events in 237 UC patients (71 in the IFX group and 166 in NIFX group).

The majority of patients in our study underwent a three stage restorative proctocolectomy with IPAA with only 15 (10.6%) patients in the IFX group and 37 (9.8%) patients in the NIFX group undergoing a two stage procedure ($P = 0.94$).

Higher levels of IFX are associated with increased rates of remission and improved endoscopic outcomes but there is concern that it may be correlated with postoperative complications as well. Waterman *et al*^[19] analyzed 108 IBD patients who underwent a colectomy (94/108 for UC), 51 patients had received biologics before surgery and 57 patients had not and they found that preoperative biological therapy was not associated with increased rates of infectious complications or poor wound healing. Preoperative serum levels of IFX were measured within 2 mo of surgery using a microplate Enzyme linked ImmunoSorbent Assay with a cut-off value of 1.4 mg/mL for detectable levels and the association between serum IFX levels and short-term complications was assessed in 19 patients with UC. Of those 19 patients, 10 had detectable levels of IFX and 9 were undetectable. As expected, the group with detectable levels had a shorter time interval between the last dose of IFX and surgery (median 18 d vs 34 d, $P = 0.03$) and while the rate of wound infection trended higher in the detectable group, this was not statistically significant (3/10 vs 0/9 respectively, $P = 0.21$); there was no difference in the rates of any other complications. A limitation of the study is that the sample size was quite small and data from larger populations is needed to draw more definitive conclusions.

In a recent study published by Lau *et al*^[25] anti-TNF- α levels were measured in 217 IBD patients treated with biologic therapy prior to surgery. An anti-TNF- α value of ≥ 0.98 mg/mL was considered a detectable level even though a cutoff of ≥ 3 μ g/mL is usually used for clinical efficacy. Patients were stratified into: Low (0.98-3 μ g/mL), medium (≥ 3 μ g/mL ≤ 8 μ g/mL), and high (≥ 8 μ g/mL) level groups. Ninety-four of the 217 patients were diagnosed with UC of which 42 patients had a three stage and 52 had a two stage restorative proctocolectomy with IPAA. The infectious complication rate between the undetectable and detectable serum anti-TNF- α drug level groups was not significantly different (9% vs 12%, $P = 0.78$). The rates of overall postoperative morbidity (40% vs 47%, $P = 0.59$) and hospital readmission (19% vs 24%, $P = 0.67$) also did not differ. They concluded that even detectable levels of anti-TNF- α agents were not associated with adverse outcomes postoperatively.

CONCLUSION

Anti-TNF- α therapy for the treatment of IBD has improved long-term outcomes including symptom management, mucosal healing, and endoscopic recurrence and is being used earlier in the course of the disease and with increased frequency. However, surgery continues to be an important part of the management of both UC

and CD. While the data is mixed, increasing evidence is emerging that surgery can safely be performed while patients are undergoing biologic therapy. More data is needed on the impact that anti-TNF- α agents will have on the rates of surgical recurrence in CD.

Abstract

Laparoscopic lavage and drainage is a novel approach for managing patients with Hinchey III diverticulitis. However, this less invasive technique has important limitations, which are highlighted in this systematic review. We performed a PubMed search and identified 6 individual series reporting the results of this procedure.

An analysis was performed regarding treatment-related morbidity, success rates, and subsequent elective sigmoid resection. Data was available for 287 patients only, of which 213 (74%) were actually presenting with Hinchey III diverticulitis. Reported success rate in this group was 94%, with 3% mortality. Causes of failure were: (1) ongoing sepsis; (2) fecal fistula formation; and (3) perforated sigmoid cancer. Although few patients developed recurrent diverticulitis in follow-up, 106 patients (37%) eventually underwent elective sigmoid resection. Our data indicate that laparoscopic lavage and drainage may benefit a highly selected group of Hinchey III patients. It is unclear whether laparoscopic lavage and drainage should be considered a curative procedure or just a damage control operation. Failure to identify patients with either: (1) feculent peritonitis (Hinchey IV); (2) persistent perforation; or (3) perforated sigmoid cancer, are causes of concern, and will limit the application of this technique.

Key words: Diverticulitis; Colon; Emergency surgery; Outcome; Laparoscopy

Core tip: Laparoscopic lavage and drainage for purulent peritonitis due to perforated diverticulitis has many limitations, which have been overlooked in the previously published case series of the literature. The available data from the unique RCT indicates that these results will not be reproduced in a trial where patients' selection is avoided. There are three main limitations to the technique: (1) the risk of missing a persistent (incompletely sealed) perforation - 30% of cases; (2) the risk of missing fecal peritonitis enclosed within the sigmoid loop - 10% of cases; and (3) the risk of missing sigmoid carcinoma - 10% of cases).

Gervaz P, Ambrosetti P. Critical appraisal of laparoscopic lavage for Hinchey III diverticulitis. *World J Gastrointest Surg* 2016; 8(5):

INTRODUCTION

Severe septic complications of sigmoid diverticulitis, such as abscesses and peritonitis, are common emergencies in Western countries. While patients presenting with Hinchey stages I / II (pericolonic and extra-mesocolic abscesses) are conservatively managed, those presenting with purulent (Hinchey III) or feculent (Hinchey IV) peritonitis undergo emergency surgery^[1]. Most surgeons agree that a Hartmann procedure remains the best approach for Hinchey IV patients^[2]. This operation, however, is associated with significant morbidity and mortality, as well as the need for a second operation, 3 mo later, to restore intestinal continuity. Patients with Hinchey III diverticulitis may benefit from less invasive approaches, and since the 1990s, laparoscopic lavage and drainage (LLD) was proposed as an alternative to resection procedures (either with or without primary anastomosis) for Hinchey III patients presenting with generalized purulent peritonitis^[3] (Table 1). According to its proponents, this novel approach represents a definitive treatment for most patients presenting with diffuse purulent peritonitis of diverticular origin^[4].

Unfortunately, 20 years after its first description^[5], it appears that LLD has failed to gain popularity: There are less than 15 series published so far, and many are limited to less than 10 patients, which is surprising in the view of the large number of emergency procedures performed for complicated sigmoid diverticulitis. As an example, between 1996 and 2006, there were 500000 admissions in English NHS hospitals for a primary diagnosis of diverticular disease and 22000 patients underwent emergency surgery^[6]. The aim of this systematic review is to critically assess the existing data regarding the use of LLD for Hinchey III diverticulitis.

DEFINITIONS

Hinchey III diverticulitis

Hinchey III stage is defined by the presence of pus in the four quadrants of the abdomen. It's a generalized peritonitis of diverticular origin but there is absence of feces in the abdominal cavity. Hinchey III is a life-threatening condition with a high morbidity and mortality. Many patients present often with renal failure, dehydration, and require immediate surgical attention. Of note, the distinction between stages III and IV is not possible by clinical examination, and the definitive diagnosis is made in the operating room during surgical exploration: In some cases, computed tomography scan imaging provides useful preoperative information, and may demonstrate the presence extra-intestinal feces (Figures 1 and 2).

Either the presence of a small amount of fluid in the Douglas pouch, or the presence of free air in the

peritoneal cavity are not sufficient criteria for classifying the patient's condition as Hinchey III. Both findings are common in Hinchey I / II patients, but these latter two categories have a much better prognostic due to the absence of diffuse peritonitis.

Laparoscopic lavage-drainage

Laparoscopic lavage is a technique, which aims at treating the consequences of the perforation, and not the cause itself. Since many patients have, at the time of surgery, a perforation, which is sealed by the omentum or the small bowel, no attempt should be made to mobilize the sigmoid loop. A 4-trocars technique is recommended in order to gain access to the Douglas pouch and thoroughly wash the abdominal cavity with 5-10 L of warm saline, until the fluid in the suction catheter comes back clear. Two drains are left in the Douglas pouch and the left iliac fossa usually, and intravenous (*iv*) antibiotics prescribed for 5-10 d postoperatively^[7].

RATIONALE

Laparoscopic lavage is primarily a damage control approach, which aims at minimizing the consequences, and not treating the cause of peritonitis itself. In the case of Hinchey III diverticulitis, the assumption made by the proponents of the technique is that the sigmoid perforation is sealed at the time of the operation, so that LLD and *iv* antibiotics are sufficient to cure the patient. This may be true for some Hinchey III patients, but recent evidence suggest that 37% of patients who underwent emergency sigmoid resection showed persistent bowel perforation on review of histology^[8].

The critical point is to determine whether: (1) LLD is a definitive technique - meaning that the patients' problems of diverticulitis are for ever taken care of; or (2) LLD is merely a damage control procedure, which aims to delaying definitive treatment (elective sigmoid resection) a couple of months later^[9]? It is interesting to note that the authors of the various series do not always agree on that issue. To simplify and summarize the current debate, authors from the United Kingdom generally consider that laparoscopic lavage is a definitive treatment and that diverticulitis recurrence rarely occurs afterwards, thus precluding the need for subsequent sigmoid resection^[10]. By contrast, authors from France believe that most patients successfully managed with LLD in the emergency setting will eventually need a sigmoid resection - they consider in fact that this approach is not a definitive treatment for diverticulitis^[3]. These differences in the philosophy of this approach are important to emphasize, since its results are to be evaluated in a different manner.

DATA ANALYSIS

We performed a PubMed search with the terms "perforated diverticulitis" and "laparoscopic lavage" and

Figure 1 Computed tomography scan of Hinchey III diverticulitis.

Figure 2 Computed tomography scan of Hinchey IV diverticulitis - a contra-indication for laparoscopic lavage and drainage.

retrieved 6 series for a total of 279 patients who underwent LLD, but 200 patients only were classified as Hinchey III^[7,11-15]. No indication was given upon the selection process, therefore it is impossible to know how many patients were not considered candidates for LLD; the small number of procedures raises the question that those 200 patients were selected in some way, most probably because they presented with less severe condition. Interestingly, the literature search revealed that LLD is often performed in patients with Hinchey II diverticulitis, a condition that usually does not require operative management: Thus, 25% of patients underwent unnecessary surgery, and represent a subgroup in which a so-called “minimally invasive” approach was actually overtreatment.

Reported success rates in these 6 series were extremely good: 94% of patients were successfully managed with LLD, with minimal (2%) mortality. Causes of failure were: (1) persistent sepsis; (2) fecal fistula formation; and (3) perforated sigmoid cancer. Although few patients developed recurrent diverticulitis in follow-up, 98 (49%) eventually underwent elective sigmoid resection (Table 2). There were wide variations (2%-50%) in the rate of recurrent diverticulitis after LLD. Not surprisingly, these differences translated into wide variations in the rate of subsequent sigmoid resections (0%-100%).

Table 1 Hinchey classification and stage-adjusted outcomes and therapeutic approaches

Stage	Definition	Mortality (%)	Treatment
I	Small abscess (> 4 cm)	0	<i>iv</i> antibiotics
II	Large (> 4 cm) abscess	5	<i>iv</i> antibiotics + drainage
III	Purulent peritonitis	25	LLD, PA or Hartmann
IV	Fecal peritonitis	50	Hartmann

PA: Left colectomy with primary anastomosis; LLD: Laparoscopic lavage and drainage; *iv*: Intravenous.

PROSPECTIVE RANDOMIZED TRIALS

So far, there is only one published RCT on this topic (LADIES^[16]), but laparoscopic lavage is currently assessed in 3 other trials, conducted in Ireland (LAPLAND) and Scandinavia (SCANDIV AND DILALA^[17,18]). The Dutch LADIEs trial, however, was prematurely interrupted because of an exceedingly high rate of complications in the LLD group. The causes of failure in the lavage group were: Death (4%); surgical re-intervention (20%); recurrent abscess (20%); even worse, 5 (11%) patients were eventually diagnosed with sigmoid carcinoma. The authors of the study reported that, since the surgeons made no attempt to free the sigmoid colon from adjacent structures, large persistent perforations were missed. In the small group (46 patients) of LLD, there were a total of 28 surgical re-interventions, and it is therefore not surprising that the Safety Monitoring Board of the study decided to interrupt patients’ inclusion in the LLD arm of the trial.

The first lesson from the RCT is therefore that LLD is definitively not indicated for Hinchey IV patients. LLD is also not a good operation for patients with a persistent perforation. These individuals present with severe comorbidities and have a high operative mortality due to sepsis. Resection surgery still remains the best option in this situation. We believe that the main problem of LLD is the absence of a surgical diagnosis: If the surgeon deliberately abandons the prospect of removing adhesions surrounding the source of infection, then he may overlook: (1) the cause of perforation (cancer vs diverticulitis); (2) the severity of perforation (sealed vs persistent); and (3) the presence of extra-digestive

feculent discharge.

DISCUSSION

LLD is not a panacea, and so far did not meet expectations, as proven by the low number of patients who benefitted from this approach in the surgical literature (less than 200, compared to the huge number of emergency laparotomies performed every year for peritonitis of diverticular origin)^[19]. LLD has no benefit in patients with Hinchey II, and no efficacy in patients with Hinchey IV diverticulitis. Thus, its indications remain strictly limited to Hinchey III, as initially proposed. A percentage of patients with perforated sigmoid carcinomas will be misdiagnosed as Hinchey III, thus these individuals also will not benefit from LLD - and this important limitation should be explained to the patient and his family before the operation. Recent evidence suggests that the rate of occult neoplasia is 10% in patients presenting with sigmoid perforation^[20,21].

Finally, a high number of patients will recur after laparoscopic lavage, and present again with similar symptoms 2-6 mo after LLD. In our experience, this approach should therefore not be considered as a definitive treatment, but preferably as an attempt to avoid sigmoidectomy in the emergency setting. In summary, this approach has important limitations: It is not needed for Hinchey I - II patients; it is not efficient for Hinchey IV patients; most patients with Hinchey III diverticulitis will not be cured, and will require a definitive resection, meaning a second operation three months later, or will be exposed to a high risk of recurrence. Finally, a small but significant percentage of patients with perforated cancers will be misdiagnosed and re-operated with a worst prognosis and probably a very difficult operation 2-4 wk later. In conclusion, this approach has important limitations, and is not a safe alternative to sigmoid resection surgery for patients with Hinchey III diverticulitis.

CONCLUSION

Laparoscopic lavage and drainage for purulent peritonitis due to perforated diverticulitis has many limitations, which have been overlooked in the previously published case series of the literature; actually, it seems likely that the excellent results of these series are a result of a strong selection bias, as well as the inclusion of many patients with Hinchey II diverticulitis. The available data from the unique RCT indicates that these results will not be reproduced in a trial where patients' selection is avoided. There are three main limitations to the technique: (1) the risk of missing a persistent (incompletely sealed) perforation - 30% of cases; (2) the risk of missing fecal peritonitis enclosed within the sigmoid loop - 10% of cases; and (3) the risk of missing sigmoid carcinoma - 10% of cases). LLD is deemed to fail in this group of patients. We conclude that LLD is not a safe approach for a majority of patients presenting

with diffuse purulent peritonitis of diverticular origin.

Abstract

Surgical fraternity has not yet arrived at any consensus for adequate treatment of choledocholithiasis. Sequential treatment in the form of pre-operative endoscopic retrograde cholangio-pancreatography followed by laparoscopic cholecystectomy (LC) is considered as

optimal treatment till date. With refinements in technique and expertise in field of minimal access surgery, many centres in the world have started offering one stage management of choledocholithiasis by LC with laparoscopic common bile duct exploration (LCBDE). Various modalities have been tried for entering into concurrent common bile duct (CBD) [transcystic (TC) vs transcholedochal (TD)], for confirming stone clearance (intraoperative cholangiogram vs choledochoscopy), and for closure of choledochotomy (T-tube vs biliary stent vs primary closure) during LCBDE. Both TC and TD approaches are safe and effective. TD stone extraction is involved with an increased risk of bile leaks and requires more expertise in intra-corporeal suturing and choledochoscopy. Choice depends on number of stones, size of stone, diameter of cystic duct and CBD. This review article was undertaken to evaluate the role of LCBDE for the management of choledocholithiasis.

Key words: Laparoscopic common bile duct exploration; Choledochoscopy; Cholangiogram; Choledocholithiasis; Primary closure

INTRODUCTION

The incidence of gallstones varies from 6%-10% in adult population^[1]. Three percent to 14.7% of patients of gallstones have concurrent common bile duct (CBD) stones as well^[2]. "Gold Standard" for management of gallstones is laparoscopic cholecystectomy (LC) but there is no consensus for treatment of CBD stones. In the era of open surgery, treatment was straight-forward; open cholecystectomy with open CBD exploration though it carried high morbidity and mortality. With the advent of non invasive and minimal invasive techniques, option of pre-operative endoscopic retrograde cholangiopancreatography (ERCP) followed by LC emerged as adequate treatment. Major disadvantages of ERCP are that it is a two stage procedure and is associated with life threatening complications like pancreatitis, bleeding and duodenal perforation. It has also been reported that sphincterotomy may cause papillary stenosis and increased risk of bile duct cancer^[2,3].

With refinements in technique and expertise in field of minimal access surgery, many centres in the world have started offering one stage management of choledocholithiasis by LC with laparoscopic CBD exploration (LCBDE). Only few randomized trials are available comparing pre-operative ERCP followed by LC with single stage LC and LCBDE^[4,5]. There is no consensus even for the technique of LCBDE. Various modalities have been tried for entering into CBD [transcystic (TC) vs transcholedochal (TD)], for confirming stone clearance [intraoperative cholangiogram (IOC) vs choledochoscopy], and for closure of choledochotomy (T-tube vs biliary stent vs primary closure).

REVIEW OF LITERATURE

Literature search was performed to answer these questions. Online search engines like PubMed, Google, springer link library and Cochrane database systematic review were utilized and review articles, prospective and retrospective studies which detailed or compared the various treatment strategies for CBD stones were selected and analyzed.

Sequential vs one stage management

Two randomized trials have compared pre-operative ERCP followed by LC with one stage LC and LCBDE^[4,5]. Results of the two modalities were comparable in terms of stone clearance and complications but duration of hospitalization was shorter with LCBDE in both studies^[4,5]. In a study done by Rogers *et al*^[5], 122 patients were randomized into either group. Hospital stay was significantly shorter for LC + LCBDE [mean (SD), 55 (45) h vs 98 (83) h; $P < 0.001$]. There was no difference in patient acceptance and quality of life scores among the two groups. A prospective analysis done ($n = 150$) by Mohamed *et al*^[6] showed that the laparoscopic management of CBD stones is as safe and effective as the sequential ERCP followed by LC with nearly the same

stone clearance rate, hospital stay, and complications.

Liu *et al*^[7] did a meta-analysis and found that there was no significant difference between laparoscopic CBD exploration group and pre-operative endoscopic sphincterotomy group in terms of complications or retained stones ($P > 0.05$). Success rate was higher in LCBDE group with reduced hospital expenses, mean operative time and duration of hospitalization ($P < 0.05$)^[7].

Another meta-analysis done by Nagaraja *et al*^[8], reported higher incidence of ERCP related complications in patients undergoing pre-operative ERCP [odds ratio (OR) = 2.40, 95%CI: 1.21-4.75].

Costi *et al*^[9] performed a case-control study comparing a single stage laparoscopic approach ($n = 22$) with sequential treatment ($n = 15$). They found two groups to be similar in terms of early and late complications. The postoperative hospitalization was significantly less in the single stage group^[9]. Bansal *et al*^[10] conducted a prospective randomized trial comparing single stage laparoscopic treatment with sequential treatment of CBD stones. Fifteen patients were randomized to each group. Stone clearance rates and complications were similar in both groups. They concluded that single stage approach seems to be better due to smaller number of procedures and hospital visits^[10].

Cochrane systematic review was done by Dasari *et al*^[11] in 2013. They included five trials ($n = 580$). Two hundred and eighty-five patients underwent LC + LCBDE and 295 patients received sequential treatment in the form of ERCP + LC. There was no significant difference among two groups in terms of mortality (0.7% vs 1%), morbidity (15% vs 13%) or incidence of retained stones (8% vs 11%).

A meta-analysis of single-stage vs sequential treatment for cholelithiasis with common bile duct stones was carried out by Zhu *et al*^[12] recently. Eight randomized controlled trials, which involved 1130 patients, were included in this study. The meta-analysis revealed that the CBD stone clearance rate in the single-stage group was higher (OR = 1.56, 95%CI: 1.05-2.33, $P = 0.03$). The lengths of hospitalization (MD = -1.02, 95%CI: -1.99 to -0.04, $P = 0.04$) and total operative times (MD = -16.78, 95%CI: -27.55 to -6.01, $P = 0.002$) were also shorter in the single-stage group. There was no statistically significant difference among the two groups regarding postoperative morbidity (OR = 1.12, 95%CI: 0.79-1.59, $P = 0.52$), mortality (OR = 0.29, 95%CI: 0.06-1.41, $P = 0.13$) and conversion to other procedures (OR = 0.82, 95%CI: 0.37-1.82, $P = 0.62$).

TC vs TD

Hongjun *et al*^[13] compared TC approach ($n = 80$) with TD approach ($n = 209$) and found that there was no significant difference between the two approaches for cystic duct diameter (0.47 ± 0.09 cm vs 0.47 ± 0.08 cm), procedure time (91.94 ± 34.21 min vs 96.13 ± 32.15 min), complications (2.5% vs 2.87%) and

duration of hospitalization (9.82 ± 3.48 d vs 10.74 ± 5.34 d) (all $P > 0.05$). A significant difference was noticed in terms of the common bile duct diameter (1.18 ± 0.29 cm vs 1.04 ± 0.24 cm, $P < 0.05$)^[13].

Wang *et al*^[14] reported that TC LCBDE is safe and effective in elderly population. TC approach was successful in 157 of 165 patients (95.15%). Five patients were converted to laparoscopic TD approach and T-tube drainage whereas three patients were managed by laparotomy and open CBD exploration. No significant complications were reported in the study. The mean blood loss was 43 ± 20 mL and mean operative time was 102 ± 35 min. The postoperative hospitalization was 3 ± 0.5 d^[14].

A systematic review done by Reinders *et al*^[15] included eight randomized trials with 965 patients. Successful bile duct clearance varied between 80.4% and 100% in the TC groups and 58.3% and 100% in the TD groups. There were more bile leaks after TD stone extraction (11%) than after TC stone extraction (1.7%). They concluded that TD stone extraction is associated with an increased risk of bile leaks and should only be done by highly experienced surgeons; TC stone extraction seems a more accessible technique with lower complication rates^[4,5,10,16-20].

Chander *et al*^[21] have concluded that TD route is better in Asian patients with multiple, large stones and dilated CBD.

IOC vs choledochoscopy

Only two studies were found comparing IOC with choledochoscopy for confirming stone clearance. Topal *et al*^[22] found similar results with both techniques, though operative time was longer in IOC group. Vindal *et al*^[23] in a prospective randomized study compared IOC ($n = 65$) with intra-operative choledochoscopy ($n = 67$). Mean operative time was 170 min in group A and 140 min in group B ($P < 0.001$). There was no significant difference in complications among the two groups^[23]. They found choledochoscopy to be better and less time consuming than IOC for determining bile duct clearance after TD LCBDE.

Primary closure vs T-tube vs biliary stent

In a retrospective study done by Yi *et al*^[24], long term results of primary closure (group P, $n = 91$) after LCBDE were compared with T-tube drainage (group T, $n = 51$). The mean operative time was significantly less in group P than group T (168.9 ± 50.1 min vs 198.0 ± 59.6 min, $P = 0.002$). The duration of hospitalization was significantly less in group P than in group T (8.59 ± 6.0 d for group P vs 14.96 ± 5.4 d for group T, $P = 0.001$). The stone recurrence rates in group P and group T were 4.4% and 5.9%, respectively ($P = 0.722$) (mean follow-up 48.8 mo). There was no sign of biliary stricture or other biliary complications in follow-up in either group. They concluded that primary closure after LCBDE with choledochoscopy is as safe and effective as T-tube drainage in terms of long-term results^[24].

Dong *et al*^[25] compared primary closure (group A, $n = 101$) with T-tube drainage (group B, $n = 93$) after LCBDE. The mean operative time was less in group A than in group B (102.6 ± 15.2 min vs 128.6 ± 20.4 min, $P < 0.05$). Postoperative hospitalization was longer in group B (4.9 ± 3.2 d) than in group A (3.2 ± 2.1 d). The hospital expenses were also significantly less in group A. Three patients experienced complications in postoperative period, which were related to T-tube usage in group B^[25].

In other study, Leida *et al*^[26] showed that patients with primary closure of the CBD returned to work faster (12.6 ± 5.1 d vs 20.4 ± 13.2 d). This group also showed advantages of significantly lower hospital expenses and less postoperative complications than T-tube drainage group (15% vs 27.5%)^[26].

Lyon *et al*^[27] compared use of biliary stent ($n = 82$) with T-tube drainage ($n = 34$) after LCBDE in a prospective non-randomized study. The duration of hospitalization for patients who underwent biliary stent or T-tube insertion after LCBDE were 1 and 3.4 d, respectively ($P < 0.001$). In the T-tube group, two patients required laparoscopic washout due to bile leaks. They concluded that ante-grade biliary stent insertion is associated with low hospital expenses and increased patient satisfaction^[27].

Dietrich *et al*^[28] compared biliary stent with T-tube drainage in a series of 48 patients who underwent LCBDE. Patients with T-tube drainage had more procedure-related complications ($P < 0.0001$) and a prolonged hospital stay ($P = 0.03$).

A retrograde study done by Abellán Morcillo *et al*^[29], compared T-tube closure ($n = 36$), biliary stent ($n = 133$) and primary closure ($n = 16$). In the stented group, they found an 11.6% incidence of pancreatitis and a 26.1% incidence of hyperamylasemia whereas in the primary closure group, a clear improvement of complications and hospital stay was observed^[29].

Chen *et al*^[30] in their study observed that primary closure is safe after LCBDE ($n = 194$).

Estellés Vidagany *et al*^[31] did primary closure after LCBDE in 160 patients. Bile leakage was reported in 11 patients (6.8%). In 7 out of 11 patients (63.6%), no further intervention was needed and the leak closed on its own. Six patients were reoperated (3.75%), two for biliary peritonitis and four for haemoperitoneum. The success rate for stone clearance was 96.2%. No mortality or CBD stricture was reported in the study. They concluded that primary closure after LCBDE is a safe technique with excellent results^[31].

Hua *et al*^[32] studied rate of bile leak following primary closure in LCBDE *via* TD approach. Of 157 LCBDE procedures, 138 (87.9%) were successfully managed with primary closure of the choledochotomy. Eight patients (5.1%) underwent closure over a T-tube after LCBDE and 11 patients (7.0%) were converted to open surgery. The success rate for CBD stone clearance was 98.1%. Postoperative bile leak was seen in 6 patients (3.8%).

Table 1 Effective and important factors in common bile duct stones approach

Factor	Trans-cystic approach	Trans-ductal approach
Single stone	Yes	Yes
Multiple stones	Yes	Yes
Stones < 6 mm diameter each	Yes	Yes
Stones > 6 mm diameter each	No	Yes
Intrahepatic stones	No	Yes
Diameter of cystic duct < 4 mm	No	Yes
Diameter of cystic duct > 4 mm	Yes	Yes
Diameter of common bile duct < 6 mm	Yes	No
Diameter of common bile duct > 6 mm	Yes	Yes
Suturing ability-poor	Yes	No

Gurusamy *et al*^[33] published a cochrane systematic review comparing T-tube with primary closure after LCBDE. They included three trials randomizing 295 participants: 147 to T-tube drainage vs 148 to primary closure. The operative time was significantly more in the T-tube drainage group compared with the primary closure group (MD 21.22 min; 95%CI: 12.44 to 30.00 min). The duration of hospitalization was significantly more in the T-tube drainage group compared with the primary closure group (MD 3.26 d; 95%CI: 2.49 to 4.04 d). According to one trial, the participants randomized to T-tube drainage took approximately eight days more to return to work than the participants randomized to the primary closure group ($P < 0.005$). They concluded that T-tube drainage is associated with significantly longer operative time and hospital stay as compared with primary closure after LCBDE. They also emphasized that currently available evidence cannot justify the routine use of T-tube drainage after LCBDE^[33].

Podda *et al*^[34] did a meta-analysis of all studies comparing primary duct closure and T-tube drainage after LCBDE (total 16 studies, 1770 patients). Primary duct closure showed a significant advantage over T-tube in terms of postoperative bile peritonitis ($P = 0.02$), operative time, duration of hospitalization, and median hospital cost (all $P < 0.00001$).

DISCUSSION

Pre-operative ERCP followed by LC is the most commonly used treatment modality for management of choledocholithiasis. ERCP carries a high rate of morbidity and mortality mostly due to post-procedure pancreatitis, duodenal perforation and bleeding. It also causes injury to sphincter of oddi which should be avoided in younger patients. LCBDE offers a one stage treatment with similar or better stone clearance rate and with a shorter hospital stay. It also preserves function of sphincter of oddi and hence prevents reflux related complications^[2,3]. LCBDE has been found to be safe even in elderly population^[14,35]. A Cochrane systematic review by Martin *et al*^[36] concluded that a single-stage treatment in the form of LCBDE *via* TC approach is the procedure of choice for intraoperatively discovered CBD calculi.

Despite the simplicity and success of LCBDE, many surgeons across the globe are still not comfortable or confident regarding the procedure. Petelin *et al*^[37] did a web based survey among United States surgeons regarding their choice for managing choledocholithiasis. For preoperatively known CBD calculi, 86% preferred preoperative ERCP. Those in metropolitan areas were more likely to choose preoperative ERCP than those in nonmetropolitan areas (88% vs 79%, $P < 0.001$). For CBD stones discovered intraoperatively, 30% chose LCBDE as their preferred method of management with no difference between metropolitan and nonmetropolitan areas ($P = 0.335$). The top reasons for not performing LCBDE were: Availability of a reliable ERCP, lack of equipment, and lack of skill performing LCBDE. They concluded that many surgeons are uncomfortable performing LCBDE, and advanced training may be needed. There is a risk of surgeons losing the art, which may still be required in cases of unavailability or failure of ERCP^[38].

Both TC and TD approaches are safe and effective. TD stone extraction is associated with a increased risk of bile leaks and requires more expertise in intracorporeal suturing and choledochoscopy^[21]. TC stone extraction seems a more accessible technique with lower complication rates. Choice depends on number of stones, size of stone, diameter of cystic duct and CBD (Table 1)^[39].

Stone clearance during LCBDE can be confirmed by IOC or choledochoscopy. Intra-operative choledochoscopy is better than IOC for determining ductal clearance after TD LCBDE and is less cumbersome and less time-consuming.

Choledochotomy after LCBDE (TD approach) is conventionally managed by T-tube closure. Primary closure of choledochotomy is a safe and effective option with less operative time and hospital stay. Biliary stent also reduces cost and hospital stay as compared to T-tube. There is lack of randomized trial comparing primary closure with biliary stent.

In patients having cholangitis, it is advisable to go for drainage of biliary obstruction by ERCP followed by LC. LCBDE can be offered to all other patients with CBD stones if expertise is available^[21]. If laparoscopic exploration fails, it is prudent to convert it to open bile duct exploration and removal of ductal stones.

Abstract

AIM: To assess the safety of enhanced recovery after surgery (ERAS) program in gastrectomy and influences on nutrition state and insulin-resistance.

METHODS: Our ERAS program involved shortening the fasting periods and preoperative carbohydrate loading. Eighty gastrectomy patients were randomly assigned to either the conventional group (CG) or ERAS group (EG). We assessed the clinical characteristics and postoperative outcomes prospectively. The primary endpoint was noninferiority in timely discharge from the hospital within 12 d. Secondary endpoints were the incidence of aspiration at anesthesia induction, incidence of postoperative complications, health related quality of life (HRQOL) using the SF8 Health Survey questionnaire, nutrition state [*e.g.*, albumin, trans-thyretin (TTR), retinal-binding protein (RBP), and transferrin (Tf)], the homeostasis model assessment-insulin resistance (HOMA-R) index, postoperative urine volume,

postoperative weight change, and postoperative oral intake.

RESULTS: The ERAS program was noninferior to the conventional program in achieving discharge from the hospital within 12 d (95.0% *vs* 92.5% respectively; 95%CI: -10.0%-16.0%). There was no significant difference in postoperative morbidity between the two groups. Adverse events such as vomiting and aspiration associated with the induction of general anesthesia were not observed. There were no significant differences with respect to postoperative urine volume, weight change, and oral intake between the two groups. EG patients with preoperative HOMA-R scores above 2.5 experienced significant attenuation of their HOMA-R scores on postoperative day 1 compared to CG patients ($P = 0.014$). There were no significant differences with respect to rapid turnover proteins (TTR, RBP and Tf) or HRQOL scores using the SF8 method.

CONCLUSION: Applying the ERAS program to patients who undergo gastrectomy is safe, and improves insulin resistance with no deterioration in QOL.

Key words: Gastrectomy; Carbon hydrogen oxygen; Insulin resistance; Enhanced recovery after surgery; Randomized controlled trial

INTRODUCTION

Gastrectomy is a high-risk procedure owing to the stress of surgery and resulting complications. In the past few decades, oral intake was not permitted for a long period of time after surgery because of the chance that intraluminal pressure on the anastomosis would induce leakage. To that end, enhanced recovery after surgery (ERAS) programs were introduced, and found to be safe and useful for patients undergoing colectomy^[1]. Previous reports have shown the benefits of ERAS programs such as controlling preoperative carbohydrate loading to regulate blood sugar^[2,3] and early rehabilitation to prevent pneumonia, bowel obstruction, and thrombosis^[1]. Postoperative early feeding signifi-

cantly reduces hospital stay yet does not increase postoperative complications^[4,5]. Similar programs have recently been introduced for gastrectomy patients, with a number of reports having been published in the past few years^[6-10]. Moreover, postoperative oral feeding is being steadily introduced at earlier time points. In 2014, a report on the safety of commencing oral intake on postoperative day (POD) 1 after gastrectomy was published^[11]. Although this report proposed that introducing postoperative oral feeding sooner is safe, the overall consequences of early postoperative feeding are still unclear.

In April 2012, we revised our clinical pathway for gastrectomy, employing a modified ERAS protocol originally used for colorectal resection. In this study, we compared postoperative outcomes between patients who received perioperative care according to our modified ERAS protocol, which involved shorter fasting periods and increased carbohydrate loading, and those who received conventional perioperative care. We evaluated the clinical consequence of this protocol in gastric surgery, assessing safety as well as postoperative nutrition state, insulin-resistance, and quality of life (QOL).

MATERIALS AND METHODS

Patients

This study was a prospective, single center, randomized phase II clinical trial. We studied consecutive patients who underwent gastrectomy at the Department of Gastroenterological and Transplant Surgery, Hiroshima University, between September 2011 and February 2015. Eighty patients were randomly categorized into 2 groups; 40 patients were assigned to each of the conventional treatment group (CG) and the ERAS group (EG). Patients were assigned according to the stratified randomization method by age (< 70 *vs* ≥ 70) and surgical approach (abdominal *vs* laparoscopic surgery). All patients completed their treatment. This study was approved by the institutional review board of the study institution (Hiroshima University, Japan, No.Rin-269) and was conducted in accordance with the Declaration of Helsinki. The study was registered at University Hospital Medical Information Network Clinical Trial Registry (UMIN000020538). Voluntary written informed consent was obtained from all subjects enrolled in this study.

Perioperative care

Patients in both groups were managed perioperatively using equivalent standardized clinical pathway protocols except for perioperative nutrition and intravenous fluid. In the EG, intravenous fluid was restricted to a minimal daily requirement during the first 3 postoperative days. Additional intravenous fluid was administered when patient showed poor oral intake of water or food. The CG received intravenous fluid for 1 wk postoperatively.

Regarding perioperative oral nutrition, patients in the EG received 875 mL of carbohydrate-rich (157 g)

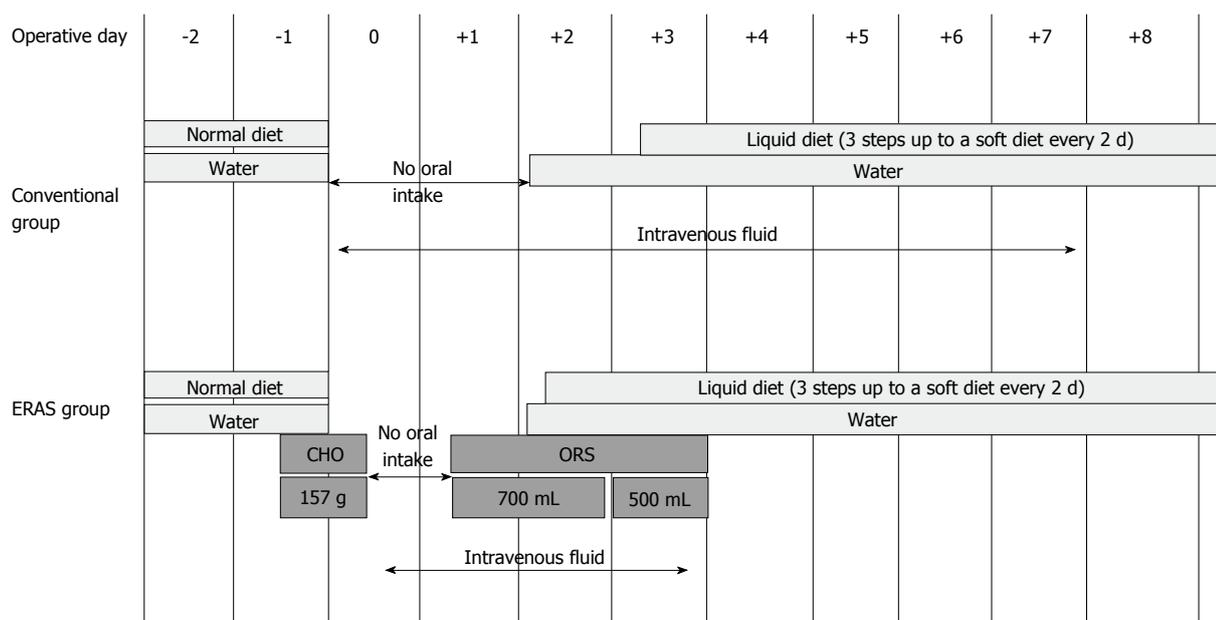

Figure 1 Schema of the study plan for patients participating in the enhanced recovery after surgery program and those subjected to conventional perioperative treatment. CHO: Carbon hydrogen oxygen; ERAS: Enhanced recovery after surgery; ORS: Oral rehydration solution.

fluid until 2 h before the surgery. On POD 1, the patients commenced oral intake with water and oral rehydration solution. On POD 2, patients began to consume a liquid diet. In the CG, patients were allowed to drink water until the day before the surgery. On POD 2, these patients commenced oral intake beginning with water; liquid diets were offered on POD 3 (Figure 1).

Hospital discharge was recommended based on the following criteria: (1) No requirement for intravenous nutrition; (2) Tolerable pain with no or oral-only analgesics; (3) The ability to fully ambulate without assistance; and (4) A willingness to go home.

Data collection

All data were retrieved from the patients' database and clinical records. The primary endpoint was noninferiority in achieving discharge from the hospital within 12 d. Secondary endpoints were the incidence of aspiration at the induction of anesthesia, incidence of postoperative complications, health related QOL (HRQOL) using the SF8 Health Survey questionnaire^[12,13], nutrition state [e.g., albumin (ALB), transthyretin (TTR), retinal-binding protein (RBP), and transferrin (Tf)], the homeostasis model assessment-insulin resistance (HOMA-R) index, postoperative urine volume, postoperative weight change, and postoperative oral intake. HRQOL comprised of 2 components: the physical component summary (PCS) and the mental component summary (MCS). Complications were defined as being of grades ≥ 2 according to the Clavien-Dindo classification within 30 d after surgery. HOMA-R was calculated as immunoreactive insulin \times fasting blood sugar/405.

Statistical analysis

All analyses were conducted according to a statistical

analysis plan. We tested the noninferiority of ERAS with respect to the rate of achievement of discharge from the hospital within 12 d; the targeted noninferiority margin was 15 percentage points.

Assuming a success rate of 85% for the achievement of hospital discharge within 12 d for EG, and a success rate of 90% achievement of the same for CG, the number of patients required to establish noninferiority with 80% power was 33 for each study group. With a presumed dropout rate of 10%, we planned to enroll 80 patients in total.

Patients' backgrounds were analyzed using the Fisher's exact test to compare categorical data (Table 1). Logistic regression analysis was used to compare outcomes between groups (Table 2). Statistical analyses were conducted using the SPSS statistical software (version 19; SPSS Inc., Chicago, IL, United States). Statistical comparisons of parameters were performed using Student's *t*-test. A *P* value of < 0.05 was considered statistically significant.

RESULTS

Clinical characteristics

The clinical characteristics of the patients in both the CG and EG are described in Table 1. There were no significant differences with respect to gender, age, body mass index), American Society of Anesthesiologists - physical status, surgical method, surgical approach, or tumor characteristics.

Postoperative outcomes

Table 2 summarizes postoperative outcomes in both groups. For the primary endpoint (rate of achievement of discharge from the hospital within 12 d), a successful

Table 1 Comparison of characteristics between conventional group and enhanced recovery after surgery group

Characteristics	Conventional group (n = 40)	ERAS group (n = 40)	P value

Gastric cancer	31	34	
Submucosal tumor (GIST or schwannoma)	9	6	

BMI: Body mass index; ASA-PS: American Society of Anesthesiologists - physical status; ERAS: Enhanced recovery after surgery; GIST: Gastrointestinal mesenchymal tumor.

outcome was achieved in 38 of 40 patients (95.0%) in the EG compared to 37 of 40 (92.5%) patients in the CG (Table 2). The lower limit of the two-sided 95%CI for the difference between the study arms (10%) was within the protocol-specified noninferiority margin of 15%. Therefore, ERAS treatment met our criteria for noninferiority to conventional treatment. Mean postoperative hospital stay was also similar between the two groups, as was postoperative morbidity.

Postoperative nutrition state and insulin resistance

Figure 2A shows the results of rapid turnover proteins analysis. Mean serum ALB values on the preoperative day and PODs 1, 3 and 7 in the CG vs EG were 4.40 g/dL vs 4.41 g/dL, 3.11 g/dL vs 3.0 g/dL, 2.86 g/dL vs 2.85 g/dL, and 3.42 g/dL vs 3.44 g/dL, respectively. Mean serum TTR values on the preoperative day and PODs 1, 3 and 7 in the CG vs EG were 24.7 mg/dL vs 24.4 mg/dL, 20.4 mg/dL vs 19.0 mg/dL, 14.6 mg/dL vs 13.1 mg/dL, and 20.0 mg/dL vs 18.4 mg/dL, respectively. Mean serum RBP values on the preoperative day and PODs 1, 3 and 7 in the CG vs EG were 4.18 mg/dL vs 3.82 mg/dL, 2.46 mg/dL vs 1.87 mg/dL, 1.34 mg/dL vs 0.88 mg/dL, and 3.36 mg/dL vs 3.09 mg/dL, respectively. Mean serum Tf values on the preoperative day and POD 7 in the CG vs EG were 201.6 mg/dL vs 205.6 mg/dL and 192.7 mg/dL vs 186.4 mg/dL, respectively. There were no significant differences with respect to ALB, TTR, RBP, and Tf between the two groups. Figure 2B shows the results of HOMA-R analysis. Mean HOMA-R scores on the

preoperative day and PODs 1, 3 and 7 in the CG vs EG were 2.46 vs 3.21, 8.83 vs 6.54, 4.04 vs 2.72, and 2.23 vs 3.17, respectively. There was no significant difference between the two groups at any point. Insulin resistance is defined as the HOMA-R score being over 2.5. In a subgroup analysis of patients with insulin resistance (CG: $n = 11$, EG: $n = 20$), the mean HOMA-R scores on the preoperative day and PODs 1, 3 and 7 in the CG vs EG were 2.95 vs 2.39, 15.05 vs 6.64, 4.19 vs 3.12, and 2.23 vs 3.17, respectively. There was a significant attenuation of the HOMA-R score on POD 1 in the EG compared to the CG ($P = 0.014$).

Quality of life analyses

Figure 3 shows the HRQOL scores obtained using the SF8 Health Survey questionnaire. The mean PCS scores on the preoperative day and PODs 2 and 7 in the CG vs EG were 52.5 vs 50.8, 39.2 vs 37.7, and 44.0 vs 42.4 ($P = 0.284$), respectively. The mean MCS scores on the preoperative day and PODs 2 and 7 in the CG vs EG were 49.9 vs 48.6, 48.4 vs 47.3, and 49.7 vs 49.3, respectively. There were no significant differences with respect to PCS and MCS between the two groups.

Adverse events and other factors

Adverse events such as vomiting and aspiration associated with the induction of general anesthesia were not observed. There were no significant differences with respect to postoperative urine volume, weight change, and oral intake between the two groups (data not shown).

DISCUSSION

There are some reports on the usefulness of ERAS programs for gastrectomy^[6-11]; however, the data are not yet conclusive. Almost every report concerning gastrectomy described the safety of ERAS but not its influence on nutrition state, insulin resistance, QOL, and other such parameters. In this study, we evaluated the effect of postoperative early oral nutrition and preoperative carbohydrate loading.

Our data showed that postoperative early oral nutrition did not increase morbidity, and the rate of achieving discharge from the hospital within 12 d was not compromised. Thus, our ERAS program was deemed to be safe. In fact, the period of hospital stay tended to be shorter in the EG compared to the CG, although the difference was not significant. Most patients do not wish to be discharged until they can ingest soft foods. We surmise that hospital stay can be further shortened if we inform the patients prior to their surgeries that they can be eligible for discharge once they no longer require intravenous nutrition, in order to incentivize them.

It was reported that marked insulin resistance was present after upper abdominal surgery^[14]. Studies in diabetics undergoing surgery have shown that postoperative hyperglycemia has negative effects on wound infection^[15]. This observation is not surprising, because

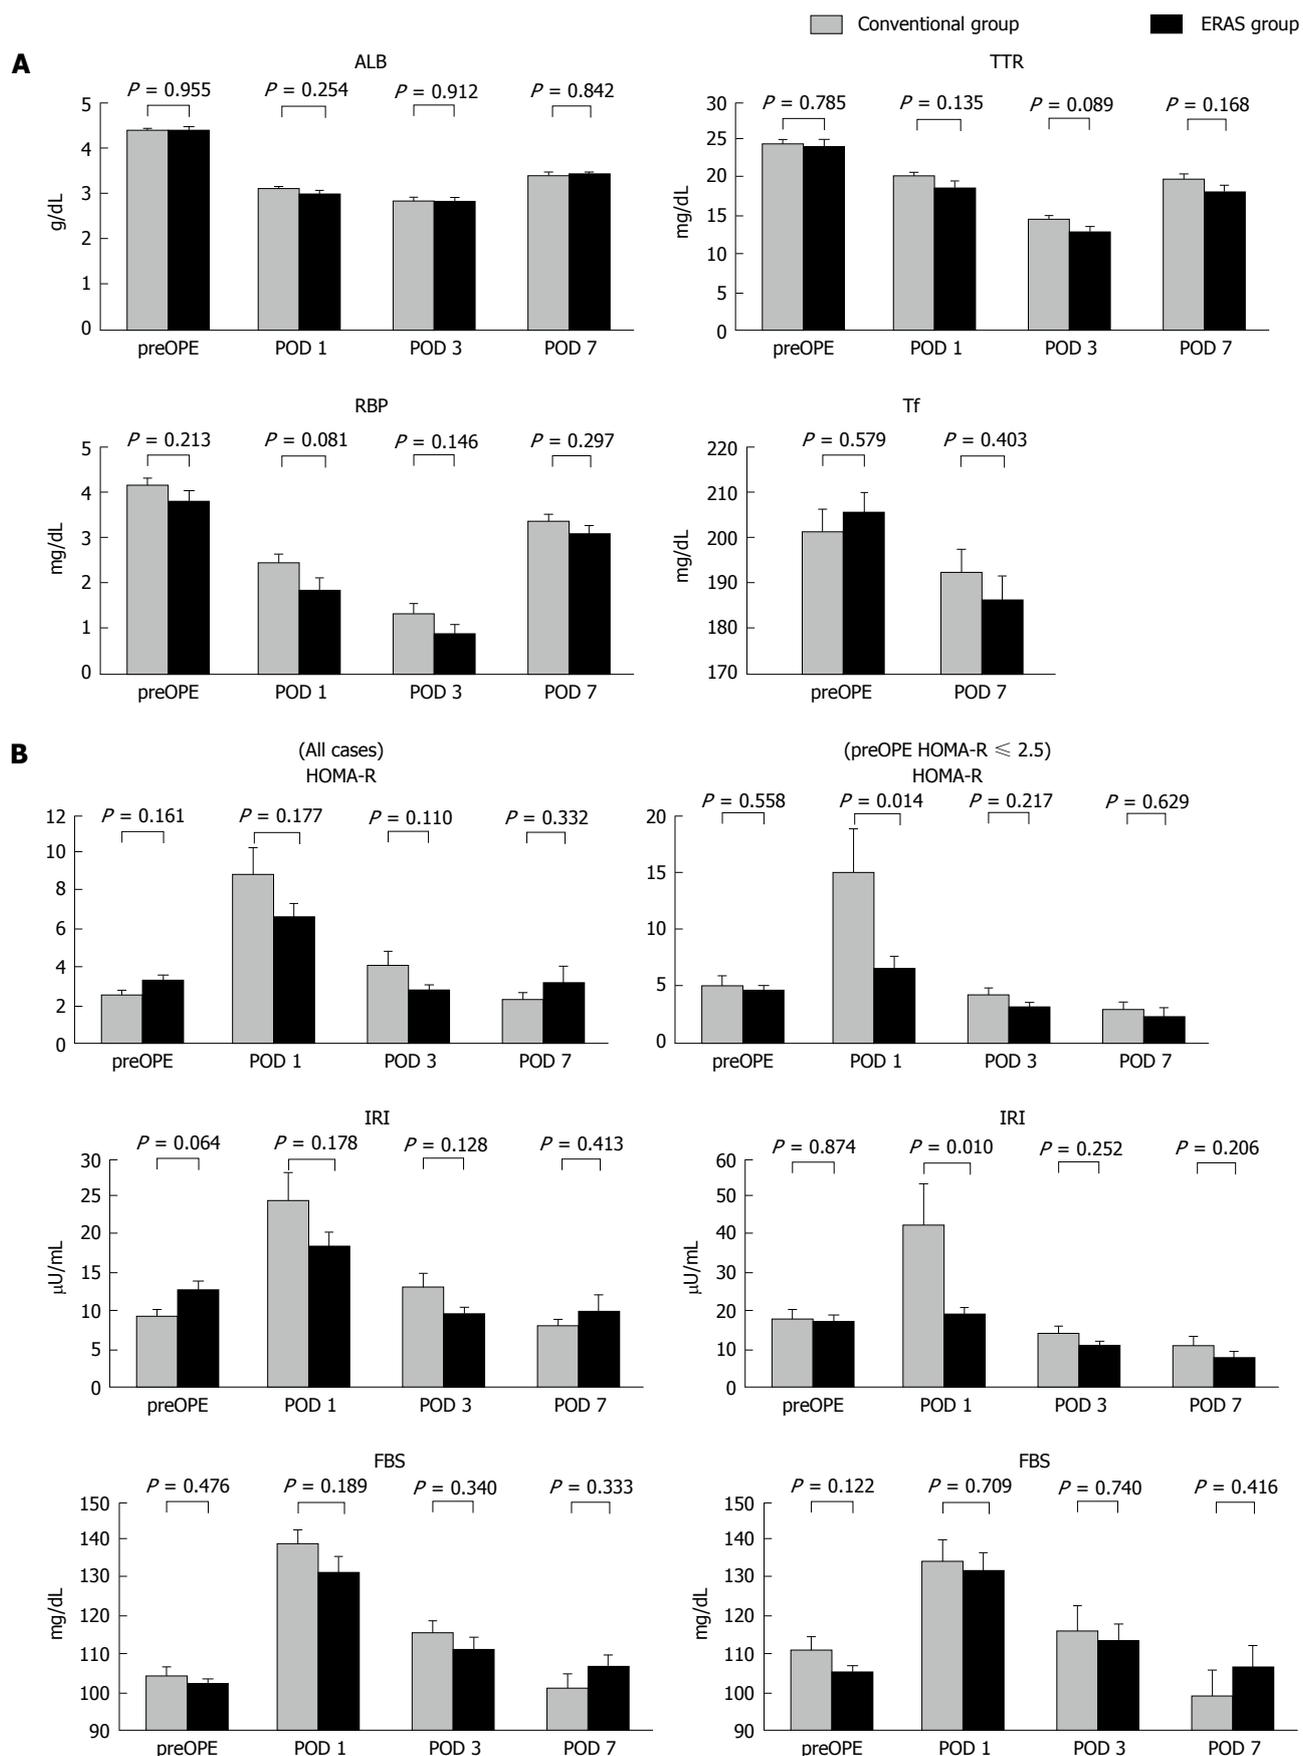

Figure 2 Changes in various serum factors during the perioperative period. A: Rapid turnover proteins; B: Insulin resistance index for all cases (left panel) and for the subgroup of patients in which the preOPE HOMA-R score was over 2.5 (right panel). ALB: Albumin; TTR: Transthyretin; RBP: Retinal-binding protein; Tf: Transferrin; HOMA-R: Homeostatic model analysis ratio-insulin resistance; IRI: Immunoreactive insulin; FBS: Fasting blood sugar; preOPE: Preoperative; POD: Postoperative day.

Table 2 Comparison of postoperative outcomes between conventional group and enhanced recovery after surgery group

	Conventional group (n = 40)	ERAS group (n = 40)	Difference (95%CI)	P value
Accomplishment of the discharge from the hospital within 12 d	92.5% (37/40)	95.0% (38/40)	2.5% (-10.0%-16.0%)	0.646
Postoperative hospital stay (d)	10.4 (7-23)	9.8 (6-20)	-0.58 (-1.63-0.48)	0.280
Postoperative morbidity (Clavien-Dindo grade \geq 2)	12.5% (5/40)	10.0% (4/40)	-2.5% (-19.0%-14.0%)	0.724

poor glucose control in diabetes is associated with complications. There are two main reasons for experiencing postoperative insulin resistance. One is that the perioperative starvation induces the accumulation of lipid products in skeletal muscles and interferes with insulin signaling to produce insulin resistance^[16]. The other is that the reaction of a living body to the surgical stress induces stress hormones (such as catecholamines, cortisol, and glucagon) as well as the release of the inflammatory cytokine interleukin-6^[2,17,18]. To reduce postoperative insulin resistance, preoperative carbohydrate loading may be useful to counter preoperative starvation^[2,3]. In this study, therefore, patients in the EG were administered carbohydrate-rich liquids until 2 h before surgery. There were no significant differences in insulin resistance between the two groups in the overall analysis. However, in subgroup analysis of patients with high preoperative HOMA-R, there was significant improvement in postoperative insulin resistance in the EG (Figure 2), presumably due to preoperative carbohydrate loading. This study is the first to suggest that preoperative carbohydrate loading in gastrectomy patients attenuates postoperative insulin resistance and thus lowers the risk of additional complications. It is reported that preoperative carbohydrate-rich beverages also reduce preoperative thirst, hunger and anxiety^[19], and also carry postoperative benefits such as a small reduction in the length of hospital stay when compared with placebo-administered or fasting adult patients undergoing elective surgery^[20]. However, the clinical consequences of improving postoperative insulin resistance are still unclear. In our study, the morbidity rate and the length of hospital stay were similar between EG and CG; however, further investigations are required to clarify the clinical influence of improving postoperative insulin resistance.

Our study was not able to demonstrate any benefit of the ERAS program on nutritional state. In the CG, oral intake began on POD 2, whereas it commenced on POD 1 in the EG. This interval is too short to allow assessment of benefits on nutrition states. In terms of HRQOL, there was no significant difference between the two groups. We expected that a shorter period of fasting would have decreased mental stress in EG; however, data obtained through the SF8 Health Survey questionnaire did not reveal any such benefits. A more thorough questionnaire might better reflect early postoperative HRQOL status.

In conclusion, we demonstrated the non-inferiority of the ERAS program with respect to the rate of achieving discharge from the hospital within 12 d post-gastrectomy. Moreover, our results suggest that our ERAS program for gastrectomy is safe and improves postoperative insulin resistance in those patients who were originally insulin resistant. To our knowledge, this study is also the first to demonstrate that preoperative carbohydrate loading in gastrectomy patients attenuates postoperative insulin resistance. However, we did not observe any advantage in postoperative nutrition state and HRQOL due to our ERAS program. It is still uncertain whether the ERAS program is superior to conventional programs because the clinical benefits attributed to this program were not significant.

COMMENTS

Background

There are some reports on the safety of enhanced recovery after surgery (ERAS) programs for gastrectomy. In this study, the authors evaluated the effect of postoperative early oral nutrition and preoperative carbohydrate loading.

Research frontiers

Almost every report concerning gastrectomy described the safety of ERAS but

not its influence on nutrition state, insulin resistance, quality of life, and other such parameters.

Innovations and breakthroughs

The authors demonstrated that their ERAS program for gastrectomy is safe and improves postoperative insulin resistance in those patients who were originally insulin resistant.

Applications

It is still uncertain whether the ERAS program is superior to conventional programs because the clinical benefits attributed to this program were not significant.

Terminology

ERAS program consist of many elements, including preoperative education, preoperative carbohydrate loading, omission of bowel preparation, epidural analgesia without opioids, early postoperative enteral feeding, early mobilization of patients, and thromboprophylaxis.

Peer-review

The authors proposed a good trial of ERAS in patients after gastrectomy for gastric cancer. It's a promising idea to improve the recovery efficiency of patients. This manuscript was designed well, written fluently, and deduced credibly.

Abstract

AIM: To identify therapeutic agents for the prophylaxis of gastrointestinal anastomotic leakage (AL) under complicated conditions.

METHODS: The PubMed and EMBASE databases were searched for English articles published between January 1975 and September 2014. Studies with the primary purpose of improving anastomotic healing in the colon or rectum under complicated preoperative and/or intraoperative conditions were included. We excluded studies investigating the adverse effects or risk assessment of an active intervention. Furthermore, investigations of biophysical materials, sealants, electrical stimulation and nutrients were excluded. The primary study outcome was biomechanical anastomotic strength or AL. The meta-analysis focused on therapeutic agents that were investigated in one animal model using the same outcome by at least three independent research groups.

RESULTS: The 65 studies included were divided into 7 different complicated animal models: Bowel ischemia, ischemia/reperfusion, bowel obstruction, obstructive jaundice, peritonitis, chemotherapy and radiotherapy. In total, 48 different therapeutic compounds were examined. The majority of investigated agents (65%) were reported as beneficial for anastomotic healing. Twelve of the agents (25%) were tested more than once in the same model, whereas 13 (27%) of the agents were tested in two or more models of complicated healing. Two therapeutic agents met our inclusion criteria for the meta-analysis. Postoperative hyperbaric oxygen therapy significantly increased anastomotic

bursting pressure in ischemic colon anastomoses by a mean of 28 mmHg (95%CI: 17 to 39 mmHg, $P < 0.00001$). Granulocyte macrophage-colony stimulating factor failed to show a significant increase in anastomotic bursting pressure (95%CI: -20 to 21 mmHg, $P = 0.97$) vs controls in experimental chemotherapeutic models.

CONCLUSION: This systematic review identified potential therapeutic agents, but more studies are needed before concluding that any of these are useful for AL prophylaxis.

Core tip: Anastomotic leakage is a challenging complication after colorectal surgery. Although many pharmaceutical compounds have the potential to improve anastomotic healing, none has reached the clinical setting. This study reviewed 65 experimental studies investigating 48 different therapeutic agents for the improvement of anastomotic healing under complicated conditions due to ischemia, ischemia/reperfusion, obstructive bowel, obstructive jaundice, peritonitis, chemotherapy or radiotherapy. Of the 31 agents reported to enhance anastomotic healing, one was subjected to a meta-analysis. Hyperbaric oxygen therapy significantly improved anastomotic healing in rat models complicated by bowel ischemia. Further exploration is needed to define agents that reduce AL in high-risk patients.

Nerström M, Krarup PM, Jorgensen LN, Ågren MS. Therapeutic improvement of colonic anastomotic healing under complicated conditions: A systematic review. *World J Gastrointest Surg* 2016; 8(5): 389-401 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i5/389.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i5.389>

INTRODUCTION

Colorectal surgery with construction of a primary anastomosis is performed for conditions such as cancer, diverticulitis, ulcerative colitis, ischemia or stoma reversal.

Despite improvements in preoperative management and surgical techniques, anastomotic leakage (AL) remains a major complication. The incidences of AL after colonic resection and rectal resection are 3%-7% and 10%-20%^[1-3], respectively. AL is associated with increased risk of morbidity, short-term mortality, permanent ostomy, tumor recurrence and a diminished overall long-term survival^[2,4-8].

In animal models of anastomotic healing, anastomotic bursting pressure (BPR) and anastomotic break-

ing strength (BST) are the most common surrogate outcomes of anastomotic healing. BPR reflects the resistance to increased intraluminal pressure, whereas BST reflects the increased longitudinal load. The collagen concentration is important for anastomotic integrity and declines to a minimum 3 d after the construction of colonic anastomoses under normal healing conditions^[9,10].

Previous studies have identified several local and systemic factors with deleterious effects on anastomotic wound healing, including ischemia^[11,12], reperfusion^[13-15], bowel obstruction^[16], obstructive jaundice^[17], peritonitis^[11,16,18,19], chemotherapy^[20] and radiotherapy^[3,20]. Reperfusion after intestinal ischemia provokes local and systemic inflammatory responses^[13-15], and ischemia ultimately leads to tissue necrosis and bowel perforation^[21,22]. Acute bowel obstruction is associated with ischemia, inflammation and loss of collagen in the colonic wall^[9,23,24]. Obstructive jaundice compromises systemic immune functions^[17]. Impaired collagen synthesis is observed in peritonitis^[25] and with the use of chemotherapeutic agents^[26]. Preoperative radiotherapy, which is used to downsize rectal tumors, induces inflammation^[3,27]. Despite the well-known risk of compromised anastomotic healing under these conditions, surgical resection and construction of a primary anastomosis are pivotal in the treatment algorithm.

A recent meta-analysis identified seven compounds, including iloprost, tacrolimus, erythropoietin (EPO), growth hormone (GH), insulin-like growth factor-1 (IGF-1), hyperbaric oxygen therapy (HBOT) and synthetic inhibitors of matrix metalloproteinases (MMPs), all of which have the potential to improve anastomotic healing under non-complicated conditions^[28]. Several compounds have also been tested in different experimental models of complicating conditions^[29].

The aim of the present systematic review was to identify therapeutic agents that are potentially capable of abolishing or reducing the deleterious effects on anastomotic healing caused by ischemia, ischemia/reperfusion (I/R), obstructive bowel, obstructive jaundice, peritonitis, chemotherapy or radiotherapy.

MATERIALS AND METHODS

Methods

This systematic review was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines^[30].

Search strategy

The PubMed and EMBASE databases were searched for articles published between January 1975 and September 2014 using the following syntax: ((Surgical anastomo*) OR (intestinal anastomo*) OR (anastomo* AND leak*) OR (anastomo* AND dehiscence) OR (surgical wound dehiscence) OR (anastomo* AND failure) OR (anastomo* AND rupture)) AND ((colorectal surgery) OR (surgical anastomo*) OR (colo* AND surgery) OR (rect* AND surgery) OR (large intestine and surgery)

OR (colorectal resection)) AND ((burst* pressure) OR (breaking strength) OR (anastomo* AND strength) OR (wound rupture) OR (biomechanical strength) OR (mechanical strength) OR (wound healing) OR (autopsy) OR (anastomo* AND leak*)) AND (((peritonitis) OR (infection) OR (sepsis)) OR ((ischemia) OR (hypoperfusion)) OR ((ileus) OR (bowel obstruction) OR (large bowel obstruction) OR (intestinal obstruction)) OR ((radiation) OR (radiotherapy) OR (radiochemotherapy) OR (chemotherapy))).

Cross-references from the included studies were manually reviewed.

Data extraction and outcomes

Titles of the articles identified in the search were reviewed, and potentially relevant abstracts or full-text articles, if necessary, were assessed for eligibility. Two or more authors decided whether a study qualified for inclusion, and disagreements were solved by discussion among the four authors.

The abstracted data included the complicated animal model used, the investigated compound, the time of administration, the species, the gender, the sample size, the dosage, the route, the day of anastomotic testing, the primary outcome and the effects on BPR, BST or AL of the compound investigated.

Missing data were gathered by contacting the authors.

Inclusion and exclusion criteria

English publications with the primary aim of investigating the potential beneficial properties of a pharmacological agent to improve anastomotic healing during complicated conditions were included. Studies on animals or humans with colo-colonic or colorectal anastomoses without a protecting ostomy reporting BPR, BST and AL relative to a proper control group were included.

Studies with the aim of clarifying adverse effects or risks of a therapeutic agent on anastomotic healing in complicated conditions were excluded. Likewise, studies on the effects of electrical stimulation, mechanical enforcement, such as biofragmentable anastomotic rings, endoluminal prosthesis/tube or amniotic membranes, together with sealants, such as fibrin glue, cyanoacrylates or collagen matrix bound coagulation factor sealants, and nutrients were also excluded.

Statistical analysis

Compounds investigated in one complicated animal model by at least three independent research groups using the same primary outcome were subjected to a meta-analysis. For these analyses, Review Manager (RevMan, Version 5.3. Copenhagen: The Nordic Cochrane Centre, The Cochrane Collaboration, 2014) was used. Pooled estimates were calculated using the inverse-variance weighting method with the DerSimonian-Laird random-effects model. Heterogeneity among the studies was determined using I^2 tests. The level of statistical significance was 0.05.

RESULTS

A total of 65 studies were included in the study (Figure 1). These studies were divided into 7 different animal models (Figure 2): Bowel ischemia models ($n = 21$) in rats ($n = 20$) and dogs ($n = 1$), I/R injury models ($n = 8$) in rats, models of colonic obstruction ($n = 5$) in rats ($n = 4$) and guinea pigs ($n = 1$), an obstructive jaundice model in the rat ($n = 1$), models of peritonitis ($n = 16$) in rats ($n = 15$) and mice ($n = 1$), chemotherapeutic models ($n = 8$) in rats and irradiation models ($n = 6$) in rats ($n = 5$) and pigs ($n = 1$). The reported outcomes were BPR ($n = 62$), BST ($n = 4$) and AL ($n = 5$). More than one outcome was applied in 6 studies. No human studies were retrieved by our search criteria.

Forty-eight different compounds were identified; 12 (25%) compounds were tested more than once in the same model, and 13 (27%) were tested in more than one complicated model. Enhancement of anastomotic healing was reported for 31 (65%) of the compounds; a non-significant effect was reported for 7 (15%) of the compounds, inconsistent results were reported for 9 (18%) different compounds and 1 (2%) compound was found to be detrimental to anastomotic healing.

Bowel ischemia

Twenty-two different compounds were tested in models of intestinal ischemia (Table 1). Experimentally, ischemia in the anastomotic segment was induced by ligation^[21,31-33] or coagulation^[34] of vessels in the mesocolon. The anastomosis was then constructed in the ischemic segment during the same surgical procedure.

Four studies tested the effect of postoperative HBOT in rats^[31,33,35,36]. The meta-analysis demonstrated that HBOT significantly increased anastomotic BPR by a mean 28 mmHg (95%CI: 17 to 39 mmHg, $P < 0.00001$) compared with controls (Figure 3A). The inconsistency between studies was moderately large ($I^2 = 40\%$). HBOT increases tissue oxygenation^[31,33,35,36], which may explain the elevated hydroxyproline concentration in the anastomosis^[33,35]. HBOT was ineffective when only administered preoperatively^[33]. The possible adverse effects of HBOT are oxygen toxicity, air embolization and pneumothorax^[31,33,35].

Guzel *et al.*^[35] found that rats receiving a post-operative intraperitoneal injection of β -1,3-glucan together with HBOT increased BPR by 67% compared with 50% for HBOT alone. β -1,3-glucan alone also significantly improved BPR^[35]. Supplementing post-operative HBOT with low molecular weight heparin (enoxaparin) had no further effect on BPR despite increasing neovascularization in the anastomotic area^[36]. Enoxaparin did not significantly improve BPR^[36].

Growth factors and hormones are pivotal in wound healing^[37]. Vascular endothelial growth factor (VEGF)-A and fibroblast growth factor (FGF)-2 plasmids were injected directly into the anastomotic tissue intraoperatively. The gene therapy increased VEGF and FGF-2

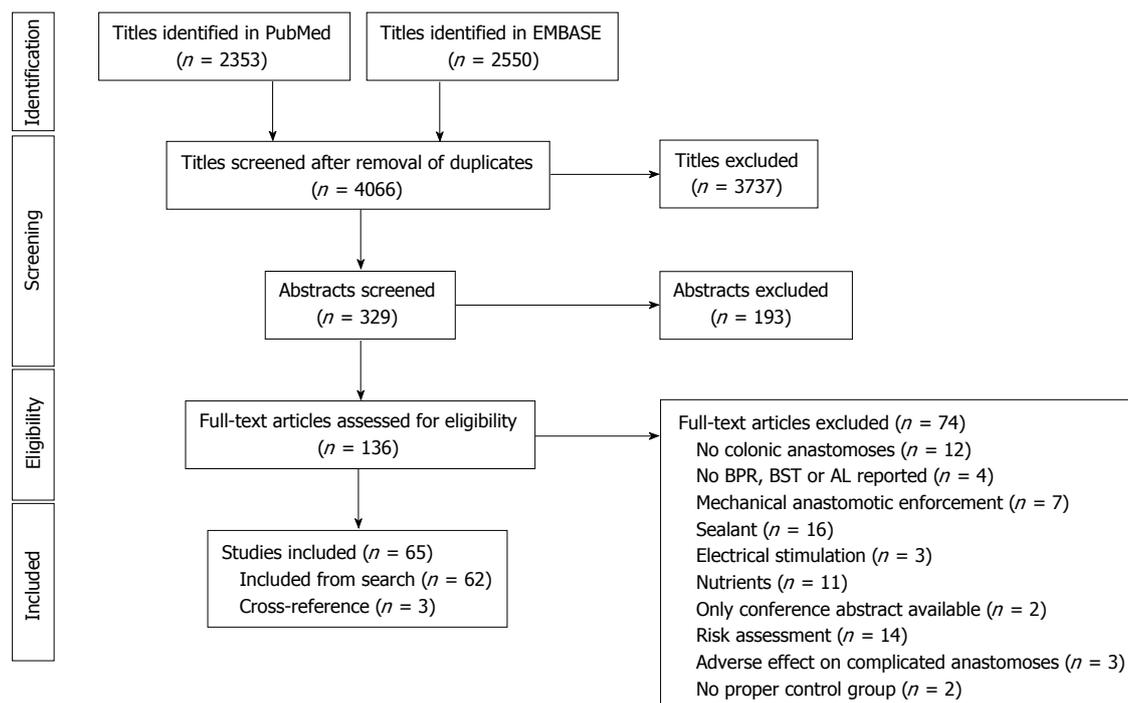

Figure 1 Flow diagram of the identified and selected studies. BPR: Bursting pressure; BST: Breaking strength; AL: Anastomotic leakage.

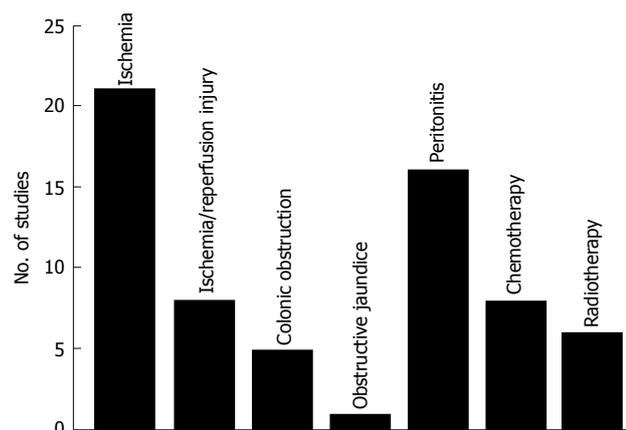

Figure 2 Number of studies included, divided into the 7 models of complicated anastomotic wound healing.

protein levels, BPR, angiogenesis, fibroblast activity and collagen deposition^[21]. VEGF-A and FGF-2 plasmids combined were more effective than the growth factor genes administered individually^[21]. The possibility of synergism between growth factors other than these two would be worthwhile to explore^[21]. Platelet-derived growth factor (PDGF)-BB in a gel applied once to the suture line immediately after construction of the anastomosis increased BPR on day 4^[38]. The mechanism remains elusive because PDGF-BB did not increase hydroxyproline as an indicator of collagen levels^[38]. The anabolic hormones, GH and nandrolone, enhanced early anastomotic healing, presumably by increasing IGF-1 and structural proteins^[32].

Although the main role of leptin is regulation of body weight and energy expenditure, *in vitro* studies have

indicated a direct mitogenic effect of leptin on colonic epithelial cells^[39]. Intraperitoneal leptin also increased the anastomotic strength of right-sided colon anastomoses in rats^[39].

Pentoxifylline enhanced anastomotic BPR on day 8^[34], but not on day 5^[40].

The vasoactive adrenomedullin increased BPR and hydroxyproline levels on postoperative days 3 and 7^[41]. Furthermore, adrenomedullin treatment decreased anastomotic tissue concentrations of tumor necrosis factor- α and interleukin-6^[41]. Increased vascularization and less oxidative damage of the anastomoses were observed with adrenomedullin^[41]. Adrenomedullin causes significant hypotension that may impair the colonic blood flow^[41]. Another caveat is that adrenomedullin may induce neoplasia^[41,42].

The beneficial effects of the endothelin receptor antagonist, bosentan, on anastomotic healing were possibly due to the increased blood flow and increased hydroxyproline level in the anastomotic area^[43]. Bosentan significantly reduced adhesion formation^[43].

Allopurinol reduced the induced superoxide anion production in ischemic anastomoses and increased the hydroxyproline levels^[22].

Allogeneic mesenchymal stem cells (MSCs) derived from bone marrow of rats were cryopreserved. The cells were thawed and injected (1×10^6 viable MSCs) into newly constructed anastomoses in ischemic rat colon. This cell therapy resulted in enhanced BPR on both day 4 and day 7^[44], whereas systemically applied MSCs resulted in a significant effect on day 4 only^[45].

Locally applied granulocyte macrophage-colony stimulating factor (GM-CSF) enhanced anastomotic BPR on days 3 and 7^[46].

A study on the effect of a prostacyclin analogue (OP-41483) on AL was undertaken in dogs with colonic ischemia of variable severity^[47]. Colonic ischemia was induced by devascularization of marginal vessels resulting in slight (40%-60% decrease in colonic blood flow), moderate (60%-80%) or severe (80%-100%) ischemia measured by a hydrogen gas clearance method^[47]. There was no significant difference in AL in the animals with slight ischemia. In the groups with moderate ischemia, OP-41483 prevented the occurrence of AL, possibly by increasing the blood flow in the anastomotic area. All animals with severe bowel ischemia died due to major anastomotic dehiscence^[47].

The enteral combination of neomycin and erythromycin decreased AL significantly in rats, whereas a parenteral combination of clindamycin and gentamicin was ineffective^[48].

The extracellular matrix protein, amelogenin, en-

hanced anastomotic BPR. The mechanism of action remains elusive because amelogenin had no effect on hydroxyproline levels^[49].

Vinpocetine^[40], sildenafil^[50] and the mast cell degranulating agent compound 48/80^[51] had no statistically significant impact on BPR in ischemic colon.

I/R injury

All eight agents tested in rat I/R injury models were evaluated in single studies (Table 2). Before^[52] or, more commonly, after construction of an anastomosis, I/R injury is induced by occluding mesenteric vessels of a 2-3 cm segment of the left colon^[53] or by occluding the superior mesenteric artery^[54-57] with microvascular clamps for 30-60 min before reperfusion.

Notably, antithrombin III (ATIII)^[56] and ethyl pyruvate^[57] treatment increased anastomotic BPR in the I/R injured rats by more than 60%, possibly because of an

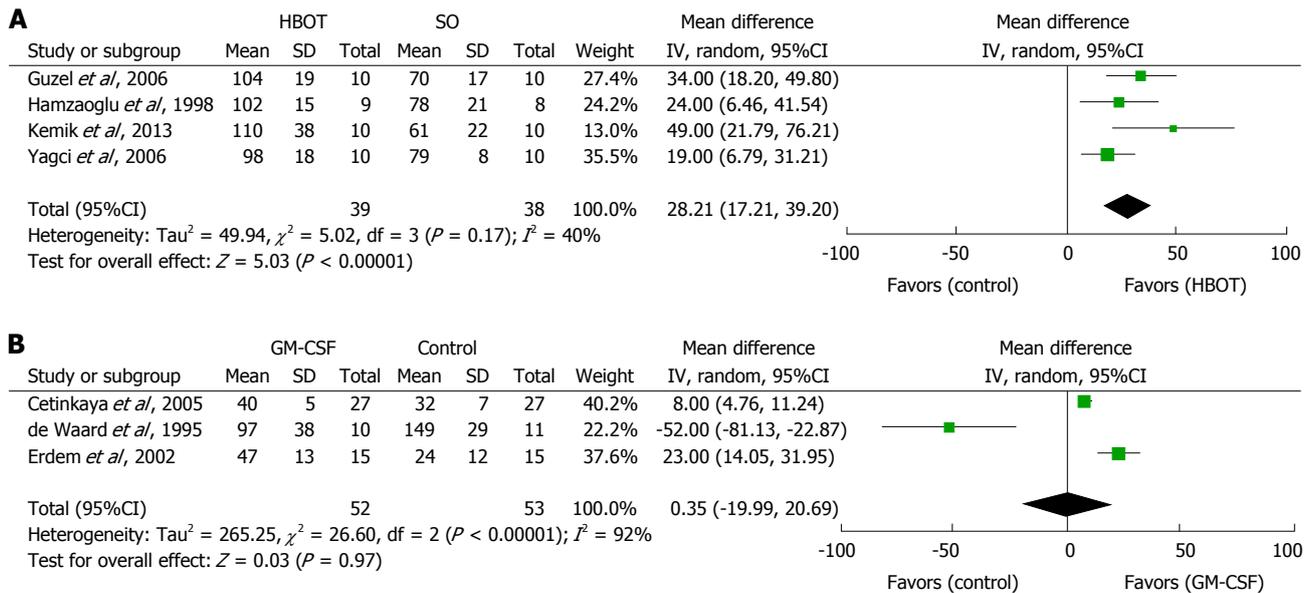

Figure 3 Forest plots of the bursting pressure in mmHg. The results of the meta-analysis for A: Hyperbaric oxygen therapy (HBOT) at days 4-5 in ischemic models (confer, Table 1); B: Granulocyte macrophage-colony stimulating factor (GM-CSF) at days 3 and 7 in chemotherapeutic models (confer, Table 5).

increase in hydroxyproline concentrations.

The antioxidant N-acetyl-cysteine (NAC) significantly increased the hydroxyproline level; histological evaluation also revealed increased collagen deposition compared with the I/R injured control group, independent of the administration route^[53].

Other compounds that prevented I/R-induced reductions in anastomotic patency included tempol^[55], the immunomodulating compounds activated protein C^[58], caffeic acid phenethyl ester^[59] and pyrrolidine dithiocarbamate^[54].

One study reported significantly increased anastomotic BPR and hydroxyproline levels after treatment with montelukast administered intraperitoneally^[52].

Colonic obstruction

Four different agents were investigated in models of colonic obstruction (Table 3). In these models, typically the left-sided colon was obstructed by suture ligation for 24 h. Re-laparotomy was then performed, the obstructed segment was excised, and an end-to-end

anastomosis was constructed^[23,60-63].

In rats with an obstructed colon, intraoperative lavage with povidone iodine (PI) increased anastomotic BPR significantly on day 6 compared with untreated controls in two independent studies^[23,60]. Because the BPR was similar to lavage with saline alone, the additional value of PI remains questionable^[23,60]. NG-nitro-L-arginine methyl ester, an inhibitor of nitric oxide synthase, was found to be detrimental to anastomotic healing in rats with an obstructed colon^[23]. Intra-abdominal irrigation is time consuming, costly, cumbersome and possibly increases the risk of spillage^[64,65]. These circumstances should be taken into account when investigating new lavage agents.

EPO administered after construction of the anastomosis of the obstructed colon significantly increased BPR on day 7 in rats and guinea pigs^[61,63]. EPO possibly enhanced anastomotic healing through increased neovascularization and fibroblast proliferation leading to more collagen in the anastomotic wound^[61,63]. Therefore, further exploration of EPO to improve anastomotic

wound healing under these conditions seems justified.

Iloprost increased BPR on days 4 and 8 in rats, possibly by stimulating angiogenesis and fibroblast activity^[62]. Moreover, iloprost reduced the levels of immunodetectable MMP-13 in the anastomotic tissue, which may explain the increased collagen deposition with iloprost. Significantly more intra-abdominal adhesions formed, which were assessed according to the scale of van der Ham *et al*^[66], in the rats with obstruction compared with the animals without obstruction^[62]. The prostacycline analog iloprost did not reduce adhesion formation in the obstructed animals^[63]. Although iloprost seemed to reduce AL (10% vs 30% for saline controls), this difference did not reach statistical significance^[63].

Obstructive jaundice

Obstructive jaundice was modeled by ligation of the common bile duct. The anastomosis was constructed 7 d later^[17]. GM-CSF, the only agent investigated in this clinical condition, increased BPR and the hydroxyproline level^[17] (Table 3). Increased mononuclear infiltration of the anastomoses was suggested to be the mechanism for the improved anastomotic wound healing with GM-CSF^[17].

Peritonitis

Sixteen different compounds were identified, none of which qualified for the meta-analysis (Table 4). Experimental peritonitis is commonly established by puncture of the colon^[67], ligated cecum^[68-71], or intraperitoneal administration of fecal suspension^[72], *Escherichia coli* suspension^[73] or the Gram-negative wall component lipopolysaccharide (endotoxin)^[74]. Anastomoses were then performed 5-14 h later. In one study, the cecum was ligated and punctured after the anastomosis was performed^[75].

In one study, the vasomodulating agent sildenafil was administered intraperitoneally after the anastomoses were constructed in female rats with peritonitis. Sildenafil decreased intra-abdominal adhesions and increased BPR by 43% on day 7 compared with the controls that received saline alone^[67]. Furthermore, sildenafil stimulated new vessel formation in the anastomoses^[67].

In another rodent peritonitis model, intravenous administration of the thrombin inhibitor ATIII increased anastomotic BPR by 34% on day 2 and by 38% on day 7 compared with the peritonitis control^[74]. Diller *et al*^[74] attributed the improved anastomotic healing with ATIII to increased numbers of perfused capillaries and reduced clot formation, although these improvements failed to reach the levels of the non-infected controls.

Unfractionated heparin (UFH) and low molecular weight heparin (LMWH) prevented the reduction in BPR in animals with peritonitis^[72]. Histopathological examinations revealed increased vascularization and collagen formation of the anastomotic wounds treated with UFH and LMWH^[72]. Notably, UFH and LMWH facilitate intraperitoneal bacterial clearance by preventing formation of fibrin that may act as a reservoir for bacteria^[72].

Ethyl pyruvate increased BPR by 51%, possibly due to its anti-inflammatory effects^[76].

Reactive oxygen species (ROS) are thought to delay wound healing under septic conditions. Tempol is a stable piperidine nitroxide that may dampen the negative impact of ROS through its intracellular scavenging capacity. Tempol also restored glutathione levels and decreased the polymorphonuclear neutrophil counts in the anastomoses^[68]. These effects contributed to the elevated hydroxyproline and BPR levels with tempol^[68].

The anti-inflammatory immunomodulating granulocyte-CSF (G-CSF)^[75], activated protein C^[69], caffeic acid phenethyl ester^[70] and pyrrolidine dithiocarbamate^[71] are attractive for prevention of the deleterious effects of peritonitis and also increase anastomotic BPR. Although G-CSF increased hydroxyproline levels, they were still lower than in the normal control group without peritonitis^[75]. Activated protein C has been shown to reduce 28-d all-cause mortality in sepsis patients and is now approved for the treatment of patients with severe sepsis^[69,77]. The usefulness of activated protein C in colonic anastomotic wound healing in the presence of peritonitis will require more study because of the increased risk of bleeding^[77].

Abdominal lavage with the taurine derivative tauro-

lidine increased BPR on days 3 and 7^[73]. Chlorhexidine lavage had no significant effect on BPR compared with 4-time lavage with 5 mL of sterile saline prior to construction of the anastomosis^[78].

Intravenous administration of hydroxyethyl starch (HES) at 15 mL/kg increased BPR on postoperative day 5 in two studies carried out by the same research group^[79,80], whereas 30 mL/kg was detrimental to anastomotic healing^[80]. These findings may be explained by the anti-inflammatory effects of HES at 15 mL/kg^[79,80], whereas at higher doses, HES reduces platelet aggregation to the injured endothelium^[80]. These facts make HES less practical for use in a clinical setting.

Postoperative HBOT in rats increased BPR by 186% on day 3 and by 74% on day 7^[81]. In another study, HBOT had no effect on BST on day 5^[82].

Local or systemic application of gentamicin^[83], as well as levamisole^[75], had no effect on BPR in male rats with peritonitis.

Chemotherapy

Five different compounds were tested in rats treated with different chemotherapeutic agents (Table 5). In these studies, 5-fluorouracil was given preoperatively^[84,85] or on postoperative days 3-8^[86-90]. Mitomycin-C was given as a single intraoperative dose^[91].

Three studies investigated the effect of GM-CSF^[86,87,91] and were subjected to meta-analysis. The combined estimate demonstrated that GM-CSF failed to increase anastomotic BPR (95%CI: -20 to 21 mmHg, $P = 0.97$) compared with controls (Figure 3B). The inconsistency between studies was large ($I^2 = 92\%$). The two studies demonstrating improved anastomotic healing also reported a significantly increased hydroxyproline concentration in the anastomoses, as well as distinct histological changes, including increased mononuclear infiltration compared with chemotherapy alone (fluorouracil or mitomycin-C)^[86,91]. de Waard *et al*^[87] found that GM-CSF increased BPR, but not BST, in fluorouracil-treated rats. They also applied a considerably lower dose of GM-CSF (5 µg)^[87] than the other two research groups (50 µg)^[86,91]. In addition, GM-CSF was administered intraperitoneally and not locally. Taken together, these data indicate that the GM-CSF dose used by de Waard *et al*^[87] was too low. In contrast, a single local application of GM-CSF in expanded polytetrafluoroethylene tubes implanted subcutaneously in humans inhibited collagen deposition dose-dependently and resulted in systemic effects on wound healing at doses of 4 µg or more^[92].

Iloprost enhanced BPR anastomotic healing on postoperative day 3^[88] and day 5^[89] compared with both the chemotherapeutic group and the non-chemotherapeutic

group, but not at later time points^[88,89]. Interestingly, iloprost significantly decreased the rate of AL from 30% to 0% in rats receiving chemotherapy^[90]. The positive effects on anastomotic strength in models of chemotherapy were possibly due to increased angiogenesis^[90] and collagen deposition with iloprost^[88,90]. Furthermore, iloprost significantly reduced the severity of intra-abdominal adhesions compared with the chemotherapeutic control group^[90].

A single study on IGF-1 treatment reported normalization of anastomotic BPR and hydroxyproline levels on day 7 in fluorouracil-treated rats^[89]. IGF-1 had no significant effects on AL^[89].

Postoperative HBOT increased BPR on day 7 in one study^[84] but had no significant effect on day 5 in another study, in which the rats received combined chemo- and radiotherapy before surgery^[85].

Interleukin-2 administered postoperatively had no effect on either BPR or BST^[87].

Radiotherapy

None of the eight agents identified and investigated in

radiotherapy models qualified for meta-analysis (Table 6). Animals were irradiated with half-body radiation^[27,93] or abdomino-pelvic radiation^[94-96] in a single dose and as rectosigmoid radiation^[97] 5 d a week for 40-45 d.

NAC is theoretically attractive in preventing oxidative damage after radiotherapy. NAC administered before and after construction of the anastomosis also increased BPR^[96]. In one study, NAC treatment increased the levels of superoxide dismutase and glutathione, but decreased malondialdehyde^[96]. Superoxide dismutase and glutathione are known to neutralize toxic substances in the cell, whereas malondialdehyde is a marker for oxidative stress^[96].

Other compounds found beneficial for the prevention of the deleterious effects of preoperative radiation include amifostine^[93,94] and magnesium chloride in combination with adenosine triphosphate^[93].

Ribose-cysteine^[93] administered before surgery improved anastomotic healing day 7 in rats receiving abdominal radiation with 40 GY, but not in irradiated pig colon days 9-11^[97]. No beneficial effects were reported by Carroll *et al*^[93], who investigated the effects of ribose-

cysteine combined with glutamine.

Pycnogenol administered preoperatively increased BPR on postoperative days 3 and 7 in male rats^[27].

EPO had no significant effect on anastomotic strength^[95].

DISCUSSION

We have previously reviewed therapeutics intended to enhance normal anastomotic repair in the colorectal region^[28]. In this paper we systematically retrieved publications on therapeutic agents intended to promote anastomotic wound healing under the influence of complicating factors, including ischemia, I/R injury, colonic obstruction, obstructive jaundice, peritonitis, chemotherapy and radiotherapy. The majority of the 48 different therapeutic compounds identified were only assessed in one study and/or in one complicated model. Meta-analysis was performed for HBOT and GM-CSF. Postoperative HBOT significantly improved wound healing in a rat model complicated by ischemia in the anastomosis. GM-CSF failed to show a beneficial effect on anastomotic healing in conjunction with chemotherapy. On the other hand, positive effects of GM-CSF were found in models of segmental ischemia^[46] and obstructive jaundice^[17]; these findings make this agent interesting for further investigation. Iloprost was found to be beneficial for early healing of anastomotic wounds in rats with colonic obstruction^[62] and in rats exposed to chemotherapy^[88,90], calling for further studies with this agent. The positive actions of NAC after I/R injury^[53] and radiotherapy^[96] justify further investigations on this antioxidant, as well.

Limitations

Because the 65 pre-clinical studies examined in our review used surrogate outcomes in models mimicking clinical phenomena, the results do not directly translate into clinical AL. Only 12 (25%) of the agents were investigated more than once in the same model. Furthermore, 13 (27%) therapeutic compounds were tested in two or more models of complicated anastomotic wound healing. We were unable to assess publication bias, for example, with Funnel plots, due to the small sample sizes of the included studies^[98].

Further exploration of the therapeutic agents identified in this review may be the next step to reach more robust conclusions regarding whether the agents could be effective in preventing AL in high-risk patients.

COMMENTS

Background

Despite improvements in preoperative management and surgical techniques, anastomotic leakage remains a major complication in gastrointestinal surgery. There are no therapeutic agents with documented prophylactic effect against this serious postoperative surgical complication. A recently published meta-analysis identified seven compounds with the potential to improve anastomotic healing under non-complicated conditions.

Research frontiers

This study is the first to systematically review therapeutic agents that are potentially capable of abolishing or reducing the deleterious effects of various known complicating factors on anastomotic healing.

Innovations and breakthroughs

The search identified 48 different therapeutic agents. A meta-analysis indicated that hyperbaric oxygen therapy improved colonic anastomotic repair in models of ischemia.

Applications

This systematic review identified therapeutic substances from pre-clinical studies on complicated anastomotic wound healing that would be worthwhile exploring further for the prevention of anastomotic leakage.

Terminology

Anastomotic leakage results in contamination of the abdominal cavity with intestinal contents, leading to peritonitis or sepsis, or in worst case mortality.

Peer-review

This systematic review assessed the efficacy of therapeutic agents against anastomotic leakage in animal models. The manuscript is excellent, very well written and educational despite being research-oriented. A widespread prospective multicenter trial would be ideal to follow up on the collected information.

World Journal of *Gastrointestinal Surgery*

World J Gastrointest Surg 2016 June 27; 8(6): 402-475

Editorial Board

2016-2019

The *World Journal of Gastrointestinal Surgery* Editorial Board consists of 332 members, representing a team of worldwide experts in pediatrics. They are from 37 countries, including Argentina (1), Australia (6), Austria (2), Belgium (6), Brazil (9), Bulgaria (2), Canada (7), China (30), Finland (2), France (9), Germany (22), Greece (7), India (11), Ireland (3), Israel (3), Italy (46), Jamaica (1), Japan (46), Lithuania (1), Malaysia (1), Netherlands (11), Pakistan (1), Poland (1), Portugal (1), Russia (1), Saudi Arabia (1), Serbia (2), Singapore (3), South Korea (8), Spain (5), Sweden (1), Switzerland (3), Thailand (2), Tunisia (1), Turkey (9), United Kingdom (11) and United States (56).

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Marcus Vinicius Motta Valadao, MD, Doctor, Instituto Nacional de Cancer, Hospital do Cancer Unidade I, Hospital do Cancêr Unidade I, Rio de Janeiro 20220-410, Brazil

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

For advanced proximal gastric cancer (GC), splenic hilar (No. 10) lymph nodes (LN) are crucial links in lymphatic drainage. According to the 14th edition of the Japanese GC treatment guidelines, a D2 lymphadenectomy is the standard surgery for advanced GC, and No. 10 LN should be dissected for advanced proximal GC. In recent years, the preservation of organ function and the use of minimally invasive technology are being accepted by an increasing number of clinicians. Laparoscopic spleen-preserving splenic hilar LN dissection has become more accepted and is gradually being used in operations. However, because of the complexity of splenic hilar anatomy, mastering the strategies for laparoscopic spleen-preserving splenic hilar LN dissection is critical for successfully completing the operation.

Key words: Gastric neoplasm; Laparoscopic; Splenic hilus; Lymphadenectomy; Strategy

Strategies of laparoscopic spleen-preserving splenic hilar lymph node dissection for advanced proximal gastric cancer. *World J Gastrointest Surg* 2016; 8(6): 402-406 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/402.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.402>

VALUE OF SPLEEN-PRESERVING SPLENIC HILAR (NO. 10) LYMPH NODE DISSECTION FOR ADVANCED PROXIMAL GASTRIC CANCER

Value of No. 10 LN dissection for advanced proximal gastric cancer

The most important purpose of radical operations for gastric cancer (GC) is to increase the long-term survival of patients. The thoroughness of lymph nodes (LNs) dissection during the surgery is directly related to a patient's postoperative survival rate. No. 10 LN dissection is an important but difficult part of a D2 radical resection for advanced proximal GC. The rate of No. 10 LN metastasis has been reported to be 9.8%-27.9%^[1-3]. Shin *et al*^[4] reported that of 319 patients, 41 (12.9%) had No. 10 LN metastasis. No. 10 LN metastasis was not observed in patients with early GC. Data from Japanese patients also revealed that the No. 10 LN metastasis rate in early proximal GC is so low (0.9%) that the No. 10 LN does not need to be dissected. However, in advanced GC, the No. 10 LN metastasis rate is 13.4% in stage T3 and 34.4% in stage T4^[5]. A 346-case analysis of laparoscopic spleen-preserving No. 10 LN dissection for proximal GC conducted by our center indicated that the incidence of No. 10 LN metastasis is 10.1% in advanced proximal GC^[6]. No. 10 LN metastasis is mainly associated with the tumor size, depth of invasion, Borrmann type and histological type. The rate of GC in the upper region is significantly higher than that in the lower third of the stomach^[7]. Koga *et al*^[8] reported that No. 10 LN metastasis frequently appears in Borrmann type IV cancer or when the primary tumor involves the serosa or the entire stomach. Okajima *et al*^[9] reported a higher No. 10 LN metastasis rate (26.7%) in GC involving the entire stomach. Moreover, the survival rate is significantly associated with No. 10 LN metastasis. Shin *et al*^[4] reported that the 5-year survival rate was significantly lower for a No. 10 LN metastasis group (11.04%) than for a non-metastasis group (51.57%) ($P < 0.05$). Chikara *et al*^[10] reported that the 5-year survival rate of patients with No. 10 LN metastasis was 23.8%, whereas the rate in patients without No. 10 LN

metastasis was 41.4% ($P < 0.05$). Thus, the No. 10 LN metastasis status is a significant prognostic factor for GC. No. 10 LN dissection is necessary in advanced upper GC because the radical excision of a tumor seems to be insufficient. Kosuga *et al*^[11] reported on 280 patients who underwent curative total gastrectomy with simultaneous splenectomy. No significant difference was found in the 5-year survival rates between patients with and without No. 10 LN metastasis (51.3% and 42.1%, respectively). Ikeguchi *et al*^[12] reported a study of patients who underwent curative total gastrectomy with simultaneous No. 10 LN dissection. This study also revealed that the 5-year survival curves of No. 10 LN-positive patients did not differ from those of No. 10 LN-negative patients. Therefore, the value of LN dissection in this area is significant. No. 10 LN dissection is becoming more accepted by an increasing number of clinicians.

Value of spleen-preserving No. 10 LN dissection for advanced proximal GC

Before the 1990s, a pancreateosplenectomy was performed to completely excise No. 10 LNs. The prophylactic dissection of No. 10 LNs using this surgical method increases the risk of distal pancreatectomy-associated complications^[13,14]. Currently, this surgical method is only performed when direct invasion of the spleen or of the body and tail of the pancreas is observed. Many subsequent studies have reported that pancreas-preserving splenectomy with No. 10 LN dissection has a similar survival rate and morbidity but significantly lower incidence of complications and mortality compared with pancreateosplenectomy. Therefore, pancreas-preserving splenectomy with No. 10 LN dissection has been recommended as a curative procedure for standard D2 dissection in place of pancreateosplenectomy^[9,15,16]. However, Yang *et al*^[17] reported a meta-analysis of 466 patients showing that gastrectomy with splenectomy was not associated with a significantly different 5-year overall survival rate relative to splenic preservation, with an RR of 1.17 (95%CI: 0.97-1.41, $P < 0.05$). Splenectomy did not prolong survival. The RR of splenectomy did not significantly influence postoperative morbidity and mortality based on a 5-year overall survival rate outcome compared to splenic preservation for proximal and whole GC (RR = 1.14, 1.76 and 1.58, respectively). In recent years, many subsequent studies have shown that the spleen is the largest peripheral immune organ in the human body. The spleen can participate in normal operation of the circulatory system for immune regulation and also has roles in the immune and endocrine systems; additionally, it contains numerous immune cells, which play important roles in anti-tumor immunity. Some researchers have applied immunotherapy postoperatively in cases of advanced GC and determined that natural killer (NK) cell activity and the IL-2 concentration were significantly higher in a spleen-preserving group than a splenectomy group. They concluded that spleen preservation in a radical

operation enables immunotherapy for patients with advanced GC^[18,19]. The Dutch scholar H.H. Hartgrink performed a multicenter randomized controlled trial that followed up 1078 patients for more than 10 years and found that morbidity and mortality were significantly increased if splenectomy was performed. In contrast, pancreas- and spleen-preserving LN dissection (D2) improved patient prognosis^[20]. Schwarz^[21] reported that with the development of surgical techniques, spleen-preserving No. 10 LN dissection is technically feasible. Therefore, spleen-preserving No. 10 LN dissection is becoming more accepted by an increasing number of clinicians.

VALUE AND PROCEDURE OF LAPAROSCOPIC SPLEEN-PRESERVING NO. 10 LN DISSECTION

Value of laparoscopic spleen-preserving No. 10 LN dissection

This operation tends to reduce surgical trauma, increase safety, and protect organ function. With further study of the disease, surgical instruments and technology have been continuously developed. Traditional open operations do not meet patients' needs. Laparoscopic D2 LN dissections are conducted by many surgeons who demonstrate a mature grasp of laparoscopic technology. The first report of laparoscopic spleen-preserving No. 10 LN dissection regarding the treatment of GC in the upper third of the stomach was published by Hyung *et al.*^[22] in 2008. In our study, the average number of LNs retrieved using laparoscopic surgery was 3.6 per patient, and no patients required an open conversion resulting from an injury to the spleen or its vessels. No complications such as hemorrhage, splenic ischemia or splenic necrosis associated with dissection of the splenic hilar region were observed postoperatively, indicating favorable short-term outcomes^[23]. Although to date the prognostic benefit of laparoscopic splenic hilar LN dissection for advanced GC is under debate, a randomized controlled trials on laparoscopic spleen-preserving No. 10 LN dissection for advanced middle or upper third GC (No. NCT02333721) is ongoing in our center. We think it could demonstrate that this procedure has potential benefit for those patients without increase in morbidity in experienced center.

Operative procedure of laparoscopic spleen-preserving No. 10 LN dissection

Regarding the different surgical approach, some experts use a medial approach. Dissection of the No. 11p, 11d, and 10 LNs is then performed with ultrasonic shears from the root of the splenic artery (SpA) toward its distal end. This procedure requires severing of the short gastric vessels (SGVs) prior to LN dissection, which is facilitated when the surgeon stands on the patient's right side. Other experts use a retropancreatic approach in which the surgeon starts

with division of the gastrosplenic ligament and severing of the left gastroepiploic and short gastric vessels. We utilize a left-sided approach in which the LNs are excised from the SLA toward the root of the SpA, and the SGVs are severed at their roots. This approach, which enables the complete removal of No. 10 LNs and the stomach, is consistent with the concept of oncological radical resection. Our center performed laparoscopic spleen-preserving No. 10 LN dissections in January 2010 during more than 500 laparoscopic GC surgeries. We have summarized an effective procedure called Huang's three-step^[24] maneuver for performing laparoscopic spleen-preserving No. 10 lymphadenectomies in clinical practice. We divided the originally complex operation steps into three steps as follows: The first step includes the dissection of LNs in the inferior pole region of the spleen, the second step includes dissection of the LN in the region of the SpA trunk, and the third step includes the dissection of LNs in the superior pole region of the spleen.

STRATEGIES OF LAPAROSCOPIC SPLEEN-PRESERVING NO. 10 LN DISSECTION

To safely and effectively perform laparoscopic spleen-preserving No. 10 LN dissection, the following points should be considered.

Importance of teamwork

At our center, we realized that stable and automatic teamwork plays an important role in laparoscopic spleen-preserving No. 10 LN dissection. Above, we not only introduced the concrete operative steps taken by each participant but also indicated the scope and methodology of each technique to simplify the complicated No. 10 LN dissection procedure and to improve the efficiency of the operation. By presenting this information, we hope to promote laparoscopic spleen-preserving No. 10 LN dissection, and we hope that this technique will become more popular.

Step over the learning curve

Similar to other laparoscopic surgeries, performing laparoscopic spleen-preserving No. 10 LN dissection requires an initial learning phase to allow the surgeon to develop adequate and stable skills. Thus, when a certain number of surgeries are performed, the surgeon's operative technique significantly improves, typically reaching a plateau over time. With respect to achieving proficiency in laparoscopic GC surgical techniques, a surgeon can be considered to have stable skills after he has performed 40 surgical training procedures^[25]. To shorten the learning curve, the surgeon should perform the procedure on patients in good condition who are younger and have fewer complications, smaller tumors, or leaner figures. These criteria facilitate a reduction in surgical risk while

increasing the surgeon's confidence, helping him to eventually achieve proficiency. An adequate ability to summarize one's experiences and lessons and to explore the operative position and anatomical approach that are most suitable for oneself will help the surgeon to gradually establish relatively stable surgical abilities.

Be familiar with the complex anatomy in this region

Because of the deep location of the splenic hilar, the narrow operative space, the fragile texture of the spleen, the tortuosity of splenic vessels and the complicated branching of the SLA, adequate exposure of the splenic hilar area is difficult. There is a high risk of injury to the splenic parenchyma or to adjacent organs such as the pancreas and adrenal gland in a No. 10 LN dissection. In addition, the splenic vessels exhibit a tortuous course, and their branches are complex. This configuration may lead to a high risk of vessel injury and result in uncontrollable hemorrhage during laparoscopic dissection in this region. Therefore, we hypothesize that 3-dimensional computed tomography (3DCT) reconstruction can be used preoperatively to detect the distribution of the splenic vessels. The research outcomes of our unit also revealed that the operative time and intraoperative blood loss were significantly decreased in the 3DCT group compared with the non-3DCT group^[26].

PROSPECT OF LAPAROSCOPIC SPLEEN-PRESERVING NO. 10 LN DISSECTION

Presently, although the long-term curative effect of laparoscopic spleen-preserving No. 10 LN dissection for advanced proximal GC is still not fully supported by evidence-based medical research, the development of minimally invasive technology, represented here by laparoscopic technology, is an inevitable trend in GC surgery. Therefore, a randomized controlled trial for spleen-preserving No. 10 LN dissection for advanced proximal GC should be conducted to further confirm the efficacy of laparoscopic spleen-preserving No. 10 LN dissection.

Moreover, not all centers can presently complete independent laparoscopic spleen-preserving No. 10 LN dissection. Surgeons at these centers must first master techniques for laparoscopic spleen-preserving No. 10 LN dissection despite the substantial learning curve. Mastery of these techniques is the key to successfully completing the operation. Providing professional training for GC surgeons, establishing an active, hands-on training program and employing experienced and senior surgeons who can convey their knowledge and experience to young doctors are critical. Improving the level of integration of laparoscopic spleen-preserving No. 10 LN dissection is also challenging. Therefore, laparoscopic spleen-preserving No. 10 LN dissection will likely become one of the standard treatments for advanced proximal GC following improvement of the

standardized operation training system and laparoscopic technology and the promotion of Huang's three-step technique.

Abstract

Liver resection is the treatment of choice for patients with colorectal liver metastases (CLM). However, major resections are often required to achieve R0 resection,

which are associated with substantial rates of morbidity and mortality. Maximizing the amount of residual liver gained increasing significance in modern liver surgery due to the high incidence of chemotherapy-associated parenchymal injury. This fact, along with the progressive expansion of resectability criteria, has led to the development of a surgical philosophy known as "parenchymal-sparing liver surgery" (PSLS). This philosophy includes a variety of resection strategies, either performed alone or in combination with ablative therapies. A profound knowledge of liver anatomy and expert intraoperative ultrasound skills are required to perform PSLS appropriately and safely. There is a clear trend toward PSLS in hepatobiliary centers worldwide as current evidence indicates that tumor biology is the most important predictor of intrahepatic recurrence and survival, rather than the extent of a negative resection margin. Tumor removal avoiding the unnecessary sacrifice of functional parenchyma has been associated with less surgical stress, fewer postoperative complications, uncompromised cancer-related outcomes and higher feasibility of future resections. The increasing evidence supporting PSLS prompts its consideration as the gold-standard surgical approach for CLM.

Key words: Colorectal liver metastases; Parenchymal-sparing hepatectomy; Ultrasound; Liver failure; Resection margins; Complications; Ablative therapies

INTRODUCTION

Colorectal carcinoma is the third most frequent cancer in the world, with nearly 1.23 million new cases diagnosed each year^[1,2]. About half of these patients will develop liver metastases during the course of the disease, causing two thirds of deaths^[3]. In terms of treatment, liver resection is the treatment of choice to prolong survival and offer a chance of cure to patients with colorectal liver metastases (CLM)^[3,4]. However, resection is not always feasible due to tumor location, contact with major vascular elements, bilaterality, insufficient liver remnant or patient comorbidities. Although not long ago the majority of patients with CLM (70%-80%) were considered unsuitable for resection at diagnosis, nowadays a greater number of patients finally undergo surgery thanks to the significant improvements in imaging modalities, surgical techniques, anesthesia, chemotherapy regimens and the expansion of resectability criteria among surgeons^[4].

Over the years, hepatobiliary surgeons have been constantly pushing the frontiers of resectability in patients with malignant liver tumors. The paradigm of resectability in modern liver surgery has shifted from "what is resected" to "what remains after resection"^[5]. Surgeons performing oncological liver surgery must balance two conflicting objectives that might jeopardize each other whenever extensive disease is present: (1) to achieve a complete tumor resection with curative intent (negative margins); and (2) to preserve as much liver parenchyma as possible to avoid liver failure. However, major hepatectomies are often required to achieve an R0 resection and these are associated with substantial rates of morbidity and mortality^[6]. Posthepatectomy liver failure (PLF) is the main cause of death after major hepatectomy and it is strictly related to the volume and quality of the future liver remnant (FLR)^[7]. Several strategies have been developed to minimize the risk of PLF and expand resectability. These strategies could be grouped into those that tend to reduce the tumor size (*e.g.*, conversion chemotherapy, endovascular procedures) and those that tend to preserve or increase the amount of liver remnant (*e.g.*, local ablation techniques, preoperative portal vein embolization, two-stage procedures). These developments led to the successful removal of multiple, often bilateral, liver lesions otherwise considered unresectable. Yet, when using classical approaches of portal vein occlusion (either ligation or embolization) to increase the amount of FLR, up to 40% of patients never become eligible for tumor resection either because of insufficient hypertrophy or disease progression during the long interval periods

(6-12 wk) usually required to achieve hypertrophy^[8,9]. Moreover, patients who fail to complete the second stage have worse survival than those treated with chemotherapy alone^[10].

Although maximizing the amount of residual liver parenchyma has always been a matter of concern among surgeons, it has become a major issue to modern liver surgery due to the high incidence of parenchymal injury associated with downsizing chemotherapy (*i.e.*, steatohepatitis, sinusoidal obstruction syndrome), where the extent of resection critically determines postoperative risk. The need of preserving non-tumor parenchyma as well as the progressive expansion of resectability criteria for CLM, mainly related to the significant reduction of what was considered a sufficient tumor margin, has led to the development of a surgical concept known as "parenchymal-sparing liver surgery" (PSLS). This philosophy gathers various surgical strategies aiming to offer the minimum sufficient margins in order to preserve as much liver parenchyma as possible, where preoperative planning and intraoperative ultrasound (US) are key factors for success. PSLS, which intends to avoid major liver resections and eventually the need of using techniques to induce FLR hypertrophy, has recently been associated with equal or better perioperative and long-term outcomes than non-PSLS^[11-13].

This review aims to critically analyze the literature available to date regarding PSLS in the treatment of patients with CLM.

HISTORICAL PERSPECTIVE AND ONCOLOGICAL BASIS

Over the years, there has been an increasing trend towards PSLS for patients with stage IV colorectal cancer in most specialized centers around the world. This has been clearly reflected by the group from Memorial Sloan-Kettering Cancer Center (MSKCC), demonstrating that the techniques used to deal with bilateral CLM changed uniformly over a 20-year period in favor of wedge resections and ablations to spare uninvolved surrounding liver instead of major hepatectomies^[12]. From an oncological perspective, there are mainly two factors closely associated with this phenomenon: (1) The evolution of the concept of resectability; and (2) The increased knowledge on tumor biology.

Tumor resectability

The concept of tumor resectability in CLM has evolved greatly in the past three decades. In the 1970s, most surgeons considered resection only in patients with single liver metastasis. In 1984, Adson *et al.*^[14] reported similar 5-year survival rates between patients with solitary metastases and those with multiple lesions (25% and 18%, respectively). Two years later, Ekberg *et al.*^[15] identified a series of poor prognostic factors associated with surgical resection and proposed to

contraindicate surgery in patients with any of the following characteristics: More than four lesions, bilobar compromise, impossibility to achieve a margin of at least 1 cm and presence of extrahepatic disease. These were known as the "Ekberg criteria" and were welcomed by various authors up to the late 1980s. During the 1990s, this concept evolved again due to the increased use of chemotherapy and more aggressive surgical treatments with favorable outcomes were performed in patients presenting the characteristics traditionally considered contraindications^[16]. Probably the most important breakthrough with regards to tumor margins was accomplished by Pawlik *et al*^[17] in 2005, who demonstrated that the width of a negative surgical margin did not affect survival, recurrence risk, or site of recurrence. In this study, which included 557 patients undergoing liver resection for CLM, negative margins had similar overall recurrence rates (1-4 mm: 38.7%; 5-9 mm: 41.2%; ≥ 10 mm: 39.2%, $P = 0.32$) and 5-year overall survival (OS) rates (1-4 mm: 62.3%; 5-9 mm: 71.1%; ≥ 10 mm: 63.0%, $P = 0.63$). This was later supported by many authors, including a recent propensity score-matched analysis in 2715 patients demonstrating that the disease-free survival (DFS) was not significantly different between patients with more than 1 mm margin (1-4.9 mm vs 5-9.9 mm vs ≥ 10 mm), and showed that a 1 mm cancer-free margin was sufficient to achieve 33% 5-year DFS^[18]. Moreover, unfortunately around 70%-80% of patients with bilateral CLM recur within five years of surgery, most of them with disease at an extrahepatic site as a component of a recurrence pattern in which a wide resection margin would not really make any difference^[12,19,20].

Along with the finding that the width of surgical margin did not correlate with liver recurrence, several surgeons started favoring limited liver resections over major hepatectomies. This laid the foundations for the development of sophisticated techniques to spare liver parenchyma. However, there are special situations where achieving a negative margin might require sacrificing more parenchyma than expected by preoperative and intraoperative evaluation. Mentha *et al*^[21] found a dangerous halo of re-growing tumor occurring at the periphery of the metastasis when chemotherapy was interrupted before surgery in patients undergoing two-staged liver resections, regardless of previous response. Therefore, a resection margin wider than 1 mm might be especially advisable when chemotherapy is interrupted for a long time before surgery.

Although securing a margin larger than 1 mm should be considered the standard of care, recent evidence suggests that in the era of modern chemotherapy, even patients with microscopic positive margins (R1) may benefit from resection because survival is similar to that of R0 resection and better than chemotherapy alone^[22,23]. Moreover it has been

demonstrated that the negative impact of positive margins is mainly restricted to patients with suboptimal response to preoperative chemotherapy^[24]. Nowadays the paradigm of resectability considers that CLM should be resected regardless of size and number, provided resection is complete (negative margins), the remaining parenchyma is sufficient to prevent PLF and there is no unresectable extrahepatic disease^[25].

Tumor biology

There are two known mechanisms for intrahepatic spread of CLM: Metastasis from the primary site and remetastasis from other existing metastases. Most liver metastases arise from circulating tumor cells that have shed into the bloodstream from the primary tumor^[26,27]. Given that the distribution of such deposits is random, the presence of a high density of micrometastases in the immediate vicinity of the main tumor indicates that the majority of such micrometastases might have derived from the closest main tumor^[27,28]. Contrarily to hepatocellular carcinoma, tumor cells from CLM do not migrate into intrahepatic portal branches to form intrahepatic secondary metastases. Instead, intrahepatic lymphatic invasion is in fact the main responsible for "remetastasis" from liver metastases^[28,29]. The incidence and distribution of intrahepatic micrometastases (IHM), defined as any microscopic lesions separated from the gross tumor by a rim of non-neoplastic parenchyma, remains controversial in the literature. Kokudo *et al*^[27] demonstrated an incidence of histological IHM of 24%. However, the incidence of genetically confirmed IHM in the study was 2% and they were located within 4 mm of the tumor border. In contrast, Wakai *et al*^[28] found in a more recent study an incidence of IHM of 58%, 95% of them located in the close zone (< 1 cm). The differences found in these studies might have been related to different patient populations, IHM detection methods and variable use of chemotherapy, as recent evidence demonstrated that neoadjuvant chemotherapy in CLM reduces the incidence of IHM^[30]. Despite the differences found in terms of IHM incidence and location, both studies recognized a 2 mm margin as the acceptable minimum requirement based on survival analysis and margin recurrence^[27,28]. Moreover, a recent retrospective study evaluating intrahepatic mechanisms of invasion on patients undergoing resection of CLM demonstrated that lymphatic vascular invasion rather than blood vascular, biliary, or sinusoidal invasion is the key prognostic marker of aggressiveness and spread of CLM, and this feature was evident only within 2 mm from the tumor edge^[31].

Segmental resections including tumor-bearing portal branches and the corresponding liver parenchyma in CLM do not appear justified at least from a theoretical point of view. On the other hand, while previous authors have advocated anatomic hepatectomies on the basis of a reduced likelihood of margin involvement, a recent meta-analysis including 1662 patients contradicted

this data demonstrating that the incidence of a positive surgical margin was equal in both anatomic resection (AR) and non-anatomic resection (NAR) groups (OR = 0.64; 95%CI: 0.31-1.32; $P = 0.23$)^[13]. Moreover, most studies evaluating long-term oncological outcomes have demonstrated that there is no benefit of AR over NAR in terms of 5-year OS and DFS in patients with similar tumor characteristics^[13,32]. Other studies have looked specifically at differences between major AR vs restricted NAR in patients with limited resectable disease (one or two lesions). Kokudo *et al*^[33] demonstrated that prophylactic large resections were useless in preventing intra- or extra-hepatic recurrence in the majority of patients, since ipsilateral recurrence developed in only 19.6% of patients undergoing limited NAR and 90% of such recurrences could undergo second hepatectomy, compared to only 20% in the AR group. In this study, equivalent 5-year OS was reported between major AR vs limited NAR (45.7% vs 40.4%). More recently, the MD Anderson group^[11] found that patients with a solitary tumor of less than 30 mm in size who underwent partial wedge resection instead of right hepatectomy, left hepatectomy or left lateral sectionectomy (LLS) had similar liver-only recurrence rates (14% vs 17%, $P = 0.44$) and significantly improved survival due to higher salvageability (68% vs 24%, $P < 0.01$). Taken together, this evidence clearly demonstrates that a combination of a first limited NAR followed by repeated hepatectomy in case of recurrence offers equivalent or even more benefits than major hepatectomy in patients with few unilobar metastases and should probably be considered now on the standard of care approach^[11,33]. Moreover, although the prognostic significance of micrometastases is still controversial, it should be taken into account that the greater the amount of liver parenchyma resected, the more likely to accelerate the growth of occult intra or extrahepatic disease as a response to growth factors and cytokines produced to stimulate liver regeneration^[11,34-36]. This fact might be especially important in patients with aggressive disease behavior. Tanaka *et al*^[37] found that the prognosis of patients having 6 or more metastases was poorer after major resection than after multiple minor resections, perhaps due to a more accelerated growth of micrometastases after a massive hepatectomy. Current evidence indicates that the hypothetical benefit of prophylactically resecting more "at-risk" parenchyma where metastases could seed does not really reduce disease recurrence and is counteracted in the clinical setting by increased patient risk, more tumor stimulation and less chances of future repeated resection. Thus, it seems to be that tumor biology (as expressed by primary tumor stage, preoperative CEA level, number and size of metastatic tumors, time from primary tumor treatment to hepatic metastases, preexisting occult metastases and the presence of extrahepatic disease) rather than the number of millimeters present at a negative surgical margin, is the most important factor determining survival in patients with CLM.

PREOPERATIVE ASSESSMENT AND PATIENT SELECTION

All patients with CLM should be discussed at a multidisciplinary tumor board and considered eligible for surgery with curative intent on a case-by-case basis. Either patients with single or multiple liver metastases are potentially eligible for a parenchymal-sparing type of surgery as has been demonstrated by several authors^[11-13,33,37]. Preoperative staging should include a multislice computed tomographic (CT) scan of the abdomen and chest, as well as an abdominal magnetic resonance imaging (MRI) for a better assessment of patients with small lesions, a fatty liver or preoperative chemotherapy^[38]. Positron emission tomography (PET) scan should be considered in case of tumor recurrence in patients with a previous liver resection or suspected distant metastasis.

Eligibility for surgery should be determined taking into account three aspects: (1) risk perspective; (2) technical resectability; and (3) oncological rationality. With regards to risk perspective, medical fitness for general anesthesia and major abdominal surgery (anesthesiological risk and patient fragility) has to be carefully evaluated preoperatively. In certain cases, this includes the evaluation of the underlying parenchymal status and function. Surgeons should be especially careful with obese patients and those who have undergone long-course chemotherapy regimens, consequently adjusting the volume of the predicted FLR to its respecting quality. For patients with normal hepatic function, a FLR of approximately 25% of total liver volume is considered sufficient to maintain liver function after resection^[39]. On the other hand, in patients with hepatic dysfunction or liver injury (*e.g.*, because of chemotherapy) a FLR of at least 40% of total liver volume is highly recommended^[40]. The surgical indication should therefore be tailored according to the existence of both patient and liver-related operative risks. PLS might be particularly beneficial for patients with a high operative risk for major resection, who would otherwise not be candidates for resection. From a technical perspective, the availability of state-of-the-art abdominal imaging is crucial to define resectability and to plan the optimal surgical procedure. However, given the widely varying concept of resectability among surgeons, as evidenced by the literature^[41], surgical exploration should be undertaken at specialized centers only when the surgical team strongly believes that a potentially curative operation will be feasible. Even though resection with negative margins of every CLM is the preferred treatment option, it has to be remarked that when selecting candidates for PLS, the combination of resection of most lesions with radiofrequency ablation of those unfavorably located could be considered for certain patients in order to offer the best possible survival^[12,42]. From an oncological perspective, evaluation of extrahepatic disease and its resectability, as well as the response to pre-operative

systemic therapy in patients with dismal prognostic factors are main considerations, as they are the most likely to benefit from this approach. Thus, associating an acceptable patient risk with a safe technical proposal and a reasonable oncological indication should be the goal of liver surgeons when selecting candidates for PLS. As in any type of liver resection, unresectable extrahepatic metastases or unresectable primary tumor, prohibitive anesthesiological risk and medical contraindications to hepatectomy still constitute contraindications for resection.

IMAGING TECHNIQUES AND OPERATIVE PLANNING

Operative planning is the key for successful treatment in patients with CLM. As mentioned before, a parenchymal-sparing approach should be preferred whenever possible. Hepatic surgery has evolved greatly in the last 20 years and advances in complementary imaging studies have played a key role in this development.

Imaging techniques

Operative planning is essentially based on imaging techniques, both pre- and intra-operatively, since the type of surgical procedure will be personalized to each patient according to the size, location and number of tumors. In the preoperative setting, multislice CT-scan utilizing tri-phase contrasted acquisitions is still the standard imaging modality for the liver, and while it is principally used for the evaluation of liver tumors, it also provides useful information about the quality of liver parenchyma, vascular distribution, total and partial liver volumes, *etc.*^[43]. Nowadays multislice CT angiography with three-dimensional (3D) reconstruction has replaced hepatic angiography for the preoperative study of vascular liver anatomy. Regarding specifically CLM evaluation, recent evidence suggests that MRI offers superior sensitivity and specificity compared with CT-scan, particularly for the detection of lesions measuring less than 1 cm^[38]. Diffusion-weighted imaging techniques of MRI improves the diagnostic accuracy because of the differences in proton diffusion between benign and malignant tissue, the last showing in general a more restricted diffusion. Furthermore, the recent introduction of new liver-specific MRI contrast agents has further improved the capacity of MRI for detecting and characterizing small lesions^[38].

With regards to the intraoperative scenario, ultrasonography deserves a particular mention since it stands out as the most important imaging aid to the surgeon and PLS is essentially an ultrasonographically-guided surgical approach^[44,45]. After being described by M. Makuuchi in 1977, intraoperative ultrasound (IOUS) exploration of the liver has gained increasing protagonism and is nowadays a fundamental component of modern liver surgery. IOUS guidance is crucial to fulfill the objective of PLS, which is essen-

tially to minimize resection margins while keeping the oncological radicality, reducing the rate of major hepatectomies and whenever possible avoiding the need for strict anatomic approaches. IOUS should be the first step of any liver surgery and has to be always carried out personally by the surgeon in charge rather than an assistant, radiologist or technician. It allows to confirm the findings of preoperative images, evaluate vascular anatomy, study the tumor-vessel relationships, assess the direction of portal flow and to guide the planned type of resection or ablation. Therefore, state-of-the-art color Doppler ultrasonography equipment with standard convex, microconvex and T-shaped probes should be present in the operative room. The liver is usually evaluated at 5 and 7.5 MHz^[44,45]. The preferred probes to obtain the best images without artifacts are those that can be sterilized and then stay in direct contact with the liver surface. If available, contrast-enhanced IOUS (CE-IOUS) may help intraoperative staging and assessment of tumor relation with the liver vascular structures. This seems to be especially important in patients who received preoperative chemotherapy, scenario in which Ruzzenente *et al.*^[46] found that CE-IOUS allowed detecting additional lesions in 14% of patients and changing the operative management in 18% of patients, therefore improving both the sensitivity of IOUS to detect CLM and the R0 resection rate.

Although standard IOUS provides real-time visualization of anatomic structures, limitations may arise from the 2D nature of the images. Recent technological advances have enabled operation planning using 3D image-processing software for both CT and US^[47,48]. Detailed 3D anatomical information could facilitate complete tumor removal while preserving a sufficient amount of functional liver tissue especially in complex liver surgery and interventional treatments. Those who favor navigation in liver surgery argue that this technology is not only useful for guiding surgical instruments during resection or ablation, but also for the treatment of patients who have received chemotherapy prior to liver resection or who have steatosis, where liver parenchyma is often difficult to evaluate with conventional US. However, despite several efforts to make real-time navigation feasible, some limitations continue to hamper its clinical application. Lack of millimetric accuracy, deformation of the liver parenchyma during resection, and breathing movements are some of the most important criticisms of this method. Recent preliminary studies using navigation systems that integrate IOUS, preoperative CT imaging and 3D anatomic models on a single display have shown promising results^[49]. Real-time navigation systems might become in the near future an important adjunct for safe liver resections, although its actual applicability for PLS has not been consistently proven yet.

Operative planning

The final technical strategy should be decided upon

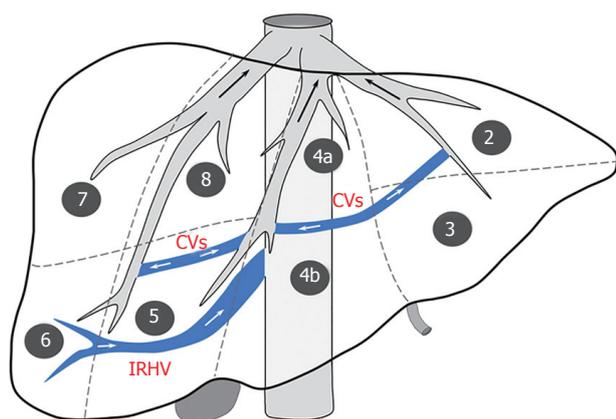

Figure 1 Diagram of liver segmentation and the anatomical variations of hepatic outflow important for parenchymal-sparing liver resections. CVs: Communicating hepatic veins; IRHV: Inferior right hepatic vein.

completion of IOUS assessment, based on the following: Unexpected discovery of new lesions or invasion of vascular structures, FLR volume, chemo-related liver toxicity and the need to perform simultaneous resection of the primary tumor or adjacent organs. Atypical resections can be used for peripheral lesions, but some tumors might require larger and eventually anatomical resections only because they are located centrally or in the vicinity of major portal pedicles or hepatic veins (HVs). With specific regards to the feasibility of PSLS related to vascular proximity, Torzilli *et al.*^[50] proposed certain criteria to define operative strategy. Whenever a tumor is near a HV close to the hepato-caval confluence and either of the following is present: (1) the tumor is not separated by a thin layer of liver parenchyma; (2) there is vessel wall discontinuation; or (3) the contact exceeds 1/3 of the vessel diameter; the vessel has to be sacrificed and AR of the segment/s (S) is many times necessary to avoid the risk of congestion if certain vascular variations are not present. In this scenario, after HV resection, the drained liver can't be spared and if the FLR is not sufficient to allow major resection, HV reconstruction could represent the only surgical option^[51]. Similarly, when a tumor is near a Glissonian pedicle and contact exceeds 2/3 of the diameter or a distal bile duct dilatation is present, it is mandatory to sacrifice the corresponding anatomic territory^[52].

Anatomical principles

The vascular anatomy of the liver should be thoroughly assessed with imaging methods before PSLS. Hepatic venous variants, as well as the pattern of venous drainage into the inferior vena cava (IVC) need to be specially investigated^[53]. This is particularly important when en-block resection of a HV and part or the entire adjacent liver segment/s needs to be performed for tumors involving HVs at the hepato-caval confluence.

More frequently, the right HV (RHV) drains S5, 6, 7 and 8; the middle HV (MHV) drains S4, 5 and 8; and the left HV (LHV) drains S2, 3 and 4. However, S6 may have an independent drainage directly into the IVC^[53].

Although this accessory HV is present in most patients (86%-100%), it is larger than 0.5 cm in less than a quarter of them, representing a variant known as inferior right HV (IRHV)^[53,54]. Another important anatomical variation is the presence of communicating veins (CVs), which connect adjacent HVs, and have been demonstrated using IOUS in up to 80% of patients with CLM at the hepato-caval confluence^[55]. The detection of the IRHV or CVs between adjacent HVs in cases with hepato-caval confluence compromise may enable safe conservative hepatectomies instead of major resections or complex vascular reconstructions (Figure 1)^[45,51]. However, to guarantee the safety of the procedure, a HV should be resected only after intraoperatively testing the proper function of these variants. As proposed by Torzilli^[52], the feeding portal branch of the segment to be spared must preserve hepatopetal blood flow (rather than hepatofugal) on Doppler US when the HV/s is occluded by using a clamp or just the fingers. Systematically using this method, these authors observed that only 2 out of 22 patients with involvement of HVs needed a major hepatectomy, and none underwent vessel reconstruction^[45].

SURGICAL TECHNIQUES

Once the feasibility of PSLS has been determined pre- and intra-operatively, resection can be carried out. Different kinds of resections have been proposed in order to maximize the amount of liver parenchyma after resection. The consideration of a certain technique as parenchymal-sparing depends on each patient. Almost any type of hepatic resection could be considered as sparing whenever it involves the willing of performing a certain procedure over another that compromises more liver parenchyma (e.g., a major central hepatectomy may be excessive for a peripheral lesion involving both S5 and 4b, but it becomes a parenchymal-sparing approach if used instead of a hemi-hepatectomy right or left for a patient with a large centrally located tumor).

From a technical point of view and for the purpose of this review, PSLS could be considered as every type of liver resection not conforming an AR of a hemiliver or extended resections as defined by the standardized Brisbane 2000 nomenclature, proposed by the International Hepato-Pancreato-Biliary Association^[56]. The sole exception to these rule would be LLS, because the left lateral liver accounts for more than 20% of total liver volume in one out of every four patients, and its preservation is always desired to increase future salvageability^[11,57]. PSLS includes both segment-oriented and non-segment-oriented variants, either as isolated procedures or in combination. The different proposals reported in the literature are summarized in Table 1. In general, segment-oriented resections are reserved for patients with multiple tumors within a single anatomic segment or those in whom the tumor is located centrally and invading the major portal pedicle or HV to an anatomic segment/s^[58]. In these cases transection

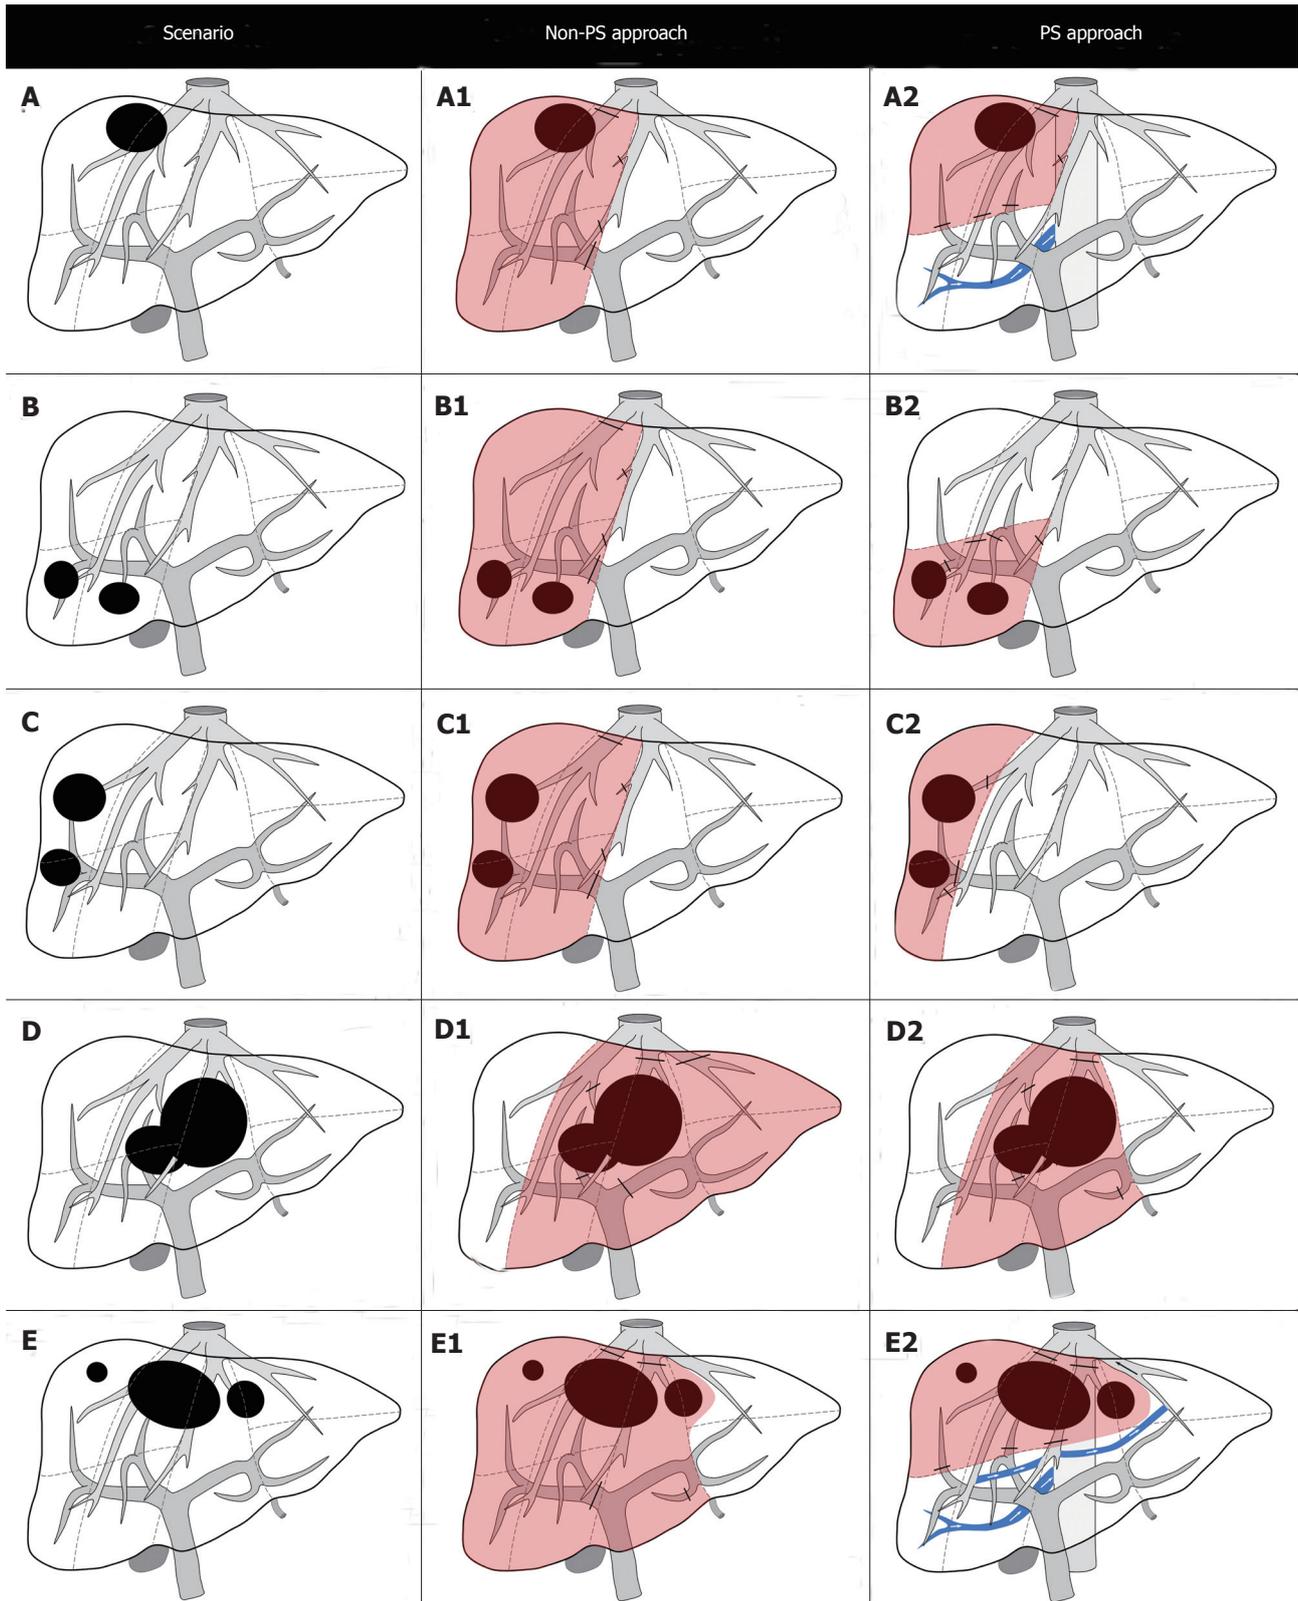

Figure 2 Diagram of segment-oriented parenchymal-sparing resections according to different surgical scenarios. A: Metastatic lesion infiltrating the RHV; A1: Right hepatectomy; A2: Bisegmentectomy 7-8 is possible due to the presence of an IRHV; B: Metastatic lesions located in S5-6; B1: Right hepatectomy; B2: Bisegmentectomy 5-6; C: Metastatic lesions in right posterior section; C1: Right hepatectomy; C2: Right posterior sectionectomy; D: Large central tumors invading the MHV; D1: Left trisectionectomy; D2: Central hepatectomy; E: Metastatic lesions invading the RHV and the MHV; E1: Right trisectionectomy extended to S2; E2: Upper transversal hepatectomy is possible due to the presence of an IRHV and communicating hepatic veins. lines are based on the combination of external anatomic landmarks, selective devascularization by clamping

Table 1 Different parenchymal-sparing operative procedures

Type of resection	Segment/s resected
Segment-oriented	
Monosegmentectomy	Any isolated segment
Bisegmentectomy	Two contiguous segments
Right posterior sectionectomy	S6 and 7
Right anterior sectionectomy	S5 and 8
Right inferior bisegmentectomy	S5 and 6
Right superior bisegmentectomy	S7 and 8
Central anterior bisegmentectomy	S4b and 5
Central posterior bisegmentectomy	S4a and 8
Left medial sectionectomy	S4a and 4b
Central hepatectomy	S4, 5 and 8
Upper Transversal Hepatectomy	S7, 8, 4a and 2 + RHV and MHV
Non-segment-oriented	
Corkscrew technique	Any segment
Mini-mesohepatectomy	Partial S8 and 4a + MHV
Mini upper-transversal hepatectomy	Partial S7, 8 + RHV
Hepatic Vein-Sparing Hepatectomy	Partial S7, 8, and 4a ± 1 paracaval
Systematic extended right posterior sectionectomy	Complete S6-7 + partial S5 and/or S8 (en-block)
Liver tunnel	Partial S4a, 8 and 1
Lower inferior hepatectomy	S3, 4b, 5, 6 and 7
Local ablation ¹	Any

¹Combined with other surgical resection. MHV: Middle hepatic vein; RHV: Right hepatic vein.

to create ischemic margins and intraoperative US. Segment-oriented operative procedures for PSLS are depicted in Figure 2. Non-segment-oriented resections (also referred as atypical or wedge resections) are usually applied for lesions smaller than 5 cm and located near the liver surface. Since anatomical boundaries are not respected, the use IOUS to guide this type of resection is paramount to clearly identify all the bile ducts and vascular branches. For non-large atypical resections, the “corkscrew technique” proposed by de Santibañes *et al.*^[59] is especially useful. In this particular technique, the liver surface is marked with electrocautery and stiches are placed surrounding the lesion in order to easily achieve traction and countertraction of the liver, thus facilitating the identification of biliary ducts and vascular branches. Non-segment-oriented operative procedures for PSLS are depicted in Figure 3.

Even though most patients treated by PSLS are usually approached by a J-shaped or bilateral subcostal incision with upper midline extension, Torzilli *et al.*^[44] recommends a J-shaped thoracophrenolaparotomy for cases with tumors involving S1, 4a, 7, and 8 close to the HV confluence into the IVC. Regarding parenchymal transection, no study has consistently demonstrated significant differences among the various existing techniques up to date. However, it is strongly recommend to use the cavitron ultrasonic surgical aspirator (CUSA) for PSLS since it facilitates a meticulous transection and provides an additional margin beyond that examined by the pathologist. This has been recently associated with an advantage in case of limited margins^[18,60,61].

There are some especially sophisticated IOUS-guided variants of PSLS that deserve to be addressed independently.

Bisegmentectomy 7-8 or right superior bisegmentectomy

Metastatic lesions located in S7-8 that infiltrate the RHV have been traditionally treated with a right hepatectomy given that the right hemiliver is theoretically drained totally (S6, 7) or partially (S5, 8) by the RHV (Figure 2A). The presence of an IRHV, allowed Makuuchi *et al.*^[62] in 1987 to report the first resection of S7-8 en-block with the RHV sparing S5 and S6 without congestion. Although the presence of IRHV is paramount when considering the possibility of sacrificing the RHV, Machado *et al.*^[63] and Capussotti *et al.*^[54] described the feasibility of resecting S7-8 and the RHV without an IRHV. These experiences were based on the anatomical assumption that S6 has several venous anastomoses with S5 and the latter drains into the MHV. The presence of these CVs was later confirmed by Torzilli *et al.*^[55] using high-frequency IOUS. In summary, a 7-8 bisegmentectomy with RHV resection can be performed safely when: (1) an IRHV is present; (2) CVs connecting the RHV with MHV are recognized; and/or (3) hepatopetal rather than hepatofugal blood flow is maintained in the feeding portal branch by color Doppler IOUS after clamping the RHV.

Mesohepatectomy or central hepatectomy

When a tumor invades the MHV at the confluence with the IVC or large central tumors are present, formal anatomic extended hepatectomies are performed by most surgeons (Figure 2D). The resection of central hepatic segments (Couinaud’s S4, 5, and 8), was first proposed by McBride *et al.*^[64] in 1972 and later validated by others as a conservative alternative, preserving more functioning liver tissue than either left or right trisectionectomy^[65,66]. Central resection could also be less extensive; either including S4b and S5 (anterior central) or S4a and S8 (posterior central). Despite being a technically demanding major resection, mesohepatectomy represents a valuable alternative to extended hepatectomy since its complication rate, postoperative recovery, and preserved liver tissue compare favorably with extended hepatic resections.

Mini-mesohepatectomy

In order to avoid major resection, mini-mesohepatectomy (MMH) has been designed by Torzilli *et al.*^[67] specifically for non-large tumors (< 5 cm) invading more than 2/3 of the circumference of the MHV close to the hepato-caval confluence (within 4 cm) (Figure 3B). It is defined as the partial removal of S8 and/or S4a including the involved tract of MHV^[68]. To carry out this technique, as for RHV ligation, at least one of these 3 criteria must be present when the surgeon fingertips compress the MHV: (1) reversed flow direction in the peripheral portion of the MHV, which suggests drainage through collateral circulation in adjacent HVs or IVC;

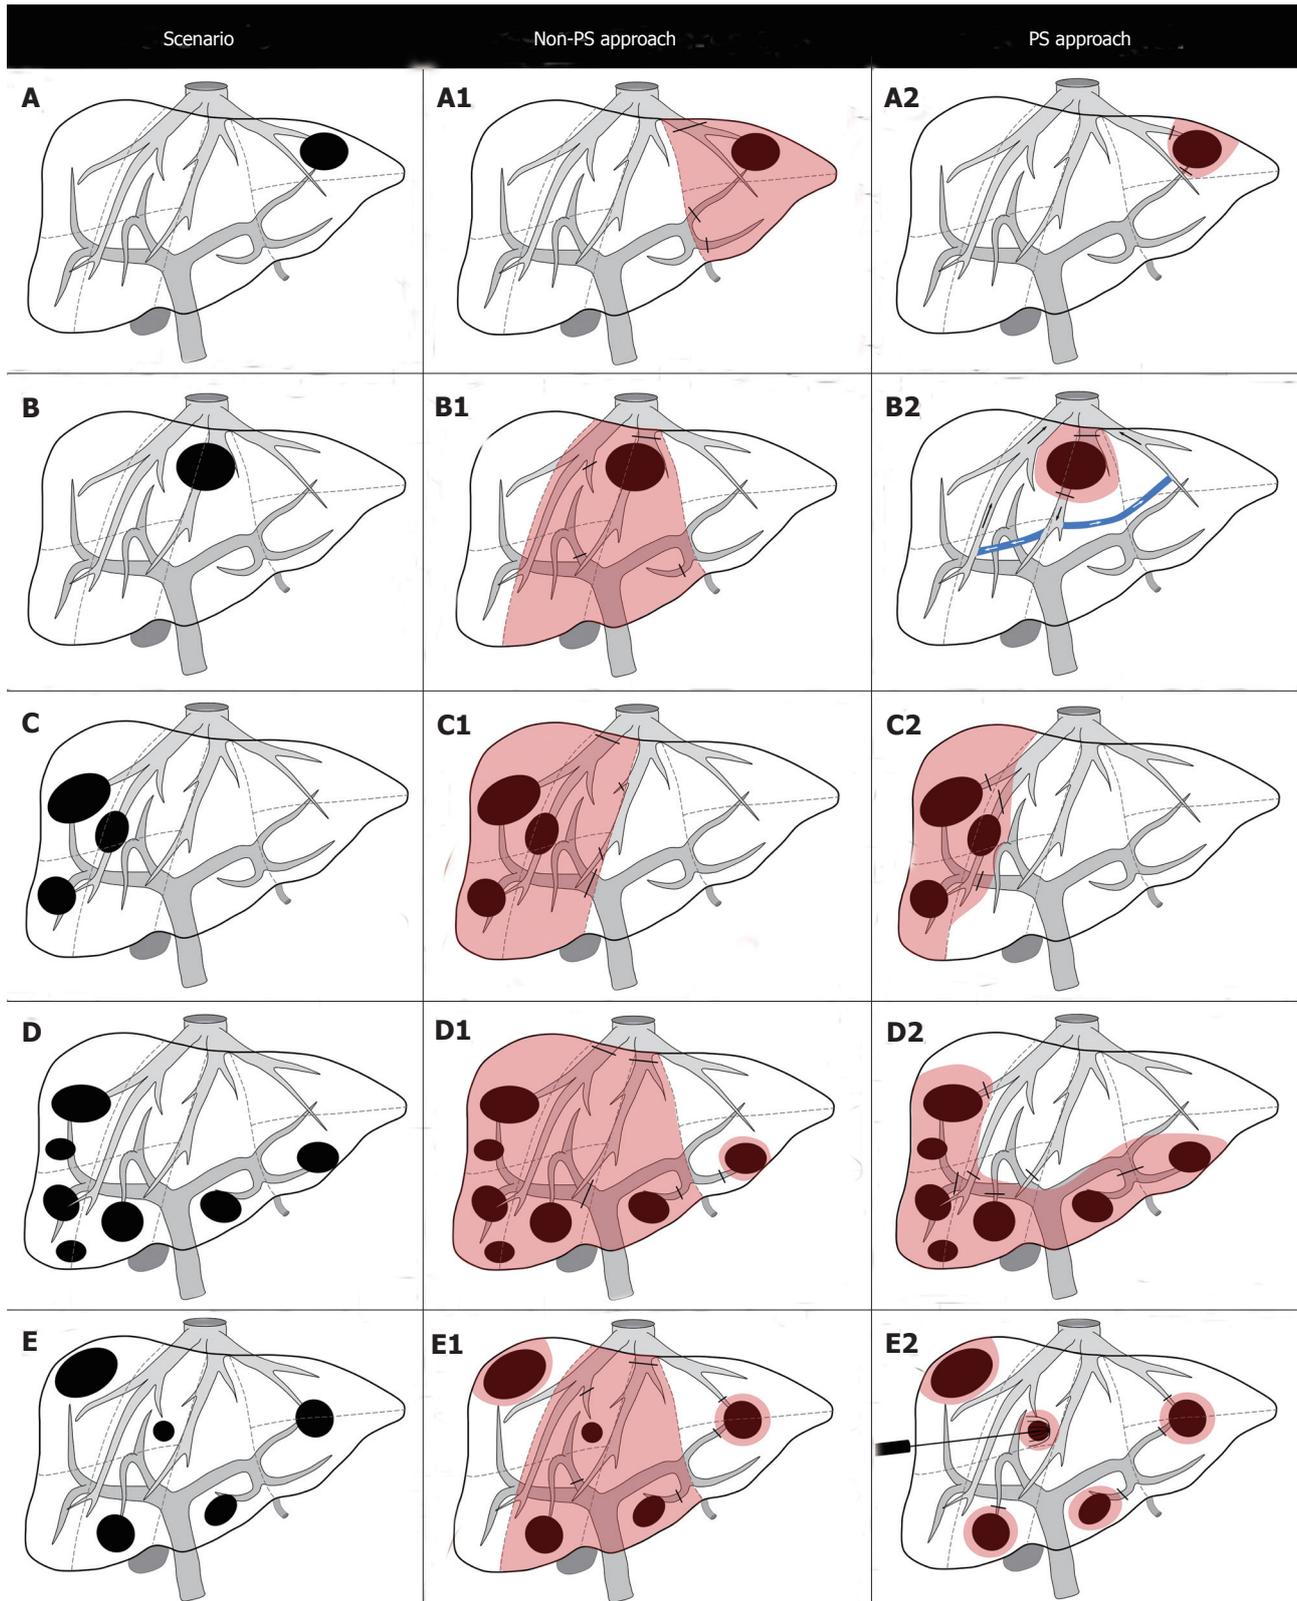

Figure 3 Diagram of non-segment-oriented parenchymal-sparing resections according to different surgical scenarios. A: Metastatic lesion in S2; A1: Left lateral sectionectomy; A2: Atypical resection of S2; B: Metastatic lesion infiltrating the MHV close to the hepato-caval confluence; B1: Central hepatectomy; B2: Mini-mesohepatectomy is possible due to the presence of communicating hepatic veins; C: Metastatic lesions in right posterior section invading the RHV and tumor in proximity of right anterior portal branch; C1: Right hepatectomy; C2: Systematic extended right posterior sectionectomy; D: Liver metastases peripherally located in S3, 4b, 5, 6 and 7; D1: Right trisectionectomy; D2: Lower inferior hepatectomy; E: Multiple bilateral metastases; E1: Atypical resections combined with central hepatectomy; E2: Multiple atypical resections combined with radiofrequency ablation. PS: Parenchymal-sparing; RHV: Right hepatic vein; MHV: Middle hepatic vein.

(2) detectable shunting collaterals between MHV and RHV or LHV; and (3) hepatopetal flow in S5, 8 and/or

S4b portal branches. The posterior wall of the MHV or of the tumor itself is used as the deepest landmark of the resection area. A crucial point is to delineate a transection plane that does not interrupt CVs. This is obtained by dividing the MHV the closest possible to its point of infiltration using IOUS guidance, preserving its distal portion for collateral circulation. Even though this interesting surgical proposal provides an alternative to limit the use or even replace central hepatectomy in certain cases, further validation of its efficacy and safety is awaited before expanding its application.

Upper transversal hepatectomy

This type of parenchymal-sparing resection, proposed by Torzilli *et al.*^[69], is specifically useful for tumors involving the RHV and MHV, or even all HVs at the hepato-caval confluence (Figure 2E). These cases are considered irresectable by most surgeons. However, a major hepatectomy with vascular reconstruction represents the only option offered by others. This last can be avoided when CVs between adjacent HVs are detected intraoperatively with US^[69]. Upper transversal hepatectomy involves total or partial resection of the superior liver segments (S7, 8, 4a and 2) accompanied by the RHV and MHV or even all HVs. It can be performed only when an IRHV is present simultaneously with CVs connecting the IRHV with the MHV and the MHV with the LHV. After checking the function of the complete inter-venous circuit by IOUS and certifying the absence of macroscopic congestion, resection is IOUS-guided preserving the CVs. More recently, an even more conservative variant of this approach has been proposed also by Torzilli *et al.*^[70], denominated "mini upper-transversal hepatectomy".

HV-sparing hepatectomy

This approach has been recently introduced by Torzilli *et al.*^[71] for metastases located in S8, 4a involving both the RHV and MHV at the hepato-caval confluence but neither the IRHV nor CVs are present at imaging. In such cases, when vascular invasion comprises 1/3 of their circumference or less, partial resection of S7, 8, and 4a \pm 1 paracaval can be performed sparing both RHV and MHV by partial resection and reconstruction by running suture. This approach has been proposed as an effective alternative to major resection performed immediately or in a staged perspective^[71].

Systematic extended right posterior sectionectomy

In case of vascular invasion of the RHV with multiple tumors in the right posterior section, and/or invasion of the right posterior portal branch (P6, 7) with tumor in close adjacency (< 5 mm) with right anterior portal branch (P5, 8), right hepatectomy is traditionally performed (Figure 3C). Systematic extended right posterior sectionectomy (SERPS) has been proposed by Torzilli *et al.*^[72] as an alternative approach, performing a right posterior sectionectomy with a tailored extension

to the right anterior section, either the right part of segment 8 \pm the RHV and/or the right part of S5 exposing but not dividing the pedicle of S5, 8 on the cut surface just enough to guarantee complete tumor removal. In all the aforementioned conditions, portal blood flow at color-Doppler IOUS in the pedicle of S5, 8 (right anterior glissonean sheath) has to be hepatopetal once RHV is clamped for carrying out SERPS. SERPS serves also as an alternative to right hepatectomy when bisegmentectomy 7-8 is not possible (in cases where there is vascular invasion of the RHV but without tumor involving S6) because there is not a proper outflow for S6 once RHV is divided (absence of IRHV and hepatofugal portal blood flow at Doppler IOUS in P6 when RHV is clamped). IOUS-guided SERPS has proven to be feasible, safe and effective^[72]. Preserving the majority of the right anterior section (S5, 8) is utmost important, as the right anterior section of the liver is most relevant in terms of volume^[73,74]. In a previous prospective series including 201 patients, SERPS was performed more frequently than right or extended right hepatectomy (10% vs 9%), avoiding such major resections^[72].

Other types of parenchymal sparing resections

There have been anecdotal reports of exceptional strategies of PSLS^[52]. The so-called "liver tunnel" represents an extension of the MMH in patients with central tumors compromising the MHV but extending from S8 vertically to S1 and the "lower inferior hepatectomy" represents the atypical en-block resection of S3, 4b, 5, 6 and 7 for liver metastases peripherally located in these segments (Figure 3D). These particularly challenging approaches deserve further validation in larger series of patients before expanding its application.

Combination of resection with local ablation

As the indications for surgical treatment of CLM have broadened, the use of multimodal therapies has become more common. Nowadays, the use of interstitial treatments (radiofrequency or microwaves) to compliment resectional strategies has proven to be a useful and rationale approach to treat patients with multiple lesions when complete resection of all metastases is not possible, therefore extending the limits of surgical treatment^[12]. In this combined approach, hepatectomy addresses the main tumor mass and the residual tumor that cannot be resected is treated with local tumor-ablative therapy (Figure 3E). Ideally, lesions treated with RFA should be less than 25 mm in size, since technically successful ablation is possible in more than 90% of the cases^[74]. However, a recent retrospective study evaluating recurrence patterns of CLM treated with ablation, found that ablation was more effective for metastases of size equal to or smaller than 10 mm^[75]. This combined approach has not been associated with a compromise in disease-

specific survival^[112], while demonstrated a reduction in the need of major resections and two-stage procedures, offering the possibility of repeated treatments for recurrences with reduced morbidity^[42,50].

USE OF LAPAROSCOPY IN PARENCHYMAL SPARING RESECTIONS

The advantages of laparoscopic hepatic resection vs open surgery in the perioperative period (*e.g.*, less blood loss, fewer complications, and shorter duration of hospitalization) as well as favorable cosmetic results have been well recognized in the literature^[76]. In addition, there is an increase body of evidence indicating that laparoscopic approach does not compromise oncological principles in selected patients^[76,77]. Traditionally, laparoscopy has been mostly used for small and subcapsular liver lesions located in peripheral liver segments (S2, 3, 4b, and 5). With regards to laparoscopic PSLS, from the beginning of laparoscopic liver surgery a parenchymal-sparing philosophy has been applied and limited NAR of accessible segments dominated the scene. Along with increasing experience in laparoscopic liver surgery, more complex laparoscopic liver resections are being practiced to treat central liver lesions or those ill located in posterior and superior segments. Recent evidence presented by experienced surgical teams demonstrates that segment-oriented parenchymal-sparing variants can be performed safely using laparoscopy^[78]. A recent retrospective study concluded that laparoscopic liver resection with a parenchymal-sparing approach does not worsen oncological outcome, allowing a higher percentage of repeat hepatectomy^[79]. Montalti *et al.*^[80] showed that the laparoscopic parenchyma-preserving approach with the CUSA is possible and that R1 margins are a risk factor for tumor recurrence but not for OS. A major limitation for this technique was the presence of multiple lesions since it was identified as the only independent risk factor for R1 margins^[80]. More recently, robot-assisted liver surgery has been introduced as a minimally invasive alternative to facilitate the parenchymal-sparing treatment of lesions located in the posterosuperior segments or when portal triad dissection is necessary, suggesting the potential of robotics to resemble techniques and outcome of open PSLS^[81]. The routine use of laparoscopic IOUS is as important as in the open approach and have also been highlighted in the literature^[82].

During the 2nd international consensus conference for laparoscopic liver resection held in Morioka (Japan) in 2014^[76], it was noted as a concern that larger procedures resecting more liver parenchyma are sometimes favored if the procedure is done laparoscopically because a smaller parenchyma-sparing operation may be more complex laparoscopically. As well, there has been a tendency towards more LLS instead of atypical resections to facilitate laparoscopic treatment

of single or few small sized metastases located in the left lateral segment. However, recent data in patients with single lesions supports atypical resection over LLS, demonstrating increased future salvageability and survival^[111]. Therefore, in light of this new evidence, LLS should be discouraged from now on, for lesions amenable to atypical resection even when performing laparoscopic surgery.

SHORT AND LONG-TERM OUTCOMES

As mentioned previously, PSLS encompasses a wide variety of surgical alternatives for a heterogeneous population of patients, therefore outcome analysis can be very complex. In terms of comparative studies, Torzilli *et al.*^[72] compared SERPS with right hepatectomy in patients matched for age, tumor size and number. They found that SERPS resulted in significantly less blood loss, less transfusions, less portal pedicle clamping with similar operative length, hospital stay and safety profile. Similarly, Ferrero *et al.*^[83] demonstrated that bisegmentectomy instead of right hepatectomy improves postoperative outcomes, offering similar survival results and increasing the opportunity to re-resection in patients with CLM of ≤ 10 cm located in the right liver lobe. Despite these few reports, for the purpose of the present review, probably the most practical way to evaluate outcomes would be to consider PSLS as the philosophy of saving parenchyma and compare it against a non-saving parenchyma philosophy, rather than each different technical variant evaluated separately. The comparison that most resembles this scenario, and even gave rise to the debate, is that of AR vs NAR in patients with CLM. There have been many studies in the literature aiming to compare the outcomes of these opposite approaches with similar results (Table 2).

Operative results and complications

From the short-term perioperative results perspective, several groups have experienced better perioperative outcomes with the increased use of a parenchymal-sparing policy^[11-13]. This association correlates well with findings from large series demonstrating that the number of segments resected is an important determinant of outcomes^[84,85]. In 2008 the MSKCC group evaluated a series of 440 patients operated on for bilateral CLM from 1992 to 2003, dividing the study in four time-periods with the purpose of determining trends over time^[12]. They found a significant trend away from large resections in favor of multiple smaller resections despite patient and tumor variables did not change over time. A significant drop in 90-d mortality (from 6.3% to 1.2%, $P = 0.02$); operative blood loss (from 950 to 490 mL, $P < 0.001$) and length of hospital stay (from 12 to 9 d, $P < 0.001$) was observed occurring simultaneously with the increased application of parenchymal-sparing techniques^[12]. In a retrospective

AR: Anatomic resection.

study comparing major AR vs minor NAR in 174 patients, Kokudo *et al*^[33] found that the mean operating time and operative blood loss were significantly greater during AR. These findings are in accordance with those of Sarpel *et al*^[86], who reported significantly more blood transfusions in patients who underwent AR compared to NAR (44% vs 16%, $P < 0.001$), despite Pringle time was similar between groups (11 ± 7 min vs 10 ± 7 min, $P = 0.313$). Even though several more recent series have confirmed a significant advantage in terms of operating time and blood loss during NAR^[11], in most studies this was not translated into a significant difference in morbidity or mortality, probably owing to an insufficient number of patients studied and the retrospective nature of the analyses^[32,33,86-88]. A recent meta-analysis of non-randomized studies was designed as an attempt to overcome these limitations^[13]. Among 1662 subjects with CLM, 989 underwent AR and 673 underwent NAR. The meta-analysis demonstrated that NAR reduced the operation time and blood transfusions, whereas it confirmed that overall morbidity (22.1% AR vs 16.6% NAR, $P = 0.32$) and mortality were similar between the two groups (0.9% AR vs 0.7% NAR, $P = 0.68$). However, it has to be taken into account that significant heterogeneity across studies was present for some of these variables. In a recent comparative study of patients matched for clinical characteristics and tumor size, the MD Anderson group found that parenchymal-sparing resection was associated with significantly reduced blood loss but equal morbidity (23% vs 26%, $P = 0.54$), major complications (3% vs 6%, $P = 0.21$) and 90-d mortality (0% vs 1%, $P = 0.23$) compared to non-parenchymal-sparing resection^[11]. Conversely, when analyzing specifically liver-related morbidity, Gold

et al^[12] showed that AR were independently associated with higher liver-related complications as opposed to wedge resections. Moreover, von Heesen *et al*^[89] found that AR had a significant higher incidence of pleural effusions requiring interventional drainage than NAR and combined resections.

Oncological results

In terms of oncological long-term results, one of the main concerns regarding PSLS has been the specimen margin status and the fact of leaving more at-risk liver parenchyma behind where liver metastasis could seed, with their potential negative impact in patient survival. So far, none of these concerns has found a solid scientific background in the current clinical field.

Among the few authors who advocated non-parenchymal-sparing resections for CLM during the 1990s, DeMatteo *et al*^[90] presented one of the most controversial evidence in 2000. In their series of 267 patients, AR resection had a significantly lower rate of positive margins compared to NAR (2% vs 16%, $P < 0.001$) resulting in longer survival for AR on univariate analysis (53 mo vs 38 mo, $P = 0.015$). In a larger study published 8 years later, the same group found that although the width of negative margin using wedge resection was significantly less than when wedge resection was not used (mean 0.5 cm vs 0.8 cm, $P = 0.02$), margin positivity did not correlate with the use of a wedge resection ($P = 0.40$)^[12]. More recent studies involving modern approaches reported that the incidence of a positive surgical margin was equal for AR and NAR either with single or multiple liver lesions^[11,32,61,86-88]. A recent meta-analysis confirmed these results^[13].

With regards to recurrence and survival, the majority of reports have found no significant differences according to the type of hepatectomy performed. The study published in 2009 from the Mount Sinai Medical Center found that the type of resection was not associated with significant differences in recurrence or survival even when adjusted for differences in preoperative risk^[86]. Another study by Lalmahomed *et al.*^[32] reported comparable median time to recurrence between AR and NAR (9 mo vs 10 mo, $P = 0.802$) in 201 patients with single or multiple liver metastases. In addition, the pattern of recurrence in terms of location and 3-year intrahepatic recurrence rate did not differ between the two groups^[32]. The 5-year DFS and OS were also similar for AR and NAR (30% vs 32%, $P = 0.599$; 49% vs 39%, $P = 0.989$). These findings were later confirmed by the meta-analysis by Sui *et al.*^[13], where 5-year OS was not significantly different between the two groups (OR = 1.13; 95%CI: 0.92-1.39, $P = 0.24$). Regarding 5-year DFS, even though no significant difference was shown between the groups, the marked heterogeneity between studies raises questions about the validity of this data. In order to overcome the effects of differences in the number of liver tumors that might influence patient survival between types of resections, some authors individualized patients with multiple metastases and analyzed them separately. In this regard, in the study presented by Tanaka *et al.*^[37], from Yokohama city in 2008, among the subgroup of patients with six or more metastases, the overall survival of those who had a major resection was significantly poorer than those who had minor resections ($P = 0.028$), although the clinical characteristics were comparable between the two groups. On the other hand, in the MSKCC study from the same year regarding the unique subgroup of patients with multiple bilateral lesions, the use of wedge resection independently correlated with worse liver recurrence-free survival but not disease-specific survival^[12]. Additionally, they found that in the era of modern multimodal tactics, disease-specific survival or liver recurrence-free survival did not change over time despite modifying the technical approach.

It has been hypothesized that in the specific subgroup of patients with multiple CLM, local failure in the liver after wedge resection may not be as critical to survival as for patients with solitary metastases. Thus suggesting that patients with a less aggressive disease behavior should probably not undergo parenchymal-sparing procedures. However, different studies have not supported this proposal. In a retrospective study by Kokudo *et al.*^[33] a subset analysis of patients with unilobar single or double tumors demonstrated that intrahepatic recurrence did not differ significantly between those who underwent major AR vs minor NAR (31.3% vs 41.2%, $P > 0.05$), and nor did patient survival. Interestingly, only 19.6% of patients in the NAR group developed ipsilateral recurrence and 90% were resected, compared to 20% of recurrences resected in the AR group^[33]. Almost fifteen years later a similar study from the MD Anderson

group^[11], but focused in patients matched for clinical characteristics and with solitary metastases equal or less than 3 cm, reported even more interesting results in the era of modern chemotherapy. They retrospectively compared 156 patients who underwent a parenchymal-sparing hepatectomy (excluding concomitant RFA) with 144 patients who underwent non-parenchymal-sparing hepatectomy, and found that no significant differences were found in OS, recurrence-free survival, and liver-only recurrence-free survival^[11]. However, a subanalysis of patients who had liver-only recurrence revealed a significantly improved 5-year OS from initial hepatectomy (72.4% vs 47.2%, $P = 0.047$) and from liver recurrence (73.6% vs 30.1%, $P = 0.018$) in the parenchymal-sparing hepatectomy group^[11]. This was explained by the fact that salvage hepatectomy for liver-only recurrence was performed significantly more often in the parenchymal-sparing hepatectomy group compared to the non-parenchymal-sparing hepatectomy group (68% vs 24%, $P < 0.01$). In this study, multivariate analysis revealed that non-PSH was a risk of noncandidacy for repeat hepatectomy^[11].

All reports addressing PSLs are retrospective in nature and most compare heterogeneous groups of patients, thus making the interpretation of data problematic. Given that results may be biased by different patient selection criteria for either approach among centers and surgeons, definitive conclusions in terms of oncological results cannot be drawn. However, the presence of an increasing body of evidence with consistent data among different centers, strongly suggests that PSLs does not compromise oncological outcome and in certain occasions long-term survival might be even better than non-parenchymal approaches in current days. Randomized controlled data is best desired to confirm these findings. However, such a study seems unfeasible from a practical and ethical point of view, given that surgical risk of anatomical major resection is greater and surgeons would be unwilling to choose an unnecessary major hepatectomy for small single tumors near the liver surface.

CONCLUSION

There is a clear trend toward a parenchymal-sparing philosophy in HPB centers worldwide. Parenchymal-sparing strategies, either by resection alone or complemented with ablative therapies, have become an essential part of modern liver surgery and every liver surgeon should be aware of their existence and feasibility. A profound knowledge of liver anatomy as well as expert IOUS skills are necessary to perform PSLs appropriately and safely. Current evidence indicates that tumor biology is the most important predictor for intrahepatic recurrence and survival rather than the amount of millimeters at a negative resection margin. Complete tumor removal avoiding the unnecessary sacrifice of functional parenchyma has been associated with less surgical stress, fewer

postoperative complications, uncompromised cancer-related outcomes and higher feasibility of future resections. The increasing evidence supporting PSLs prompts its consideration as the gold-standard surgical approach for patients bearing liver metastases from colorectal cancer.

Abstract

Laparoscopic D2 radical surgery for gastric cancer is minimally invasive but complex. In this path: (1) Repeated operation of lesser curvature side; (2) The gastrohepatic ligament is relatively fixed. Hence, it is not easy to expose the suprapancreatic area; and (3) It is not easy to dissect No. 1, 12 lymph nodes. This area may not be sufficiently cleaned or surrounding vessels may be injured during a resection. So it is critical to choose position fixing, and a clear, fast and convenient operation path. The author, based on his experience, has established a set of procedural steps called "Gao's double-way", lesser omentum approach and traditional greater omentum approach, which are described in detail in this article. The path of this first approach is described as a "W" type of dissection. The second way is the traditional greater omentum approach, whose path is described as a "M" type of dissection. This will enable laparoscopic surgeons to select a suitable path. This new approach not only simplifies the surgery but also provides more space for the subsequent operation, thereby making the surgery more simple, safe and easy.

INTRODUCTION

Clinical vignette

For the traditional laparoscopic D2 radical surgery, the abdominal cavity and lesser curvature side were initially explored. Then the gastrocolic ligament was opened to enter the greater omental bursa. That is: Open the gastrocolic ligament → Splenic hilar lymph node dissection (No. 10, 11d) → Cardial area lymph node dissection (No. 2, 110) → Infrapyloric area lymph node dissection (No. 6) → Suprapancreatic area lymph node dissection (No. 7, 9, 11p, 12p), which can be described as a "W" type of dissection^[1-3]. But the following problems exist in this path: (1) repeated operation of lesser curvature side; (2) the gastrohepatic ligament is relatively fixed. Hence, it is not easy to expose the suprapancreatic area; and (3) it is not easy to dissect No. 1, 12 lymph nodes (LN). This area may not be sufficiently cleaned or surrounding vessels may be injured during a resection. Since the hepatogastric ligament and plica gastropancreatica are anatomically complex and difficult to expose, it will be more difficult for a new surgeon to learn, especially with a less skilled assistant^[4]. So choosing a position fixing, and a clear, fast and convenient surgical path is critical. Based on our experiences of laparoscopic D2 radical surgery in more than 200 gastric cancer patients, we gradually explored a set of procedural steps called "Gao's double-way", that is, the lesser omentum approach and the traditional greater omentum approach. Herein, the detailed procedures are described.

Surgical techniques

The patient is placed in supine position, with right leg abduction, described as a "才" word, that is right leg separated position. The surgical table is declined by 10°-20° into the reverse Trendelenburg position. Therefore, the patient's upper body is elevated. This causes the intestine to move towards the lower abdomen. The surgeon stands on the patient's left side, the assistant on the right side and the camera operator stands between the patient's legs. Audio core tip lists the detailed steps of the procedure [Audio core tip: Detailed surgical steps presented in the video clips (Video core tip)].

The first way (the lesser omentum approach): Cut the hepatogastric ligament at the thinnest area and enter the lesser omentum. The location is fixed with no anatomic variation.

The first step: Assistant's left hand holds the intestinal forceps to push the liver lobe up. Fully expose the hepatogastric ligament. Right hand holds the intestinal forceps to press the liver side of the hepatogastric ligament. The surgeon's left hand provides downward traction of the gastric side of the hepatogastric ligament, so as to produce moderate tension. The right hand holds an ultrasonic knife to cut the hepatogastric ligament at the thinnest area.

The second step: Along the edge of the liver, clean left to the front of cardia, and complete the dissection of No. 1, 2 LN. When separating, be close to the liver. This area can be thoroughly cleaned, which makes it easy to separate the organization. Do not damage the inferior vena cava. Assistant's left hand holds the intestinal forceps to fully reveal the front of cardia. The surgeon dissects No. 1, 2 LN from right to left along the esophageal hiatus, from right diaphragmatic angle of esophageal gastric junction to left diaphragmatic angle.

The third step: Along the edge of the liver, clean right to hepatoduodenal ligament, and complete the dissection of No. 12 a, p LN. Assistant's left hand holds the intestinal forceps to push the liver lobe up to fully expose the hepatoduodenal ligament. Right hand holds the intestinal forceps to press the liver side of the hepatoduodenal ligament. The surgeon's left hand provides downward traction of the gastric side of the hepatoduodenal ligament, so as to produce moderate tension. The right hand holds an ultrasonic knife to dissect this area from the liver side to tumor side. Protect the hepatic artery and left portal vein.

The path of this first approach is described as a "W" type of dissection. The second way is the traditional greater omentum approach, whose path is described as a "M" type of dissection.

DISCUSSION

At present laparoscopic D2 radical surgery is a simple, greater omentum approach. However, the author's path combined the lesser omentum and the traditional greater omentum approaches. The lesser omentum approach (the first way) is as follows: Open the lesser omentum, left to cardial area lymph node dissection (No. 1, 2 LN), right to hepatoduodenal ligament lymph node dissection (No. 12a, p LN), which can be described as "M" type of dissection (Video core tip). The advantages of this approach include: (1) Due to the rapid development of modern medical imaging, the pre-surgical evaluation is quite explicit^[5], so exploration of the local lesions can be prevented. Typically, surgeons would push the liver up and explore the lesser omentum, then release the liver and continue other steps. However, the author combined the exploration and dissection to avoid repeat surgery of lesser curvature side; (2) It could also provide a convenient way of cardial area lymph node dissection (No. 1, 2, 110 LN) and hepatoduodenal ligament lymph node dissection (No. 12a, p LN); (3) When cleaning the infrapyloric area lymph node (No. 6 LN) and the suprapancreatic area (No. 7, 9, 11p, 12p LN), the area can be easily exposed thereby making the dissection more safe and convenient; (4) Open the lesser omentum, so the stomach can be lifted, which can provide larger space for dissection; (5) It can provide a larger space for the dissection of infrapyloric area LN and suprapancreatic area, thereby saving time by not changing the patient's posture; (6) The lesser side

has high incidence of gastric cancer, so after opening the lesser omentum, chemotherapy drugs could be poured into it. So the lesion area of tumor and exfoliated cells (especially gastric juice) was soaking in drugs, thereby preventing tumor spread caused by surgery; and (7) Due to the first path, the cleaning of greater omentum approach could be easier thereby making the operation more safe. For example, the dissection of hepatoduodenal ligament LN can be simplified (No. 12a, p LN). Besides, with the first approach, the space is enough for cleaning cardial area LN (No. 110 LN).

CONCLUSION

Based on the author's experiences with laparoscopic D2 radical surgery in more than 200 gastric cancer patients, this approach was summarized as "W + M".

Abstract

AIM: To analyze the impact of previous cyst-enterostomy of patients underwent congenital bile duct cysts (BDC) resection.

METHODS: A multicenter European retrospective study between 1974 and 2011 were conducted by the French Surgical Association. Only Todani subtypes I and IVb were included. Diagnostic imaging studies and operative and pathology reports underwent central revision. Patients with and without a previous history of cyst-enterostomy (CE) were compared.

RESULTS: Among 243 patients with Todani types I and IVb BDC, 16 had undergone previous CE (6.5%). Patients with a prior history of CE experienced a greater incidence of preoperative cholangitis (75% *vs* 22.9%, $P < 0.0001$), had more complicated presentations (75% *vs* 40.5%, $P = 0.007$), and were more likely to have synchronous biliary cancer (31.3% *vs* 6.2%, $P = 0.004$) than patients without a prior CE. Overall morbidity (75% *vs* 33.5%; $P < 0.0008$), severe complications (43.8% *vs* 11.9%; $P = 0.0026$) and reoperation rates (37.5% *vs* 8.8%; $P = 0.0032$) were also significantly greater in patients with previous CE, and their Mayo Risk Score, during a median follow-up of 37.5 mo (range: 4-372 mo) indicated significantly more patients with fair and poor results (46.1% *vs* 15.6%; $P = 0.0136$).

CONCLUSION: This is the large series to show that previous CE is associated with poorer short- and long-term results after Todani types I and IVb BDC resection.

Key words: Bile duct cyst; Congenital; Biliary disease; Cyst-enterostomy; Long-term outcome

Core tip: Previous cyst-enterostomy is associated with more severe clinical presentation, including increased incidence of synchronous cancer, as well as poorer short- and long-term results in patients undergoing operations for Todani types I and IVb bile duct cysts.

Impact of previous cyst-enterostomy on patients' outcome following resection of bile duct cysts. *World J Gastrointest Surg* 2016; 8(6): 427-435 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/427.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.427>

INTRODUCTION

In contrast to Asian countries^[1], congenital bile duct cysts (BDC) are rare in the United States and in Europe^[2], with an incidence between 1 in 13000 and 1 in 2 million live births^[3], respectively. whereas the incidences vary from 1 in 1000 in Japan^[4], to 1 in 13500 in United States^[5] and 1 in 15000 in Australia^[6]. For this reason, there are few published series concerning the Western experience with this disease process^[7]. The optimal surgical procedure for the management of BDC is still debated with cyst-enterostomy (CE) having been preferred in the past owing to its technical simplicity^[8,9]. However, CE has been reported to be associated with increased morbidity (especially biliary complications) and higher reoperation rates during short- and long-term follow-up in comparison to primary BDC resection^[9-11]. Additionally, a few series have emphasized the negative impact of previous CE on results of secondary BDC resection^[2]. Lastly, CE has been shown to be associated with an increased risk of cholangiocarcinoma^[12,13]. Consequently, primary resection has been considered as the treatment of choice for BDC^[9,14,15]. The purpose of the present study was to investigate the role of a previous CE on short and long-term outcomes after secondary cyst resection in a large European multicenter cohort of patients.

Study population and patients' data collection

A multicenter retrospective study was conducted under the auspices of the Association Française de Chirurgie. During a 37 years period (between 1974 and 2011), 33 centers (including 24 academic centers) from 6 different European countries have included a total of 505 patients operated from Todani type I, IVb, II, III, IVA BDC.

The patients' medical records were included on a website database (<http://www.chirurgie-viscerale.org>) using an online computerized standardized questionnaire. Patients' demographic data, previous history of surgical and/or endoscopic interventions for hepatobiliary and pancreatic (HBP) disease, clinical symptoms, biochemical and imaging studies, details of surgical procedures, pathological data, duration of follow-up and short- and long-term postoperative outcome were collected.

¹The American Society of Anesthesiology physical status score; CE: Cyst-enterostomy; ERCP: Endoscopic retrograde cholangio-pancreatography; PBM: Pancreato-biliary malunion; MBC: Main biliary confluence.

Additional data were obtained from e-mail exchanges or phone calls with the referral centers. Operative reports, pathology reports and imaging studies were systematically reviewed by the 3 senior authors (Jean-Yves Mabrut, Reza Kianmanesh and Jean François Gigot) in order to establish homogeneous disease classifications. Patients' operative risk was evaluated by using the American Society of Anesthesiology physical status score (ASA)^[16]. A pediatric patient was defined as under 15 years of age.

Complicated clinical presentation was defined by the presence of severe episodes of cholangitis or pancreatitis, portal hypertension, biliary peritonitis or

coexistent synchronous carcinoma. Disease involvement of the main biliary confluence (MBC) was also classified according to the classification reported by two of the co-authors^[17]. Postoperative morbidity and mortality were defined at 3 mo or during hospital stay. Postoperative morbidity was graded according to Dindo-Clavien' classification^[18]. Long-term outcome was evaluated according to the dedicated evaluation score reported by the Mayo Clinic^[2]. Complete cyst excision was defined as without macroscopic dilatation of bile duct after resection.

BDC subtypes were defined based on imaging studies in accordance with the Todani classification^[14]. Todani BDC subtypes included type I in 47.3% ($n = 239$), type II in 3.7% ($n = 19$), type III in 2.5% ($n = 13$), type IVa in 14.4% ($n = 73$), type IVb in 1.2% ($n = 6$) and type V in 30.7% ($n = 155$). Only patient with isolated, extrahepatic BDC disease (Type I and IVb) were included ($n = 245$). Two additional patients that did not undergo resection were excluded and thus 243 were ultimately analyzed.

A pediatric patient was defined as being aged under 15 years of age. Patients' operative risk was evaluated by using the ASA^[16]. Complicated clinical presentation was defined by the presence of severe episodes of cholangitis or pancreatitis, portal hypertension, biliary peritonitis or coexistent synchronous carcinoma. Disease involvement of the MBC was also classified according to the classification reported by two of the co-authors^[17]. Postoperative morbidity and mortality were defined at 3 mo or during hospital stay. Postoperative morbidity was graded according to Dindo-Clavien' classification^[18]. Long-term outcome was evaluated according to the dedicated evaluation score reported by the Mayo Clinic^[2].

Statistical analysis

Comparisons between patient with and without CE were performed using the χ^2 test (or the Fisher's exact test when conditions for the χ^2 test were not fulfilled) for categorical variables and using the Student t test (or the Mann-Whitney nonparametric rank sum test in case of non-normality) for continuous variables. Predictive factors of poor or fair result during long-term follow-up were analyzed by multivariate statistical analysis. Significant variables at the 0.15 level in univariate analysis were introduced in the multivariate logistic regression model. Kaplan-Meier analysis was used to predict the postoperative survival rate at 1 year and at 3 years. The log-rank test was used to compare subgroups of patients at 1 year and at 3 years. Statistical analysis was performed using SAS[®] version 9.2 (SAS Institute Inc, Cary, North Carolina, United States).

RESULTS

Patients were stratified based on a history of a previous CE. Demographic data, Todani BDC subtypes, types

of imaging studies (Table 1), clinical presentations (Table 2), coexistent HBP diseases (Table 3), types of surgical procedures (Table 4), and short- and long-term postoperative outcomes (Table 5) were then compared between the two cohorts. Finally, predictive variables of poor/fair long-term outcome are reported in Table 6.

Patients' demographic data, todani BDC subtypes and types of imaging studies

During a 37-year period (1974-2011), 243 patients underwent resections for Todani types I and IVb congenital BDC at 33 centers (including 24 academic centers). The patients' gender ratio was largely female (193/50, *i.e.*, 3.86%). Median age was 30.8 years old (range: 0.1-81 years) and 79 patients were classified at pediatric. Patients' characteristics are detailed in Table 1. Sixteen patients had undergone previous CE (16/243, *i.e.*, 6.58%), they were all adults (100% vs

65.2%; *P* = 0.0041) and significantly older (47.8-year-old vs 29.2-year-old; *P* = 0.0074) than those without a history of CE. Imaging studies used for the diagnosis of BDC were different between the 2 groups: Patients without previous history of CE were offered more non-invasive studies, whereas those patients with previous CE had been submitted to significantly more endoscopic techniques. There was no difference concerning the BDC sub-types, the MBC involvement and the presence of an anomalous pancreato-biliary malunion (PBM) (Table 1).

Clinical presentation

The median delay between the disease's first symptoms and the diagnosis of BDC was 2 mo (0-486) and was similar between the 2 groups of patients. Abdominal pain was the most common presenting symptom (43.6%) for the whole population and significantly more frequent in patients without previous CE (12.5% vs 45.8%; *P* = 0.009). The group of patients with previous CE was observed to have a significantly increased prevalence of cholangitis (75.0% vs 22.9%; *P* < 0.0001) and complicated presentation (75.0% vs 40.5%; *P* = 0.007) (Table 2).

Coexistent HBP diseases

Coexistent biliary disease (liver disease, pancreatic disease, and biliary disease) occurred in 25.1% of the present cohort and was significantly more frequent in

CE: Cyst-enterostomy.

patients with previous CE (56.2% vs 22.9%; *P* = 0.006). The occurrence of associated calculus disease (16.9%) was similar between the two groups. Synchronous biliary cancer occurred in 7.8% of the total cohort and was significantly more frequent in patients with previous CE (31.3% vs 6.2%; *P* = 0.004) (Table 3).

Preoperative treatment and type of surgery

Preoperative biliary drainage was performed in 6.6% of the whole cohort. All patients underwent surgical exploration. However, 5 adult patients without CE did not undergo BDC resection, one for no specified reason, the others respectively for locally advanced gallbladder cancer, peritoneal carcinomatosis, severe inflammation of the hepatic pedicle, performance of simple cholecystectomy. Only one patient with previous CE had severe hepatic pedicle inflammation prohibiting cyst resection. Associated bile duct stone extraction rates were similar between the two subgroups. Complete cyst excision was accomplished in 93.8% of all patients and there was no significant difference between the two groups of patients. Associated hepatectomy was more frequently performed in patients with previous CE but

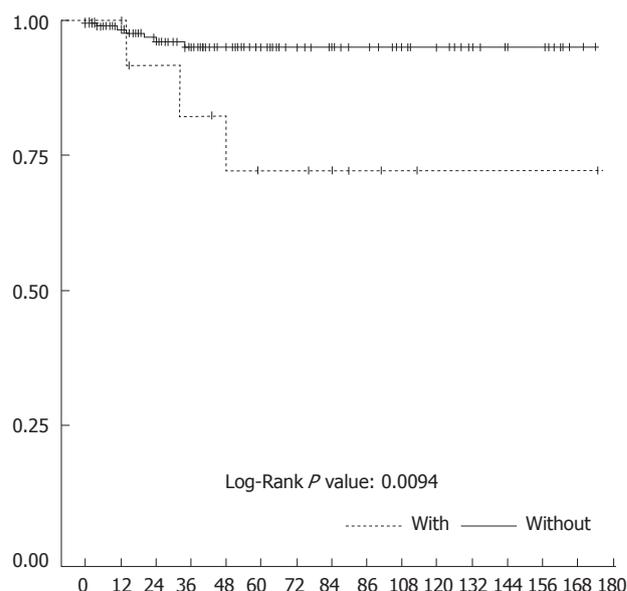

Figure 1 Comparison of overall survival between patients operated from bile duct cysts with and without previous history of cyst-enterostomy.

the difference was not significant (12.5% vs 1.8%; *P* = 0.0523). Associated pancreaticoduodenectomy was significantly more frequent in patients with previous CE (25% vs 1.8%; *P* = 0.008) (Table 4).

Postoperative mortality, morbidity and early postoperative outcome (within 3 mo)

Postoperative death due to cardiac arrhythmia, occurred in 1 patient (0.4%). Overall morbidity and severe complications rates were 36.2% and 14%, respectively. Patients with previous CE had significantly higher morbidity rates (75.0% vs 33.5%; *P* < 0.0008), more severe complications (Grade III-IV) (43.8% vs 11.9%; *P* = 0.003), more hemorrhagic complications (31.3% vs 1.3%; *P* < 0.0001), a greater reoperation rate (37.5% vs 8.8%; *P* = 0.003) and a longer median length of stay (16 vs 10 d; *P* < 0.001) than those without previous CE (Table 5).

Postoperative long-term outcome

A total of 44 patients were lost for follow-up at 3 mo, only 3 of whom belonged to the subgroup of patients with previous CE. The median follow-up in the 198 remaining patients was 37.5 mo (range: 4 to 732 mo) for the whole cohort, without any difference between both subgroups. According to the dedicated Mayo Clinic Risk score evaluating long-term results, there were significantly more patients with fair and poor results in the subgroup of patients with previous CE (*P* = 0.001). The overall 3-year survival rate was significantly lower in patients with prior CE (82.5% vs 95.9%; *P* = 0.01) (Figure 1) (Table 5).

Univariate and multivariate analysis

Predictive variables of poor and fair long-term results (according to the Mayo Clinic clinical score) were

evaluated in the 198 patients surviving surgery and with a follow-up over 3 mo. Univariate statistical analysis indicated that predictive variables of poor or fair long-term results were to be an adult patient, with prior CE, postoperative complications, postoperative biliary complications and coexistent synchronous cancer. By multivariate analysis, predictive variables of poor or fair long-term results were previous CE, synchronous cancer and postoperative biliary complications (Table 6).

DISCUSSION

The present retrospective series shows that patients submitted to secondary resection of congenital BDC following a previous cyst-enterostomy suffered more complications before, during and after surgery with poorer results during long-term follow-up. Strengths of the present series include the relatively large cohort of patients issued from a multicentric European series, and the central revision of radiological, operative and pathological data, thereby ensuring a homogeneous classification of patients and their symptoms and signs both prior and after surgery, with the use of a dedicated clinical score for long-term results. Furthermore, the analysis was performed in a homogeneous group of BDC with only extrahepatic biliary involvement, namely patients suffering from Todani types I and IVb BDC. Indeed, patients with Todani type IVA were excluded from the present series so that poor results could not be due to residual non-resected intrahepatic biliary disease.

According to the results of the present study, primary complete excision of BDC, with the construction of a wide bilio-digestive anastomosis to a healthy proximal bile duct should be the "gold standard" surgical management of patients suffering from BDC^[2,14,19]. Cyst-enterostomy must definitively be abandoned as a treatment option. Limitations of the study include its retrospective design, its long period (37 years) of patients inclusion and the number of patients without available long-term follow-up. The comparison between patients with previous cyst-enterostomy and the control group should also be considered with caution due to the small number of patients in the CE group.

However, despite cyst-enterostomy being no longer the primary approach for the surgical management of BDC, its prevalence was 17.2% in 186 patients operated

on after 1980^[2,7,20-22] and previous cyst-enterostomy was still observed in 7.3% of 354 patients operated on after 1990^[23-26]. Practically, this means that previous CE still remains a challenge during the management of BDC.

Indeed, the consequences of having undergone a cyst-enterostomy, regardless of the technique used, easily explain the more complicated clinical presentation of previously operated patients encountered in the present series: Possible mechanisms include reflux of digestive juice through the entire biliary tract, activation of pancreatic juice by enterokinases linked to pancreatico-biliary malunion^[27] or even anastomotic stricture of the CE on diseased cystic biliary tissue^[19,28,29]. Any of these can lead to severe biliary inflammation^[15], cholangitis, hepatolithiasis^[10,19,30,31] and increase the risk of carcinogenesis^[12,13,19,27]. The latter is estimated to be over 50% by Todani *et al.*^[27]. Indeed, malignant degeneration of BDC occurs more than 15 years earlier in patients with previous CE than in patients with primary carcinomas, with a median delay of 4 years in a series by Flanigan *et al.*^[13] to 10 years (range: 1-53 years of delay) in yet another by Todani *et al.*^[27] and, overall, is associated with a very poor prognosis. Finally, the reoperation rate after previous CE is high, ranging from 15.7% to 87.5%^[1,9,30,32].

The present series also shows that more complex surgical procedures had to be used for patients with a previous CE, mainly due to an increased need for a pancreaticoduodenectomy. Such an extensive procedure was linked, for half of these patients, with the presence of coexistent carcinoma, thereby, requiring tumor resection with a wide tumor-free margin. The other pancreaticoduodenectomies were mainly performed because of severe inflammation within the hepatic pedicle, probably as a result of repeated episodes of cholangitis. This feature observed during secondary BDC resection in patients with previous CE has not been reported until now.

According to several surgical series which compared primary CE with primary BDC resection with Roux-en-Y hepaticojejunostomy have reported an increased mortality rate (range: 8.3%-10% *vs* 0%-7%), morbidity rate (range: 17%-93% *vs* 0%-17%) and reoperation rate (range: 29.7%-87.5% *vs* 0%) in patients with primary CE^[9,10,30]. At the time of writing, there are only

3 studies that compared the morbidity and mortality rates between primary BDC resection and secondary BDC resection with previous CE, and these concerned series with only small numbers of patients^[2,15,19]. For patients with previous CE, Chijiwa *et al.*^[19] and Gigot *et al.*^[2] observed significantly more early postoperative complications, whilst Kaneko *et al.*^[15] reported significantly increased operative blood losses, operative time, early postoperative complications and wound infections. The present series demonstrates similar findings of an increased rate of overall and severe postoperative complications as well as hemorrhagic complications and reoperation rates for patients operated following previous CE.

The key-messages of this first large European multicenter study are that BDC patients who have undergone previous CE have more complications including carcinoma, that long-term results and survival rate are worse and that the reoperation rate is greater. It should be emphasized that these results cannot be attributed to intrahepatic disease alone as only Todani type I and IVb lesions were studied in this analysis. Late complications were also increased in the series reported by Kaneko *et al.*^[15], especially regarding late development of hepatolithiasis and pancreatic stones, though this was not reported in the series by Chijiwa *et al.*^[19]. Finally, multivariate statistical analysis confirmed in the present series that previous CE was representing an independent predictive factor of fair or poor prognosis after secondary BDC resection. Weaknesses of the present study include its retrospective nature, the number of patients excluded from long-term follow-up after 3 mo (18.1% of the whole series), the limited median follow-up duration of 37.5 mo and the small numbers of patients with previous CE.

In conclusion, this European retrospective series showed that previous CE was associated with a more complicated presentation, more coexistent HPB diseases including synchronous cancer, more complex surgery and worse early and long-term postoperative outcomes. These features confirmed the abandonment of cyst-enterostomy for the surgical management of congenital bile duct cysts.

COMMENTS

Background

Congenital bile duct cysts (BDC) are rare in the United States and in Europe. Cyst-enterostomy has been reported to be associated with increased morbidity (especially biliary complications) and higher reoperation rates during short- and

long-term follow-up in comparison to primary BDC resection. Consequently, primary resection has been considered as the treatment of choice for BDC. The purpose of the present study was to investigate the role of a previous cyst-enterostomy (CE) on short and long-term outcomes after secondary cyst resection in a large European multicenter cohort of patients.

Research frontiers

Limitation of the study includes its retrospective design, its long period (37 years), included patients and the number of patients without available long-term follow-up. The comparison between patients with previous cyst-enterostomy and the control group should also be considered with caution due to the small number of patients in the CE group. However, despite cyst-enterostomy being no longer the primary approach for the surgical management of BDC, its prevalence was 17.2% in 186 patients operated on after 1980 and previous cyst-enterostomy was still observed in 7.3% of 354 patients operated on after 1990. Practically, this means that previous CE still remains a challenge during the management of BDC.

Innovations and breakthroughs

This European retrospective series showed that previous CE was associated with a more complicated presentation, more coexistent HPB diseases including synchronous cancer, more complex surgery and worse early and long-term postoperative outcomes. These features confirmed the abandonment of cyst-enterostomy for the surgical management of congenital bile duct cysts.

Applications

These features confirmed the abandonment of cyst-enterostomy for the surgical management of congenital bile duct cysts.

Peer-review

The results of this European multicenter study are very interesting and the manuscript is well-written.

Abstract

AIM: To determine predictors of long term survival after resection of hilar cholangiocarcinoma (HC) by comparing patients surviving > 5 years with those who survived < 5 years.

METHODS: This is a retrospective study of patients with pathologically proven HC who underwent surgical resection at the Gastroenterology Surgical Center, Mansoura University, Egypt between January 2002 and April 2013. All data of the patients were collected from the medical records. Patients were divided into two groups according to their survival: Patients surviving less than 5 years and those who survived > 5 years.

RESULTS: There were 34 (14%) long term survivors (5 year survivors) among the 243 patients. Five-year survivors were younger at diagnosis than those surviving less than 5 years (mean age, 50.47 ± 4.45 vs 54.59 ± 4.98 , $P = 0.001$). Gender, clinical presentation, preoperative drainage, preoperative serum bilirubin, albumin and serum glutamic-pyruvic transaminase were similar between the two groups. The level of CA 19-9 was significantly higher in patients surviving < 5 years (395.71 ± 31.43 vs 254.06 ± 42.19 , $P = 0.0001$). Univariate analysis demonstrated nine variables to be significantly associated with survival > 5 year, including

young age ($P = 0.001$), serum CA19-9 ($P = 0.0001$), non-cirrhotic liver ($P = 0.02$), major hepatic resection ($P = 0.001$), caudate lobe resection ($P = 0.006$), well differentiated tumour ($P = 0.03$), lymph node status (0.008), R0 resection margin ($P = 0.0001$) and early postoperative liver cell failure ($P = 0.02$).

CONCLUSION: Liver status, resection of caudate lobe, lymph node status, R0 resection and CA19-9 were demonstrated to be independent risk factors for long term survival.

Key words: Hilar cholangiocarcinoma; Hepatic resection; Caudate lobe resection; CA19-9; Liver cell failure

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Hilar cholangiocarcinoma is an uncommon malignancy with a relatively poor prognosis. Surgery remains the only line of treatment offering the possibility of cure. The central location of the tumor and its close relationship to vascular structures at the hepatic hilum have resulted in a low resectability rate. Five year survivors were younger at diagnosis than those surviving less than 5 years. Major hepatic resection and caudate lobe resection achieved better R0 resection rate. Liver status, resection of caudate lobe, lymph node status, R0 resection and CA19-9 were demonstrated to be independent risk factors for long term survival.

Predictors of long term survival after hepatic resection for hilar cholangiocarcinoma: A retrospective study of 5-year survivors. *World J Gastrointest Surg* 2016; 8(6): 436-443 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/436.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.436>

INTRODUCTION

Hilar cholangiocarcinoma (HC) is the most common type of biliary tract malignancy, arising at the confluence of the right and left hepatic ducts, and comprises 40% to 60% of all cholangiocarcinomas^[1-3]. It is a complex and aggressive disease with a poor prognosis^[2-6]. The resectability rate varies from 25% to 58% of patients who are surgically explored due to locally advanced tumour or liver metastasis. The central location of the tumor and its close relationship to vascular structures at the hepatic hilum have resulted in a low resectability rate and high morbidity and mortality^[3-7].

Although the results of surgical treatment for HC were dismal, recent studies have reported improved outcomes using aggressive surgical approaches: Postoperative morbidity generally ranges from 30% to 50% and mortality is 10% or less^[5-10]. However,

the actual 5-year survival after radical resection of HC ranges from 10% to 28 % with the majority of studies reporting 20% or higher. The median survival after curative resection is about 19 to 35 mo^[10-13].

Few studies of HC have long enough followed patients to report a survival beyond 5 years^[7-10]. It has long been recognized that radical resection offers the only hope for cure and improves long term survival. Many studies have confirmed that hepatic resection combined with caudate lobe resection can achieve high rates of margin-free resection (R0) and significantly improve the overall survival^[4-6,11-15].

The aim of this study was to determine variables that are predictors of long term survival after resection of HC by comparing patients surviving 5 years after resection of HC with those who survived less than 5 years.

MATERIALS AND METHODS

This is a retrospective study of patients with pathologically proven HC who underwent surgical resection at the Gastroenterology Surgical Center, Mansoura University, Egypt between January 2002 and April 2013. Data were collected from the patient records in April 2015. Follow-up was held regularly at the outpatient clinic. The patients were treated in accordance with the center policy, with patients with liver metastasis, lymph node metastasis far beyond regional lymph nodes, and local invasion of the major vessels of the contralateral site considered to have an unresectable tumour.

Informed consent was obtained from all patients after a careful explanation of the nature of the disease and possible treatment with its complications. The study was approved by the Institution Review Board.

Patients were divided into two groups according to their survival: Patients who survived < 5 years and those surviving > 5 years.

Preoperative assessment

All patients underwent full laboratory investigations, abdominal contrast enhanced CT and/or magnetic resonance cholangiopancreatography. Upper gastrointestinal tract endoscopy was performed routinely to exclude esophageal and fundic varices. Preoperative biliary drainage (PBD) was done by endoscopic retrograde cholangiopancreatography or by ultrasound (US) guided percutaneous transhepatic drainage to improve the general condition of the patients before surgery especially if there was cholangitis. The state of the liver and the extent of cirrhosis were assessed by the modified Child-Turcotte-Pugh classification^[16].

Surgical procedure

Exploration was done through a bilateral subcostal incision with midline extension of the incision in some cases. Evaluation of the tumour, liver condition and the extent of lymphatic spread were done at first.

The choice of surgical procedure depended on tumour extension and the general condition of patients. The tumours extension was classified according to the Bismuth-Corlette classification system^[17]. All hepatobiliary resections were performed with the intent of achieving free safety margin (R0). Proximal and distal margins were assessed on frozen sections during the operation in some cases. If safety margin was proved to be positive, addition hepatobiliary resection was done as far as technically feasible until R0 was obtained if possible.

All cases underwent extrahepatic biliary resection and lymphadenectomy of locoregional lymph nodes starting from the celiac trunk up to the hilum *en bloc* with the mass. Hepatic resection was variable from minor resection, which included three or less segments to major resection, which included four or more segments according to Couinaud nomenclature. Hepatic resection was done using a harmonic scalpel with or without Pringle's maneuver to control bleeding. Biliary anastomosis was done by hepaticojejunostomy with or without stenting.

Localized resection (minimal central hepatectomy segment 4) was performed in patients with type I HC without any evidence of hepatic infiltration, lymph node metastases, cirrhotic liver, or poor general condition. Hemihepatectomy was selected in cases of single lobe atrophy, invasion of the portal or hepatic branches or extension of the tumor up to the parenchyma of that lobe. Caudate lobe resection was also done in the majority of cases within the last five years.

Postoperative management

After surgery, patients were admitted to the intensive care unit in the early postoperative days to receive the usual postoperative care by the same surgical team.

Liver function tests were performed in the postoperative period regularly on the first, third day and on the day of discharge. Abdominal ultrasonography was done routinely in all patients and repeated when there were complications. Tube drainage was carried out in cases of any significant abdominal collections.

All pathological reports were reviewed to determine the extent of the tumour, differentiation, lymph node infiltration and positive resection margin. R0 resection was defined as cases in which no gross or microscopic tumour residue was left behind, R1 resections had microscopically positive margins and R2 resections still contained some gross tumor matter^[18]. Hospital mortality was defined as death during the first 30 postoperative days.

Follow-up

Follow-up was done in the outpatient clinic at 1 mo, 6 mo, and then every year. Clinical examinations, routine laboratory investigations (complete liver function, complete blood picture and tumour markers CEA and CA 19-9), abdominal sonography and CT scans were

done at each visit.

Data collection

Preoperative clinical data, intraoperative and postoperative data were collected. Postoperative complications, survival rates and recurrence rates were recorded.

Statistical analysis

Statistical analyses of the data in this study were performed with SPSS software, version 17 (Chicago, IL, United States). Descriptive data are expressed as the mean with standard deviation. Categorical variables are described using frequency distributions. Independent sample *t* test was used to detect differences in the means of continuous variables and χ^2 test was used in cases with low expected frequencies. *P* values < 0.05 were considered significant. Variables with *P* < 0.05 were entered into the Cox regression model to determine independent factors for 5-year survival. The independent factors are expressed as odds ratios (ORs) with their 95% CIs. Survival curves were done using Kaplan-Meier method and differences in survival curves were compared by a Cox-regression analysis.

RESULTS

Between January 2002 and April 2013, surgical interventions with curative intent were performed on 278 patients who had HC. Eventually, 243 patients underwent hepatobiliary resection and 35 did not undergo any resection because of advanced disease (liver metastasis in 11 cases and local vascular infiltration in 24 cases). Of these, 34 (14%) patients were long term survivors (> 5 years) and 209 (86%) were short term survivors (< 5 years). In this study, the 1, 3 and 5 year survival rates were 53%, 35% and 22%, respectively, and the median survival was 24 mo.

Five-year survivors were younger at diagnosis than those surviving less than 5 years (mean age, 50.47 ± 4.45 vs 54.59 ± 4.98, *P* = 0.001). Gender, clinical presentation, preoperative drainage, preoperative serum bilirubin, albumin and serum glutamic-pyruvic transaminase were similar between the two groups. The level of CA19-9 was significantly higher in patients surviving < 5 years (395.71 ± 31.43 vs 254.06 ± 42.19, *P* = 0.0001) (Table 1).

Intraoperative data are shown in Table 2. Major hepatectomy, including right or left hepatectomy, was carried out in 173 (71.19%) of 243 patients besides 70 (28.8%) patients who underwent localized resection. The extent of hepatic resection had a significant impact on the survival rate. Major hepatobiliary resection was performed in 30 (88.23%) patients surviving > 5 years and in 143 (68.42%) surviving < 5 years. Segment 1 resection was done in 23 (67.64%) patients surviving > 5 years and it represented a significant factor for long term survival (*P* = 0.006). Liver status showed a

(41.8%), *P* < 0.008] and positive resection margin (R1) [6 (17.6%) vs 116 (56.7%), *P* = 0.0001] (Figure 1).

Hepatic recurrence occurred in 51 (24.4%) patients surviving < 5 years, 40 of them (78.4%) had R1, while hepatic recurrence occurred in 8 (23.52%) patients surviving > 5 years, 4 of them (50%) had R1.

Univariate analysis demonstrated nine variables (young age, serum CA19-9, non cirrhotic liver, major hepatic resection, resection of caudate lobe, well differentiated tumour, lymph node status, R0 resection margin and early postoperative LCF) to be significantly associated with survival > 5 years. These nine factors identified in univariate analysis were further analyzed in multivariate analysis. Liver status, resection of caudate lobe, lymph node status, R0 resection and serum CA19-9 were demonstrated to be independent risk factors for long term survival (Table 4).

DISCUSSION

Cholangiocarcinoma is an uncommon malignancy with a relatively poor prognosis, providing a major therapeutic

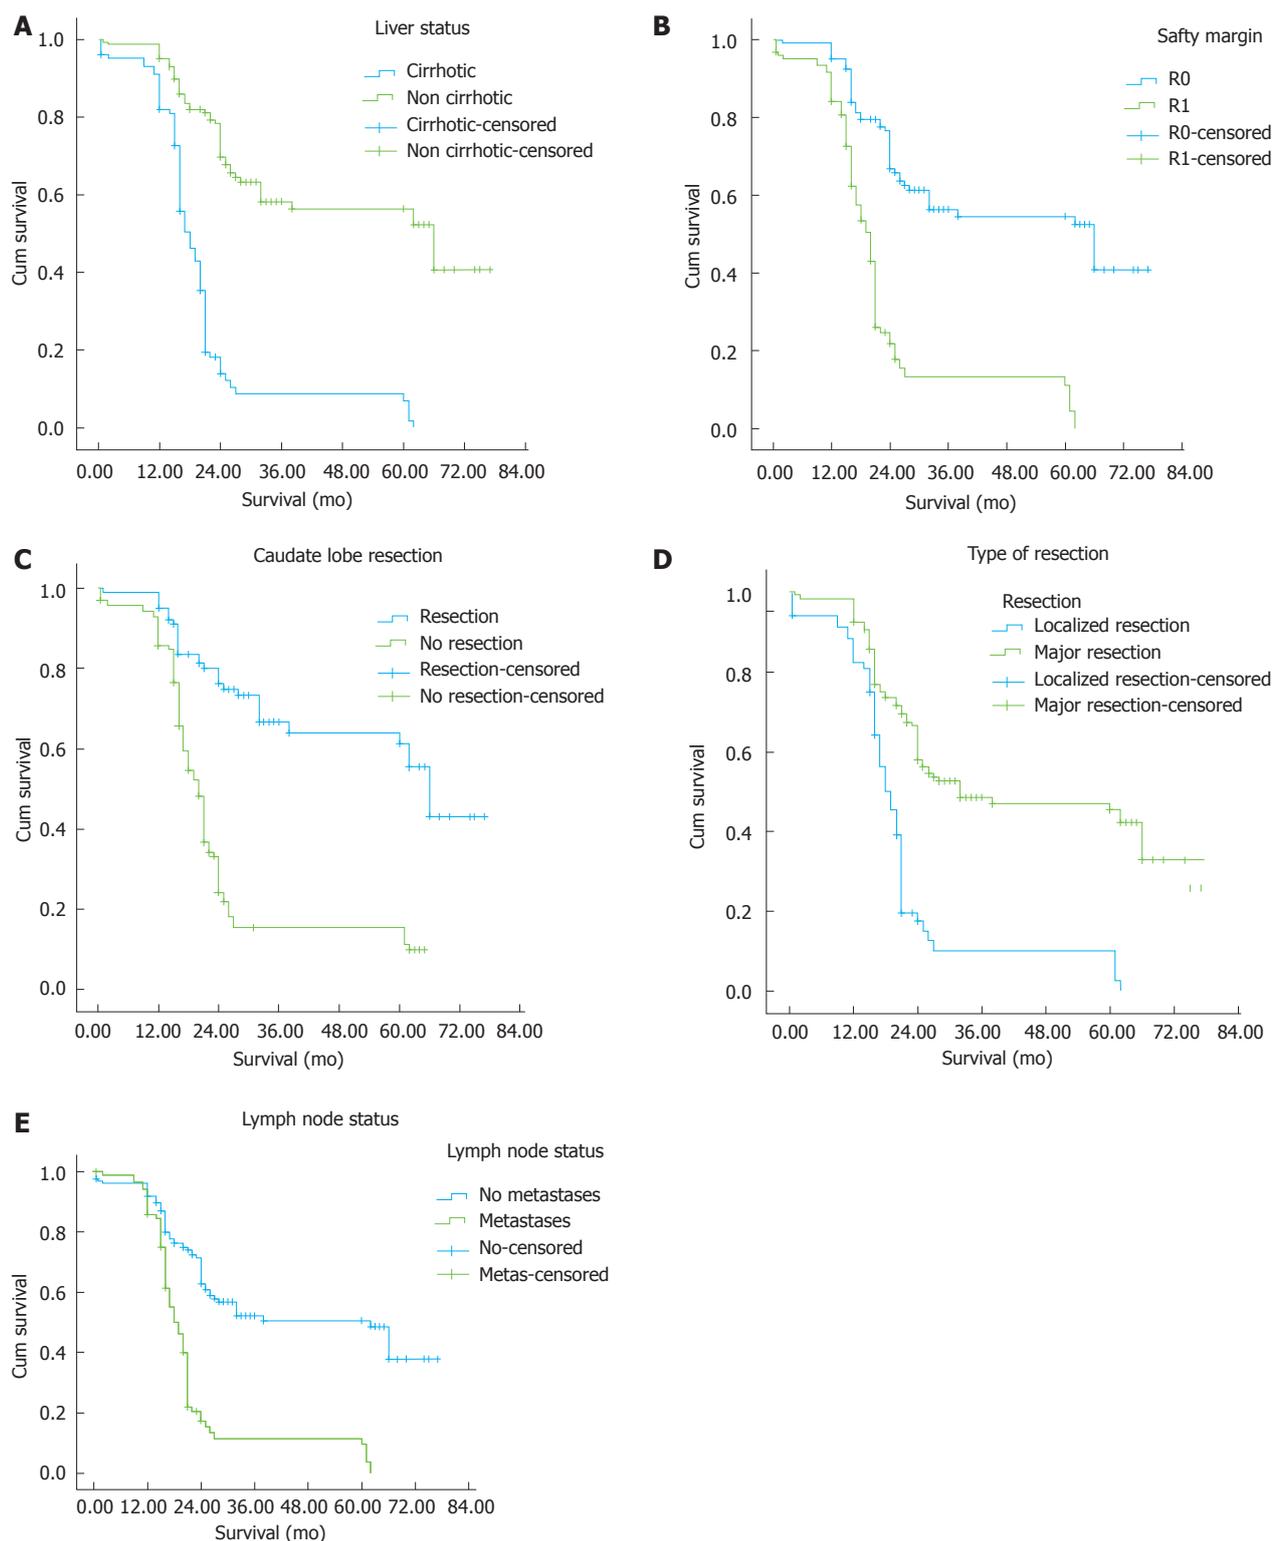

Figure 1 Actuarial survival (Kaplan Meier analysis) after resection of hilar cholangiocarcinoma. Influence of liver status (A), safety margin (B), caudate lobe resection (C), type of resection (D), and lymph node status (E).

challenge. Surgery remains the only line of treatment offering the possibility of cure, but it remains difficult because of their proximity to and possible local invasion of the portal vein, hepatic artery and the surrounding liver parenchyma and caudate lobe^[4-7,19-22]. The surgical approach for HC has changed in the last two decades

from primarily minor surgery to major hepatectomy with CBD resection and portal vein resection. Now all experienced hepatic surgeons agree to do hepatic resection with resection of the extrahepatic biliary tree when treating HC^[20-26].

The resectability rate of HC varies in different studies

from 20% to 80%. The actual 5-year survival after radical resection of HC ranges from 10 to 28% with the majority of studies reporting 20% or higher^[10-15,20-26]. In this study, the 1-, 3- and 5-year survival rates were 53%, 35% and 22%, respectively. The median survival for these cases was 24 mo. Thirty-four (14%) patients were long term survivors (> 5 years) and 209 (86%) were short term survivors (< 5 years). Five-year survivors were younger at diagnosis than those surviving less than 5 years (mean age, 50.47 ± 4.45 vs 54.59 ± 4.98, $P = 0.001$).

The role of PBD in the management of HC remains controversial. However, no evidence demonstrates that routine PBD facilitates resection, decreases postoperative morbidity or increases survival rate^[27,28]. Although PBD does not represent a significant factor affecting long term survival, it is mandatory in cases of preoperative cholangitis or bad general condition and improves the postoperative course of patients with a serum bilirubin level > 20 mg/dL^[15,26].

Curative surgery for patients with HC often necessitates hepatic resection to achieve a R0 resection and improve the long term survival because the characteristics of its growth pattern include longitudinal intraductal extension, perineural, lymphatic, and direct liver invasion^[6-9,20-26]. Major hepatic resection is considered the curative treatment for HC, but it is not always safe because postoperative liver cell failure is a common cause of death after major resection in patients with compromised liver function. However, the dilemma between major hepatic resection with potential postoperative hepatic cell failure and localized resection with potential R1 and R2 resection margins might be solved by advances in preoperative and intraoperative assessments^[15]. Recent advances in perioperative and operative techniques, instruments and care have led to a marked improvement in short and long term outcomes after major hepatic resection^[15]. Major hepatobiliary resection for HC provides R0 resection and improves survival. In this study, 88.23% of 5-year survivors underwent major hepatic resection.

As the caudate lobe is infiltrated by HC either directly due to the close anatomic relationship or by invading the biliary branches, routine caudate lobe resection should be performed for curative treatment of HC^[15,29-31]. Better R0 resection rate and long term survival have been achieved by caudate lobe resection in treating cases of HC^[15,29-34]. Nimura *et al.*^[33] found that 98% of cases of caudate lobe resection were pathologically confirmed to be tumour positive in cases of HC. However, other authors showed that the caudate lobe was infiltrated by HC in 25%-40% of cases^[15,33-35]. Segment 1 resection represents a significant factor affecting survival ($P = 0.006$) in our study. In the initial period of the study, caudate lobe resection was performed only when the caudate lobe was infiltrated, but now it is performed routinely in all cases of HC.

Safety margins after hepatic resection for cholangiocarcinoma represented a highly significant factor

affecting long term survival. Many authors have reported that negative surgical margin (R0) is an important prognostic variable. R0 resection rate in the literature varies from 14% to 80 % and overall 5-year survival rate for R0 resection from 22% to 45%^[4-7,15-17,26-30]. The frequency of R0 resection depends on the extent of hepatic resection. To obtain R0 resection, removal of the caudate lobe is required because of the high rate of infiltration (30%-39%)^[15,29-33]. In the current study five-year survivors were less likely to have a positive safety margin [6 (17.6%) vs 116 (56.7%), $P = 0.0001$]. Surgical treatment of HC with localized resection has been shown to result in early recurrence after surgery due to positive surgical margins at the hepatic edge of the bile duct with low long term survival^[4-8,15,26-30,32,36-40].

Lymph node metastasis was present in 20%-50% of cases of cholangiocarcinoma in the previous literature^[5-12,20-25,32,35-41]. When no lymph node metastasis was detected, the 5-year survival was more than 60%. In contrast, in patients with lymph node metastasis, the 5-year survival was only 21%^[25,26]. Lymph node metastasis beyond the hepatoduodenal ligament (celiac, mesenteric, or paraaortic lymph nodes) has a poor prognosis with a 5-year survival less than 12%, so it is considered a contraindication to resection.

Cirrhosis is expected to be associated with increased blood loss, need for blood transfusion and increased post-hepatectomy LCF. The treatment of HC needs careful patient selection, good perioperative assessment and care, and good decision on the extent of hepatobiliary resection. This is why to carry out the localized resection in cirrhosis and so the achievement of R0 is less in cirrhotic patients with HC^[4-7,32,38-42]. In the current study, 5-year survivors had a less cirrhotic liver than those surviving less than 5 years. This result in cirrhotic patients is attributed to more aggressive HC, localized resection without caudate lobe resection, and poor liver reserve. This can explain the worse 5-year survival in cirrhotic patients in comparison to non-cirrhotic patients^[5,30,39,42].

In conclusion, there were 34 (14%) 5-year survivors with resected HC in this study. Five-year survivors were younger at diagnosis than those surviving less than 5 years. The majority of long term survivors after resection of HC underwent major hepatic resection and caudate lobe resection. Well differentiated HC tumour, negative surgical margins and negative nodal metastasis have an impact on long term survival after hepatic resection for cholangiocarcinoma.

COMMENTS

Background

Hilar cholangiocarcinoma (HC) is an uncommon malignancy with a relatively poor prognosis. HC is the most common type of biliary tract malignancy, arising at the confluence of the right and left hepatic ducts, and comprises 40% to 60% of all cholangiocarcinomas. Surgery remains the only line of treatment offering the possibility of cure, but it remains difficult. The actual 5-year survival after radical resection of HC ranges from 10% to 28%. The median survival after curative resection is about 19 to 35 mo.

Research frontiers

Few studies of HC have long enough followed patients to report a survival beyond 5 years. It has long been recognized that radical resection offers the only hope for cure and improves long term survival. Many studies have confirmed that hepatic resection combined with caudate lobe resection can achieve high rates of margin-free resection (R0) and significantly improve the overall survival.

Innovations and breakthroughs

The surgical approach for HC has changed in the last two decades. Now all experienced hepatic surgeons agree to do hepatic resection with resection of the extrahepatic biliary tree when treating HC. Curative surgery for patients with HC often necessitates hepatic resection to achieve a R0 resection and improve the long term survival because the characteristics of its growth pattern include longitudinal intraductal extension, perineural, lymphatic and direct liver invasion.

Applications

The data in this study suggested that major hepatobiliary resection and caudate lobe resection provide R0 resection and improve survival rate for HC. As the caudate lobe is infiltrated by HC either directly due to the close anatomic relationship or by invading the biliary branches, routine caudate lobe resection should be performed for curative treatment of HC. Furthermore, this study also provided readers with important information regarding the HC treatment and variables that increase survival rate.

Terminology

HC is an uncommon malignancy with a relatively poor prognosis. HC is the most common type of biliary tract malignancy, arising at the confluence of the right and left hepatic ducts.

Peer-review

This is an interesting manuscript with a significant number of patients treating an important topic, and the aim of this study was to determine predictors of long term survival after resection of HC.

Abstract

AIM: To investigate the clinicopathological features and the significance of different prognostic factors which predict surgical overall survival in patients with gastric carcinoma.

METHODS: This retrospective study includes 80 patients diagnosed and treated at gastroenterology surgical center, Mansoura University, Egypt between February 2009 to February 2013. Prognostic factors were assessed by cox proportional hazard model.

RESULTS: There were 57 male and 23 female. The median age was 57 years (24-83). One, 3 and 5 years survival rates were 71%, 69% and 46% respectively. The median survival was 69.96 mo. During the follow-up period, 13 patients died (16%). Hospital morbidity was reported in 10 patients (12.5%). The median number of lymph nodes removed was 22 (4-41). Lymph node (LN) involvement was found in 91% of cases. After R0 resection, depth of wall invasion, LN involvement and the number (> 15) of retrieved LN, LN ratio and tumor differentiation predict survival. In multivariable analysis, tumor differentiation, curability of resection and a number of resected LN superior to 15 were found to be

independent prognostic factors.

CONCLUSION: Surgery remains the cornerstone of treatment. Tumor differentiation, curability of resection and a number of resected LN superior to 15 were found to be independent prognostic factors. Extended LN dissection does not increase the morbidity or mortality rate but markedly improves long term survival.

Key words: Cancer stomach; Prognostic factors; Lymph node metastasis; Recurrence after gastrectomy; Lymph node ratio

INTRODUCTION

Cancer of the stomach is the fifth most common cancer in the world and it is also the third leading cause of cancer death of both sexes worldwide^[1]. Prognosis is poor perhaps due to late diagnosis and frequent local-regional recurrences^[2]. It still one of the common health problems in Egypt. This requires investigation of the possible reasons for the worsening of survival and searching for prognostic factors of better survival.

Whenever possible, complete resection of the tumor with satisfactory safety margins is the standard treatment providing hope for cure^[3,4]. Many prognostic factors have been investigated to assess their significance in predicting patients' outcome. The number of metastatic lymph nodes (N stage) and the depth of the primary tumor (T stage) are currently considered the most reliable prognostic factors for patients with radically resected gastric cancer^[5-7]. Lymph node (LN) clearance remains the most challenging part of the operation, the extent of LNs dissection is classically termed D0, D1, and D2^[8,9]. The UICC/AJCC classification, suggests that at least 15 LNs should be examined for a correct assessment of N stage^[10,11].

Therefore, the surgeon experience toward more radical resection with LN removal is the most important non-TNM prognostic factors in gastric cancer. However, prognosis varies among patients with a similar tumor stage; therefore, disease staging alone cannot accurately predict the outcome for individual patients^[12].

The aim of this study was to evaluate the Clinicopathological features and the significance of different prognostic factors in patients undergoing resection for gastric cancer.

MATERIALS AND METHODS

This is a retrospective study of patients underwent gastrectomy for gastric cancer from February 2009 to February 2013, in gastroenterology surgical center, Mansoura University, Egypt. A total of 80 patients diagnosed with gastric cancer underwent gastrectomy during this period. R0 resection was defined by the complete tumor excision after surgical treatment proved by pathologic examination of the resected margins. Clinicopathological parameters, including gender and age of patients; location of the tumor; depth of invasion; LN metastasis status; operative details; morbidity and mortality; and survival and recurrence were collected. Patients with synchronous malignancies, and those who were diagnosed others than adenocarcinoma was excluded from the study. We did not use endoscopic ultrasound in our center. During the study period, the median survival for patients who did not undergo surgery and only had palliative management was 6 mo. All patients did not receive a preoperative adjuvant or neoadjuvant therapy.

Cancer staging was as described in the seventh edition of the International Union Against Cancer TNM Classification^[9].

All of the surgical procedures were performed by experienced gastric surgeons of our single institute with a definitive treatment guideline for gastric cancer. Two types of gastrectomy were performed: Subtotal gastrectomy (STG) or total gastrectomy (TG).

STG was performed for tumors located in the lower and middle third of the stomach when a 3-6 cm tumor proximal free safety margin can be achieved. All the other patients underwent TG. STG includes the removal of the greater and lesser omentum. The first portion of the duodenum was mobilized and divided at least 2 cm distal to the pylorus with at least 2 cm distal safety margin. The left gastric artery was ligated at its origin. A roux-en-Y reconstruction was done for 18 patients who left with small gastric pouches (< 20% of the stomach), while 32 patients had a loop gastrojejunostomy as they had a large remnant gastric pouches. For TG, the resection included removal of the spleen if there was a suspected LN involvement at splenic hilum. Esophagojejunostomy roux-en-Y is the most common type of reconstruction with a Roux limb is at least 45 cm long. In all patients, an extended lymphadenectomy, was used as the standard surgical procedure. All patients

did not receive adjuvant or neoadjuvant therapy.

Statistical analysis

The χ^2 or Fisher's exact test was used to compare categorical variables. Survival was calculated using the Kaplan Meyer method and groups were compared using the Log-Rank test. Factors that were deemed of potential importance on univariate analysis were included in the multivariate analysis. A probability (*P*) of less than 0.05 (two sided) was considered statistically significant. Overall mortality represented all deaths during follow-up. Cox multivariate proportional hazards regression models were used to assess the overall survival power of these parameters. All analyses were done using SPSS® software program version 21 (Chicago, United States).

RESULTS

From February 2009 to February 2013, eighty patients with gastric carcinoma were managed in our Gastroenterology Surgical Center. Their age ranged from 24 to 83 years with a mean age 55.4 ± 11.8 years (median age 57 years). Fifty seven were male (71%) and 23 female (29%), with male to female ratio (2.5:1).

Table 1 shows the co-morbidity and possible risk factors in our patients, 66 of patients (83%) had *Helicobacter pylori*, 56 (70%) of them were heavy smokers. Variable symptoms were experienced by our patients; epigastric pain was the main complaint in all patients (100%). The antrum was the most common tumor location within the stomach in 51 patients

Total	13 (16)

(64%), and the polypoid growth was the most common macroscopic feature and was found in 46 patients (58%) (Table 2).

Operative data

Total gastrectomy was performed in 30 patients (38%) and subtotal gastrectomy in 50 patients (62%). The radicality of the operation necessitates extension of the resection to the tail of the pancreas and to the spleen in 5 patients, to the colon in 2 patients and to the left liver lobe in one patient. The mean blood transfusion required for TG and STG was (1.29 ± 0.53 unit) and (0.41 ± 0.50 unit).

There is no hospital mortality. Postoperative hospital morbidity was reported in 10 patients (12.5%) (Table 3). Three patients (4%) had anastomotic leakage and were managed conservatively (2 patients after TG and 1 patient after STG). Recurrence was shown in Table 4 whereas local and gastric stump was the commonest site (11%). The median period of hospital stay was 8 d (5 to 36 d).

Table 5 shows the demographic and clinicopathological features predicting overall survival. One, 3 and 5 years survival rates were respectively 71%, 69% and 46%. The median survival was 69.96 mo (Figure 1). During the follow-up period, 13 patients died (16%). The median number of LNs removed was 22 (4-41). LN metastasis was found in 91% of cases. Survival was superior in case of negative LN resected (61 mo vs 31 mo, $P < 0.0001$). Survival also varied according to the number of removed LN. The median survival was 54.48 mo when more than 15 LN were removed vs 14.5 mo when fewer LN were resected ($P < 0.0001$) (Figure 2A). There was no statistical significance between both groups as regard the effect of extended LN dissection on morbidity ($P = 0.34$). The ratio of the number of positive nodes to the total number of nodes retrieved, *i.e.*, the LN ratio, was significantly associated with worse overall survival, it was 62 ± 2.5 mo when LN ration was ≤ 0.2 , 62 ± 2.1 mo when LN ration was between 0.2

to 0.4 and 22 \pm 4.5 mo when LN ration was $>$ 0.4; *P* $<$ 0.001 (Figure 2B).

The median survival of T1 and T2 tumors was significantly superior to T4 tumors (60 mo vs 12 mo, *P* = 0.0001) (Figure 2C). Survival was significantly higher in case of well and moderate differentiated tumor to poorly differentiated tumor (65.7 mo vs 20.8 mo, *P* $<$ 0.0001) (Figure 2D). Seventy three patients (91%) had a radical resection which is associated with prolonged survival compared to 7 patients (9%) who had a palliative one (53.8 mo vs 9.5 mo, *P* $<$ 0.0001) (Figure 2E). Patients developed a recurrent tumor (13 patients 16%) had a significant poor survival compared to the others (67 patients 84%) (12.3 mo vs 57.3 mo, *P* $<$ 0.0001).

There is no significant difference in survival rate according to age, gender, tumor location, the type of gastrectomy. On multivariable analysis (Table 6), tumor differentiation, curability of resection and a

number of resected LN superior to 15 were found to be independent prognostic factors.

DISCUSSION

The epidemiology, surgical management and outcomes for patients with carcinoma of the stomach differ significantly from one area of the world to another. We have a published data and experience from Western, Eastern and European countries. However, we have a little data from Middle East countries, and here we represent our work from a large gastroenterology and transplantation center in Egypt. Complete tumor excision with satisfactory safety margins (*i.e.*, an R0 resection according to the UICC classification) have been accepted as a major significant factor for reduction of tumor recurrences and improvement of survival time in patients with gastric cancer^[13-19]. This radical resection is the most important step to have better survival in our patients (53.8 mo vs 9.5 mo, *P* $<$ 0.0001). In our series, after R0 resection and DII lymphadenectomy, depth of wall invasion, LN metastasis, the number of resected LN, LN ratio and tumor differentiation were the independent prognostic factors.

The extent of regional lymphadenectomy required has been a matter of considerable debate. The number of LN metastases has a higher prognostic value compared to their location^[8,20] and the staging system was updated in the 2010 UICC/TNM 7th edition^[21]. The definition of LN dissections: Has been updated considering the number of removed LN rather than their location, it is as follows: D0 when less than 15 nodes are reported, D1 when 15 to 25 nodes are removed, and D2 when more than 25 nodes are reported in the pathological findings^[8,9].

There has been much argument about the mini-

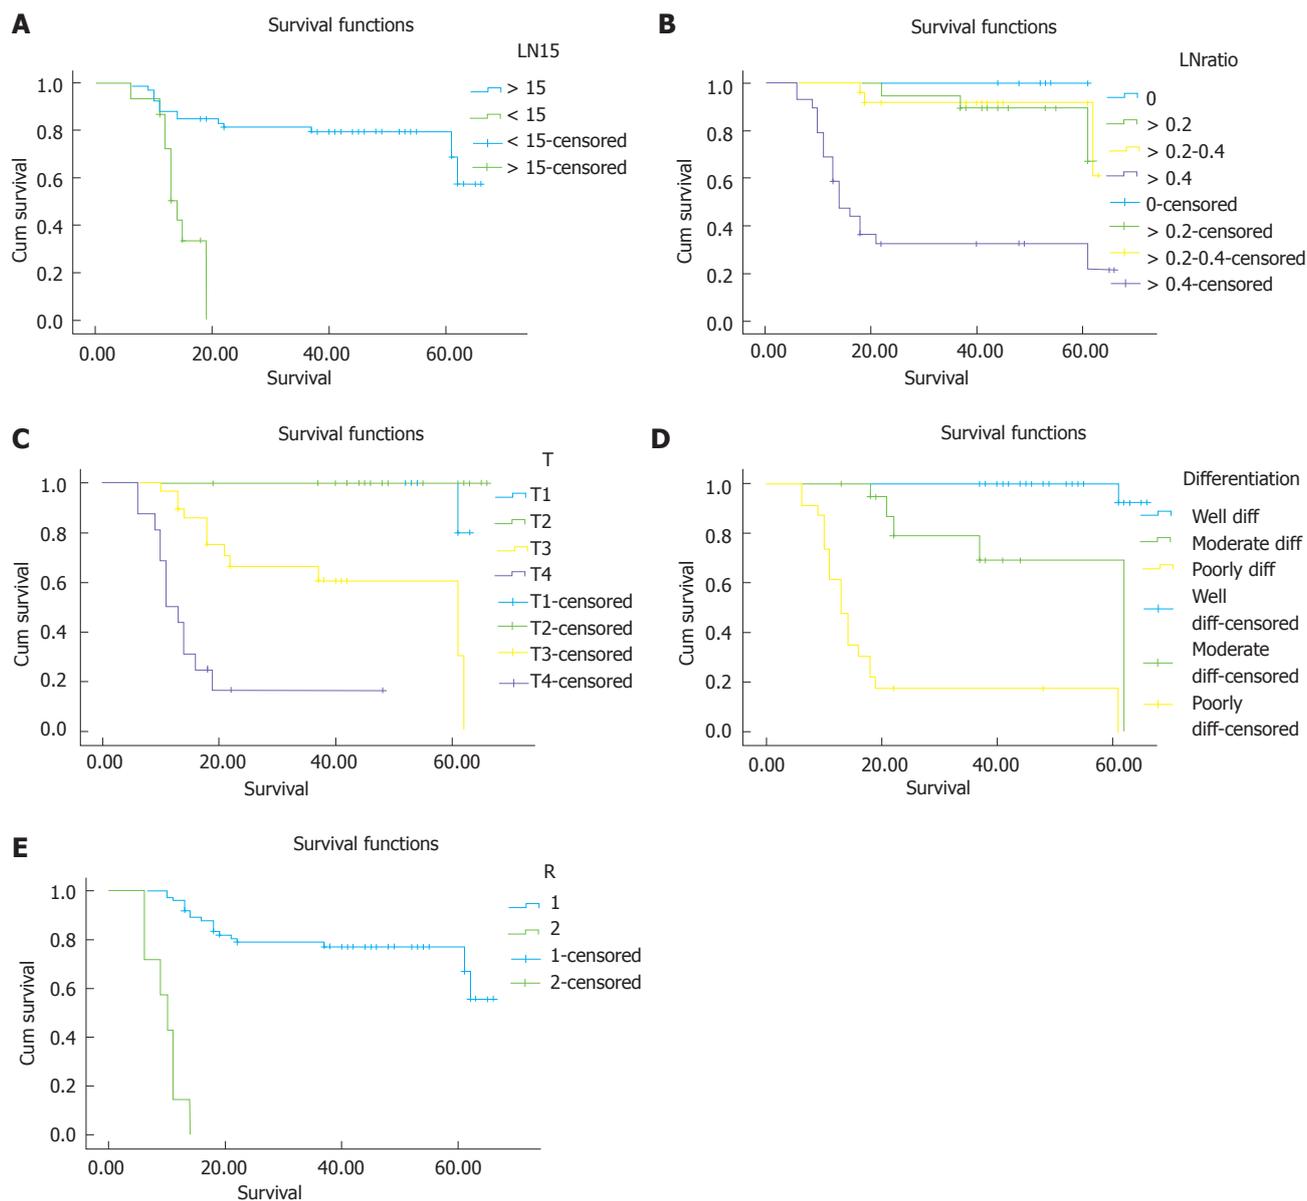

Figure 2 Actuarial survival (Kaplan Meier analysis) after resection of gastric carcinoma. A: Influence of number of affected LN; B: Influence of LN ratio; C: Influence of tumor stage; D: Influence of tumor grade; E: Influence of radicality of resection. LN: Lymph node.

imum number of LNs removed for proper staging. The Union Internationale Contre Le Cancer (UICC), has standardized the operative management of gastric cancer and propose that for proper staging, at least 15 LNs should be removed and pathologically examined^[22]. This recommendation highlights the significance of the total number of LNs removed over their relationship to the primary tumor (N1 or N2). Karpeh *et al*^[8], three years later, made a comparison between different staging systems to show their impact on the long term survival (UICC 1988 that used the location of LN vs UICC 1997 that used the number of LN). They reported that, there is superior significant value of the number of metastatic LNs more than their location.

The number of metastatic LNs increases with the depth of tumor invasion through the gastric wall layers and this had a direct relationship to long term

survival^[23-25]. In our series, the T and N stage had the highest significant prognostic factors especially after R0 resection. Survival was 54.48 mo when more than 15 LN were resected vs 14.5 mo when fewer LN were removed ($P < 0.0001$). In experienced centers, Extended LN dissection does not increase the morbidity or mortality rate but markedly improves long term survival.

The independent prognostic value of LN ratio in our monoinstitutional study was significantly associated with worse overall survival, it was 62 ± 2.5 mo when LN ratio was ≤ 0.2 , and 22 ± 4.5 mo when LN ratio was > 0.4 ; $P < 0.001$. In various Western series, the LN ratio has been considered as an effective prognostic tool after D2 lymphadenectomy^[26-32]. Bando *et al*^[27] reported that, at multivariate analysis the LN ratio was the only independent prognostic factor when the number

NS: Non-significant; NR : Not reported; LN: Lymph node.

and the side of metastatic LNs were considered in the analysis. Kunisaki *et al*^[33] reported the same result and that the LN ratio independently influenced the prognosis of a radically resected 758 patients.

The median survival of T1 and T2 tumors was significantly superior to T4 tumors (60 mo vs 12 mo, $P = 0.0001$) this is also reported by others^[4,34]. Grade refers to the degree of differentiation of tumor cells and has been shown to correlate with the neoplasm aggressiveness. The prognostic impact in gastric cancer remains to be elucidated, because several retrospective studies have failed to identify grade as an independent prognostic factor^[7]. In our study, Survival was superior in case of well and moderate differentiated tumor to poorly differentiated tumor (65.7 mo vs 20.8 mo, $P < 0.0001$) others reported the same result^[4,34]. On multivariable analysis, tumor differentiation curability of resection and a number of resected LN superior to 15 were found to be independent prognostic factors.

The recurrence after surgical excision of gastric carcinoma shows a different pattern between Eastern and Western countries. However, there are still some disputes. In Eastern countries, the hematogenous recurrence and peritoneal dissemination were the most common recurrence patterns^[35-37]. Wu *et al*^[38] reported that the peritoneal recurrence was 38.4% and the hematogenous recurrence was 32.5% of patients. Our results show that local recurrence is the most common one and account for 11%. This result is consistent with an Italian study that showed that the loco-regional recurrence was the most common recurrence pattern and account for 45% of all recurrent cases^[38]. This difference in recurrence pattern may be explained by that the low incidence of local recurrence in Eastern series is due to a different surgical strategy toward extensive LNs dissection^[39].

In this study, the 3 and 5 years survival rates were 69% and 46%, respectively. Our survival rates are similarly to those reported in Memorial Sloan-Kettering cancer center in New York^[23] and the German gastric cancer study^[3] and some other western centers^[29,34,40,41]. However, our survival results are better than a reported

study from Poland^[42]. We have a lower survival rates than those reported in Japan^[43,44]. Table 7 shows some published series on prognostic factors after resection for gastric carcinoma. Epidemiology, late discovery of the disease, differences in the staging systems and the operative strategy with extensive lymphadenectomy in Japan may explain these differences.

In conclusion, the epidemiology, surgical management and outcomes differ significantly from one area of the world to another. Surgery stills the gold-stander line of management. There might be a correlation between time to discover the disease, radicality and survival. Our study showed that after R0 resection, depth of wall invasion, LNs involvement and the number (> 15) of resected LN, In ratio and tumor differentiation predict survival. On multivariable analysis, tumor differentiation, curability of resection and a number of removed LN more than 15 were found to be independent prognostic factors. In order to have a better survival in our patients, we recommend frequent use of upper endoscopy for gastrointestinal symptoms for early detection of gastric cancer.

COMMENTS

Background

The epidemiology and the surgical outcomes for patients with carcinoma of the stomach vary significantly from one part of the world to another. However, prognosis varies among patients with a similar tumor stage; therefore, disease staging alone cannot accurately predict the outcome for individual patients. There might be a correlation between time to discover the disease, radicality of resection and survival. The experience of the surgeons toward more radical resection with lymph node (LN) removal is the most important non-TNM prognostic factors in gastric cancer.

Research frontiers

Prognosis is poor perhaps due to late diagnosis and frequent local-regional recurrences. This requires investigation of the possible reasons for the worsening of survival and searching for prognostic factors of better survival. Complete resection of the tumor with satisfactory safety margins is the standard treatment. Many prognostic factors have been investigated to assess their significance in predicting patients' outcome. The number of metastatic LNs (N stage) and the depth of the primary tumor (T stage) are currently considered the most reliable prognostic factors for patients with radically resected gastric cancer. LN clearance remains the most challenging part of the operation, the UICC/AJCC classification,

suggests that at least 15 LNs should be examined for a correct assessment of N stage.

Innovations and breakthroughs

The authors have a published data and experience from Western, Eastern and European countries. However, we have a little data from Middle East countries, and here we represent the authors' work from a large gastroenterology and transplantation center in Egypt. The aim of this study was to evaluate the Clinicopathological features and the significance of different prognostic factors in patients undergoing resection for gastric cancer. Clinicopathological parameters, including gender and age of patients; location of the tumor; depth of invasion; LN metastasis status; operative details; morbidity and mortality; and survival and recurrence were collected. All of the surgical procedures were performed by experienced gastric surgeons of the single institute with a definitive treatment guideline for gastric cancer. In all patients, an extended lymphadenectomy, was used as the standard surgical procedure.

Applications

Epidemiology, late discovery of the disease, differences in the staging systems and the operative strategy with extensive lymphadenectomy may explain the difference between prognostic factors between different parts of the world. The center is a referral tertiary center, most of their patients comes with a relatively advanced tumor stage. Intra-operatively there was much LN involvement. So their policy is to remove of all suspected LN involved with the disease to reach satisfactory radical resections. In order to have a better survival in their patients, they recommend frequent use of upper endoscopy for gastrointestinal symptoms for early detection of gastric cancer.

Terminology

The extent of LNs dissection is classically termed D0, D1, and D2 LN dissection was initially classified as D1 to D4, depending on the extent and removal of each LN station according to the primary tumor location. In distal subtotal gastrectomy, D1 included removal of only LN stations 1, 3, 4, 5, 6 and 7 surrounding the stomach, whereas D2 included D1 LN dissection and station 8a, 12a, 9 and 11. D3 and D4 LN dissections occur when the other LN stations are removed. This system has been revised and now reflects the number of retrieved LNs rather than their location. Hence, it is as follows: D0 when less than 15 nodes are reported, D1 when 15 to 25 nodes are removed, and D2 when more than 25 nodes are reported in the pathological findings.

Peer-review

The authors present their surgical experience in the treatment of gastric cancer in one the Middle East centers. Their study included 80 patients with different clinicopathological characteristics in an attempt to investigate the impact of in study mentioned variables on the patients' survival following surgical management.

Abstract

AIM: To evaluate the long-term clinical and oncological outcomes of laparoscopic rectal resection (LRR) and the impact of conversion in patients with rectal cancer.

METHODS: An analysis was performed on a prospective database of 633 consecutive patients with rectal cancer who underwent surgical resection. Patients were compared in three groups: Open surgery (OP), laparoscopic surgery, and converted laparoscopic surgery. Short-term outcomes, long-term outcomes, and survival analysis were compared.

RESULTS: Among 633 patients studied, 200 patients had successful laparoscopic resections with a conversion rate of 11.1% (25 out of 225). Factors predictive of survival on univariate analysis include the laparoscopic approach ($P = 0.016$), together with factors such as age, ASA status, stage of disease, tumor grade, presence of perineural invasion and vascular emboli, circumferential resection margin < 2 mm, and postoperative adjuvant chemotherapy. The survival benefit of laparoscopic surgery was no longer significant on multivariate

analysis ($P = 0.148$). Neither 5-year overall survival (70.5% vs 61.8%, $P = 0.217$) nor 5-year cancer free survival (64.3% vs 66.6%, $P = 0.854$) were significantly different between the laparoscopic group and the converted group.

CONCLUSION: LRR has equivalent long-term oncologic outcomes when compared to OP. Laparoscopic conversion does not confer a worse prognosis.

Key words: Rectal cancer; Laparoscopic; Outcomes; Conversion; Prognosis

Core tip: Laparoscopic rectal resection (LRR) remains controversial in view of concerns over its long term oncological outcome and the adverse impact conversion may have on survival. Our retrospective study has demonstrated that LRR has equivalent long-term oncologic outcomes when compared to open surgery. Conversion was also found not to confer a worse prognosis.

Critical appraisal of laparoscopic vs open rectal cancer surgery. *World J Gastrointest Surg* 2016; 8(6): 452-460 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/452.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.452>

INTRODUCTION

Surgical management for rectal cancer remains challenging. With the advent of total mesorectal excision (TME) in rectal cancer surgery, local recurrence rates have improved significantly and there is an increasing rate of sphincter-saving surgery when technically and oncologically feasible. However, despite the use of pre- or post-operative adjuvant chemoradiotherapy, local and distant tumor recurrence remains a concern.

While laparoscopic colectomy has established its oncologic equivalence compared to open surgery (OP) in colon cancer, laparoscopic rectal resection (LRR) for rectal cancer remains controversial. Although LRR has been shown to confer short-term benefits, in terms of blood loss, length of stay, recovery of bowel function, and cosmesis, concerns about the long-term oncologic outcomes persists^[1-5]. The necessity for a TME creates a more difficult learning curve for LRR compared to a laparoscopic colectomy. There is also the need to achieve a balance between sphincter preservation without compromising the adequacy of the distal resection margin^[6]. These challenges induce a higher rate of conversion compared to colonic resection^[2] and a recent Cochrane review has noted that conversion rates in LRR can be as high as 35%^[7]. This is an important concern as it has been suggested

that conversion to OP after attempted LRR not only has higher morbidity, but may also adversely affect long-term oncologic outcomes^[2,8-11]. Several publications have attempted to address this issue but the study populations often consisted of a mixture of patients with colon and rectal cancer^[12-14]. This is suboptimal as the prognosis and recurrence pattern of colon and rectal cancer are distinctly different. There are few publications that address the long-term outcomes of laparoscopic conversion specifically in the context of rectal cancer^[10,15,16].

Therefore, the objective of this study is to evaluate the long-term clinical and oncological outcomes of LRR as well as the impact of laparoscopic conversion on the long-term oncological outcomes of patients with rectal cancer.

MATERIALS AND METHODS

An analysis of a prospectively maintained database of 633 consecutive patients with rectal cancer who underwent surgical resection from January 2005 to December 2009 in the Department of Colorectal Surgery at Singapore General Hospital was performed. Patients who presented with recurrent cancer, Inflammatory Bowel Disease, Familial Adenomatous Polyposis, or other polyposis syndromes were excluded. Data on patient demographics, pre-operative, operative, and post-operative course were collected prospectively and maintained in a database by a research assistant.

All cases were performed by consultant surgeons within the department. The decision for laparoscopic or open approach was left to the discretion of the individual surgeon.

For the laparoscopic approach, we preferred the medial approach with early mobilization, ligation and division of the inferior mesenteric artery at its origin after the ureter has been identified. The inferior mesenteric vein was ligated and divided at the inferior border of the pancreas. This was followed by mobilization of the left colon from the lateral sidewall, with mobilization of the splenic flexure if deemed necessary to achieve a tension free anastomosis. Total meso-rectal excision or wide meso-rectal excision up to at least 2 cm distal to the tumor was performed for all cases when feasible. Distal transection was performed using articulating staplers. The specimen is exteriorized *via* extension of the port sites with proximal transection performed extracorporeally. Pneumoperitoneum is then re-established and intra-corporeal circular stapled anastomosis performed under direct vision.

OP was performed *via* a midline laparotomy or left iliac fossa incision as described in a previous publication^[17].

Patients were compared in three groups: OP, laparoscopic surgery (LS), and converted laparoscopic surgery (CON) with their definitions as follows: (1) OP: Completion of surgical resection and anastomosis *via*

midline laparotomy or left iliac fossa incision; (2) LS: Surgery accomplished using the laparoscopic technique as described above. Patients analyzed under the LS group included patients who underwent laparoscopic-assisted surgery as described in a previous publication by our department^[18]. These were patients who had vascular ligation and the majority of bowel mobilization was accomplished intra-corporeally *via* the laparoscopic approach with the following modifications: (a) extension of one port site wound or the utilization of a new wound to complete colonic mobilization and bowel transection for reasons such as the presence of adhesions, excessive tumor fixation, or uncertain tumor location; (b) extracorporeal rectal anastomosis due to technical difficulties such as a narrow pelvis, bulky tumor, or defective equipment; and (c) extension of wounds to repair the anastomosis due to leaks on testing after completion of a pure laparoscopic resection; (3) CON: The laparoscopic approach is aborted after insertion of ports and initial bowel mobilization. This can be due to the presence of dense adhesions, undiagnosed tumor invasion of surrounding organs, or troubleshooting complications such as uncontrolled bleeding, bowel perforation, or injury of adjacent viscera such as ureters or small bowel. Conversion is also defined if the anastomosis requires a complete takedown and revision.

Pre-operative staging

All cases were evaluated preoperatively by plain chest radiograph/computed tomography (CT) of the thorax and CT of the abdomen and pelvis. T-staging with an endo-rectal ultrasound was performed pre-operatively in clinical T1 and T2, mid and low rectal tumors. Magnetic resonance imaging (MRI) of the pelvis was performed for all lower rectum tumors. Upper rectum is defined as 11-15 cm, middle rectum as 6-10 cm, and lower rectum as 0-5 cm from the anal verge. These measurements were recorded by the consultant surgeon after digital rectal examination and endoscopy. Disease staging according to the American Joint Committee Cancer (AJCC) Cancer Staging Manual 7th Edition was adopted^[19].

Neoadjuvant/adjuvant therapy

In our institution, a selective neoadjuvant chemoradiation policy is adopted based on data from previous publications that have consistently shown low local recurrence rates with oncologically adequate surgery alone^[20-22]. If sphincter preservation with good margins can be performed after initial evaluation, neoadjuvant treatment is usually not routinely recommended in our local population. Neoadjuvant treatment is mainly performed in patients who present with a threatened circumferential resection margin, defined as within 2 mm of the circumferential resection margin based on pre-operative staging.

The neoadjuvant regimen consisted of long-course

preoperative radiotherapy (45-50 Gy in 25-28 daily fractions over 5 wk) combined with 5-fluorouracil or oral capecitabine. Patients proceeded with surgical resection 6 to 8 wk after completion of neoadjuvant chemoradiotherapy. Decision for adjuvant chemotherapy was decided after discussion at a multi-disciplinary tumor board meeting.

Perioperative care for all patients was standardized using existing clinical care pathways.

Follow-up details

Post-operatively, the patients were followed-up at three monthly intervals for the first two years, six monthly for the next three years, and then yearly thereafter. At each consultation, carcinoembryonic antigen (CEA) levels were measured and full history and physical examination (including digital rectal examination) were performed. Colonoscopy was performed within six months of surgery if initial complete evaluation was not possible pre-operatively due to tumor obstruction or stenosis. Those who had an initial complete evaluation underwent colonoscopy at the first year follow up, and again at 3-yearly intervals post-operatively. Patients with suspicious symptoms and signs of rising CEA trend on follow-up will be evaluated earlier with colonoscopy and/or radiological imaging (including computerized tomography of the chest, abdomen, and pelvis, bone scan, and positron emission tomography scans if applicable).

Local recurrence was defined as the first clinical, radiologic, and/or pathologic evident tumor of the same histological type, within the true pelvis, at the anastomosis or in the region of the anastomosis. Distant recurrence was defined as similar evidence of spread outside the primary tumor at sites including but not limited to the liver, lungs, bone, brain, and para-aortic region. Patients who were first diagnosed with local recurrence but later developed distant metastasis were classified under the local recurrence group. Mortality data and the cause of death were obtained from the Singapore Cancer Registry.

Short-term outcomes assessed included wound infections, post-operative ileus, anastomotic leaks, pneumonia, peri-operative cardiac events, duration of hospitalization, and 30-d mortality.

Long-term outcomes assessed included the occurrence of intestinal obstruction, incisional hernias, and the oncologic outcomes of local/distal recurrence.

Survival analysis was performed *via* the comparison of progression free survival and overall survival (OS).

Statistical analysis

All statistical analysis was performed by a qualified biostatistician. Demographic and clinicopathological characteristics of the patients were compared across the 3 groups using χ^2 and *t* tests for categorical and continuous variables respectively. Distribution of selected short- and long-term outcomes among the patients

undergoing surgery was compared using Fisher's exact test. Comparison of the median duration of hospitalization was performed using the Kruskal-Wallis nonparametric test as it deviates from the Normality assumption.

OS was calculated from the date of diagnosis to the date of death or last follow-up. Cancer-free survival (CFS) was calculated from the date of diagnosis to the date of disease progression (local or distant relapse) or last follow-up. The 5-year OS and CFS were estimated using Kaplan Meier method and the survival curves were compared using log-rank tests. Multivariate Cox proportional hazards models, using variables found to be significant on univariate analysis, were used to estimate hazard ratios with their 95%CI. A significance level of 0.05 was chosen throughout. All analyses were performed using R 3.1.1 (2014, Vienna, Austria).

RESULTS

Six hundred and thirty-three patients underwent surgical resection for primary rectal cancers during the

Table 2 Reasons for laparoscopic conversion to open surgery

Reason for conversion	No. of patients (% within converted patients)
Excessive adhesions	12 (48)
Advanced tumor or excessive tumor fixation	3 (12)
Difficult anatomy	3 (12)
Intraoperative complications (e.g., bleeding, ureteric/urinary tract injury, bowel perforation/injury)	4 (16)
Intolerant of tilt and pneumoperitoneum	3 (12)

study duration. The demographic characteristics of the study population are illustrated in Table 1. Two hundred and twenty-five patients (35.5%) underwent attempted laparoscopic resection of the rectal tumor. Among these, 200 patients had successful laparoscopic resection with 77 patients (34.2%) requiring a laparoscopic-assisted approach, predominantly due to anatomic difficulties during the LS (50 out of 77 patients). Patients in the OP group were older [66 years old (OP) vs 59 years (LS), $P < 0.001$] and had slightly higher proportion of patients with ASA 3 and 4 [13.5% (OP) vs 10% (LS), $P = 0.002$]. The proportion of patients who underwent neoadjuvant chemotherapy and radiotherapy was also higher among patients in the OP group compared to LS group [3.4% vs 2.5% (chemotherapy) and 2.9% vs 1.5% (radiotherapy) respectively]. The laparoscopic conversion rate was 11.1% (25 out of 225) with the reasons for conversion illustrated in Table 2. All conversions to OP were unplanned pre-operatively. Close to half (12 out of 25) of the patients were converted due to the presence of excessive adhesions. The oncologic and peri-operative outcomes of the entire study cohort are presented in Table 3. Duration of surgery was significantly longer in the LS compared to the OP group [162 min (LS) vs 119 min (OP), $P < 0.001$]. Length of hospitalization was shorter in the LS group compared to OP group (7 d vs 8 d, $P < 0.001$).

Comparison of short-term and long-term outcomes between the 3 groups is illustrated in Table 4 and there were no significant differences between the 3 groups. The 5-year CFS and OS for the 3 group of patients is illustrated in Figure 1. Results of the univariate and multivariate analyses for predictive factors of survival are summarized in Table 5. Factors found to be predictive of survival on univariate analysis include the laparoscopic approach ($P = 0.016$), together with factors such as age, ASA status, stage of disease, tumor grade, presence of perineural invasion and vascular emboli, CRM < 2 mm, and postoperative adjuvant chemotherapy. The survival benefit of LS was no longer significant on multivariate analysis ($P = 0.148$) and only age, stage of disease, tumor grade, and CRM < 2 mm remained significant. After excluding open cases, neither 5-year OS (70.5% vs 61.8%, $P = 0.217$) nor 5-year CFS (64.3% vs 66.6%, $P = 0.854$) were

significantly different between the laparoscopic group and the converted group.

DISCUSSION

In our study, the 5-year OS was 70.5% in the LS group vs 52.7% in the OP group. While the laparoscopic technique appeared to confer survival benefit on

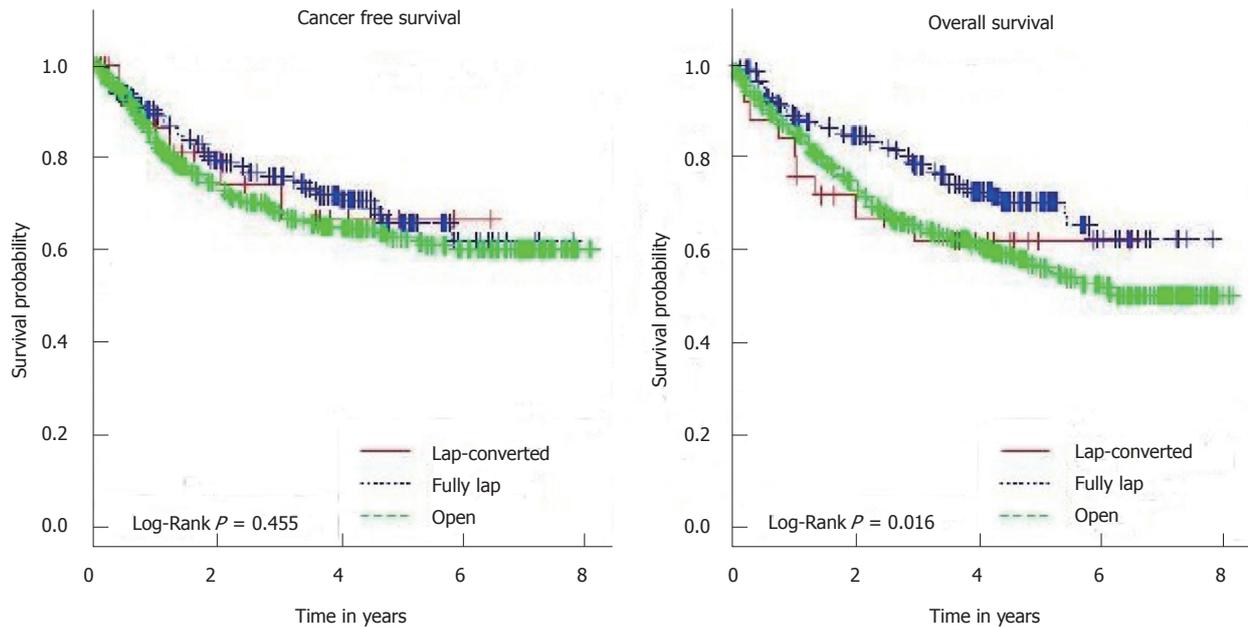

univariate analysis, this is likely attributed to the inherent selection bias in the study as patients chosen for OP tend to be older and with more advanced ASA status. As such, the differences in survival were no longer significant when subjected to multivariate analysis. There was also no difference in the local or systemic recurrence rates between all groups. These results are in line with several published studies comparing at least 5-year survival data of laparoscopic against open rectal resections (Table 6)^[4,6,23-30]. They are also congruent with the findings of two recent randomized trials comparing laparoscopic with open resection in rectal cancer^[31,32]. However, conflicting results were seen when pathologic adequacy of surgical resection was used as the outcome of interest. Both the ALaCaRT and the ACOSOG Z6051 trial failed to demonstrate non inferiority in terms of oncologic adequacy of resection when LS was compared to OP^[33,34]. These results have cast doubt on the role of LS in rectal cancer. Hopefully, the long term follow up data of the above two studies will help shed light on the contentious issue of LS in rectal cancer.

Studies assessing the impact of conversion on oncological outcomes have shown conflicting results and a recent meta-analysis found that conversion was associated with an adverse long-term oncological outcome^[35]. Postulated mechanisms include the increased inflammatory response associated with conversion and requirement for blood transfusion in converted cases that may subsequently increase recurrence risks^[36]. However, both colonic and rectal resections were included in the above meta-analysis,

with the former constituting the majority of the pooled patient population. Subset analysis of laparoscopic conversion in our study cohort revealed that conversion did not have an adverse impact on long-term oncologic outcomes in rectal cancer. Several studies have reported

the impact of conversion in LRR for cancer^[6,8,10,15,16,37]. While most studies had similar findings to ours, Rottoli *et al*^[15] concluded that conversion could have a negative impact on long-term overall recurrence rate. It is noted in this study, however, that 8 out of 26 (30.7%) patients

Table 6 Summary of studies reporting at least 5 year survival outcomes of laparoscopic vs open rectal resection

Ref.	Type of study	No. of patients with rectal cancer	5 yr overall survival	Remarks
Lujan <i>et al</i> ^[4]	Randomized Controlled Trial	204 (103 open, 101 lap)	75.3% (open) vs 72.1% (lap) <i>P</i> = 0.980	Middle and low rectal cancers only

Agha <i>et al</i> ^[23]	Retrospective	225 (all laparoscopic)	50.5% (lap)	10 yr overall survival

were converted due to advanced tumors and may thus explain poorer survival. In contrast, the majority of our conversions were due to adhesions (> 50%) and not advanced disease (12%) (Table 2). Thus it was not surprising that laparoscopic conversion had no impact on long-term oncologic outcomes.

The major limitation of our study lies in its retrospective nature which makes it susceptible to the effects of confounding and selection bias. While formal matching of the various groups of the study cohort was not performed due to numerical limitations, majority of the clinical demographics and tumor pathological characteristics between groups were similar, allowing for meaningful comparison. While we acknowledge the antecedent limitations of the retrospective nature of our study, it does have several strengths. Firstly, to the best of our knowledge, this is the largest study cohort evaluating the long-term outcomes (5-year survival data) of surgical resection in rectal cancers. Unlike other studies, conversions were clearly defined which facilitates comparison of findings in other institutions. Thus, we believe that this study will add value to the available literature on surgical resection for rectal cancer.

LRR is safe and has equivalent long-term oncologic outcomes when compared to OP. Laparoscopic conversion does not appear to confer an adverse outcome. Further evaluation of long-term data from updated randomized studies comprising of larger number of patients may be required to discern more differences.

COMMENTS

Background

Laparoscopic resection for rectal cancer remains controversial. The authors evaluate the long-term clinical and oncological outcomes of laparoscopic rectal

resection and the impact of conversion in patients with rectal cancer.

Research frontiers

The impact of laparoscopic conversion in rectal cancer remains unknown. This study assesses the impact of laparoscopic conversion in patients with rectal cancer.

Innovations and breakthroughs

Laparoscopic surgery for rectal cancer has equivalent long term oncological outcomes when compared with open surgery. Conversion in rectal cancer was not shown to be associated with an adverse outcome.

Applications

Laparoscopic resection for rectal cancer is feasible with no adverse impact on long term oncological outcomes even in the event of conversion.

Terminology

LRR: Laparoscopic rectal resection; OP: Open surgery; LS: Laparoscopic surgery; CON: Converted laparoscopic surgery.

Peer-review

The paper describes a single-center experience on laparoscopic surgery for rectal cancer. It is well written and references are updated.

Abstract

Solitary fibrous tumor (SFT) is a mesenchymal tumor typically located in the pleura, but can also be found as an asymptomatic mass in other areas, including the liver, peritoneum, kidney and salivary glands. However, SFT rarely locates in the pancreas. We present such a case of pancreatic SFT, along with a review of all reported cases. A 55-year-old man was treated surgically for an asymptomatic pancreatic mass after a rigorous preoperative control. Histologic examination of the resected specimen showed characteristics of an SFT. As only 15 cases of pancreatic SFT have been reported so far, an attempt to compare the cases was considered intriguing. We found that patients with pancreatic SFT were mainly women (81.25%), with a median age of 54 years at the time of diagnosis and a median tumor size of 5.83 cm. Pancreatic SFTs were revealed incidentally in 50% of cases, and all of them showed an enhancement through arterial computed tomography. All tumors were positive for CD34, ten were positive for Bcl-2, and twelve were negative for S100. The diagnosis of this pancreatic tumor is established by a combination of clinical suspicion, imaging procedures and histological findings, and is confirmed by immunohistochemical staining. Although the behavior of SFTs is rather benign, close clinical follow-up is recommended due to a potentially malignant nature.

Key words: Solitary fibrous tumor; Pancreas; Mesenchymal tumors; Differential diagnosis; Solitary fibrous tumor treatment

Core tip: Solitary fibrous tumor (SFT) is a mesenchymal tumor that rarely locates in the pancreas. We present the case of a 55-year-old man with a pancreatic lesion that proved to be an SFT after thorough pre- and post-operative control. The characteristics of this case and the other fifteen cases of pancreatic SFT reported in the literature are described.

Solitary fibrous tumor of the pancreas: Case report and review of the literature. *World J Gastrointest Surg* 2016; 8(6): 461-466 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/461.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.461>

INTRODUCTION

Solitary fibrous tumor (SFT) was described as a distinct type of mesenchymal tumor for the first time at 1931^[1]. SFT can be benign or malignant and is typically located in the pleura, but the tumor can also be found as an asymptomatic mass in other areas such as the liver, peritoneum, kidney and salivary glands^[2-4]. SFTs often occur in middle age (40-70 years), especially in the fifth decade of life, and metastases can be detected in 10% to 15% of the cases^[4-6]. This type of tumor appears very rarely in the pancreas, as only 15 cases have been reported so far.

CASE REPORT

A 55-year-old man was admitted in our surgical department for further evaluation of an asymptomatic pancreatic mass that had been found incidentally by upper abdomen ultrasonography. No specific symptoms were mentioned except vague abdominal pain. Clinical examination and laboratory results were unremarkable, and the levels of tumor markers (CEA, CA 19-9, CA 15-3) were within normal ranges. The patient's medical history included coronary heart disease (one myocardial infarction and coronary artery bypass surgery seven years ago), open cholecystectomy (27 years ago), choledocholithiasis treated with endoscopic retrograde cholangiopancreatography (5 years ago), dyslipidemia and hypertension under medication.

During ultrasound examination of the abdomen for non-specific pain, a hypoechoic solid mass of 2.8 cm × 3.1 cm on the pancreatic body (Figure 1) and a possible dilation of the common bile duct were found. Further imaging was performed. Computed tomography (CT) scans revealed a 3.9-cm-diameter exophytic mass arising from the pancreatic body that was enhanced from the arterial to portal venous phase (Figure 2). T1-weighted magnetic resonance imaging

Figure 1 Ultrasound echo showing a 2.8 cm × 3.1 cm hypoechoic solid mass located on the pancreatic body.

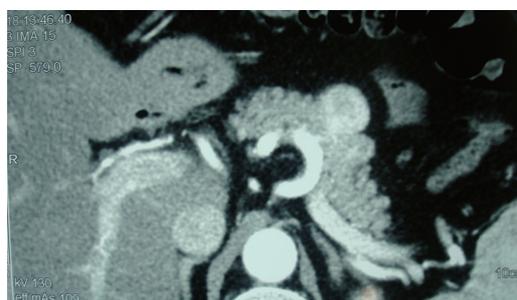

Figure 2 Computed tomography scan revealing a 3.9 cm exophytic mass, arising from the pancreatic body, which was enhanced from the arterial to portal venous phase.

(MRI) scans showed a hypointense mass. Regional lymphadenopathy was not found on the CT or MRI images. Magnetic resonance cholangiopancreatography imaging revealed a pancreatic body cystic portion with heterogeneous internal echogenicities of mixed substantial and necrotic parts. Although the main pancreatic duct was not dilated, the common bile duct displayed a filling deficit. The upper digestive tract endoscopy showed no abnormalities.

Based on the above findings, we considered that the differential diagnosis of the mass should include exophytic non-functioning islet tumor, solid pseudo-papillary mass of the pancreas, gastrointestinal stromal tumor (GIST), neuroendocrine tumor and heman-giopericytoma of the pancreas.

The surgical removal of the mass was considered necessary and the patient underwent a pancreatectomy including body and tail, whereas the spleen was maintained. The resected mass measured 3.6 cm in its greatest diameter and had an ovoid shape with well-capsulated, smooth margins and a yellowish-grey hue (Figures 3 and 4). The abdominal exploration did not show any signs of metastasis or tumor infiltration into neighboring organs.

On histopathological examination, the mass showed characteristics of a neoplasm, including spindle-shaped tumor cells with elongated nuclei. Mitoses were scarce. The neoplasm presented a storiform pattern with

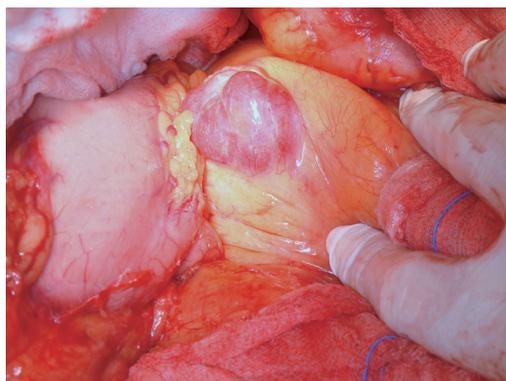

Figure 3 Intra-operative appearance of the pancreatic mass.

Figure 4 Pancreatic mass specimen.

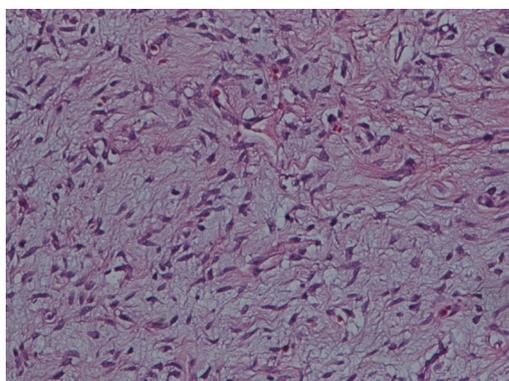

Figure 5 Solitary fibrous tumor with a hyalinized area, HE stain. Magnification: $\times 400$.

alternating hypocellular and hypercellular areas, and some areas showed myxoid degeneration. There were a large number of blood vessels within the stroma (Figure 5).

Immunohistochemically, the tumor cells were positive for CD34, CD99, Bcl-2 (Figure 6) and vimentin, and exhibited focal positivity for S-100 protein. Only a small number of cells were positive for the cell proliferation marker Ki-67/MIB-1. The tumor cells were negative for smooth muscle actin (SMA), keratin, cytokeratin (AE1/AE3), CD117, epithelial membrane antigen and desmin. The final diagnosis was pancreatic

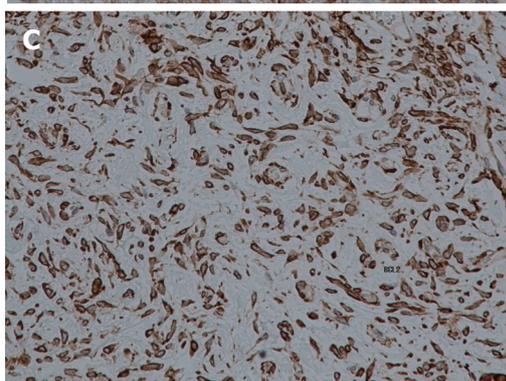

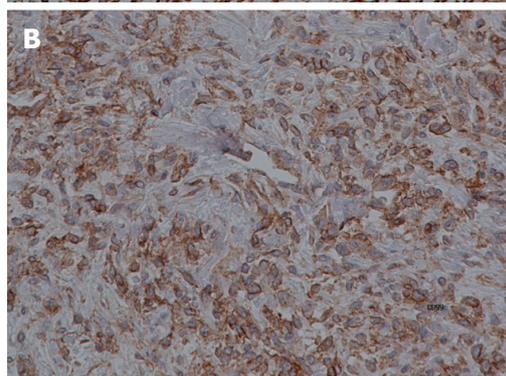

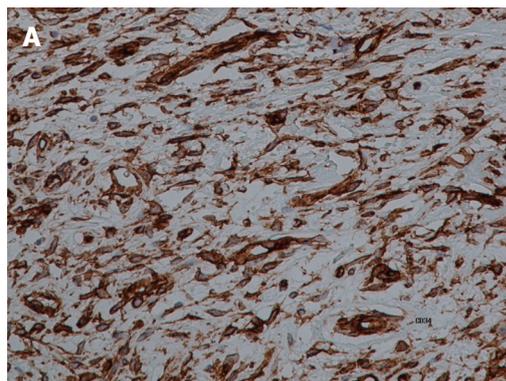

Figure 6 Immunohistochemical staining (brown) for CD34 (A), CD99 (B) and Bcl-2 (C). Magnification: $\times 400$.

SFT with a low grade of malignancy.

After surgery, the patient was led to the intensive care unit. His post-operative course was uneventful and he was discharged on the 9th postoperative day with the recommendation to follow a non-fat diet. Chemotherapy was not considered necessary. In the 6- and 12-mo follow-up periods the patient was asymptomatic and in good health.

DISCUSSION

Mesenchymal tumors of the pancreas include leiomyosarcoma, peripheral nerve tumors, fibro-histiocytic tumors and vascular tumors^[7-9]. Differential diagnosis is based on histology and immunohistochemistry findings and, therefore, diagnosis is often very difficult before surgery.

On the other hand, pancreatic SFTs are very rare, as only 16 cases have been reported in the literature^[1,3-16], including our case. The patients were mainly women

CT: Computed tomography.

(13/16, 81.25%), with a median age of 54 years at the time of diagnosis (range: 24-78 years, median age: 50 years for males, 55.46 years for females) and a median tumor size of 5.83 cm (range: 1.5-18.5 cm). In six cases the tumor was located in the pancreatic body (37%) and in seven cases the tumor was located in the pancreatic head (43.75%) (Table 1). The tumor was revealed incidentally in half the cases; however, in the other half, the main symptom was pain (jaundice was presented in only one case). Regarding imaging, all tumors showed an enhancement through arterial and portal CT. The results of MRI imaging were described for seven cases: These tumors were hypointense in T1-weighted images and hyperintense in T2-weighted images (Table 2).

All cases were treated surgically except for one case which was diagnosed after biopsy. By immunohistochemistry, all tumors were positive for CD34, ten tumors were positive for Bcl-2, and only one tumor was

positive for S100. Many tumors were positive for keratin types. Controls for CD117 (1 positive, 10 negatives), CD19 (11 positives, 1 negative) and SMA (4 positives, 5 negatives) didn't show the same results in all cases (Table 3).

Most pancreatic SFTs presented as well-circumscribed, often partially-encapsulated masses^[9] with a multinodular, whitish and firm appearance. On microscope sections, the tumors showed a patternless architecture characterized by alternating hypocellular and hypercellular areas separated by thick bands of collagen and branching hemangiopericytoma-like vessels^[6]. The tumor cells were round-to-spindle-shaped and the mitoses were scarce. Tumor necrosis and infiltrative margins were observed in malignant neoplasms occurring in other locations.

The differential diagnosis of SFT includes leiomyosarcoma, liposarcoma, fibrosarcoma, fibrous histiocytoma, hemangioendothelioma, hemangiopericytoma, hemangioma, lymphangioma, islet cell tumor, paraganglioma, neuroectodermal tumor, and schwannoma^[12]. The main diagnostic consideration based on imaging findings is thought to be endocrine neoplasms^[3,5]. These are composed of round cells with granular, eosinophilic cytoplasm and are positive for synaptophysin and chromogranin. As leiomyosarcomas are considered to be more frequent than SFTs in the pancreas, the former must be differentiated by their nuclear atypia and increased mitotic activity^[1,5]. Moreover, GISTs are positive for CD34, vimentin and CD117 but SFTs are negative for CD117^[1,5,9].

In our case, preoperative CT and MRI scans strongly showed the typical pattern of SFTs^[15]. Histopathological examination of the resected tumor revealed that it was covered with a fibrous capsule and contained necrotic tissue, favoring the diagnosis of SFT. Immunohistochemistry findings confirmed the diagnosis.

The diagnosis of pancreatic SFT is established from a combination of clinical suspicion (mainly women

of middle age, with abdominal pain and nonspecific symptoms), imaging procedures (ultrasound, CT and MRI) and histological findings, and is confirmed by immunohistochemistry. Although SFTs are usually benign, clinical follow-up is recommended because

these tumors can become malignant^[1,5].

COMMENTS

Case characteristics

Asymptomatic 55-year-old male.

Clinical diagnosis

Abdominal pain.

Differential diagnosis

Upper abdomen tumors.

Imaging diagnosis

Exophytic mass of the pancreatic body.

Pathologic diagnosis

Pancreatic solitary fibrous tumor (SFT).

Treatment

Pancreatectomy (body and tail).

Related reports

Fifteen case reports of this rare condition.

Term explanation

Mesenchymal tumors arise from mesodermally-derived tissues, and can be either benign or malignant.

Experiences and lessons

This report discusses the basic characteristics of pancreatic SFTs, based on all the cases reported so far.

Peer-review

The authors report a case of a rare pancreatic tumor and compare it to cases in the existing bibliography.

Abstract

Hemobilia is an uncommon and potential life-threatening condition mainly due to hepato-biliary tree traumatic or iatrogenic injuries. Spontaneously ruptured aneurysm of the hepatic artery is seldom described. We report the case of an 89-year-old woman presenting with abdominal pain, jaundice and gastrointestinal bleeding, whose ultrasound and computed tomography revealed a non-traumatic, spontaneous aneurysm of the right hepatic artery. The oeso-gastro-duodenoscopy and colonoscopy did not reveal any bleeding at the ampulla of Vater, nor anywhere else. Selective angiography confirmed the diagnosis of hepatic artery aneurysm and revealed a full hepatic artery originating from the superior mesenteric artery. The patient was successfully treated by selective embolization of microcoils. We discuss the etiologies of hemobilia and its treatment with selective embolization, which remains favored over surgical treatment. Although aneurysm of the hepatic artery is rare, especially without trauma, a high index of suspicion is needed in order to ensure appropriate treatment.

Key words: Hemobilia; Hepatic artery aneurysm; Obstructive jaundice; Supra-selective micro-embolization; Gastrointestinal hemorrhage

Core tip: Non-traumatic aneurysm of the hepatic artery leading to hemobilia as the source of gastrointestinal bleeding may be subtle to recognize, not only because

of its low incidence but also because of its inconsistent clinical signs. These aneurysms are more commonly seen after a traumatic event on the biliary tree, however in rare cases, it occurs spontaneously, mainly in the settings of vascular degeneration and chronic gallbladder inflammatory disease. Moreover, the hepatic artery is known for multiple anatomical variants, some of which are rare. Our patient presented with both uncommon conditions and was successfully treated with micro-coils embolization.

Vultaggio F, Morère PH, Constantin C, Christodoulou M, Roulin D. INTRODUCTION

Bleeding into the biliary tree was first described by Glisson^[1] in 1654 and later named hemobilia by Sandblom^[2] in 1948. Its classical triad - Quincke's triad - includes colicky right upper quadrant abdominal pain, jaundice and gastrointestinal hemorrhage, and is seen in 20% of hemobilia^[3]. Only about 10% of cases of hemobilia are secondary to a ruptured aneurysm of the hepatic artery^[4], which is located in intrahepatic branches in 20%^[5,6]. The occurrence of hemobilia consecutive to a spontaneously ruptured aneurysm of the hepatic artery remains uncommon and its treatment modalities are not evidence-based, although supra-selective embolization seems to overcome surgery in the management^[7]. This case represents not only a rare case of spontaneous aneurysm of the hepatic artery but also illustrates an anatomical variant of its origin. Our patient was successfully treated with supra-selective microcoils embolization.

CASE REPORT

An 89-year-old woman presented to the emergency department with increased epigastric and hyponchondrium colic since one month, associated with inappetence, nausea, vomiting and several episodes of hematemesis and hematochezia for the last 24 h. She did not have temperature during that period of time. She is known for an aorto-coronary bypass and four stents in 2001, as well as hypertension. Her current medication includes acetylsalicylic acid, amlodipine, atorvastatin, nicorandil and molsidomine. There is no history of trauma, and she is not known for hepatobiliary or gastrointestinal tract disorders.

At admission, she was hemodynamically stable and afebrile. She presented with mild scleral icterus. There was no abdominal tenderness. On rectal examination, no traces of blood were found. The laboratory tests

Figure 1 Right hepatic artery branch aneurysm. Transversal view on contrast enhanced abdominal computed tomography exhibiting a 10 mm × 6 mm aneurysm originating from a branch of the right hepatic artery irrigating segment VIII. The darker halo surrounding the aneurysm reflects secondary hepatic parenchyma lower perfusion due to mass effect. The lithiasic gallbladder is not seen on this image.

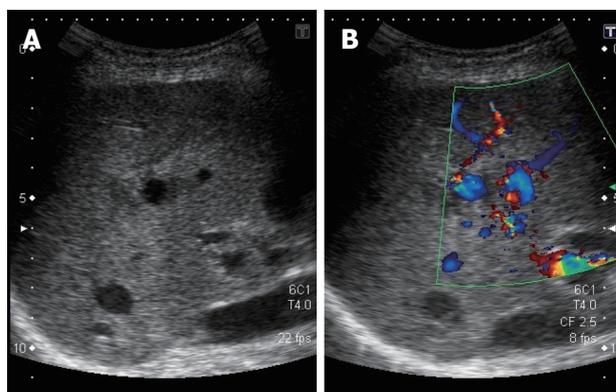

Figure 2 Aneurysm on hepatic Doppler-ultrasound. Sagittal view of the liver representing the aneurysm at the center of the echographic field (A) and Doppler signals confirming the blood flow inside the aneurysm (B). The branch from the hepatic artery the aneurysm is originating from is not seen on the image.

showed mild anemia with a hemoglobin count of 98 g/L (normal 117-157 g/L), a white blood cell count (WBC) of 11 g/L (normal 4-10 g/L), cytotoxicity and cholestasis with aspartate aminotransferase (ASAT) 111 U/L (normal < 35 U/L), alanine aminotransferase (ALAT) 103 U/L (normal < 35 U/L), gamma-GT 247 U/L (normal < 40 U/L), alkaline phosphatase 473 U/L (normal < 130 U/L), total and direct bilirubin 20 and 14 μmol/L respectively (normal < 17 and < 5 μmol/L respectively).

The abdominal computed tomography (CT) scan revealed a 10 mm × 6 mm aneurysm of a branch of the right hepatic artery irrigating segment VIII, and a lithiasic gallbladder with thickened wall (Figure 1), without signs of cholecystitis. The ultrasound (US) revealed a thrombosed aneurysm of the hepatic artery with ectasia of the upward biliary tree (Figure 2).

The upper endoscopy did not show evidence of blood at the ampulla of Vater, but revealed signs of uncomplicated gastritis. Colonoscopy showed sigmoidal diverticulosis, without any source of active bleeding.

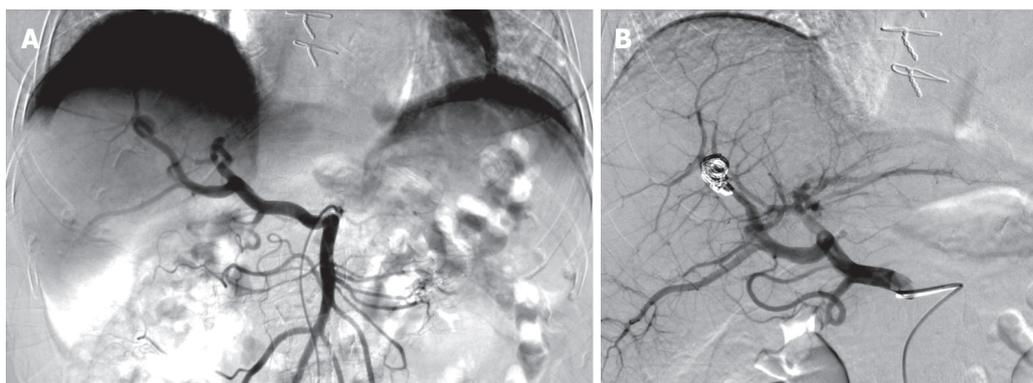

Figure 3 Supra-selective angiography of the hepatic artery branch aneurysm. A: The left image is before embolization; it shows the hepatic artery splitting and the aneurysm taking source from one of the right branches; B: The right image is after supra-selective embolization of the aneurysm with microcoils. The catheter is still visible. Note that the hepatic artery originates from the superior mesenteric artery. This exhibits a full hepatic artery variant, type IX in Michels' classification.

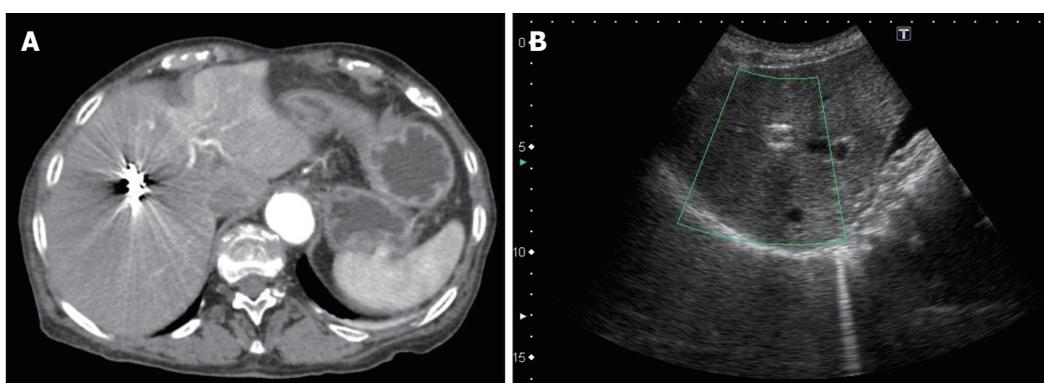

Figure 4 Post embolization imaging. A: Transversal view on the contrast enhanced abdominal computed tomography performed two days after embolization showing that the coils are in place and the absence of blood extravasation; B: Thirty-days control liver ultrasound showing coils in place in the sagittal plane.

Her hemoglobin continued to drop to 83 g/L, necessitating the transfusions of two units of blood. Since our only source of potential bleeding was this aneurysm, we practiced an angiography by catheterization of the right femoral artery with a 5-French catheter. We performed a supra-selective catheterization of the right hepatic artery with a 3-French microcatheter and embolization of the aneurysm with four 4 mm × 37 mm and two 8 mm × 140 mm microcoils. During the procedure, we realized that the hepatic artery was originating directly from the superior mesenteric artery. Thus, the aneurysm was located on the right branch of this particular hepatic artery (Figure 3).

The patient was dismissed two days later without any complications. There were no recurrences at the follow-up CT and US, at day two and thirty respectively (Figure 4).

Two months later, the patient returned to the emergency department with paroxysmal right upper quadrant colicky abdominal pain and jaundice. No blood loss was observed. She was hemodynamically stable and her physical exam did not reveal any abdominal pain upon palpation, nor fever at 36.8 °C. Her laboratory tests exhibited anemia with a hemoglobin at 96 g/L, an inflammatory syndrome with a WBC of 40 g/L and

a C-reactive protein of 117 mg/L, as well as cholestasis and cytolysis (ASAT 167 U/L, ALAT 92 U/L, gamma-GT 330 U/L, alkaline phosphatase 912 U/L, total and direct bilirubin 84 and 75 μmol/L). She benefited from an antibiotic therapy with intravenous ceftriaxone and metronidazole for 72 h, with a shift to ciprofloxacin and metronidazole *per os* for 2 wk. The cholangiography-MRI showed no traces of choledocolithiasis, but a dilated principal and intrahepatic bile ducts, a thick gallbladder wall with sludge and cholelithiasis. There were no signs of recurrent bleeding at the site of micro-embolization, nor any abscess (Figure 4). During hospitalization, she evolved without any complications. Both pain and jaundice resolved and her laboratory tests returned towards normal values before she was dismissed at day seven.

DISCUSSION

The most common causes of hemobilia are due to iatrogenic complications after diagnostic or therapeutic hepatobiliary procedures, and accounts for more than half to two thirds of the cases^[3,8], while non-traumatic causes include aneurysmal disease, which accounts for 10%, and is mainly seen in the setting of atherosclerosis,

gallbladder inflammatory diseases, hepatobiliary tract infections or neoplasia, and autoimmune systemic diseases such as juvenile polyarteritis nodosa, Behçet's disease or rheumatoid arthritis^[3,9]. Our patient was known and treated for arterial disease, which might have played a predominant role in the physiopathology of her disease.

Although upper gastrointestinal tract endoscopy is a crucial step in order to establish both diagnosis and treatment of an ongoing gastrointestinal bleeding, its ability in detecting active bleeding at the ampulla of Vater is only in about half of the patients with hemobilia^[10,11]. Nevertheless, this procedure remains mandatory to rule out and treat other more frequent causes of upper gastrointestinal bleeding.

Angiography is now favored over surgery as the best procedure for diagnosing and treating hemobilia, although there is currently no gold standard established in the literature^[12]. Angiography reveals more than 90% of sources of active bleeding^[3,12], while its success rate in managing the bleeding is more than 80% with a good tolerance and minimal risks compared to surgery^[3,12].

Although our patient presented a cholangitis, cholangiography-MRI at two months showed that the coils were in place and no recurrences had occurred. Since no signs of intraductal obstacle, extrinsic compression, or microlithiasis were found, we hypothesize that a blood clot migrated into the biliary tree, leading to cholangitis. The evolution with antibiotics was uneventful.

Our patient exhibited a relatively rare variant of full hepatic artery originating from the superior mesenteric artery (Figure 3), variant IX in Michels' classification, which is seen in about 4.5% of the population^[13]. Knowing that the hepatic artery is present in its classical anatomy in only 55%, it is crucial that the operator takes these specificities into account when performing the angiography and subsequent embolization.

In conclusion, ruptured aneurysm of the hepatic artery without trauma leading to hemobilia is a rare and life-threatening condition. Clinicians need a high index of suspicion in order to diagnose and treat it adequately. The first line treatment is now angiography and supra-selective embolization, as it has superseded surgical intervention.

COMMENTS

Case characteristics

An 89-year-old female with history of abdominal pain, inappetence, vomiting and several episodes of hematemesis and hematochezia.

Clinical diagnosis

The patient was jaundiced.

Differential diagnosis

Bleeding gastro-duodenal ulcer; biliary tumor; Mallory-Weiss syndrome.

Laboratory diagnosis

White blood cell 11 g/L, aspartate aminotransferase 111 U/L, alanine aminotransferase 103 U/L, gamma-GT 247 U/L, alkaline phosphatase 473 U/L, total

bilirubin 20 µmol/L, direct bilirubin 14 µmol/L.

Imaging diagnosis

Ruptured aneurysm of the branch of the right branch of a full hepatic artery originating from the superior mesenteric artery.

Treatment

Fluid challenge, blood transfusion, selective arteriography with selective microcoils embolization, antibiotherapy.

Term explanation

Hemobilia is a rare case of upper gastrointestinal bleeding due to arterio-biliary fistula.

Experiences and lessons

Focusing on the clinical recognition of hemobilia in this particular setting of gastrointestinal bleeding and a positive experience with selective angiography and embolization for diagnosis and treatment. It requires a high index of suspicion particularly in the absence of an established traumatic or iatrogenic event.

Peer-review

The authors demonstrated a rare case of spontaneous aneurysm of the right hepatic artery, and that the patient has been successfully treated by selective embolization of micro coils.

Abstract

Duplication of alimentary tract (DAT) presenting as an ileoileal intussusception is a very rare clinical entity. Herein, a case of an ileoileal intussusception due to DAT is presented. A 32-year-old woman was hospitalized due to diffuse, intermittent abdominal pain, vomiting and constipation for 3 d associated with abdominal distention. Plain abdominal X-ray revealed dilated small bowel. Abdominal computed tomography showed grossly dilated small bowel with "sausage" and "doughnut" signs of small bowel intussusception. She underwent laparotomy, with findings of ileoileal intussusception due to a cystic lesion adjacent to the mesenteric side. Resection of the cystic lesion along with the affected segment of intestine, with an end to end anastomosis was performed. The histopathology was consistent with enteric duplication cyst. This case highlights the DAT, although, an uncommon cause of adult ileoileal intussusception should be considered in the differential diagnosis of intussusception in adults, particularly when the leading point is a cystic lesion.

Key words: Enteric cyst; Ileoileal intussusception; Duplication of alimentary tract; Small intestinal obstruction; Doughnut sign

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: I have reported this case of ileoileal intussusception in an adult due to duplication of alimentary tract (DAT) being the cause of intussusception. Although intussusception is a well-known surgical condition, the presence of DAT as a leading point is extremely

rare. Only few cases have been reported in the English literature. Computed tomography, although identified the intussusception, the exploratory laparotomy established the DAT as a leading point for the ileoileal intussusception. Resection of the enteric cyst along with the affected intestine, and end to end anastomosis was performed. The histopathology was consistent with enteric duplication cyst.

Al-Qahtani HH. Enteric duplication cyst as a leading point for ileoileal intussusception in an adult: A rare cause of complete small bowel obstruction. *World J Gastrointest Surg* 2016; 8(6): 472-475 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i6/472.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i6.472>

INTRODUCTION

Duplication of the gastrointestinal tract is a rare congenital malformation which has been termed by Fiorani *et al*^[1] as duplication of alimentary tract (DAT). Midgut is the most common site of DAT, with the majority of cases reported in the distal small bowel^[2]. The presenting symptoms and signs of DAT include nausea, vomiting, bright red blood per rectum, abdominal distention and palpable abdominal mass. The clinical presentation of DAT with intestinal obstruction is either due to adjacent pressure on the bowel wall, volvulus, or rarely due to intussusception^[3]. A rare case of DAT causing ileoileal intussusception, in which the treatment was segmental resection of the affected ileum with an end to end anastomosis is herein presented. The objective in presenting this case is to raise the awareness among clinicians of this rare cause of small bowel obstruction. The case is discussed in the context of other reported cases in the literature.

CASE REPORT

A 32-year-old woman presented to the emergency department (ED) with diffuse intermittent abdominal pain, vomiting, and constipation for 3 d associated with progressive abdominal distention. On examination, she was dehydrated, with a blood pressure of 100/55 mmHg, pulse rate of 110 beat/min, temperature of 37.6 °C. The abdomen was diffusely distended with mild diffuse discomfort and exaggerated bowel sounds. Digital and proctoscopic examinations were normal with empty rectum. Immediate resuscitation in the ED was started with intravenous infusion of crystalloid fluids through large bore intravenous cannulae. A nasogastric tube was inserted which drained large amount of greenish fluids. A Foley catheter was inserted, with drainage of concentrated, minimal amounts of urine. Laboratory values revealed a white blood cell count of 14.6 × 10⁹/L [normal range (NR) = 4.3-10.8], hemoglobin 14.4 g/dL (NR = 14-18), urea

8.5 mmol/L (NR = 3.6-7.1), creatinine 129 mmol/L (NR < 133 mmol/L), and normal coagulation profile. Plain abdominal X-ray revealed dilated small bowel loops (Figure 1). Abdominal computed tomography (CT) showed grossly dilated small bowel loops with "sausage" and "doughnut" signs of small bowel intussusception. She underwent exploratory laparotomy with a provisional diagnosis of small bowel obstruction due to intussusception. Abdominal exploration revealed massively dilated small bowel proximal to ileoileal intussusception. After manual reduction of the intussusception, segmental ileal resection with an end to end anastomosis was performed. Exploration of the resected segment showed the leading point of intussusception was a cystic lesion measuring 4 cm in diameter which was located adjacent to the mesenteric side of the ileum (Figure 2). The histopathology showed an ileal duplication cyst lined by enteric mucosa with distinct muscular layer in the cyst wall. The patient was discharged from the hospital on 7th day postoperatively with an uneventful postoperative course.

DISCUSSION

DAT has been defined by Ladd *et al*^[4] as a tubular or spherical shaped anomaly that is adherent or attached to and shared the identical phenotypic characteristics with the normal gastrointestinal tract (GIT). It is a rare congenital malformation which can occur anywhere in the GIT from the mouth to the anus, with few cases reported in extraintestinal spaces such as oropharynx, retroperitoneum and spines^[5]. It is a separate entity from GIT with their own lumen, which can occur either on the mesenteric or the contralateral side^[6]. As the mucosa of the DAT is functional and separate from the intestine, they can expand as their mucosa secret fluids and become symptomatic^[6].

The most widely accepted theory for the DAT formation is that the duplication of GIT occurs during embryological development due to a pinching off of diverticulum^[5]. The majority of cases have been reported in infants and childhood, however, rarely it has been reported in adults as well^[7]. The most commonly reported clinical manifestation of DAT in adult is small bowel obstruction but rarely it may serve as a lead point for intussusception of small bowel, GIT bleeding or iron deficiency anemia due to chronic blood loss^[3,5,6]. The etiology of GIT bleeding is varied from abrasion, irritation, or ulceration of mucosal layer within the duplication cyst, or it may arise due to either a disruption of the common blood supply or malignancy which may result in gradual or brisk blood loss^[5].

The adult patient reported here presented with a classical symptoms and signs of small bowel obstruction. Intussusception in adults is account for about 5% of all intussusceptions and the underlying cause of only 1% of bowel obstruction^[8]. However, a definite underlying cause is present in about 90% of intussusception in adults^[9]. A wide variety of ileal lesions may be responsible for ileoileal

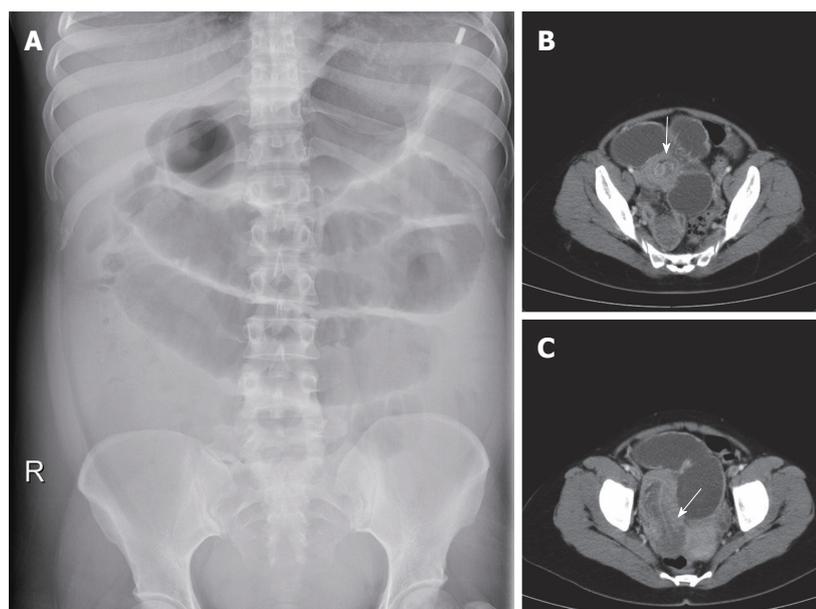

Figure 1 Plain abdominal X-ray revealed dilated small bowel loops. A: Plain abdominal radiograph showing dilated small bowel; B: Abdominal computed tomography showing grossly dilated small bowel loops with “doughnut”; and C: “sausage” signs of small bowel intussusception.

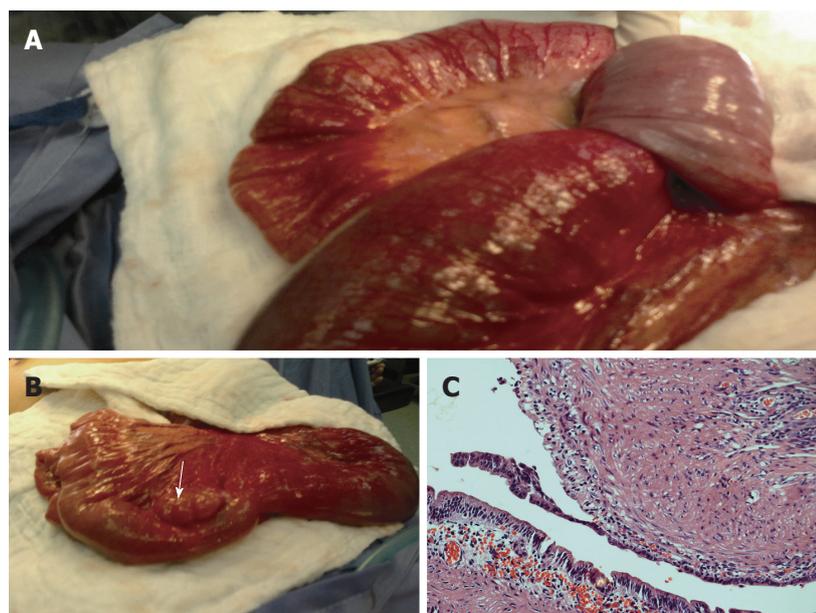

Figure 2 The leading point of intussusception was a cystic lesion measuring 4 cm in diameter which was located adjacent to the mesenteric side of the ileum. Intraoperative photography revealing the (A) ileoileal intussusception (B) enteric cyst in the mesenteric side of the ileal loop which was the lead point of the intussusception and (C) Histopathology of enteric duplication cyst lined by columnar intestinal mucosa with underlying muscular layer. The outer layer of the cyst wall was fused with normal intestine (H/E stain × 200).

intussusception. Benign tumors including inflammatory fibroid polyp, hamartomatous polyp, lipoma, as well as malignant tumors such as ileal cancer and lymphoma and Meckel's diverticulum have all been described as lead points for ileoileal intussusception^[3]. In our patient, the lead point was DAT in the mesenteric side of the mid-part of the ileum. Both DAT and intussusception are unusual pathological entities in adult patients, and it is very rare to have the combination of both events in one patient^[3]. Although it has been reported in infants and childhood^[10,11], to the best of our knowledge, this

is the second adult case of DAT identified as a lead point for ileoileal intussusception. Ultrasonography in intussusception may show a “doughnut” configuration on transverse view, while on longitudinal view it may show “pseudokidney” configuration. The detection of excess fluid should raise the suspicion of a lead point lesion^[7].

Abdominal CT scan is the most sensitive diagnostic tool for the imaging of intussusceptions. It reveals a pathognomonic appearance of soft tissue mass consisting of the central intussusceptum and the outer

intussusciens. It appears as "sausage-shaped", when the CT scan beam is parallel to the intussusception, and it appears as a "target" when the beam is perpendicular to its axis^[12]. Clinical and radiological signs of DAT may mimic those of intussusception. Hence, the diagnosis can generally be established only by surgical evaluation^[13]. In the present case, CT scan revealed grossly distended proximal small bowel, and both sausage-shape and target signs with diagnosis of small bowel obstruction due to intussusception. However, the DAT was not clear in CT scan as a lead point for intussusception. The differential diagnosis of DAT in association with ileoileal intussusception primarily includes lymphangioma, omental cyst, mesenteric lymphoma, fluid encapsulated in the mesentery during intussusception, Meckel's diverticulum and intramural neoplasm^[3]. A correct and timely diagnosis is necessary not only to resect the underlying lesion that serve as the lead point for intussusception but also to avoid the serious complications of bowel infarction and perforation secondary to obstruction. Resection of the affected bowel and the DAT is recommended to relief the bowel obstruction and to avoid the patient further complications^[7]. This patient underwent exploratory laparotomy with presumed diagnosis of complete small bowel obstruction due to intussusception. Abdominal exploration revealed intussusception in the ileum due to cystic lesion located in the mesenteric side of the bowel. The affected bowel was resected with the cystic lesion and end to end bowel anastomosis was established.

In conclusion, a rare case of ileoileal intussusception due to DAT in a young adult woman is reported herein. This case highlights the DAT as an uncommon cause of adult ileoileal intussusception. DAT should be considered in the differential diagnosis of intussusception in adults particularly when the leading point is a cystic lesion. Treatment of choice is resection of the lead point with the affected small intestine and end to end anastomoses.

COMMENTS

Case characteristics

A 32-year-old woman presented to the emergency department with diffuse intermittent abdominal pain, vomiting, and constipation for 3 d associated with progressive abdominal distention.

Clinical diagnosis

The abdomen was diffusely distended with mild diffuse discomfort and exaggerated bowel sounds.

Differential diagnosis

The clinical condition could be small bowel obstruction or large bowel obstruction.

Laboratory diagnosis

Leukocytic count was high.

Imaging diagnosis

Abdominal computed tomography showed grossly dilated small bowel loops with "sausage" and "doughnut" signs of small bowel intussusception.

Treatment

Exploratory laparotomy, resection of ileoileal intussusception and the leading point was cystic lesion measuring 4 cm in diameter which was located adjacent to the mesenteric side of the ileum.

Pathological diagnosis

Enteric duplication cyst as a leading point of intussusception.

Experiences and lessons

Enteric duplication cyst should be considered in the differential diagnosis of intussusception in adults particularly when the leading point is a cystic lesion.

Peer-review

The author describes a rare case of ileoileal intussusception due to enteric duplication cyst in adult patient.

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (World J Gastrointest Surg, WJGS, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Umbilical hernia occurs in 20% of the patients with liver cirrhosis complicated with ascites. Due to the enormous intraabdominal pressure secondary to the ascites, umbilical hernia in these patients has a tendency to enlarge rapidly and to complicate. The treatment of umbilical hernia in these patients is a surgical challenge. Ascites control is the mainstay to reduce hernia recurrence and postoperative complications, such as wound infection, evisceration, ascites drainage, and peritonitis. Intermittent paracentesis, temporary peritoneal dialysis catheter or transjugular intrahepatic portosystemic shunt may be necessary to control ascites. Hernia repair is indicated in patients in whom medical treatment is effective in controlling ascites. Patients who have a good perspective to be transplanted within 3-6 mo, herniorrhaphy should be performed during transplantation. Hernia repair with mesh is associated with lower recurrence rate, but with higher surgical site infection when compared to hernia correction with conventional fascial suture. There is no consensus on the best abdominal wall layer in which the mesh should be placed: Onlay, sublay, or underlay. Many studies have demonstrated several advantages of the laparoscopic umbilical herniorrhaphy in cirrhotic patients compared with open surgical treatment.

Core tip: Umbilical hernia management in cirrhotics is controversial. Indication, timing, and surgical options of herniorrhaphy such as mesh use and laparoscopic

access in these patients remain controversial. This comprehensive review shows that umbilical hernia prevalence is very high in cirrhotic patients with ascites. The etiopathogenesis of umbilical hernia in these patients is discussed in detail. Umbilical hernia management changed markedly in the last decades due to better medical care of cirrhotic patients. Ascites control is the mainstay to avoid surgical complications and recurrence.

Coelho JCU, Claus CMP, Campos ACL, Costa MAR, Blum C. Umbilical hernia in patients with liver cirrhosis: A surgical challenge. *World J Gastrointest Surg* 2016; 8(7): 476-482 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i7/476.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i7.476>

INTRODUCTION

Umbilical hernia is a common condition, with a prevalence of 2% in the general adult population^[1]. Hernia incidence in cirrhotics with ascites is 20%^[2,3]. Umbilical hernia in these patients has a tendency to enlarge quickly and become symptomatic^[4]. Unlike the general population, in which female sex and obesity are risk factors for umbilical hernia, cirrhotic patients who form umbilical hernias are more likely to be men with ascites^[2-4].

The treatment of cirrhotic patients with umbilical hernia is controversial^[5-8]. In the past, these patients were usually treated expectantly due to the elevated rate of complication and hernia recurrence^[5,6]. Nonetheless, expectant management may lead to severe complications, such as hernia incarceration and necrosis and perforation of the overlying skin followed by evisceration, ascites drainage, and peritonitis^[7,8]. Many recent studies showed that the results of surgical repair depend on the presence of ascites and liver function grade^[9-12]. Elective umbilical herniorrhaphy is safe and effective in most cirrhotic patients in which ascites is adequately controlled^[12]. However, it should be avoided in patients in which ascites is not controlled.

At present, there is no high-quality prospective randomized study on management of cirrhotic patients with umbilical hernia to guide decision-making^[4]. Indication, timing, and technical aspects of herniorrhaphy in these patients remain controversial^[6-10]. Use of mesh and laparoscopic access is also subject to debate^[13-15]. Our objective in the present article is to review the management of cirrhotic patients with umbilical hernia, including the indications and results of the surgical treatment. Use of mesh and the laparoscopic access employed in the surgical repair is also reviewed.

PREVALENCE AND ETIOPATHOGENESIS

Umbilical hernia is the third most common abdominal hernia in the general population, after inguinal hernia and incisional hernia^[1]. In cirrhotic patients, the preva-

lence of umbilical hernia is higher^[16]. Nearly 20% of cirrhotic patients with ascites have umbilical hernia^[2,3]. Prevalence of inguinal hernias is relatively unaffected by ascites^[6].

Umbilical hernia etiology in cirrhotics is multifactorial^[3-5]. Elevated abdominal pressure secondary to ascites may initiate protrusion of abdominal content through a potential defect at umbilicus^[15]. Ascites is possibly the major etiologic factor^[6-10]. In cirrhotics, umbilical hernias occur almost exclusively in patients with persistent ascites^[11-14]. In addition to increase intra-abdominal pressure, ascites correlates with liver dysfunction. Other important contributory factor is abdominal wall muscle weakness due to hypoalbuminemia and recanalization, dilation and varices formation of the umbilical vein at the umbilicus as a result of portal hypertension^[16,17].

In the general population with no co-morbidities, acquired umbilical hernia increases in size very slowly^[1]. On the contrary, in individuals with intraabdominal pressure elevated, such as in cirrhotic patients with ascites, umbilical hernia size increases rapidly^[6,16]. In addition, ascites is also important in the development of complications in these patients. Ascites may precipitate hernia incarceration of intestine or omentum into the dense fibrous ring at the neck of the hernia^[17-20]. Enormous increase of intraabdominal pressure secondary to tense ascites may also cause pressure necrosis and perforation of the overlying skin followed by evisceration, ascites drainage, and peritonitis^[19,21].

INDICATIONS AND TIMING OF HERNIA REPAIR

Elective umbilical herniorrhaphy in the general population is the standard treatment^[1]. Hernia repair in individuals with no co-morbidities is an operation associated with low complication rate^[9]. On the contrary, umbilical herniorrhaphy in cirrhotic patients may cause expressive morbidity, such as wound infection and dehiscence, ascitic drainage through the incision, peritonitis, liver failure, and hernia recurrence^[9,10]. Furthermore, presence of umbilical hernia reduces the quality of life^[22].

Historically, cirrhotic patients who were subjected to umbilical herniorrhaphy had elevated morbidity and mortality rates that correlated with the severity of liver dysfunction^[9,10,16]. The potential complications include decompensation of liver disease, hemorrhage, hepatic encephalopathy, hepatorenal syndrome, hepatopulmonary syndrome, infection, and high hernia recurrence rate^[7,8]. Therefore, in the past, surgeons avoided to perform elective umbilical herniorrhaphy in cirrhotic patients despite the operation simplicity^[9,23-26].

Umbilical herniorrhaphy in cirrhotics was performed only in patients with hernia complications. Conservative management was the initial option. Nonetheless, expectant management is associated with elevated rate of complications, such as hernia incarceration,

evisceration, ascites drainage, and peritonitis^[2,18,21]. Morbidity and mortality are high when umbilical hernia repair is performed on these patients^[2,18,27,28].

With improvement in the medical care of cirrhotic patients in the last decades, some studies have showed a significant reduction of umbilical herniorrhaphy complications in these patients^[4,6,23]. Marsman *et al*^[7] have compared elective surgical repair ($n = 17$) with expectant treatment ($n = 13$) in cirrhotic patients with umbilical hernia and ascites. The authors reported that expectant treatment was associated with elevated morbidity and mortality^[7]. Hospital admission for hernia incarceration was observed in 10 of 13 patients (77%), of which 6 needed emergency herniorrhaphy^[7]. Two patients (15%) who were subjected to expectant treatment died from hernia complications. Conversely, no complications or hernia recurrence was recorded in 12 of 17 patients (71%) who underwent elective herniorrhaphy.

Other studies have also describe superior results and have suggested elective umbilical herniorrhaphy in cirrhotic patients in order to avoid complications associated with conservative management^[5,8,9].

Indications and the optimal timing to repair an umbilical hernia in cirrhotic patients remain controversial. Several studies have demonstrated that umbilical hernia repair outcomes in cirrhotics depend on the presence of ascites and liver function grade^[6,8]. Child's classification and MELD score have been employed to determine the surgical risk^[29-31]. Some other adverse predictors include esophageal varices, age older than 65 years, and albumin level lower than 3.0 g/dL^[10].

Most studies have demonstrated that effective treatment of ascites is the essential for umbilical herniorrhaphy in cirrhotic patients^[5,7]. In addition, effective ascites control also reduces complications, such as wound infection, evisceration, ascites drainage from the wound, and peritonitis^[6].

Medical treatment of ascites with sodium restriction, diuretics, and paracentesis should be the first step in the management. In patients with no significant comorbidities in whom medical treatment is effective in controlling the ascites, umbilical hernia repair is indicated^[6].

If medical treatment fails, ascites drainage or shunting is indicated either before or at hernia correction^[7-9]. Presently, intermittent paracentesis, temporary peritoneal dialysis catheter or transjugular intrahepatic portosystemic shunt (TIPS) may be employed. These procedures significantly reduce the incidence of hernia recurrence and wound dehiscence^[23,32].

Slakey *et al*^[32] suggested that the insertion of temporary peritoneal dialysis catheter at the end of umbilical herniorrhaphy in cirrhotic patients was effective in controlling ascites and reducing the complication rate. This approach has some advantages, such as outpatient care during the postoperative period and easy removal of the catheter^[32]. However, peritoneal catheters are

associated with a high risk of bacterial infections, which significantly increase mortality and should be discouraged^[33].

In a survey performed recently with members of the Canadian Hepato-Pancreato-Biliary Society, the preferred choice to ascites treatment in these patients was the use of temporary peritoneal dialysis catheter until wound healing was completed^[23]. However, others reported that preoperative TIPS was preferable^[27].

Rapid preoperative ascites drainage, either by paracentesis or peritoneal dialysis catheter ascites, is not a risk free procedure, and may cause strangulation of the hernia^[10,23,27]. Therefore, it is recommended that ascites drainage should be gradual. Other shuntings, such as portocaval shunt and peritoneovenous shunt, are rarely employed at present. In patients in whom the shunt is effective, surgical treatment of umbilical hernia can be safely performed in most cases^[4,34].

In patients in whom ascites control is ineffective, the best alternative is to repair the hernia during the transplant operation, if the patient is on the waiting list for liver transplant^[16,35]. Otherwise, surgical repair should not be recommended. Based on literature data, an algorithm for the management of cirrhotic patients with umbilical and ascites is shown in Figure 1.

HERNIA REPAIR IN CANDIDATES TO LIVER TRANSPLANTATION

Liver transplant candidates may underwent umbilical herniorrhaphy during the transplant operation. Patients who have a good perspective to be transplanted within 3-6 mo, herniorrhaphy should be done during transplantation^[7]. Postponement of hernia correction is not advisable due to the risk of post-transplant intestinal strangulation of an uncorrected umbilical hernia^[6,7,16]. Pressure bandage should be applied carefully on the hernia until transplantation to avoid complications^[16].

Some patients with patent large umbilical vein who underwent umbilical hernia repair may need emergency liver transplantation due to acute liver failure^[16]. Ligation of a large patent umbilical vein during hernia repair may cause acute liver failure as a result of acute portal vein thrombosis or embolization^[16,25].

The umbilical hernia may be repaired at the end of liver transplantation either from inside the abdomen through the same incision employed for the transplantation or through an additional para-umbilical incision^[16]. In a retrospective study, de Goede *et al*^[16] reported the only study of the literature comparing the two incisions. The recurrence hernia rate was higher in the same incision group than in the separate incision group (40% vs 6%)^[16]. The number of patients was small in this retrospective study to allow recommendations. At present, the decision of which incision should be used for umbilical hernia repair during liver transplantation is based on the surgeon's experience^[7,16].

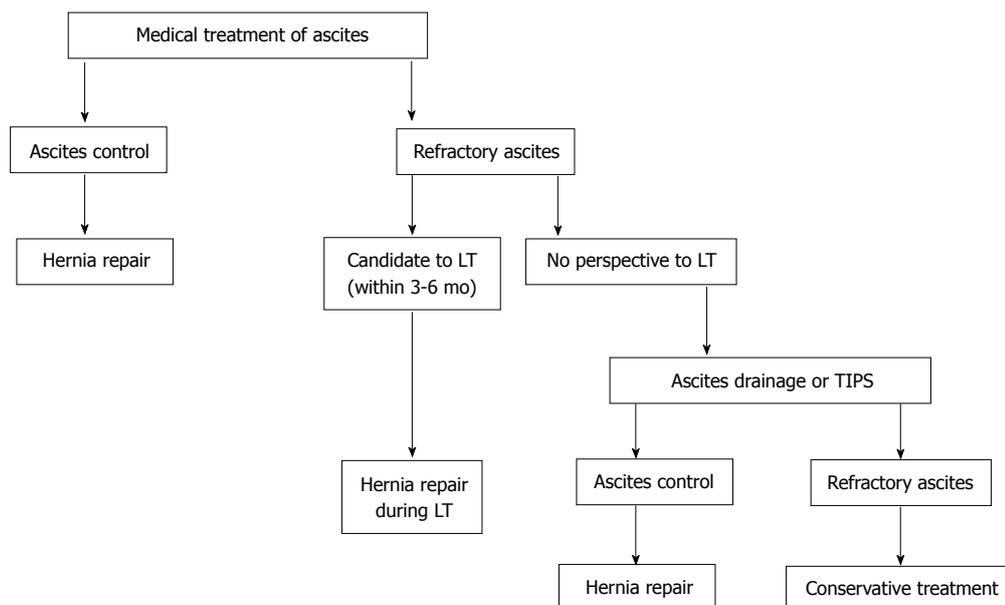

Figure 1 Management of umbilical hernia in patients with liver cirrhosis and ascites. LT: Liver transplantation; TIPS: Transjugular intrahepatic portosystemic shunt.

TREATMENT OF COMPLICATED HERNIA

The rate of complications is high in cirrhotic patients with umbilical hernia and ascites, mainly due to the enormous intraabdominal pressure that enlarges the hernia rapidly^[7]. These complications include infection, incarceration, strangulation, and rupture. Non-operative management of these complications is associated with elevated morbidity and mortality^[2,7,18,23]. The mortality rate ranges from 60% to 80% following conservative management of ruptured umbilical hernia and 6% to 20% after urgent herniorrhaphy^[2,23]. Therefore, complicated umbilical hernia in cirrhotics with ascites should be corrected urgently^[2,23].

Initially, the patient should be subjected to appropriate resuscitation with intravenous fluids and antibiotics to prevent or treat ascitic fluid infection^[2]. Sterile dressing is indicated in patients with ascitic fluid drainage or cutaneous infection. After patient stabilization, umbilical herniorrhaphy should be done with sutures^[2,18]. Mesh should be avoided to decrease the risk of infection^[2,18]. Ascites control is important to reduce complications and hernia recurrence^[7-9].

HERNIA REPAIR WITH OR WITHOUT MESH

As a result of elevated recurrence rate following the correction of abdominal hernias, including umbilical hernia, in cirrhotic patients, prosthetic mesh repair has been introduced and revolutionized hernia surgery^[13,36]. Hernia repair with mesh compared with suture repair reduces hernia recurrence rate, but increases the risk of some complications, including infection, seroma, mesh erosion, and intestinal adhesion, obstruction, and fistula^[36-38].

Several studies have demonstrated that elective mesh umbilical herniorrhaphy in cirrhotic patients with ascites is simple, safe, effective, and reduce hernia recurrence markedly^[4,7,12]. However, many surgeons are still reluctant to employ mesh for hernia correction in these patients because of the risk of wound complications^[12,23]. A significant complication in this group of patients is ascites leakage through the wound, which elevates the possibility of wound and mesh infection, followed by need of mesh removal^[36].

In a recent randomized study, 80 cirrhotic patients subjected to umbilical hernia repair were divided into two groups, with a follow-up of 6 to 28 mo^[4]. Hernia recurrence rate was lower in the group in which polypropylene mesh was used compared to the group without mesh in which the hernia correction was performed by conventional fascial suture (14.2% vs 2.7%)^[4]. In this study, surgical site infection was more likely to occur in the mesh group than in the group without mesh, even though no patient needed mesh removal^[2]. No mesh exposure or fistulas were observed in this series.

Techniques of mesh placement include onlay, inlay, sublay, and underlay^[36,38]. In the onlay repair, the mesh is sutured on external oblique fascia, after dissection of the subcutaneous tissue and closing of the fascia^[36]. In the inlay technique, the mesh is placed in the hernia defect and sutured circumferentially to the edges of the fascia^[36]. In the sublay procedure, the mesh is inserted in the preperitoneal space or retro-rectus^[36]. In the underlay procedure, the mesh is placed intraperitoneally and fixed to the abdominal wall, usually with tackers^[36].

The risks of complications are related to the space in which the mesh is placed^[36]. In the onlay technique, wound complications are more frequent, such as seroma, hematoma, ascites drainage, and infection of the surgical incision and mesh. This is due to the

Table 1 Advantages of laparoscopic umbilical hernia repair in patients with liver cirrhosis^[15,36,37]

Minimally invasive
Tension free repair
Minimal ascites leakage through the wound
Less damage to the large collateral veins
Restricts electrolyte and protein loss due to non-exposure of viscera
Reduced blood loss
Decreased pain
Better aesthetics
Early recovery
Reduced hernia recurrence

extensive detachment of subcutaneous tissue from the fascia, which typically creates a dead space between the mesh fixed on the fascia and the subcutaneous tissue. At present, inlay repair is used only occasionally due to high wound infection and recurrence rates^[36].

Wound complications are less common in the sublay and underlay mesh repair techniques because the mesh lies quite deep in the preperitoneal space and intraperitoneally respectively and therefore distant from the subcutaneous tissue and skin^[13,36-38]. In the underlay technique, the mesh is in contact with abdominal contents and therefore is subjected to complications, such as intestine adhesion, obstruction, erosion, and fistula^[12,13,36,39]. For open surgery, the best abdominal wall layer to place the mesh is still controversial^[3,12,14,36]. For laparoscopic umbilical herniorrhaphy, the mesh is routinely inserted intraperitoneally and fixed to the abdominal wall^[13,37,38].

At present, countless types and brands of mesh for hernia repair are available. They may be absorbable and permanent synthetic meshes, allograft material, and xenograft material. There is no consensus on the best mesh^[12-14,36,37]. The selection is based on several aspects, including type of hernia, presence of infection, location or space of mesh placement, cost and surgeons's preference. The most common mesh used in onlay, inlay, and sublay techniques is the polypropylene mesh^[13,37,38]. For intraperitoneal mesh placement (underlay technique), synthetic meshes with different coatings or composite meshes are preferred in order to avoid intestine adhesion, occlusion, and fistula^[12,14,38].

OPEN OR LAPAROSCOPIC HERNIA REPAIR

The first laparoscopic umbilical herniorrhaphy was described by Sarit *et al*^[3] in 2003 in a patient with liver cirrhosis complicated with strangulated hernia. Several studies have documented the advantages of the less invasive laparoscopic access compared with the open surgical approach to treat umbilical hernia in cirrhotic patients^[13,15,37]. The laparoscopic umbilical herniorrhaphy is a minimally invasive and tension-free procedure in which a mesh is placed and fixed into the abdominal wall to close the inlet of the hernia^[21,40].

By minimizing the access incision, the laparoscopic approach reduces postoperative pain, recovery time, and morbidity^[15]. Advantages of laparoscopic umbilical herniorrhaphy in cirrhotics with ascites compared to open surgical treatment are shown in Table 1.

One possible disadvantage of laparoscopic herniorrhaphy is the higher cost, mainly of the equipment and material^[23,37,38,41,42]. As mentioned earlier, expansive synthetic meshes with different coatings or composite meshes are needed for laparoscopic hernia repair in order to avoid intestine adherence, occlusion, and fistula. Although, several studies have demonstrated higher costs of laparoscopic abdominal hernia repair, there is no specific study on cost associated with laparoscopic umbilical herniorrhaphy in cirrhotic patients^[3,39,41,42]. Considering the postoperative advantages of laparoscopic approach, additional studies are essential to establish the cost-effectiveness of umbilical herniorrhaphy in cirrhotics^[23,40].

The laparoscopic approach has been also used for complicated umbilical hernia in cirrhotics. Sarit *et al*^[3] performed laparoscopic repair for a strangulated umbilical hernia with refractory ascites successfully by releasing the incarcerated bowel loops and fixing a mesh.

Some technical details are important to be observed at laparoscopic umbilical herniorrhaphy in cirrhotic patients with ascites in order to avoid complications. Oblique insertion of trocars into abdominal wall may avoid postoperative ascitic fistula^[3]. Angulation of trocar insertion allows the layers of the abdominal wall to overlap and obstruct potential ascitic drainage. Veres's needle and trocar must be inserted carefully in the left subcostal region to avoid lesion of an enlarged spleen secondary to portal hypertension. In order to decrease the risk of hemorrhage, reduction of incarcerated umbilical hernia contents should be performed meticulously due to the proximity and adherence of umbilical varices^[17].

HERNIA RECURRENCE

Umbilical hernia recurrence rate in cirrhotics with ascites ranges from 0% to 40%^[3,4,6,7]. Effective ascites management is essential to achieve umbilical hernia repair success as well as to reduce recurrence rate. In a recent literature review, McKay *et al*^[23] identified only 3 retrospective studies comparing the hernia recurrence in cirrhotic patients with ascites control and without control. When the data of these studies were grouped in a meta-analysis evaluation, the recurrence rate was 45% (22 of 49 patients) in the ascites uncontrolled group and 4% (2 of 47 patients) in the controlled group. The authors concluded that uncontrolled ascites strongly correlates with umbilical hernia recurrence in cirrhotic patients^[7,23].

Several studies have reported lower umbilical hernia recurrence following hernia repair with mesh than repair without mesh in cirrhotic patients with ascites^[3,4]. In a randomized study with 80 cirrhotic patients who were

subjected to umbilical hernia repair, Ammar^[4] reported recurrence rate of 2.7% after hernia repair with polypropylene mesh compared with 14.2% following hernia repair without mesh. However, the rate of wound complications, such as seroma, hematoma, and wound and mesh infection, is higher following umbilical hernia repair with mesh.

In summary, most studies have demonstrated that cirrhotic patients with ascites should have umbilical herniorrhaphy electively after ascites control^[12]. When hernia complications occur, such as infection, incarceration, strangulation, and rupture, umbilical herniorrhaphy should be performed urgently. Ascites control is critical to reduce hernia recurrence and postoperative complications. For patients scheduled for liver transplantation, umbilical herniorrhaphy should be done during transplantation.

CONCLUSION

Expectant treatment of cirrhotic patients with umbilical hernia and ascites is associated with elevated rate of complications, such as incarceration, evisceration, ascites drainage and peritonitis. These complications require emergency surgical treatment, which carries expressive morbidity and mortality. Conversely, elective hernia correction may be performed with much less complications and it is therefore advocated. Ascites control is essential to reduce perioperative complications and recurrence. In candidates to liver transplantation, umbilical herniorrhaphy should be performed during transplantation, unless the patient presents with significant symptoms or hernia complication or if the perspective to be transplanted exceeds 3-6 mo. This review has major limitations due to lack of high-quality randomized studies. Most publications on umbilical hernia management in cirrhotic patients are case series or retrospective cohort studies with small number of patients. Definitive answers await large-scale prospective randomized controlled studies.

Abstract

Chronic haemorrhagic radiation proctitis (CHRP) is a difficult problem faced by the patients following radiation for pelvic malignancy. There is no standard

treatment for this condition, but many methods of treatment are available. The aim of this study was to review the literature to see whether there is an improvement in the available evidence in comparison with previously published systematic reviews in treating patients with CHRP. The PubMed/Medline database and Google Scholar search was selectively searched. Studies, which treated patients with rectal bleeding due to chronic radiation proctitis or CHRP, were included. Seventy studies were finally selected out of which 14 were randomized controlled clinical trials. Though these studies could not be compared, it could be seen that there was an improvement in the methodology of the studies. There was an objective assessment of symptoms, signs and an objective assessment of outcomes. But, still, there were only a few studies that looked into the quality of life following treatment of CHRP. To increase recruitment to trials, a national registry of cases with established late radiation toxicity would facilitate the further improvement of such studies. Some of the conclusions that could be reached based on the available evidence are 4% formalin should be the first line treatment for patients with CHRP. Formalin and argon plasma coagulation (APC) are equally effective, but formalin is better for severe disease. Refractory patients, not responding to formalin or APC, need to be referred for hyperbaric oxygen therapy or surgery. Radio-frequency ablation is a promising modality that needs to be studied further in randomized trials.

Key words: Radiotherapy; Complications; Systematic review; Proctitis; Formalin

INTRODUCTION

One to five percent of patients who receive radiotherapy as adjuvant or neoadjuvant therapy for pelvic malignancy will develop chronic haemorrhagic radiation proctitis (CHRP). In one of the recently published series, it was noted that 1319 patients received radiation for carcinoma of cervix over a period of 22 mo and 124 similar patients during the same period needed treatment for CHRP in the same centre^[1]. The meaning of the above sentence shows the magnitude of the problem of CHRP. Newer methods of radiotherapy like three-dimensional conformal radiation therapy and intensity-modulated radiation therapy can use higher doses of radiation to the target tissues with less exposure to adjacent normal tissues. Protons and neutrons, so-called particle radiation, are also being tested but the long-term outcomes of these modalities are not known, and these are expensive. The use of brachytherapy is also found to be associated with fewer complications. Thus, the incidence of CHRP is related to the dose of radiation, the area of exposure, methods of delivery, the use of cytoprotective agents and other factors^[2].

Because the rectum has a fixed position in the pelvis, it becomes more susceptible to radiation injury. Acute radiation injury of rectum occurs within three months of starting radiotherapy. It is an inflammatory process of rectal mucosa with a loss of microvilli, oedema, and ulceration. It is self-limiting and manifests as abdominal pain, tenesmus, diarrhoea, incontinence and urgency and resolves within three months^[3]. Unlike acute radiation proctitis, chronic radiation proctitis takes a period of 3 mo after pelvic radiation, but usual median time is 8-12 mo. It can also continue from acute phase^[3]. It is due to obliterative endarteritis, submucosal fibrosis, and neo-vascularization (Figure 1). Chronic radiation proctitis can present with rectal bleeding, tenesmus, mucus discharge, diarrhoea, incontinence, and urgency. It may be asymptomatic also. The diagnosis of radiation proctitis should be suspected if a patient presents with the above mentioned symptoms and gives a history of pelvic radiation. The diagnosis is confirmed by sigmoidoscopy or colonoscopy that shows

pale, friable mucosa with telangiectasia. Rectovaginal, recto-urethral, recto-vesicular fistulizing disease is a late-presenting sign. There is no role of biopsy to confirm the diagnosis since it may produce complications.

There is no standard treatment for CHRP. However many treatments are available like amino salicylates, butyric acid enema, steroid enemas, formalin, argon plasma coagulation (APC), hyperbaric oxygen, radiofrequency ablation and even surgical therapy. The outcome of any of these medical and surgical treatment can be disappointing^[1]. There are not many good-quality placebo-controlled trials.

In this study, our aim was to review the literature to see whether there is an improvement in the available evidence in comparison with previously published systematic reviews in treating patients with CHRP. The PubMed/Medline literature database was selectively searched for articles with the keywords "Proctitis/drug therapy"(Mesh) or "Proctitis/radiotherapy"(Mesh) or "Proctitis/surgery"(Mesh) and "radiotherapy", "Management of CHRP" "Related Review articles". In addition Google search and Google Scholar search was also made using key words "Radiation proctitis" "Formalin" "Endoscopic therapy" "APC" "Radiofrequency ablation" "cryotherapy" "Hyperbaric oxygen therapy" and "surgery". The literature search was mostly limited to articles in English and human patients. No limitations for the year of publication were applied. All the studies that treated patients with rectal bleeding due to chronic radiation proctitis or CHRP were included in the review. Studies of patients treating acute radiation proctitis were excluded.

We could find 142 articles in total. After removing the duplicates and studies on acute radiation proctitis, there were about 86 articles. Out of these 86, 16 were further excluded because of various reasons such as anecdotal studies. Various studies that were found to be relevant are summarized below. Importance was given to randomized controlled clinical trials.

STUDIES USING ANTI-INFLAMMATORY DRUGS, STEROIDS, SUCRALFATE AND PENTOSAN POLYPSULPHATE

Sulfasalazine or 5-aminosalicylates, steroids are the drugs used initially for treating CHRP. Their mechanism of action is by inhibition of prostaglandin synthesis. It may also be due to inhibition of folate-dependent enzymes^[4]. Sucralfate stimulates epithelial healing and forms a protective barrier^[5]. Sucralfate is shown to be better than anti-inflammatory agents^[6]. Pentosan polysulphate is similar to sucralfate. There are more than seven to eight publications using these drugs.

In a prospective double-blind, randomized controlled trial involving 37 consecutive patients with radiation-induced proctosigmoiditis^[6], there were 36 females treated for cervical cancer and one male treated for prostate cancer. The mean duration after completion

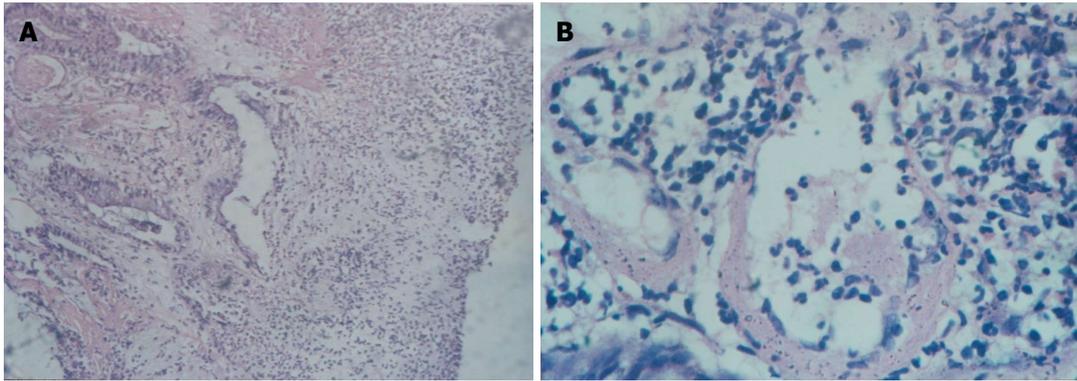

Figure 1 Chronic radiation proctitis. A: Chronic radiation proctitis (low power view). This picture shows the mucosa with severe oedema, non-specific inflammation, lymphocytosis, hyalinization in the stroma and fibrin thrombi in the postcapillary venules (Hematoxylin and Eosin stain, 10 ×); B: Chronic radiation proctitis (High power view). This picture shows two veins in the lamina propria, one with patchy occlusive fibrin thrombus. The wall shows thickening and hyalinization. A dense non-specific inflammation including few eosinophils also seen (Hematoxylin and Eosin stain, 40 ×).

of the radiotherapy was 8.3 mo. These patients were randomized to receive either 3 g oral sulfasalazine plus 20 mg twice daily of rectal prednisolone enemas (group I, $n = 18$) or 2 g of rectal sucralfate enema plus oral placebo (group II, $n = 19$) for four weeks. These two groups were comparable with respect to demography, clinical symptoms and endoscopic staging of the disease. Patients in Sucralfate enema showed a better clinical response although endoscopically the response was not statistically significant. Follow-up was limited to 4 wk.

Rougier *et al*^[7,8], in their randomized trial, compared betamethasone enema (5 mg bd) with hydrocortisone mousse (90 mg bd) and concluded that hydrocortisone group had a better outcome. There were 32 patients with CHRP in this study. The outcomes used were bowel activity, tenesmus, rectal bleeding and endoscopic grading. Follow-up was limited to 4 wk.

In another randomized study by Cavčić *et al*^[9], compared combination of oral metronidazole (400 mg tds), mesalamine (1 g tds) and rectal betamethasone to oral mesalamine and rectal betamethasone and found that the rectal bleeding and ulcers were significantly lower in the metronidazole group. In this study, there were sixty patients randomized into either group. The efficacy of metronidazole was assessed on the basis of rectal bleeding, diarrhoea and proctosigmoidoscopy in all patients. The follow-up was up to 12 mo. Grigsby *et al*^[10] prospectively showed the benefit of oral pentosan polysulphate given for a period of 1 year in 13 patients.

STUDIES USING SHORT-CHAIN FATTY ACID ENEMAS

Short-chain fatty acids (SCFA) stimulate the growth of colonic mucosa. The vasodilatation effect may improve the blood flow of colonic mucosa^[11]. Butyric acid is the main SCFA. There are more than six studies using SCFA. Many of them are case series.

Two randomized studies showed non-significant

improvement of symptoms and signs but both the studies were underpowered^[12,13]. Talley *et al*^[12] in their randomized double-blind placebo-controlled cross over trial of 15 patients treated one group with the butyric acid enema and another group with normal saline placebo. Symptoms score, endoscopic scores and even histology were compared.

Similarly, Pinto *et al*^[13] in their randomized prospective double blind controlled trial of 19 patients treated one group with SCFA enema and another group with placebo. In this study apart from symptoms and endoscopic features, biopsies for mucosal DNA and protein content were also measured. Patients were followed up to 6 mo.

Though we were treating patients with CHRP in our institute since 1985, study on chronic haemorrhagic proctitis were started in 1999. The first study on CHRP in our institute, done by Senthil Kumar *et al*^[14] in 2001, compared sucralfate-steroid enema (25 mg of prednisolone and 1 g of sucralfate twice daily for 14 d) with butyric acid retention enema (60 mL containing 40 mmol of butyric acid twice daily for 14 d) in a double-blind randomized controlled trial. There were thirty patients randomly allocated. They were followed up to 4 wk. Outcomes were measured by the improvement in the colonoscopic grading of severity and clinical symptoms. Histopathological improvements were also compared by taking the biopsy before and after treatment. The conclusion was that both the methods of treatment were equally effective since there was relief of symptoms of radiation proctitis in both the methods of treatment without improvements in endoscopic scores or histology. However, the sucralfate-steroid enema was easier to prepare^[14]. No toxicities were reported in any of these studies.

STUDIES USING FORMALIN THERAPY

Formalin scleroses and seals fragile neovasculature in tissues damaged due to radiation and prevents further bleeding. In 1986, Rubinstein was the first

to use formalin for a CHRP patient to get a good response^[15]. Following this, there are several reports in the literature^[16-30]. But the majority are retrospective in nature, a few are prospective studies. The technique and the concentration of formalin used in these studies also differ. The two main methods of using it are 4% solution as irrigation or as soaks. There are reports of using 10% solution of formalin also^[31]. There are four randomized trials using formalin for CHRP.

Ours is one of the first published randomized trial comparing the efficacy of the 4% formalin dab with Sucralfate-steroid retention enema (100 mg of prednisolone and 1 g sucralfate in 100 mL of normal saline twice daily for 14 d)^[1]. In this study, 102 patients were randomly allocated to either of the treatment arms. This study objectively assessed the symptoms scores using the radiation proctopathy system assessment scale (RPSAS) and also the sigmoidoscopic grade (Modified Chi grading) before and after treatment and found that Formalin dab is superior to sucralfate-steroid enema in treating CHRP involving only the rectum. It was also observed that a single session of formalin dab can effectively treat CHRP in 90% of the patients, and multiple sessions could effectively treat 99% of the patients whereas sucralfate-steroid enema was effective only in 75% of patients. These patients were followed up to 9 mo. There was no complications or toxicity.

Following this Yeoh *et al.*^[32] showed in their randomized study that APC and topical formalin had comparable efficacy in the durable control of rectal bleeding associated with chronic radiation proctitis but had no beneficial effect on anorectal dysfunction. In this study thirty patients were randomized into each group. Anorectal symptoms, (modified LENT-SOMA questionnaire) anorectal manometry and anorectal morphology by endorectal ultrasound were assessed before and after treatment.

Guo *et al.*^[33] in their randomized trial showed that 10% formalin is associated with complications and 4% formalin should be the choice for treating CHRP. In this study 122 patients were randomized into 4% or 10% formalin application. Outcomes were compared with symptoms score and rectoscopy scores. Follow-up was up to 1 year. Wong *et al.*^[34] from their prospective database, after a decade of experience of treating patients with radiation proctitis, have shown that formalin is more effective than APC in treating patients with CHRP. APC has the potential to complement topical formalin application and can be used to treat the proximal and distal rectum concurrently.

The contrary report has been published by Alfadhil *et al.*^[35] in their retrospective comparative study of 22 patients who received formalin application or APC. Improvement in Hb% was used to assess the outcome. The severity of the proctitis was not assessed before the treatment. The lag time between radiation and endoscopic treatment was not known. The study was underpowered, and the groups were not comparable.

The details of the adverse events not mentioned. They concluded that APC is more effective than formalin and has less adverse effects.

Sahakitrungruang *et al.*^[36] in their randomized controlled trial comparing colonic irrigation with oral antibiotics administration vs 4% formalin application for treatment of CHRP have shown that the former method is better than 4% formalin application. Fifty patients were randomly allocated to each arm. Daily self-administered colonic irrigation of 1 L tap water and a 1-wk period of oral antibiotics-ciprofloxacin and metronidazole were given in one arm. Four percent formalin application for 3 min was done in another arm. Patient's satisfaction was surveyed. The limitation was that the study was a 2-armed design without a crossover trial. Hence, it could not illustrate whether the antibiotics and irrigation were equally important. Some of the adverse events noted in the literature regarding the use of formalin for CHRP are the rectal stricture, worsening of incontinence, anococcygeal pain, and formalin colitis^[24,30].

STUDIES USING THERMAL COAGULATION THERAPY

Endoscopic coagulation with a variety of devices has been reported to be effective for CHRP^[7]. The technique involves coagulation of a bleeding point rather than the entire friable mucosa. Several treatment sessions are often required^[7]. The modalities include heater probe, bipolar Electrocoagulation, neodymium:yttrium-aluminium-garnet (Nd:YAG) laser, potassium titanyl phosphate (KTP) laser, argon laser and APC. Simple heater probe and APC are preferred for their better safety profile^[37].

Both the heater probe and bipolar cautery are contact probes. The heater probe has a Teflon-coated heating element at its tip that delivers standardized energy over set times. Bipolar electrocautery probe has a pair of electrodes at its tip through which current is passed using the tissue for conduction^[38]. Jensen *et al.*^[39] in his randomized study showed that 21 patients treated either with a heater probe, or bipolar cautery showed benefits without much difference between the two modalities^[39]. A mean of four sessions was needed in each arm during treatment in this study. Patients were followed up to one year. The increase in haematocrit, endoscopic resolution, and patient satisfaction were compared. No complications were noted.

Nd:YAG laser is the first endoscopic laser used for treating CHRP. Some of the complications reported with this are transmural necrosis, fibrosis, necrosis, stricture formation and recto-vaginal fistula. Nd:YAG laser use for CHRP has declined due to several reasons, firstly its cost; second, the need to aim directly at telangiectasias and the possibility of severe endoscopic damage if the laser strikes the endoscope in retroflexion^[40]. Taylor *et al.*^[41] used KTP laser for treating 26 patients

with bleeding secondary to CHRP using 4-10 W and a median of two sessions. They reported a symptomatic improvement in 65% patients while there was no change in 7 (30%), and symptom like hematochezia increased in 1 (5%). Similarly, there are only case series using argon laser for treating CHRP.

There are more than 15 published reports of APC for CHRP. Many are retrospective studies, and some of them are prospective case series. Many of the series report unsuccessful medical treatment before going for APC. In APC bipolar diathermy current is applied using inert argon gas as a conducting medium. It can be applied tangentially and radially.

Karamanolis *et al*^[42] showed in their prospective study treating more than 56 patients, that APC was successful in all patients with mild and in almost all patients with moderate CHRP. In contrast, APC failed in 50% of patients, wherever the presence of severe mucosal damage was present. The grading of severity was based on endoscopic criteria taking into consideration telangiectasia distribution and surface area involved. For APC application, a 2.3 mm diameter front firing APC probe inserted through the working channel of the flexible sigmoidoscope was used. The argon flow rate and the electrical power were set at 2 L/min and 40 W, respectively. Patients were followed up for a mean of 17 mo. Patients required 1-2 sessions of APC for mild proctitis while patients with moderately to the severe form required a statistically significantly higher number of APC sessions. In cases of severe and diffuse involvement of the rectum, multiple treatments sessions are required, and success is less certain as shown by other reports also^[43-51]. In many of these series, the response is objectively scored using bleeding severity score, haematological parameters, and endoscopic scores.

Chrusciewska-Kiliszek *et al*^[52] in their randomized, double-blind trial comparing oral sucralfate or placebo following APC for CHRP have shown that additional sucralfate treatment after APC did not influence the clinical or endoscopic outcomes. One hundred and seventeen patients completed the treatment protocol, 57 in the sucralfate group and 60 in the placebo group. Patients were graded clinically and endoscopically according to the Chutkan and Gilinski scales before and at 8 and 16 wk after initial APC treatment (1.5-2 L/min, 25-40 W) and after 52 wk (clinical only)^[52]. Complications (1%-15%) following APC, such as pain, ulceration, perforation, explosion, extensive necrosis and rectal stricture have been cited in the literature^[42].

STUDIES USING RADIO-FREQUENCY ABLATION

There are more than five reports of case series and retrospective studies using radio-frequency ablation (RFA) for CHRP. Many case series have shown, using BARRx Halo90 electrode catheter that was fit on the

distal end of the flexible sigmoidoscope, an energy density of 12 J/cm² at a power density of 40 W/cm², hemostasis could be obtained after 1 to 2 sessions^[53-56].

Several benefits RFA have been claimed, these include squamous re-epithelialization, lack of stricturing and ulceration. Using RFA much broader area of tissue can be treated simultaneously compared to the point by point approach by other methods^[37]. The radio-frequency unit is mobile and can be used in different rooms of an endoscopy unit. Zhou *et al*^[54] have used real-time endoscopic optical coherence tomography (EOCT) to visualize epithelialization and subsurface tissue microvasculature pre- and post-treatment RFA in their case series and have shown the potential of EOCT for follow-up assessment of endoscopic therapies.

STUDIES USING CRYOABLATION

Cryoablation is similar to APC and involves the non-contact application of liquid nitrogen or carbon-dioxide to tissues for superficial ablation. It is possible to treat a larger surface area like in RFA. Its effect is due to ischemic necrosis which can be immediate or delayed.

There are only case series of 20 patients. During cryoablation, a decompressive rectal tube has to be inserted because of the risk of over insufflation and perforation. Cryotherapy units are less mobile. Unlike in Radiofrequency ablation, the depth of tissue penetration may be more here. This may lead to strictures. However, colonic lavage is not necessary since there is no risk of explosion. The number of required sessions range from one to four^[57-59].

STUDIES USING HYPERBARIC OXYGEN THERAPY

There are more than 12 published studies using hyperbaric oxygen therapy (HBOT) for CHRP. New reports have started appearing in the literature regarding the efficacy of HBOT.

Clark *et al*^[60] in their randomized controlled double-blind crossover trial (150 patients) with a long-term follow-up, up to 5 years, showed that in patients with refractory CHRP, HBOT had a significant healing response. Primary outcome measures involved were the late effect in normal tissue-subjective, objective, management, analytic (SOMA-LENT) score and standardized clinical assessment. The secondary outcome was the change in the quality of life^[60].

In one of the largest Australasian study using HBOT for chronic radiation injuries, Tahir *et al*^[61] showed a clinical response rate for CHRP of 95%, where around half of the cases had a durable major response, with some patients experiencing symptom relief lasting as long as seven years.

At pressure greater than atmospheric pressure and using 100% oxygen, HBOT has an angiogenic effect and has been shown to cause an eight to nine-fold increase

in the vascular density of soft tissues over air-breathing controls^[7]. HBO acts to stimulate collagen formation and re-epithelialization. There is no uniformity in the methods of treatment using HBOT^[42,61-65]. Although it can be perceived from the studies that HBOT is useful in refractory radiation proctitis, there is marked variation between the studies. There are no major adverse effects. Minor adverse event recorded is transient aural barotrauma. The reported number of HBOT sessions for a successful treatment range from 12 to 90. The cost of HBOT is high, and hence, it is not widely applicable.

Other interventions

Oxidative stress is thought to be one of the mechanisms in the development of chronic radiation proctitis and antioxidants have been used to treat CHRP. Use of vitamin C and E have been reported. Kennedy *et al*^[66] treated twenty consecutive patients with CHRP. They used a combination of vitamin E at a dose of 400 IU tid and vitamin C at a dose of 500 mg tid. They assessed the response by symptom index and lifestyle questionnaire. A good number of study patients in the study seem to benefit. This pilot study was not studied further.

Retinol palmitate (vitamin A) has been shown to increase wound healing because of increased collagen cross-linking. This has been used in a randomized study to show improvement of symptoms of chronic radiation proctopathy by Ehrenpreis *et al*^[67]. They randomized 19 patients, 10 patients to retinol palmitate group and nine to the placebo group. Five placebo nonresponders were crossed over to the retinol palmitate. The RPSAS scores before and every 30 d for 90 d were measured. The definition of response was a reduction in two or more symptoms or by at least two RPSAS^[67]. There was a significant improvement in symptoms in the treatment group compared with the control and also when the controls were crossed over to treatment. But the study was underpowered.

Surgical interventions

Surgery is the last resort in patients with CHRP. Around 10%-25% of patients with CHRP finally need surgery^[68]. Intractable bleeding, perforation, stricture, and fistula are some of the indication for surgery in patients with chronic radiation proctitis. There are case reports of non-surgical dilatation for strictures for this condition^[69]. Significant improvement of bleeding by diversion has been shown by one of the retrospective study^[70]. Fistula with the adjacent structures may need resection or resection with reconstruction with a diverting stoma. Whenever surgical treatment became a necessity, studies report poor outcomes with high complications (15%-80%) and mortality (3%-9%)^[70-73]. Since nonoperative interventions are commonly used nowadays in managing patients with CHRP, There are no recently published series on surgical interventions on this issue.

Discussion

Evidence-based medicine requires the systematic and critical evaluation of published and unpublished trials^[74]. In 2002, when Denton *et al*^[7] first published their systemic review of the non-surgical intervention of late radiation proctitis, they could identify only six randomized controlled trials. The majority of the evidence available was either one individual's or one center's experience with a specific intervention without comparison to a control or another agent. This is probably due to the low incidence of chronic radiation proctitis in the majority of centers and the difficulties that co-exist in compiling a series large enough to be randomized between therapies^[34].

Thirteen years later we could identify a total of 14 randomized controlled trials treating 804 patients with CHRP. In many of these studies, we could get the details of the reason for radiation therapy and the dosage. The diagnosis was based on the history and the endoscopic findings. At present, there is no validated score for CHRP, which can be used universally for grading the severity. There can be the inter-observer difference of the same findings. Tissue biopsy may not be conclusive. Patients may not tell their exact symptoms unless directed questions are asked. The severity of the radiation proctitis was graded in many of the studies objectively using symptoms score like RPSAS^[1,67] or LENT-SOMA scale^[32,60] and intraluminal findings by the sigmoidoscopic or colonoscopic grade (modified Chi grading^[1] or Chutkan and Gilinski scales^[52]). But different studies used different severity scores and hence the inter-institutional comparison of data is still difficult. The same is true with the outcome measures. Yeoh *et al*^[32] have tried to see the rectal functions as well as morphology by using anorectal manometry and endorectal ultrasound. Zhou *et al*^[54] have shown the most efficient objective assessment of the response to treatment by using EOCT. There were only a few studies that surveyed the quality of life following treatment^[36,60]. However, unlike the previous studies, follow-up of recent studies is fairly long and is usually more than 9 to 12 mo^[1,33,36,52,60]. With these randomized trials it is possible to say that there is evidence to make the following judgments: (1) Sucralfate enema appears to have a better effect than anti-inflammatory agents; (2) Anti-inflammatory drugs appear to have a better effect if used with oral metronidazole; (3) Rectal hydrocortisone appears to have a better effect than rectal betamethasone; (4) Sucralfate-steroid retention enema and short chain fatty acid enema are both equally but moderately effective in treating CHRP, but sucralfate-steroid enema is easy to prepare; (5) Four percent formalin is more effective than sucralfate-steroid retention enema and can be effective in 99% of the patients of CHRP; (6) Four percent formalin should be preferred over 10% formalin in treating patients with CHRP since 10% formalin is likely to cause adverse events; (7) Heater probe and bipolar

cautery are equally effective in treating patients with CHRP; (8) Both APC and formalin don't improve the rectal dysfunction but only stop the bleeding; (9) Both APC and formalin are equally effective, but formalin may be better in severe disease; (10) Additional oral treatment after APC will not improve the outcomes; (11) Radiofrequency ablation is a promising upcoming modality of treating CHRP but more robust data in the form of randomized trials needed; (12) HBOT is the only treatment modality, currently, which addresses the underlying problem and effective in treating CHRP patients but is costly and available in a few centers; (13) Vitamin A and other modalities have to be kept in mind while treating these patients since some report shows its efficacy. Further trials and robust data needed to show its efficacy; and (14) Surgical intervention is to be kept as a last resort in patients not responding to any of the methods described above.

Looking at the available evidence, it is clear that there is some improvement in the methodology of these studies. There is an objective assessment of symptoms and signs and also the objective assessment of the outcomes in some of these studies. The major drawback is that the objective assessment is not uniform, different studies using different scores. Also, not much importance is given to the quality of life assessment following treatment. It has been felt by the previous reviewers that one study, even if well conducted, will not be able to modify the changes in practice^[7]. It has been felt by Denton *et al*^[7] that in order to increase recruitment to trials a national registry of CHRP cases would facilitate multicenter trials with uniform entry criteria, uniform baseline and uniform therapeutic assessments providing standardized outcome data^[75].

Limitations of this review: The search was limited to PubMed/Medline, Google and Google Scholar and was not complete and was limited to English language journals only. Individual authors were not contacted.

CONCLUSION

Based on this evidence, it can be concluded that the first line treatment of a patient with CHRP, the most effective way of treating CHRP, should be 4% formalin application. Since it is cheap, easily available, can be applied easily and effective in 99% of the patients. If the radiation proctitis extends beyond rectum, then APC will be a better alternative. Alternatively, both formalin and APC can be used as complementary methods. Those patients who are refractory to formalin or APC may be referred for treatment with HBOT. In centers where radiofrequency ablation is available, further randomized studies should be done to see the efficacy of it in treating patients with CHRP. Those patients with CHRP who do not respond to any of the modality may need surgery in the form of diversion colostomy. Those patients with CHRP presenting with complications like stricture, fistula or other complications like obstructions may need surgery at presentation.

Abstract

AIM: To compare the outcomes of a cohort of Crohn's disease (CD) patients undergoing early surgery (ES) to those undergoing initial medical therapy (IMT).

METHODS: We performed a review of a prospective database CD patients managed at a single tertiary institution. Inclusion criteria were all patients with ileal or ileocolonic CD between 1995-2014. Patients with incomplete data, isolated colonic or perianal CD were excluded. Primary endpoints included the need for, and time to subsequent surgery. Secondary endpoints included the number and duration of hospital admissions, and medical therapy.

RESULTS: Forty-two patients underwent ES and 115 underwent IMT. The operative intervention rate at 5 years in the ES group was 14.2% *vs* IMT 31.3% (HR = 0.41, 95%CI: 0.23-0.72, $P = 0.041$). The ES group had fewer hospital admissions per patient [median 1 *vs* 3 ($P = 0.012$)] and fewer patients required anti-TNF therapy than IMT (33.3% *vs* 57%, $P = 0.003$). A subgroup analysis of 62 IMT patients who had undergone surgery were compared to ES patients, and showed similar 5 year (from index surgery) re-operation rates 16.1% *vs* 14.3%. In this subset, a significant difference was still found in median number of hospital admissions favouring ES, 1 *vs* 2 ($P = 0.002$).

CONCLUSION: Our data supports other recent studies suggesting that patients with ileocolonic CD may have a more benign disease course if undergoing early surgical intervention, with fewer admissions to hospital and a

trend to reduced overall operation rates.

Key words: Crohn's disease; Surgery; Inflammatory bowel disease; Terminal ileitis; Operation

Core tip: This study supports the growing body of evidence that asserts that selected patients with ileocolonic Crohn's have reduced requirement for medical therapy and a trend to fewer surgical interventions. Expanding on the evidence, this study also demonstrated fewer admissions to hospital for Crohn's disease related illness.

INTRODUCTION

Surgery is often an integral part of the management algorithm for patients with Crohn's disease (CD), with up to 20%-40% requiring surgery within in their first year^[1-4] and up to 80% at some time during their disease^[5]. As a chronic condition with a relapsing remitting course, surgery does not provide cure, but is an adjunct for the management of acute complications of penetrating and stricturing disease and also after maximal medical therapy fails to control disease or presents unacceptable side effects. Advances in medical therapy have seen a reduction in long-term steroid use and longer disease remission. Despite these advances older studies suggest no reduction in the proportion of patients requiring surgery. In a retrospective series, Cosnes *et al*^[6], reported that 35% patients required surgery at 5 years, which was the same as historical cohorts.

However, the advent of biologic agents has significantly influenced the clinical course of patients of CD and also surgical decision-making. ACCENT 1 reported higher clinical remission (OR = 2.7) in patients receiving maintenance infliximab compared with placebo^[7]. Similar findings have been reported for Adalimumab with higher rates of clinical remission compared with placebo (36% vs 12%)^[8]. Additionally in a report from the Nationwide Inpatient Sample in the United States, rates of surgical intervention have fallen from 17.3% in 1997 to 12.4% in 2007^[9].

Contention exists in the literature regarding the optimal timing of surgery in the management algorithm of CD, particularly in patients with short segment disease where resection of all macroscopic disease is feasible. Some evidence suggests that early surgery (ES) in CD may lead to a longer time to clinical recurrence^[10]

and lower long-term reoperation rate (14% at 5 years) compared with later surgery (30% at 5 years)^[11]. Additionally, ES cohorts are reported to have reduced requirements for steroids and immunosuppression^[3,11]. This study aims to determine whether patients who have ES for ileal or ileocolonic CD run a more benign clinical course, as determined by the need for fewer operations, hospital admissions and the ongoing medical therapy required for disease control than those managed with conventional medical therapy.

MATERIALS AND METHODS

This study is a cohort comparison study between patients who underwent ES compared with those that underwent initial medical therapy (IMT). We examined a consecutive series of patients with ileal and ileocolonic CD managed at a major metropolitan teaching hospital from 1995 to 2014. Data were extracted from a clinical IBD database within the IBD service at the Royal Adelaide Hospital. This database was prospectively maintained from 2007, and prior to this, data were sourced from case notes review. Additional data were collected from review of medical records and pathology records.

ES was defined as patients who have undergone upfront surgery for CD due to an acute complication and those who underwent surgery within 6 mo of their diagnosis of CD. This arbitrary time frame was chosen as within this time period there is limited scope to have established of medical therapy. Acute complications included abdominal pain with peritonism, obstruction, perforation or fistulisation. The IMT cohort included patients with a histological or clinical diagnosis of CD made after 1995 referred to our health service who have undergone at least 6 mo of medical therapy. Patients diagnosed prior to this date were excluded. Patients in this cohort who went on to require bowel resection for their disease were also identified for a subgroup analysis and considered to have deferred surgery (DS).

Data collected included patient demographics, disease phenotype according to the Montreal classification^[12], medical and surgical therapy. The primary endpoint for each patient was need for subsequent surgical resection. Secondary endpoints were the number of hospitalizations and days in hospital over the duration of their disease. All inpatient care data (number of admissions and total length of stay) were captured by a statewide computer database, which records admissions to all public hospitals within the state in this period.

Inclusion criteria were patients with ileal or ileocolonic CD, with or without perianal involvement. Patients with isolated colonic or isolated perianal CD or those with incomplete records were excluded.

Data regarding patients' medical therapy for CD were collected, but due to the retrospective nature of

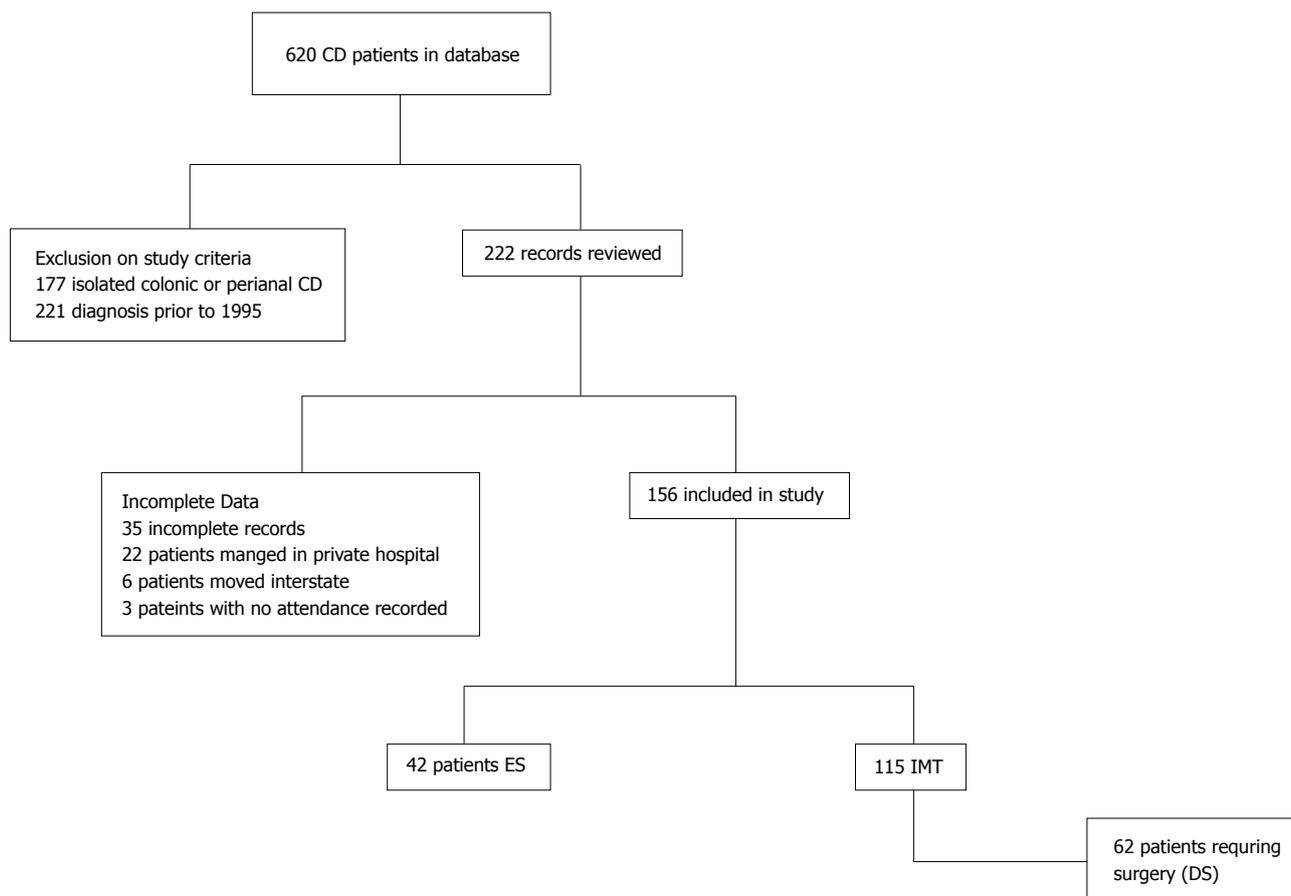

Figure 1 Consort diagram. ES: Early surgery; IMT: Initial medical therapy; DS: Deferred surgery; CD: Crohn's disease.

the database prior to 2007, the accuracy of fine details such as time course, dose and duration of therapy could not be assured. Consequently, medical therapies received by each patient are reported as a categorical outcome, described by type of treatment (none, steroid, immunosuppressive or biologic therapy).

This project was reviewed and approved by the Royal Adelaide Hospital Human Research Ethics committee. As this was a clinical audit, individual patient consent was not necessary and not sought. Data were tabulated in a Microsoft Excel™ spreadsheet. Statistical analyses were performed utilizing SPSS™ ver. 22. Differences between groups were compared using the χ^2 test for categorical data, and ordinal data were compared using the Student's *t*-test or Mann-Whitney-*U* test for non-parametric distributions. To determine a difference in time to further surgery between groups, Kaplan-Meier analyses were performed and differences tested using the Mantel-Cox log rank test.

RESULTS

A total of 620 patients with CD were identified on the database. Exclusions are shown on a consort diagram (Figure 1). A total of 157 patients met inclusion criteria and were included in the study. There were 42 patients in the ES cohort, who either presented with

an acute complication requiring emergency surgery or underwent an operation within 6 m of diagnosis due to a progression or complication of CD. The remaining 115 patients were treated with IMT, 62 (53.9%) of whom underwent surgery by the end of the study period (DS).

Demographics of the cohorts are shown in Table 1. Patients in the ES group were significantly older with a median age at diagnosis of 34.5 years (24-45) compared to 24 (19-33) in the IMT group ($P = 0.0001$) and a shorter duration of disease (ES 5.6 years, IMT 8.9, $P = 0.014$). Not surprisingly, ES patients were more likely to have a stricturing or penetrating phenotype than IMT patients. The DS cohort, who were medically treated patients who went on to have a resection, had the same proportion of patients with penetrating and stricturing disease (B2 and B3), 38.7% and 54.8% respectively as the ES patients (40.5% and 52.4% respectively $P = 0.968$). There was also a significant difference in disease location, with a higher proportion of L3 disease compared to L1 disease and subsequently in the proportion of patients with perianal disease in the IMT cohort.

Table 2 outlines the mode of presentation of patients requiring ES. Over half the ES cohort presented with either acute obstruction or perforation necessitating emergency surgery and data was unavailable for 5 patients in this cohort. In contrast, of the patients in

¹Patients in the DS group are a subset of IMT patients. IMT: Initial medical therapy; DS: Deferred surgery; IQR: Interquartile range; M: Male; F: Female.

Table 2 Indications for early surgery *n* (%)

Clinical details	Early surgery (<i>n</i> = 42)	Deferred surgery (<i>n</i> = 62)
Indication for surgery		
Acute obstruction - emergency resection	9 (21.4)	4 (23.0)
Subacute obstruction - elective resection	-	20 (32.3)
Perforation	15 (35.7)	7 (11.3)
Fistula/phlegmon	5 (11.9)	15 (24.2)
Abdominal pain	5 (11.9)	2 (3.2)
Haemorrhage	3 (7.1)	-
Not specified	5 (11.9)	14 (23.0)

the DS cohort, 11 patients presented with an acute complication necessitating emergency surgery despite upfront medical therapy, 4 with acute obstruction and 7 with perforation. Thirty-five (56.5%) of the DS cohort required surgery due to progression in obstructive symptoms (6.5%) or fistula formation (24.2%).

The number of patients in each cohort requiring surgical resection, hospital admission and medical therapy is shown in Table 3. The proportion of patients requiring subsequent resection at 5 years was significantly lower in the ES group compared with the IMT group (14.2% vs 31.3%, $P = 0.041$). Of note though, 57.3% of IMT patients required no surgery. Endpoints for the DS subgroup of patients were determined from the time of their index operation, allowing a fairer comparison to the ES group, as the two cohorts have all undergone one operation. The rate of subsequent surgery in the subgroup of 62 DS patients was 16.1%, which was not significantly different to the ES cohort. The median duration of between diagnosis and index operation in the DS cohort was 46.4 mo (IQR 23-97). The extent of resection and need for stoma were similar in each group and shown in Table 4.

The ES group had a higher estimated proportion of patients not having a subsequent resection at 10 years than those having IMT (Figure 2) (83.7% vs 52.7%; $P_{\text{Log-rank}} = 0.0001$). The comparison of ES to DS groups is

shown in Figure 3 with an estimated probability of no subsequent surgery at 10 years of 83.7% and 43.7% ($P_{\text{Log-rank}} = 0.032$) respectively.

The median number of hospital admissions differed between the two groups, with the ES group having fewer admissions than each of the IMT and DS patients (ES 1 vs IMT 3, $P = 0.012$) and vs (DS subset 2, $P = 0.002$). The median number of days in hospital over the duration of each patients' disease did not differ significantly between the groups. However, this includes the index admission for surgery in the ES cohort.

Rates of immunomodulator and steroid use were similar when comparing the ES group to both IMT and DS cohorts. The proportion of patients receiving biologic therapy was significantly lower in the ES cohort than those having IMT (ES 33.3% vs IMT 60.0%, $P = 0.004$) and also the DS subgroup (ES 33.3% vs DS 67.7%, $P = 0.001$). The proportion of patients requiring no treatment for their disease differed between the groups (ES 23.8% vs IMT 4.3% vs DS 0%, $P < 0.0001$).

DISCUSSION

CD remains a challenging chronic condition where there has been a progressive evolution in the positioning and roles of medical and surgical therapy. Our study has found that 31.3% of patients initially managed with medical therapy will come to surgery within 5 years, in line with other studies^[2,4,6,13]. This is significantly higher than the 5 year subsequent resection rate of those patients undergoing ES (14.2%).

An alternative interpretation of our data is that 68.7% of patients undergoing medical therapy avoided the need for surgery altogether within a 5 year period. However, the IMT cohort likely represented a less aggressive phenotype of CD as demonstrated by lower rates of stricturing and penetrating disease in this group compared with the ES group. The IMT patients who have had subsequent surgery (DS), had a similar phenotype to the ES group and comparison between

Figure 3 Cumulative event curve: Time to further surgical resection in early surgery vs deferred surgery.

these two groups may be more relevant. Indeed at 5 years, similar numbers had had further resection (ES 14.2% vs DS 16.1%), even a trend to higher rates of surgery in the DS group by the end of the study (ES 16.7% vs DS 32.3%). The estimated proportion of patients not requiring subsequent surgery at 10 years for the ES and DS groups were 83.7% and 43.7% respectively. These findings are similar to reports by Golovics *et al*^[3] and Latella *et al*^[11], which give validation to these results across different healthcare settings in different countries.

This is the only study to the authors' knowledge that additionally examined inpatient healthcare utilization (hospital admissions and length total cumulative of stay) as an endpoint in comparing ES and IMT. The ES patients had fewer hospital admissions for the duration of their disease than IMT patients and the subset of DS patients [ES 67, IMT 107, DS 50 (median, months)] suggesting disease control may be better in the ES group. However a conservative interpretation of this is necessary given the longer follow-up and higher incidence of L3 and perianal disease in the IMT group.

What is difficult to quantify in the literature is the health related quality of life (HRQOL) of medically managed patients. There is a paucity of data in the literature examining this, whilst more surgical data exist with Thirlby *et al*^[14] reporting an improvement in 7 of 8 domains in HRQOL at 12 mo after surgical resection. Casellas *et al*^[15] reported significant differences in HRQOL scores between patients with active disease and those in disease remission. Such assessments at diffe-

rent time intervals of the two cohorts would be valuable in determining the true effect of ES and whether early resection conferred an improvement in quality of life and disease control.

We did not find a difference in steroid use between the groups, unlike Aratari *et al*^[10], who reported a need for corticosteroid therapy in 39.8% of ES patients compared with 62.1% of medically treated CD at 5 years. The similar rates of immunomodulator use we observed in ES and IMT patients, 76.2% and 87.8% respectively, are in line with current evidence supporting pro-active tailored post resection therapy to reduce clinical and endoscopic recurrence^[16-18].

Immune modulators and biologic agents have added to the armamentarium of medical therapy for CD. Careful consideration should be given regarding the timing of surgery in patients with ileal CD, especially where there is a stricturing or penetrating phenotype, and this should be balanced against the aggressive pursuit of medically induced clinical remission. This balance of medical therapy and surgery may best be achieved in a multidisciplinary environment involving gastroenterologists, surgeons and radiologists. Patients with CD are now often coming to surgery on at least an immunomodulator, and in our cohort 67.7% on a biologic agent. Recent systematic reviews reported an increase in the post-operative, infective and anastomotic complications in patients on anti-TNF α agents^[19,20] which lends further weight for considering earlier surgery.

It is clear that biologic agents improve rates of clinical remission and HRQOL scores in the short

term^[21-23]. Long term it is unclear whether they alter disease course. Disease recurrence rates at 5 years were reported at 36.6% with infliximab therapy^[24] suggesting that for some the response is short lived for some patients. Resection rates in the literature are contradictory, with some studies reporting a decline in surgical resection^[24,25], whilst others have reported no change despite increasing use of biologic agents^[6,26-28], which may reflect the use of biologic agents at a later stage in the disease process where fibrosis and scarring predominate over inflammation, reducing their efficacy.

It is worth noting that the European evidence based consensus from the European Crohn's and Colitis Organization recommends resection for patients with ileocolic disease with obstructive symptoms^[29]. Silverstein *et al.*^[30] reported on the high costs associated with surgical intervention, accounting for 44% of the total lifetime health costs (USD17562) in a patient with CD, but also that it offered the longest remissions. However, this study pre-dates the widespread use of biologic agents and the high costs associated with them. A Canadian study estimated a direct health care cost of USD21416 per patient for the first year of Infliximab treatment^[31]. No formal cost analysis was performed, however, given the lower proportion of patients requiring medical therapy in the ES cohort, the cost effectiveness of ES vs IMT should be explored as, notably 23.8% of the ES cohort avoided the need for ongoing medical therapy altogether.

There are naturally limitations to any retrospective analysis, which prevent strong conclusions being drawn. However, a study prospectively randomizing to early and DS would be difficult to conduct, require long follow up and may not be ethically acceptable. We therefore need to examine real world data such as these whilst taking account of possible sources of bias. Data was not available regarding short term complication rates of surgery and medical therapy so not included in this study. We have used the emergency operation for an acute complication as a surrogate for ES. The phenotypes of the two cohorts are different, however, we feel that the ES group had generally a more aggressive phenotype given then higher proportion of penetrating and stricturing disease presenting with an acute complication requiring resection at index presentation. The younger patients higher proportion of L3 disease in the IMT group reflects a real world cohort with potentially multifocal disease in whom the treating team have adopted medical therapy upfront. However we still believe the groups are comparable as, despite this, the type of surgery and extent of bowel resection are similar between the ES and medically treated cohorts. Our definition of ES is arbitrary, but in six months medical therapy is unlikely to be established. Being a tertiary centre, there is a potential for a referral bias, with less complex disease managed at regional centres.

Our study lends weight to the argument that in

selected patients with stricturing or penetrating ileocolonic CD, those undergoing ES may have a more benign disease course, possibly with less need for further surgical intervention and fewer hospital admissions for CD related illness. This is perhaps even more meaningful, given that a significant number of these patients present with aggressive phenotypes requiring ES. Surgery should not be considered as treatment of last resort after all medical therapy has failed. Rather a more considered approach to the timing of resection for symptomatic patients is needed, possibly to achieve longer periods of disease remission with reduced drug exposure and costs to health care.

COMMENTS

Background

Despite the advances in medical therapy for patients Crohn's disease (CD), from the introduction in immunomodulatory agents and biologic agents targeting TNF- α , there has been minimal decline in the rate of surgical resection in these patients. There is evidence in support of an aggressive "top-down" strategy, utilizing more effective agents earlier in the disease course such as the immunomodulators and biologic agents to control the inflammatory process and prevent progression. It must be considered whether a more aggressive approach still, with early surgery (ES) in selected patients may further improve outcomes in these patients.

Research frontiers

The authors in selecting patients with symptomatic ileo-colonic CD, undertaking early surgical resection prior to starting medical therapy for their CD may confer a benefit in the long term, regarding the need for further surgery reduced requirement for medical therapy in maintaining control of their disease.

Innovations and breakthrough

This study supports evidence in the literature that ES may confer a benefit in selected patients with CD, as patients required fewer admissions to hospital, spent fewer total days in hospital by the end of this study period in spite of the inclusion of their index admission for their acute presentation and operation. In addition, the authors found a longer time duration between their index operation and their subsequent operation when compared to those undergoing initial medical therapy.

Applications

Decision making in the management of patients with CD is complex and best undertaken in a multidisciplinary setting. Traditionally surgery has been reserved as an act of last resort. This study suggests a bolder approach may be of benefit in symptomatic patients with ileal or ileocolonic disease.

Peer-review

It is a study about an interesting topic in CD: The effectiveness of ES in avoiding CD recurrence.

Abstract**AIM:** To compare outcomes of patients with non-variceal upper gastrointestinal bleeding (NVUGIB) taking aspirin for primary prophylaxis to those not taking it.**METHODS:** Patients not known to have any vascular disease (coronary artery or cerebrovascular disease) who were admitted to the American University of Beirut Medical Center between 1993 and 2010 with NVUGIB were included. The frequencies of in-hospital mortality, re-bleeding, severe bleeding, need for surgery or embolization, and of a composite outcome defined as the occurrence of any of the 4 bleeding related adverse outcomes were compared between patients receiving aspirin and those on no antithrombotics. We also compared frequency of in hospital complications and length of hospital stay between the two groups.**RESULTS:** Of 357 eligible patients, 94 were on aspirin and 263 patients were on no antithrombotics (control

group). Patients in the aspirin group were older, the mean age was 58 years in controls and 67 years in the aspirin group ($P < 0.001$). Patients in the aspirin group had significantly more co-morbidities, including diabetes mellitus and hypertension [25 (27%) *vs* 31 (112%) and 44 (47%) *vs* 74 (28%) respectively, ($P = 0.001$)], as well as dyslipidemia [21 (22%) *vs* 16 (6%), $P < 0.0001$]. Smoking was more frequent in the aspirin group [34 (41%) *vs* 60 (27%), $P = 0.02$]. The frequencies of endoscopic therapy and surgery were similar in both groups. Patients who were on aspirin had lower in-hospital mortality rates (2.1% *vs* 13.7%, $P = 0.002$), shorter hospital stay (4.9 d *vs* 7 d, $P = 0.01$), and fewer composite outcomes (10.6% *vs* 24%, $P = 0.01$). The frequencies of in-hospital complications and re-bleeding were similar in the two groups.

CONCLUSION: Patients who present with NVUGIB while receiving aspirin for primary prophylaxis had fewer adverse outcomes. Thus aspirin may have a protective effect beyond its cardiovascular benefits.

Core tip: Aspirin is known to increase the risk of upper gastrointestinal bleeding (UGIB), and it is customary to stop aspirin in patients presenting with gastrointestinal bleeding. Some studies have shown that being on aspirin is associated with better outcome in those patients. Our study compared clinical outcomes in patients who presented with non-variceal UGIB while taking aspirin for primary prophylaxis only to those of patients not taking aspirin. We found that patients taking aspirin had lower mortality and shorter hospital stay than patients not taking aspirin.

Souk KM, Tamim HM, Abu Daya HA, Rockey DC, Barada KA. Aspirin use for primary prophylaxis: Adverse outcomes in non-variceal upper gastrointestinal bleeding. *World J Gastrointest Surg* 2016; 8(7): 501-507 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i7/501.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i7.501>

INTRODUCTION

Aspirin is being used widely in primary and secondary prevention of cardiovascular diseases, and it is taken by more than 25%-33% of people older than 65 years^[1]. In addition, both individual studies and meta-analysis of trials of anti-platelet therapy indicate that aspirin and other anti-platelet drugs reduce the risk of serious vascular events by approximately 25%^[2].

Despite its cardiovascular protection, aspirin is associated with a 2 fold increase in risk of upper gastr-

ointestinal bleeding (UGIB)^[3]. However, most studies suggest that aspirin decreases mortality and hospital stay in patients with non-variceal upper gastrointestinal bleeding (NVUGIB)^[4,5], while some report no significant effect^[6].

We recently reported that being on aspirin on presentation confers protection against mortality and morbidity in peptic disease related-UGIB^[7], and in patients with NVUGIB overall^[8]. We also reported that in-hospital mortality from cardiovascular causes in patients taking aspirin was similar to controls. Hence, it is not clear if the protective effect of aspirin is due to its known cardiovascular benefits. This study aims to determine if the protective effect of aspirin in NVUGIB persists in patients with no known cardiovascular or cerebrovascular disease. This is done by comparing clinical outcomes in patients presenting with NVUGIB while receiving aspirin as primary prophylaxis to those who are not taking it.

MATERIALS AND METHODS

This was a retrospective cohort study of patients admitted to American University of Beirut Medical Center (AUBMC) with NVUGIB between 1993 and 2010. AUBMC is a tertiary referral medical center that provides health care for around 1.5 million people in Lebanon.

The study was approved by the Institutional Review Board of AUBMC (IM.KB.09).

Inclusion and exclusion criteria

In this study we included all patients who were admitted with hematemesis, coffee ground vomiting, and/or melena in the presence of an identified source of UGIB site on upper gastrointestinal endoscopy^[7]. We also considered patients with hematochezia to have UGIB if upper endoscopy showed a source of bleeding and colonoscopy was negative. For patients who didn't have endoscopy, we classified patients as having UGIB if they had coffee ground emesis, hematemesis or melena.

We excluded all patients who presented with melena and/or hematochezia who had a colonic source of bleeding. Patients who met the criteria of UGIB from esophageal/gastric varices and those who had occult gastrointestinal or small bowel bleeding were excluded.

We also excluded all patients with documented history of coronary artery disease, cerebrovascular accident/transient ischemic attack (TIA), peripheral vascular disease, and those on any non-aspirin anti-platelets or anticoagulants.

Data collection

Medical records of patients with signs and symptoms of UGIB were reviewed, using the ICD-9/ICD-10 coding system (codes for the following symptoms: UGIB, melena, hematochezia, hematemesis, coffee ground emesis). The data was collected from charts using a standardized data collection form. During chart review,

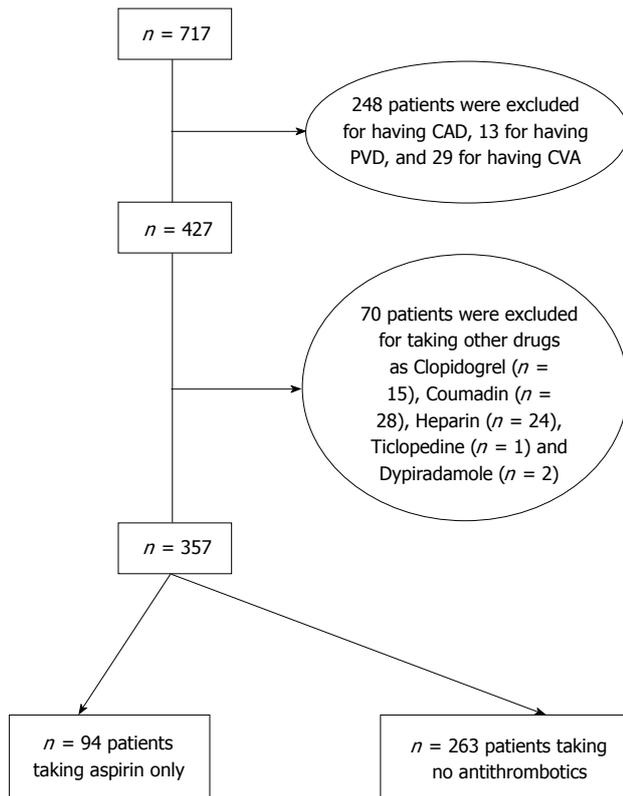

Figure 1 The flow and inclusion/exclusion criteria of patients with non-variceal upper gastrointestinal bleeding in the study. CAD: Coronary artery disease; PVD: Peripheral vascular disease; CVA: Cerebrovascular accident.

we extracted the following information: Patient's age, sex, comorbid conditions (hypertension, diabetes mellitus, renal insufficiency, dyslipidemia, active systemic or gastrointestinal cancer, congestive heart failure, valvular heart disease, atrial fibrillation and deep vein thrombosis); mode of clinical presentation; duration of bleeding; vital signs and initial blood studies obtained upon arrival to the emergency room including complete blood count, international normalized ratio (INR), and prothrombin time; management in the emergency room and the hospital including blood transfusion. We also recorded findings on diagnostic upper gastrointestinal endoscopy and the source of bleeding; type of therapeutic endoscopic procedure undertaken whenever applicable; angiography and embolization, surgical treatment and in hospital mortality. The frequency of the following outcomes were determined: In-hospital mortality, need for surgery, severe bleeding (hypotension with a systolic blood pressure < 90 mmHg on admission, tachycardia with heart rate > 119 beat/min, or transfusion of more than 3 units of packed red blood cells), re-bleeding (re-bleeding after 24 h from the initial endoscopic evaluation) and therapy (recurrence of bleeding within 1 mo from discharge was also considered rebleeding), in-hospital complications including myocardial infarction, angina, deep vein thrombosis, pulmonary embolism, stroke, TIA, pneumonia, urinary tract infection, skin infections, sepsis, acute respiratory distress syndrome,

renal failure, need for mechanical ventilation, and disseminated intravascular coagulopathy; duration of hospitalization, need for blood transfusion, and number of blood units transfused were also recorded. The primary outcome was in-hospital mortality. The secondary outcomes included re-bleeding, severe bleeding, need for surgery or embolization, and the occurrence of any bleeding related composite outcome defined as the occurrence of any of the following: In hospital mortality, re-bleeding, severe bleeding, need for surgery or embolization^[7]. We also compared in hospital complications and length of hospital stay. We divided the patients into two main groups: Those who were on aspirin upon presentation, and those who were not. We compared all the characteristics and outcomes listed above between the two groups.

Statistical analysis

Data management and analysis were carried out using the Statistical Analysis Software (SAS, version 9.1). Descriptive analyses were carried out by calculating the numbers and percent for categorical variables, and the mean and standard deviation SD for the continuous ones. Bivariate analyses were performed using the χ^2 test or the independent student *t*-test, as appropriate.

To control for the effect of potentially confounding variables, multivariable analyses were carried out while controlling for different risk factors. For categorical outcomes multivariate logistic regression analyses were carried out where the OR, 95%CI, and *P*-value were reported. On the other hand, for continuous variables multivariate linear regression was carried out where the β -coefficient, 95%CI, and *P*-value were reported. Variables included in the regression model were those of either statistical or clinical significance. A *P* value < 0.05 indicates statistical significance.

RESULTS

Subjects

A total of 1175 patients were admitted with acute gastrointestinal bleeding between 1993 and 2010. Out of the 1175 patients, 717 patients had NVUGIB, of which 357 were included in this study. A total of 94 patients were on aspirin only and 263 patients were on no antithrombotics (control group, Figure 1).

Demographics and clinical characteristics

The mean age was 58 years in controls and 67 years in the aspirin group ($P < 0.001$). Most patients were males. Patients on aspirin were more likely to have diabetes mellitus and hypertension [25 (27%) vs 31 (112%) and 44 (47%) vs 74 (28%) respectively, ($P = 0.001$)], as well as dyslipidemia [21 (22%) vs 16 (6%), $P < 0.0001$]. Smoking was more frequent in the aspirin group [34 (41%) vs 60 (27%), $P = 0.02$] (Table 1).

Controls had a higher prevalence of cancer (20.9% vs 6.4%, $P < 0.001$) and were more likely to have a history of peptic ulcer disease. The use of PPI was

Table 1 Clinical characteristics of patients with non-variceal upper gastrointestinal bleeding in both groups *n* (%)

Group	No anti-thrombotics <i>n</i> = 263	Aspirin <i>n</i> = 94	<i>P</i> value
Age mean (SD)	58.4 (19.1)	66.8 (13.1)	< 0.001
Male gender	169 (64.3)	71 (75.5)	0.05
Smoking	60 (27.0)	34 (41.0)	0.02
Diabetes mellitus	31 (11.8)	25 (26.6)	0.001
Hypertension	74 (28.1)	44 (46.8)	0.001
Dyslipidemia	16 (6.1)	21 (22.3)	< 0.0001
Cancer	55 (20.9)	6 (6.4)	0.001
NSAIDS	47 (17.9)	16 (17.0)	0.85
PPI	29 (11.0)	4 (4.3)	0.05
History of peptic ulcer disease	69 (26.2)	13 (13.8)	0.01

P < 0.05 is considered significant. NVUGIB: Non-variceal upper gastrointestinal bleeding; Aspirin: Aspirin only; No anti-thrombotics: Including clopidogrel, coumadin, heparin, ticlopedine and dipyridamole; SD: Standard deviation; NSAIDS: Non steroidal anti-inflammatory drug; PPI: Proton pump inhibitor.

higher in controls [29 (11%) vs 4 (4%), *P* = 0.05] (Table 1). Controls also had a higher INR than patients on aspirin (Table 2).

Presentation and endoscopic findings

Upon presentation, patients in the aspirin group had more syncope and melena, but less hematemesis than controls [21.3% vs 12.5%, *P* = 0.04, 51 (54.3%) vs 109 (41.4%), *P* = 0.03 and 18.1% vs 28.9%, *P* = 0.04, respectively]. Upper gastrointestinal endoscopy was done on 83% of patients in the aspirin group and 71.5% of patients in the control group. The prevalence of peptic lesions found at endoscopy was higher in the aspirin group, including gastric ulcers (28.7% vs 15.2%, *P* = 0.004), erosive duodenitis (16% vs 5.3%, *P* = 0.001), and erosive gastritis (40.4% vs 12.9%, *P* < 0.0001) (Table 2).

In hospital medical and endoscopic management

The percentage of patients transfused with blood was similar in both groups, 70.2% in aspirin vs 61.2% in control (*P* = 0.12); and the average was 4 units of packed red blood cells per transfused patient. In both groups, the frequencies of endoscopic therapy and surgery were similar (Table 2).

Outcomes

After adjusting for age and comorbidities (congestive heart failure, systemic cancer, diabetes mellitus, chronic renal failure), patients on aspirin were less likely to die in-hospital (OR = 0.15, 95%CI: 0.03-0.64, *P* = 0.002), less likely to experience the composite outcome (OR = 0.42, 95%CI: 0.20-0.89, *P* = 0.01), and tended to have a shorter hospital stay (4.9 d vs 7 d, *P* = 0.01) compared to controls. However, they had similar rates of in-hospital complications, re-bleeding and severe bleeding (Table 3).

P < 0.05 is considered significant. NVUGIB: Non-variceal upper gastrointestinal bleeding; Aspirin: Aspirin only; No anti-thrombotics: Including clopidogrel, coumadin, heparin, ticlopedine and dipyridamole; SD: Standard deviation; Hgb: Hemoglobin; Hct: Hematocrit; INR: International normalized ratio; AVM: Arteriovenous malformation; Surgery as any type of surgical procedure performed to control gastrointestinal bleeding.

Because the prevalence of cancer was higher in the control group, we did a multivariate analysis in which cancer was considered a covariate rather than one of the comorbidities. The protective effect of aspirin against in hospital mortality remained unchanged.

As there were some patients who did not have endoscopy, a multivariate analysis was done on patients who had endoscopy. Regarding the mortality, it was significantly lower with aspirin group vs non aspirin OR: 0.68, 95%CI: 0.63-0.74; but this difference was not seen with severe bleeding OR = 1.03, 95%CI: 0.69-1.52 and rebleeding OR = 1.51, 95%CI: 0.67-3.39.

DISCUSSION

Our study suggests that patients without known vascular disease who present with NVUGIB while taking aspirin appear to have better outcomes than patients not taking any antithrombotics. Specifically, these patients had lower mortality and morbidity, and shorter hospital stay than patients not on antithrombotics.

It is known that patients who have more than one risk factor for developing vascular events are more likely to use aspirin as primary prophylaxis^[9]. In this

¹Complications-infection composite: Including pneumonia, aspiration pneumonia, sepsis, urinary tract infection, skin infection; ²Complications-respiratory composite: Including ARDS and mechanical ventilation; ³Composite outcome include mortality, severe bleeding, re-bleeding, need for surgery or embolization. Severe hemorrhage was defined as BP < 90 mmHg, HR > 120 b/min, Hb < 7 g/dL on presentation, or transfusion of > 3 units of blood during hospitalization; rebleeding was defined as recurrence of hematemesis, coffee ground emesis, or melena occurring after 24 h from initial endoscopic evaluation and/or hemostatic therapy and initial stabilization, accompanied by either a decrease in hemoglobin concentration of at least 2 g/L or change in vital signs. *P* < 0.05 is considered significant. Aspirin: Aspirin only; No anti-thrombotics: Including clopidogrel, coumadin, heparin, ticlopedine and dipyridamole; OR: Odds ratio; DIC: Disseminated intravascular coagulation.

study, patients on aspirin were older and had more comorbidity, yet they had lower mortality rates compared to controls. This occurred even though both groups had similar frequencies of therapeutic endoscopic procedures, arterial embolization and surgery making it unlikely that those contributed to the better outcome in the aspirin group. Thus, the contribution of this study is that aspirin's beneficial effect in NVUGIB appears to extend to patients not known to have vascular disease.

It has been previously reported that patients with UGIB receiving or maintained on aspirin had improved outcomes. For example, in a randomized trial of aspirin *vs* placebo in patients who presented with peptic ulcer bleeding while taking aspirin, half of the deaths in the placebo group were due to non-cardiovascular causes, further suggesting that aspirin's protective effect is not solely due to its cardiovascular benefits^[10]. In two relatively large Italian prospective database studies, use of low dose aspirin upon presentation with UGIB was an independent predictor of better outcome including lower 30-d mortality^[11,12]. This was true for both outpatient and inpatient NVUGIB. Furthermore, in a large pan-European retrospective cohort, it was reported that use of low or high dose aspirin was an independent predictor of lower 30 d mortality in NVUGIB^[13]. Finally, in a retrospective cohort of 766 patients with UGIB due to peptic ulcers, it was reported that patients using aspirin upon presentation had a markedly decreased risk of fatal outcome (OR = 0.12, 95%CI: 0.012-0.67)^[6]. Thus, the protective effect of aspirin seems to hold true for both low and high dose aspirin, and seems to cover patients with peptic ulcer related and non-peptic ulcer related NVUGIB. However, in the studies mentioned above, it was not clear whether control patients were taking other antithrombotics, and whether patients taking aspirin were using other antithrombotics con-

comitantly. Furthermore, in none of them was a cause of death analysis undertaken to determine how aspirin exerted its protective effect. In contrast, three studies reported no effect of aspirin on mortality in patients with UGIB. In a prospective observational study of 392 patients there was no effect of antiplatelet therapy (aspirin and/or clopidogrel) on re-bleeding, urgent surgery or mortality^[14]. In another study, patients using aspirin/NSAIDs had similar mortality to those not using them. Finally, it was reported that aspirin users had lower 30-d mortality than controls among 7204 patients with peptic ulcer bleeding, but this was of borderline significance^[5]. To our knowledge, there are no studies showing that aspirin increases mortality in NVUGIB.

Controls in our study had a higher prevalence of systemic cancer. In order to determine if cancer could explain, in part, the high mortality in controls, we conducted two multivariate analyses, one in which the presence of cancer was included in the composite comorbidity score, and another one in which cancer was considered a covariate. The analysis revealed that the protective effect of aspirin against in-hospital mortality remained unchanged^[8].

The mechanism for the lower rate of bleeding related hospital complications and mortality is open to speculation. Aspirin is a non-steroidal anti-inflammatory drug with inhibitory effects on cyclo-oxygenases (COX). COX inhibition has vasoconstrictive and anti-natriuretic effects, which are mediated by inhibition of prostaglandin E-2 and prostacyclin synthesis^[15]. Aspirin has been reported to inhibit nitric oxide synthesis, which in turn inhibit vasodilatation^[16]. By constricting the vessels in the gastrointestinal system, it may decrease the severity of NVUGIB. We recognize limitations in our study. Patients with risk factors for vascular disease were not excluded, and therefore some of our patients could

have occult or latent vascular disease where aspirin protects this population against in hospital complications and mortality. The study design is not prospective or a randomized controlled trial. It is a single institution study and the sample size was small, so the applicability of the findings to other populations requires further testing. We do not have long term follow up on our patients and not all patients had endoscopy. Furthermore, the Forrest classification of bleeding lesions was not documented on all patients, which is a limitation of our study. Finally, the control group had higher INR level which may increase the risk of adverse outcomes. However, our study has several strengths. First, this is the first study to examine the effect of aspirin use as primary prophylaxis on clinical outcomes in patients with NVUGIB. Second, data collection was performed using the ICD-9 codes resulting in the identification of all the potential cases of UGIB, after which each case was reviewed individually by using well developed criteria. Finally, the study was conducted in a tertiary care referral center where all diagnostic and therapeutic procedures are standardized.

In conclusion, aspirin used for primary prophylaxis has a protective effect against adverse outcomes in patients admitted with NVUGIB, and this benefit probably extends beyond its known cardio-protective effect. Further prospective and randomized controlled trials are needed to validate these findings.

COMMENTS

Background

Aspirin is being widely used as primary and secondary prophylaxis for cardiovascular disease. However, aspirin use is associated with a 2 fold increase in risk of upper gastrointestinal bleeding (UGIB).

Research frontiers

Most studies suggest that aspirin decreases mortality and hospital stay in patients with non-variceal upper gastrointestinal bleeding (NVUGIB), while some report no significant effect. However, these studies included patients using aspirin as secondary prophylaxis.

Innovations and breakthroughs

In this study the authors compared clinical outcomes in patients that presented with NVUGIB while taking aspirin for primary prophylaxis to those of patients not taking aspirin. The authors found that the use of aspirin was associated with a better outcome, less mortality and shorter in-hospital stay.

Applications

The findings may have an impact on the practice of discontinuing aspirin in patients presenting with NVUGIB, even in those taking it for primary prophylaxis.

Terminology

Aspirin use as primary prophylaxis is defined as the use of aspirin in patients with no documented cardiovascular or cerebrovascular disease.

Peer-review

This is an interesting retrospective study comparing aspirin use with none and the outcomes of NVUGIB. The better results with aspirin use are surprising despite having patients with a poorer overall status compared to the control group.

Abstract

AIM: To report our experience with perineal repair (Delorme's procedure) of rectal prolapse with particular focus on treatment of the recurrence.

METHODS: Clinical records of 40 patients who underwent Delorme's procedure between 2003 and 2014 were reviewed to obtain the following data: Gender; duration of symptoms, length of prolapse, operation time, ASA grade, length of post-operative stay, procedure-related complications, development and treatment of recurrent prolapse. Analysis of post-operative complications, rate and time of recurrence and factors influencing the choice of the procedure for recurrent disease was conducted. Continuous variables were expressed as the median with interquartile range (IQR). Statistical analysis was carried out using the Fisher exact test.

RESULTS: Median age at the time of surgery was 76 years (IQR: 71-81.5) and there were 38 females and 2 males. The median duration of symptoms was 6 mo (IQR: 3.5-12) and majority of patients presented electively whereas four patients presented in the emergency department with irreducible rectal prolapse. The median length of prolapse was 5 cm (IQR: 5-7), median operative time was 100 min (IQR: 85-120) and median post-operative stay was 4 d (IQR: 3-6). Approximately

16% of the patients suffered minor complications such as - urinary retention, delayed defaecation and infected haematoma. One patient died constituting post-operative mortality of 2.5%. Median follow-up was 6.5 mo (IQR: 2.15-16). Overall recurrence rate was 28% ($n = 12$). Recurrence rate for patients undergoing an urgent Delorme's procedure who presented as an emergency was higher (75.0%) compared to those treated electively (20.5%), P value 0.034. Median time interval from surgery to the development of recurrence was 16 mo (IQR: 5-30). There were three patients who developed an early recurrence, within two weeks of the initial procedure. The management of the recurrent prolapse was as follows: No further intervention ($n = 1$), repeat Delorme's procedure ($n = 3$), Altemeier's procedure ($n = 5$) and rectopexy with faecal diversion ($n = 3$). One patient was lost during follow up.

CONCLUSION: Delorme's procedure is a suitable treatment for rectal prolapse due to low morbidity and mortality and acceptable rate of recurrence. The management of the recurrent rectal prolapse is often restricted to the pelvic approach by the same patient-related factors that influenced the choice of the initial operation, *i.e.*, Delorme's procedure. Early recurrence developing within days or weeks often represents a technical failure and may require abdominal rectopexy with faecal diversion.

Key words: Rectal prolapse; Recurrence; Perineal repair; Delorme's procedure

INTRODUCTION

Full-thickness prolapse of the rectum is defined as a complete protrusion of the rectal wall through the anus. Although benign, the disease can be debilitating and affect patients' quality of life. The incidence of rectal

prolapse is reported as 10 per 1000 in patients aged over 65 years^[1] and the majority of affected individuals (80%-95%) are women.

More than 130 surgical operations have been described to treat the prolapse which can broadly be classified into perineal and abdominal procedures, indicating that none is entirely satisfactory^[2]. Perineal repair of rectal prolapse, as we understand it now, was named after Edmond Delorme - a French military surgeon who described a technique of mucosal stripping for treatment of procidentia in 1899^[3]. It gained popularity and today remains the most frequently used type of perineal procedure. In elderly patients with significant co-morbidities Delorme's is often a first choice procedure being the least invasive and, therefore, carrying less of surgical and anaesthetic risks. The perceived disadvantage of Delorme's procedure is high rates of prolapse recurrence making it sub-optimal operation for young and healthy patients who are able to withstand abdominal rectopexy^[4]. The choice of the procedure to deal with the recurrent rectal prolapse is often even more difficult due to the absence of established consensus among colorectal surgeons or guidelines to support decision-making process.

The primary aim of this study was to analyse our experience with the treatment of recurrent rectal prolapsed after failed perineal repair (Delorme's procedure) and, in particular, factors that influenced further management. We also report our experience with Delorme's procedure as a treatment of primary rectal prolapse.

MATERIALS AND METHODS

This was a retrospective observational study where we identified 40 consecutive cases of patients who underwent perineal repair of rectal prolapse (Delorme's procedure) by one specialist team (DYA) in Southport and Ormskirk Hospital and Renacres Hospital between 2003 and 2014. Only patients who underwent Delorme's operation as the first procedure undertaken by the team were included. Patients undergoing all other types of perineal procedures, such as excision of mucosal prolapse and perineal recto-sigmoidectomy (Altemier's procedure) were excluded. All patient records were analysed to obtain the following data: Gender; duration of symptoms, length of prolapse, operation time, ASA grade, length of post-operative stay, procedure-related complications, development and treatment of recurrent prolapse and factors influencing the choice of the procedure for recurrent disease. Post-operative complications were classified according to the Clavien-Dindo classification^[5]. The last follow-up date was considered as the date of the last documented physical examination. Treatment algorithm used for management of recurrent rectal prolapse is shown in Figure 1.

Statistical analysis

Continuous variables were expressed using non-

parametric statistics, median with interquartile range (IQR), due to small sample size. Statistical analysis was carried out using the Fischer exact test. Results were considered significant with a probability value of $P < 0.05$. All calculations were performed using Origin software (OriginPro 9). Statistical methods used in the study were independently evaluated by an expert in Biomedical Statistics.

RESULTS

There were 38 females and 2 males in our cohort with the median age of 76 years (IQR: 71-81.5) at the time of surgery (Table 1). The median duration of symptoms was 6 mo (IQR: 3.5-12). Thirty six patients presented electively whereas four patients presented in the emergency department with irreducible rectal prolapse. The median length of prolapse was 5 cm (IQR: 5-7), median operative time was 100 min (IQR: 85-120) and median post-operative stay was 4 d (IQR: 3-6). The majority of patients had no post-operative complications, seven (16%) suffered minor complications, *i.e.*, grade 1 or 2 such as - urinary

retention, delayed defaecation and infected haematoma - as defined by Clavien-Dindo classification. One patient died of pneumonia and congestive cardiac failure due to ischaemic heart disease, constituting post-operative mortality of 2.5%. Median follow-up was 6.5 mo (IQR: 2.15-16). Surgical morbidity was higher in patients undergoing surgery for recurrent rectal prolapse (2/7, 28.5%) vs primary Delorme's (4/36, 11.1%), P value 0.004, and the only mortality in the case series was that of a patient who had surgery for recurrent prolapse. Peri-operative and follow up data are shown in Table 2. Median duration of follow-up was 6.5 mo (range from 2 to 16 mo), the overall recurrence rate was 28% ($n = 12$). A summary of patients' outcome is shown in Figure 2. Recurrence rate for patients undergoing an urgent Delorme's procedure who presented as an emergency was higher (3/4, 75%) compared to those treated electively (9/39, 23%), P value 0.034. No other factors included in the analysis were identified to be statistically significant predictors of recurrence. Median duration of recurrence was 16 mo (IQR: 5-30) and there were three patients who developed an early recurrence, within two weeks of the initial procedure. The manage-

ment of the recurrent prolapse was as follows: No further intervention ($n = 1$), repeat Delorme's ($n = 3$), Altemeier's procedure ($n = 5$) and rectopexy with faecal diversion ($n = 3$). One patient was lost during follow up.

DISCUSSION

Rectal prolapse is a profoundly disabling condition which in Western populations occurs predominantly in elderly women. Surgery is the only way to address the pathology but the choice of operation can be influenced by patient, surgeon and disease-related factors. Traditionally abdominal rectopexy was advocated in young and fit patients and perineal procedures, including Delorme's, were reserved for elderly individuals who are less likely to tolerate abdominal intervention. With introduction of minimally invasive laparoscopic approach many surgeons argue that abdominal rectopexy can be safely applied in most patients with better recurrence-free outcome and minimal long-term complications such as constipation. The advantage of Delorme's procedure is that it combines minimal morbidity and shorter hospital stay with acceptable functional outcome and recurrence rate. Thus, the results of PROSPER trial, the largest randomised controlled trial comparing perineal with abdominal approaches in 293 patients, showed that there was no significant difference in recurrence rates, bowel function or quality of life between any of the treatments. Interestingly, abdominal surgery arm had the rate of recurrence much higher than previously published^[6]. Delorme's is an alternative to abdominal rectopexy not only in elderly but also in patients with a short prolapse and those wishing to avoid abdominal intervention^[7]. It is therefore not surprising that perineal procedures (Delorme's and Altemeier's) comprise 50% to 60% of all operations performed for rectal prolapse^[8]. In our series Delorme's operation was the preferred strategy for treatment unless the length of the prolapse (more than 10 cm) necessitated its resection either perineally (Altemeier's procedure) or abdominally (resection rectopexy). The overall recurrence rate in our cohort was 28% which may seem high in comparison with 20% based on the results of a meta-analysis^[9]. Sub-group analysis of electively operated patients, following exclusion of those who had urgent surgery for irreducible prolapse, reveals a recurrence rate of 18.6%. The vast majority (80%) of our patients had no post-operative complications. The only patient who died in our cohort suffered an early recurrence and had little choice but to accept abdominal rectopexy with de-functioning sigmoid loop colostomy. She developed congestive cardiac failure and pneumonia and died on the 43rd day after the second abdominal procedure, thus confirming limited physiological reserves (ASA-3) that influenced the initial choice of perineal repair.

The best management of recurrent rectal prolapse remains uncertain^[10] and there are few publications addressing this issue. A recent systematic review evaluating the results of abdominal or perineal surgery for

recurrent rectal prolapse, undertaken with the aim of developing an evidence-based treatment algorithm was unable to formulate one due to the variation in surgical techniques and heterogeneity in the quality of studies^[10]. Steele *et al.*^[11] advise that abdominal repair of recurrent rectal prolapse should be undertaken if the patient's risk profile permits. In our experience the same clinical factors, *i.e.*, lack of physiological reserves, restricted repeat surgery to perineal approach exactly as they had done at the time of the initial operation. Delorme's procedure, however, can be safely repeated. When the length of the prolapsed bowel precluded its successful plication our preferred alternative was perineal recto-sigmoidectomy (Altemeier's procedure) which was successfully performed in almost half of recurrences. Figure 1 outlines the algorithm we have adopted for the management of recurrent rectal prolapse after failed Delorme's procedure. We echo the opinion of Pikarskey *et al.*^[12] that outcome of surgery for rectal prolapse is similar in cases of primary or recurrent prolapse. Early recurrence often represents a technical failure in the background of generalised pelvic floor weakness. In three of our patients it happened on day 7, 10 and 14 after Delorme's procedure due to "cheese-wiring" of plicating sutures and the prolapsed demucosed and inflamed rectum proved particularly difficult to manage. We chose to address it by urgent laparotomy, posterior rectopexy without incorporation of synthetic mesh and formation of defunctioning loop colostomy. This was the only practical choice as the defunctioning stoma offered the benefit of faecal diversion in conditions of rectal inflammation, served as an additional point of bowel fixation anteriorly to the abdominal wall and addressed the likely faecal incontinence in the conditions of generalised pelvic floor weakness.

Our study, being retrospective observational in its design, has inevitable limitations in comparison with a randomised controlled trial. However, a randomised controlled trial aimed to answer some of the questions that have been raised in this paper such as, for example, the best treatment of early post-operative recurrence after failed Derome's procedure may prove to be difficult, if not impossible, to set up.

Delorme's procedure is a suitable treatment in the majority of patients with rectal prolapse regardless the age. It is an attractive choice due to low morbidity and mortality and has acceptable rate of recurrence, at least in the elective setting. The management of the recurrent rectal prolapse is often restricted to the pelvic approach by the same patient-related factors that influenced the choice of the initial operation, *i.e.*, Delorme's procedure. In the event of late recurrence Delorme's procedure can be easily repeated. Long recurrent prolapse requires resection and is best addressed by perineal recto-sigmoidectomy (Altemeier's procedure). Early recurrence developing within days or weeks often represents a technical failure that is difficult to treat and in sufficiently fit patients may require abdominal rectopexy combined

with faecal diversion.

COMMENTS

Background

Many surgical procedures have been described for treatment of full-thickness rectal prolapse indicating that none of them is entirely satisfactory. The choice of the procedure to deal with the recurrent prolapse is even more difficult due to the absence of established consensus among surgeons.

Research frontiers

At present there is insufficient evidence to formulate guidance on the management of the recurrent rectal prolapse as the outcome of such treatment depends on multiple patient and disease-related factors that are often beyond surgeons' control. There is also not enough knowledge to answer the question about the best treatment of early recurrence developing in the immediate post-operative period after failed Delorme's procedure. This study was aimed to assess the outcome of treatment of recurrent rectal prolapse after previous perineal repair (Delorme's procedure) and, in particular, factors that influenced decision-making process. The authors also report their experience of Delorme's procedure as a treatment of primary rectal prolapse.

Innovations and breakthroughs

This retrospective observational study challenges the view that patients with recurrent rectal prolapse after previous Delorme's procedure can be best served with abdominal rectopexy. Despite the perceived better recurrence-free outcome of abdominal interventions the practical reality is that the vast majority of such patients cannot have abdominal rectopexy for the same patient-related reasons why it could be carried out in the first instance. This study also attempts to address the management of the difficult clinical problem of recurrence developing in the early post-operative period after failed Delorme's procedure. In such a scenario the reported experience with urgent laparotomy and posterior suture rectopexy combined with defunctioning sigmoid loop colostomy is encouraging.

Applications

This study may assist surgeons in making decisions about the management of recurrent rectal prolapse. Future studies on the treatment of early post-operative recurrence will be of potential interest.

Terminology

The term rectal prolapse refers to a full-thickness (or complete) protrusion of the rectal wall through the anus.

Peer-review

The authors reported their retrospective data regarding the Delorme's procedure, which is one of the interesting topics.

Abstract

AIM: To evaluate accuracy of three-dimensional endoanal ultrasound (3D-EAUS) as compared to 2D-EAUS and physical examination (PE) in diagnosis of perianal fistulas and correlate with intraoperative findings.

METHODS: A prospective observational consecutive study was performed with patients included over a two years period. All patients were studied and operated on by the Colorectal Unit surgeons. The inclusion criteria were patients over 18, diagnosed with a criptoglandular perianal fistula. The PE, 2D-EAUS and 3D-EAUS was performed preoperatively by the same colorectal surgeon at the outpatient clinic prior to surgery and the fistula anatomy was defined and they were classified in intersphincteric, high or low transsphincteric, supra-sphincteric and extrasphincteric. Special attention was paid to the presence of a secondary tract, the location of the internal opening (IO) and the site of external opening. The results of these different examinations were compared to the intraoperative findings. Data regarding location of the IO, primary tract, secondary tract, and the presence of abscesses or cavities was

analysed.

RESULTS: Seventy patients with a mean age of 47 years (range 21-77), 51 male were included. Low transsphincteric fistulas were the most frequent type found (33, 47.1%) followed by high transsphincteric (24, 34.3%) and intersphincteric fistulas (13, 18.6%). There are no significant differences between the number of IO diagnosed by the different techniques employed and surgery ($P > 0.05$) and, there is a good concordance between intraoperative findings and the 2D-EAUS ($k = 0.67$) and 3D-EAUS ($k = 0.75$) for the diagnosis of the primary tract. The ROC curves for the diagnosis of transsphincteric fistulas show that both ultrasound techniques are adequate for the diagnosis of low transsphincteric fistulas, 3D-EAUS is superior for the diagnosis of high transsphincteric fistulas and PE is weak for the diagnosis of both types.

CONCLUSION: 3D-EAUS shows a higher accuracy than 2D-EAUS for assessing height of primary tract in transsphincteric fistulas. Both techniques show a good concordance with intraoperative finding for diagnosis of primary tracts.

Three-dimensional endoanal ultrasound for diagnosis of perianal fistulas: Reliable and objective technique. *World J Gastrointest Surg* 2016; 8(7): 513-520 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i7/513.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i7.513>

INTRODUCTION

Management of perianal fistulas continues to be a challenge for the surgeon. The correct classification of the fistulas and their relationship with the anal sphincters is fundamental in choosing the adequate treatment.

Magnetic Resonance Imaging (MRI) and endoanal ultrasound (EAUS) have become the most valuable tools for diagnosing anal pathology. Two dimensional EAUS (2D-EAUS) affords sufficient information to be able to make adequate decisions in the management

of these patients^[1-4]. It does not however measure volumes of the elements of the anal canal, and gives less information regarding the anatomic structures involved^[5-7]. These limitations have been overcome with the introduction of three dimensional EAUS (3D-EAUS).

For many authors, the characteristics of 3D-EAUS (easy access, cost and accuracy) have made it the first choice for the diagnosis of perianal fistulas. To date, examination under anesthesia has been considered the gold standard. There are some groups that now believe MRI is better as it can diagnose fistulas and secondary tracts which are not seen during surgery^[8], though there are no studies as yet which investigate the value of 3D-EAUS for this purpose.

The objective of this study was to evaluate the diagnostic accuracy of 3D-EAUS vs 2D-EAUS vs physical examination (PE) for the diagnosis of perianal fistulas and correlate the results with the intraoperative findings.

MATERIALS AND METHODS

A prospective observational consecutive study was performed with patients included over a two year period. All patients were studied and operated on by surgeon from the Colorectal Unit, Hospital Clínico Universitario, Valencia. The study protocol was approved by the hospital ethics committee and all patients signed an informed consent form.

The inclusion criteria were patients 18 years and over, diagnosed with a cryptoglandular perianal fistula. The exclusion criteria were patients operated in other centres, patients with chronic inflammatory bowel disease, suprasphincteric or extrasphincteric fistulas, and patients who were already receiving nonsurgical treatment which could affect the results such as plugs, biological glues or stem cell therapy, etc.

Study protocol

History and PE: A meticulous history was taken during the first consultation. PE performed in the prone jack-knife position included palpation of the perianal region and a digital rectal exam. The fistula anatomy was defined and they were classified as intersphincteric, high or low transsphincteric, suprasphincteric and extrasphincteric. Special attention was paid to the presence of a secondary tract, the location of the internal opening (IO) and the site of the external opening (EO).

EAUS: All ultrasounds were performed by the same surgeon with over 10 years' experience in EAUS using the B and K Medical Systems Pro Focus 2202® scanner and B-K 2050 probe (B-K Medical, Herlev, Denmark).

Ultrasound evaluation was carried out at a frequency of 10 MHz initially in 2D and followed by 3D using 0.2 mm slices throughout the length of the anal canal and producing 300 sequential images that were automatically reconstructed as a cube, which could be worked on later.

This automated reconstruction of the images reduces human error as the ultrasound probe does not need to be moved throughout the examination and can be subsequently saved allowing post examination analysis of the 3D-EAUS scan in coronal, sagittal or axial planes as deemed necessary.

All patients were examined in the prone jack-knife position. The ultrasound was systematically performed from the upper to the lower third of the anal canal. When examining the inferior third of the anal canal it is important to keep the buttocks separated because the subcutaneous tissue can be confused with images of the external anal sphincter (EAS) and therefore overestimate the length of the anal canal and of the EAS. When the EO was open the examination was repeated after instilling 10% hydrogen peroxide solution through a cannula.

2D-EAUS: The IO was classified with or without the instillation of hydrogen peroxide according to the criteria proposed by Cho D-Y^[9], distance from the anal margin and radial location. The primary fistulous tract was classified as: (1) Not seen; (2) Intersphincteric: Crosses the intersphincteric space without crossing the EAS; (3) Low transsphincteric: Crosses both sphincters or the EAS in the lower two thirds of the anal canal; (4) High transsphincteric: Crosses both sphincters in the upper third of the anal canal; (5) Suprasphincteric: Crosses the intersphincteric space and courses above the upper border of the puborectalis muscle; and (6) Extrasphincteric: Lies external to the sphincteric apparatus.

Other data obtained with this technique were the presence of secondary tracts (hypoechoic tracts which join the primary tract at some point) and the presence of cavities and perianal abscesses.

3D-EAUS: Sagittal, oblique, transverse and coronal images can be obtained and recorded in video format to be reviewed later if necessary. The location and distance of the IO from the anal margin are recorded together with possible secondary tracts and abscesses, confirming or improving the information obtained from the 2D-EAUS.

Once the examination is finalized, the images can be recovered and reviewed, taking meticulous measurements. There are a series of endosonography images that can lead to error in the measurements if the examination is not performed by someone experienced in the field. The separation of the EAS from the puborectalis muscle can be seen on sagittal section as a hypoechoic line, which when combined with the transverse axial image, perfectly defines the proximal limit of the EAS. The proximal limit of the internal anal sphincter (IAS) is defined as the anorectal junction and quantitative measurements are taken in mm. The following measurements were taken in all patients: Total length of the anal canal, length of the puborectalis

muscle, total length of the EAS, total length of the IAS, length of the IAS and EAS involved by the fistula and percentage of sphincter involved by the fistula with respect to the total sphincter length.

According to the measurements obtained, the fistulas were classified by 3D-EAUS as: (1) Unidentified; (2) Intersphincteric: Crosses the intersphincteric space without crossing the EAS; (3) Low transsphincteric: Involves less than 66% of the EAS; (4) High transsphincteric: Involves over 66% of the EAS; (5) Suprasphincteric: Crosses the intersphincteric space and courses above the upper border of the puborectalis muscle; and (6) Extrasphincteric: lies external to the sphincteric apparatus.

Surgery: All patients were operated in the prone jack-knife position with locoregional anesthesia. Surgery is started with a PE under anesthesia using a Hill Ferguson retractor and the EO is probed up to the IO. The presence of secondary tracts and other pathology, which could modify the surgery, is ruled out. If the IO is not seen, 10% hydrogen peroxide is instilled through the EO. At this point, data regarding the site, type, and distance from the anal marginal are taken. The type of surgery to be performed is then chosen.

Statistical analysis

Data from the PE, 2D-EAUS and 3D-EAUS are compared with data from the examination under anesthesia considered the gold standard. The concordance rate and Kappa coefficient (degree of non-random agreement between different measurements of the same variable) are calculated. The Kappa coefficient varies between -1 and 1, considering: $k = -1$, agreement due to chance; $k < 0.2$, poor agreement; $k = 0.2-0.4$, low; $k = 0.4-0.6$, moderate; $k = 0.6-0.8$, good; $k = 0.8-1$, very good. Furthermore, the sensitivity, specificity and predictive values were calculated for each test. The chi-square test was used to compare differences between percentages. The ROC curves (curves for the receiver operating characteristics) have been determined for the diagnosis of transsphincteric fistulas by PE, 2D-EAUS and 3D-EAUS. The ideal diagnostic test has sensitivity and specificity equal to 1 (upper left corner of the curve) and will be poorer the closer it is to the diagonal (area under the curve = 0.50). Therefore, the minimum requirement for a diagnostic method would be an area under the curve greater than 0.50.

In all cases a value of $P < 0.05$ was considered statistically significant. Statistical analysis was performed using IBM SPSS version 19.0 for Windows (SPSS, Chicago, IL, United States).

RESULTS

Seventy patients with a diagnosis of perianal fistula of criptoglandular origin were eventually included (Figure 1). The most frequent type were low transsphincteric fistulas (33, 47.1%), followed by high transsphincteric

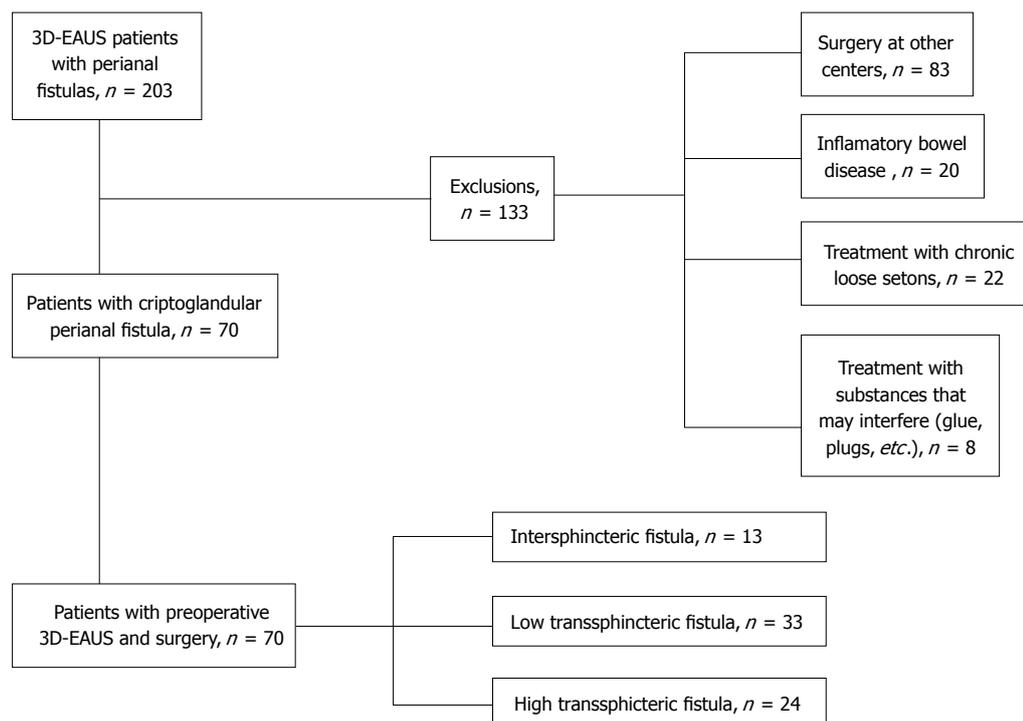

Figure 1 Patient distribution. 3D-EAUS: Three-dimensional endoanal ultrasound.

fistulas (24, 34.3%) and finally intersphincteric fistulas (13, 18.6%). Gynaecological history and past perianal surgeries can be seen in Table 1. Median duration of symptoms at first consultation was 12 mo (range 1-120).

Correlation with intraoperative findings

Findings for PE, 2D-EAUS, 3D-EAUS and surgery are in Table 2.

Internal opening: Sixty-seven IOs were found in 70 patients intraoperative. The majority of IO were found by digital rectal examination (n = 53; 75.7%). Both 2D-EAUS and 3D-EAUS diagnosed 67 IO in 70 patients (95.7%). Both examinations failed to find the IO in 3 patients despite the instillation of hydrogen peroxide. Two of the patients not diagnosed by EAUS do not coincide with those not found during surgery. There are

no significant differences between the number of IO diagnosed between the different techniques employed and surgery (P > 0.05) (Table 3).

Primary fistula tract

Thirteen intersphincteric fistulas, 33 low transsphincteric and 24 high transsphincteric fistulas were diagnosed intraoperatively. PE could not classify 10 patients due to pain, or because the tract could not be palpated during the examination. Thirty-seven patients were correctly diagnosed (52.9%). 55 (78.6%) and 58 (82.8%) were diagnosed by 2D-EAUS and 3D-EAUS respectively as shown in Table 3. One patient could not be classified by 2D-EAUS or 3D-EAUS due to the difficulty in differentiating the fistulous tract from fibrosis secondary to prior anal surgeries. There is a good concordance between intraoperative and ultrasound diagnosis

Table 3 Concordance grade and k coefficient (k) between intraoperative findings and the different diagnostic techniques used

	PE		2D-EAUS		3D-EAUS	
	Concordance	k	Concordance	k	Concordance	k

	3D-EAUS	90	88	56	98

2D-EAUS: Two-dimensional endoanal ultrasound; 3D-EAUS: Three-dimensional endoanal ultrasound; PE: Physical examination; IO: Internal opening; S: Sensitivity; SP: Specificity; PPV: Positive predictive value; NPV: Negative predictive value.

of primary tract, the highest concordance was with 3D-EAUS (k = 0.67 and k = 0.75, respectively). There is a tendency to overestimate fistula height with 2DEAUS as can be seen by the lower specificity for high transsphincteric fistulas and lower sensitivity for low transsphincteric fistulas shown in Table 4.

Secondary fistulous tracts: One or more secondary fistula tracts were diagnosed by 2D-EAUS and 3D-EAUS in 15 and 16 patients respectively with a good concordance with surgical findings (91.4%, k = 0.66; 92.8%, k = 0.60) (Table 3).

Abscesses and adjacent cavities: 2D-EAUS diagnosed abscesses in 17 (24.3%) patients and 3D-EAUS in 19 (27.1%) patients. 12 cases (17.1%) were diagnosed by PE. 8 patients (11.4%) presented with an abscess at the time of surgery. There was a moderate concordance between EAUS and surgery (k=0.57, k = 0.54, respectively). There was a low concordance between PE and intraoperative findings (k = 0.30) (Table 3).

Table 5 Results of receiver operative characteristic curves for the diagnosis of transsphincteric fistulas

		Area under curve	95%CI	P value
Low transsphincteric fistula	PE	0.608	0.474-0.742	0.120
	2D-EAUS	0.819	0.714-0.924	0.0001
	3D-EAUS	0.829	0.724-0.934	0.0001
High transsphincteric fistula	PE	0.672	0.541-0.803	0.019
	2D-EAUS	0.842	0.745-0.939	0.0001
	3D-EAUS	0.910	0.835-0.985	0.0001

2D-EAUS: Two-dimensional endoanal ultrasound; 3D-EAUS: Three-dimensional endoanal ultrasound; PE: Physical examination.

The sensitivity and specificity (efficacy indexes) of the different examinations with respect to intraoperative findings are shown in Table 4.

ROC curves (Receiver Operating Characteristic) for the diagnosis of transsphincteric fistulas by PE and 2D/3D-EAUS are adequate for the diagnosis of low transsphincteric fistulas. 3D-EAUS is superior for the diagnosis of high transsphincteric fistulas (Figure 2). PE is clearly deficient for the classification of transsphincteric fistulas (Table 5).

DISCUSSION

3D-EAUS is a novel technique for the diagnosis of perianal fistulas and multiple studies such as ours demonstrate its' superiority with respect to 2D-EAUS. 3D-EAUS is a useful tool that gives a more reliable preoperative diagnosis of perianal fistulas with accurate diagnosis of the IO, primary tracts, secondary tracts and adjacent abscesses or cavities. Ratto *et al*^[10] published a rate of exact diagnosis with 3D-EAUS of primary and secondary tracts of 98.5% and 96.4% for the IO compared with 89.9%, 83.3% and 87.9% respectively with 2D-EAUS. Santoro *et al*^[11,12] in their study in 57 patients confirm that 3D-EAUS improves diagnosis accuracy of the IO when compared to 2D-EAUS (2D-EAUS: 66.7% vs 3D-EAUS: 89.5%; P = 0.0033). However, both techniques were similar for diagnosis of primary and secondary tracts and abscesses^[11,12]. Our study showed a 97.1% concordance for the diagnosis of the IO (for both types of EAUS), 78.6% for primary tracts, 91.4% for secondary tracts and 87.1% for cavities and abscesses with 2D-EAUS as opposed to

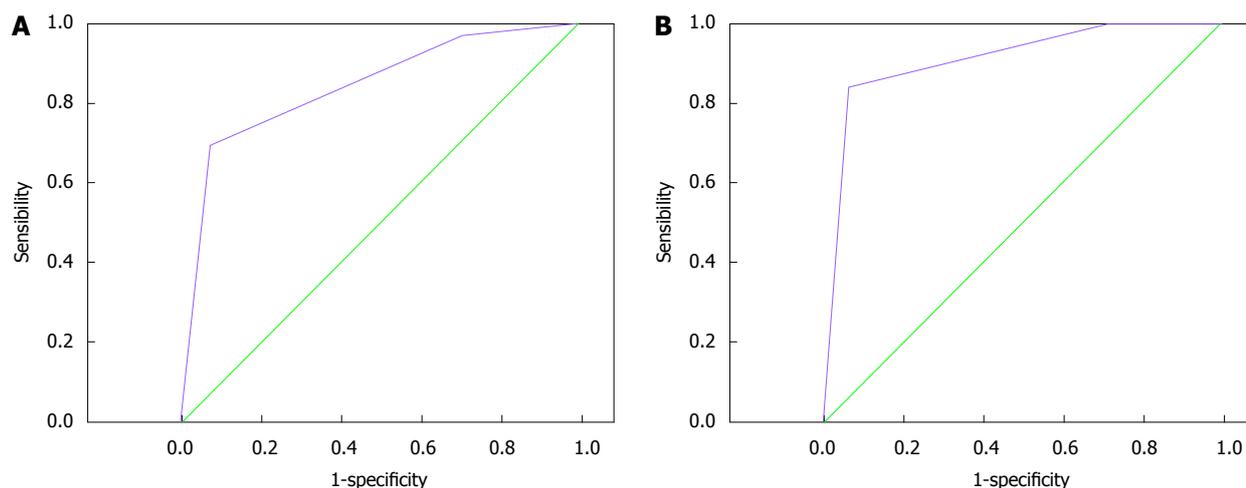

Figure 2 Receiver operating characteristic curves for the diagnosis of high transsphincteric fistulas with two-dimensional endoanal ultrasound (A) (area under curve = 0.842; 95%CI: 0.745-0.939; $P = 0.0001$) and three-dimensional endoanal ultrasound (B) (area under curve = 0.910; 95%CI: 0.835-0.985; $P = 0.0001$).

82.8%, 92.8% and 85.7% respectively when using 3D-EAUS. A preliminary study in 29 patients carried out by our group showed a concordance rate between intraoperative findings (gold standard) and 3D-EAUS of 79% for primary fistula tracts validating the latter as a useful technique in the evaluation of perianal fistulas^[13].

There are various classifications for perianal fistulas. As a practical method, various authors have modified the Parks classification^[14]. The subdivision of transsphincteric fistulas with regards to the level at which they cross the anal canal tends to be arbitrary dividing these in equal thirds. We propose a new division of transsphincteric fistulas dividing them into low (less than 66% of the total length of the EAS involved) and high (over 66% of the EAS involved). This way we can simplify the classification and guide the indication for surgery.

This study shows a good correlation between 3D-EAUS and surgical findings, with superior results to PE and 2D-EAUS, in particular with regards to high transsphincteric fistulas which are the ones raising more doubts in diagnosis and choice of treatment. According to our results, 2D-EAUS in particular for high transsphincteric fistulas tends to overestimate the amount of anal sphincter involved thus classifying them as higher than they really are, as can be seen by the lower specificity for high transsphincteric fistulas and lower sensitivity for low transsphincteric fistulas. These errors are minimized with 3D-EAUS with a notable improvement in sensitivity and specificity. According to the ROC curves, the best technique for diagnosing high transsphincteric fistulas is 3D-EAUS. Although both types of EAUS are adequate for the diagnosis of low transsphincteric fistulas, 3D-EAUS seems to be slightly superior.

The large variability between examinations have not allowed for the calculation of the IO Kappa coefficient, there were no significant differences between examination techniques and surgical findings with

regards to diagnosis of the IO. These results are similar to the study in 21 patients published by Poen *et al*^[15]. The three examinations show high sensitivity and specificity when diagnosing the location and distance from the anal margin of the IO.

Even though both types of EAUS have a good concordance 3D-EAUS has shown a higher concordance and accuracy than 2D-EAUS when compared to intraoperative findings ($k = 0.75$ vs $k = 0.67$). Various studies have shown a very good concordance between 2D and 3D-EAUS and surgery for diagnosis of the primary tract using the instillation of hydrogen peroxide^[8,13]. We did not use hydrogen peroxide in all our patients and included patients with a closed EO. This could explain the difference in results.

Similar to the results published by Poen *et al*^[15] ($k = 0.61$), 3D-EAUS shows a good concordance with surgery for the diagnosis of secondary tracts ($k = 0.60$). The concordance coefficient for 2D-EAUS is slightly higher than 3D-EAUS ($k = 0.66$ vs $k = 0.60$). In addition, EAUS diagnosed more secondary tracts than surgery. These complex or high fistulous tracts could go unnoticed during surgery. As a result of these findings we should possibly reconsider, as have done other authors, which of these examinations is truly the gold standard for the diagnosis of perianal fistulas. Surgery may not be the best diagnostic tool and we should consider MRI with an endoanal coil or 3D-EAUS^[16].

The diagnosis of adjacent abscesses and cavities shows a moderate concordance with surgery (2D-EAUS, $k = 0.57$; 3D-EAUS, $k = 0.54$) and insignificant concordance with PE. This is probably due to the fact that these cavities may not be obvious on PE but as patients had to wait sometime between examination and surgery there were probably changes (improvement or deterioration) in these parameters.

There are various studies that defend the routine use of preoperative 2D-EAUS for the diagnosis of both simple and complex perianal fistulas^[14,17]. Some

simple perianal fistulas can be diagnosed on PE and we believe a routine EAUS is unnecessary. 3D-EAUS has clearly overtaken 2D-EAUS however, and is more efficient offering more detailed information^[10,18]. Due to the common problem that these fistulas represent and the difficulty in obtaining a definitive treatment, there are various groups that as we do, use 3D-EAUS for the preoperative diagnosis of perianal fistulas^[19]. Murad-Regadas *et al*^[20] published a study in 33 patients confirming that preoperative 3D-EAUS was useful for the diagnosis of anterior transsphincteric fistulas, assisting in choosing the most appropriate treatment and reducing the incontinence rates.

Our work shows the value of 3D-EAUS in predicting the amount of sphincter involved by the fistula in an objective and quantitative manner, and allowing a more accurate classification of the fistula.

Despite the results obtained in this study there were some limitations. These include the low number of patients included even though this was similar or superior to other published studies, the exclusion of suprasphincteric and extrasphincteric fistulas, whose prevalence is very low and where the role of IRM vs 3D-EAUS is debatable^[7,16]; and that all measurements and scans in this study were performed by the same surgeon. This last point may be beneficial on the one hand as it reduces interobserver variability, but at the same time may offer some bias. We believe it would be more correct to perform the measurements by two independent examiners and then analyse the differences between them.

According to our results we can conclude that 3D-EAUS is more accurate than 2D-EAUS for estimating the height of the primary tract in transsphincteric fistulas. Both 2D and 3D-EAUS techniques show a good concordance with examination under anesthesia for the diagnosis of primary tracts with slightly superior results for 3D-EAUS. Therefore, we agree with other authors that EAUS is a fundamental tool in the evaluation of perianal fistulas allowing for a better classification. 3D-EAUS provides new advantages with respect to 2D-EAUS and is a superior technique allowing for objective and quantitative, and not only subjective, information.

COMMENTS

Background

Perianal fistulas are a common problem in the general population and affect around 10 per 100000 population per year. The relationship between fistulous tract, the sphincters and adequate management is still a challenge today. Imaging techniques play an important role in diagnosis. Various authors including us prefer endoanal ultrasound (EAUS). It is cheaper, easy to use with training, fast, non-invasive and can be used in the operating room if necessary.

Research frontiers

Controversy has been raised over the last few years over which technique [magnetic resonance imaging (MRI), ultrasound or examination under anesthesia] is the gold standard for diagnosis of perianal fistulas. The choice between EAUS and MRI mainly depends on their availability. MRI may seem to

offer better results for the diagnosis of perianal fistulas but is outweighed by its' expense and lower availability. In addition, three-dimensional (3D)-EAUS has considerably improved when compared with MRI.

Innovations and breakthroughs

This study compares the results of PE, 2D-EAUS and 3D-EAUS with examination under anesthesia for perianal fistulas providing concordance data for the different techniques. This allows the authors to determine which technique is best in each case, the need to use them as diagnostic tools and for providing optimal management of perianal fistulas.

Applications

The results of this study suggest 3D-EAUS is superior to 2D-EAUS for the diagnosis of high transsphincteric fistulas and could now be considered the gold standard for diagnosis of this pathology. EAUS is a fundamental tool for the evaluation of perianal fistulas offers an accurate classification and therefore better treatment.

Terminology

Perianal fistulas are a chronic phase of a suppurated anal disease. The currently available imaging techniques for classifying anal fistulas are: Fistulography (no longer used), MRI and EAUS. EAUS can be 2D EAUS (distance, area and volume measurements cannot be taken, with poorer imaging of spatial relations and loss of relevant information) or 3D-EAUS (offers a view of all planes and distances, angles, areas and volumes can be accurately measured).

Peer-review

The paper offers an interesting comparison of the diagnostic yield of 2D-EAUS vs 3D-EAUS for perianal fistulas. The gold standard in the present study are intraoperative findings, although other groups think that MRI can demonstrate perianal fistulas missed by the surgeon.

Abstract

AIM: To evaluate published trials examining oral post-operative protein supplementation in patients having undergone gastrointestinal surgery and assessment of reported results.

METHODS: Database searches (MEDLINE, BIOSIS, EMBASE, Cochrane Trials, Cinahl, and CAB), searches of reference lists of relevant papers, and expert referral were used to identify prospective randomized controlled clinical trials. The following terms were used to locate articles: "oral" or "enteral" and "postoperative care" or "post-surgical" and "proteins" or "milk proteins" or "dietary proteins" or "dietary supplements" or "nutritional supplements". In databases that allowed added limitations, results were limited to clinical trials that studied humans, and publications between 1990 and 2014. Quality of collated studies was evaluated using a qualitative assessment tool and the collective results interpreted.

RESULTS: Searches identified 629 papers of which, following review, 7 were deemed eligible for qualitative evaluation. Protein supplementation does not appear to affect mortality but does reduce weight loss, and improve nutritional status. Reduction in grip strength deterioration was observed in a majority of studies, and approximately half of the studies described reduced complication rates. No changes in duration of hospital stay or plasma protein levels were reported. There is evidence to suggest that protein supplementation should be routinely provided post-operatively to this population. However, despite comprehensive searches, clinical trials that varied only the amount of protein provided *via* oral nutritional supplements (discrete from other nutritional

components) were not found. At present, there is some evidence to support routinely prescribed oral nutritional supplements that contain protein for gastrointestinal surgery patients in the immediate post-operative stage.

CONCLUSION: The optimal level of protein supplementation required to maximise recovery in gastrointestinal surgery patients is effectively unknown, and may warrant further study.

Key words: Protein supplementation; Gastrointestinal surgery; Clinical trial; Oral supplementation; Systematic review

Core tip: Malnutrition in hospitalized patients can negatively impact recovery; protein and energy deficiencies have been documented in gastrointestinal surgery patients and trials have demonstrated benefits of peri-operative nutritional strategies, although post-operative oral nutritional supplementation have been studied to a lesser extent. The outcome of our work is that clinical trials that varied only the protein provided *via* oral supplements were not found. There is evidence to support oral protein supplements for gastrointestinal surgery patients immediately post-operatively. But the optimal level of protein supplementation required to maximise recovery in gastrointestinal surgery patients is effectively unknown, and may warrant further study.

Crickmer M, Dunne CP, O'Regan A, Coffey JC, Dunne SS. Benefits of post-operative oral protein supplementation in gastrointestinal surgery patients: A systematic review of clinical trials. *World J Gastrointest Surg* 2016; 8(7): 521-532 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i7/521.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i7.521>

INTRODUCTION

Malnutrition has been associated with increased incidence of complications such as sepsis, pneumonia, wound infections, clotting disorders, and wound dehiscence^[1,2]. Patients undergoing major gastrointestinal surgery can suffer periods of undernourishment, not only as a consequence of their presenting illness, but also due to reduced food intake and the resulting catabolic state that prevails in the post-operative period. In this population, malnutrition has been found to increase post-operative morbidity and mortality rates as well as the duration and subsequent cost of hospital stay^[3,4]. These despite multimodal nutritional regimens, include pre-operative carbohydrate loading.

In this context, nutritional supplementation has been suggested as a routine post-operative procedure for gastrointestinal surgery patients given the putative negative nitrogen balance. Indeed, intervention in

the form of post-operative protein supplementation (in the context of allowable free-fluids or light diet by mouth) has remained of interest as an effective way to improve patient recovery despite an apparent paucity of trials adequately addressing the optimum, or even appropriate, quantity of proteins or peptides. As the physiological nitrogen balance is affected by both energy and protein consumption, knowledge of the levels of each that best enable avoidance of catabolic loss after gastrointestinal surgery could benefit patient outcomes^[5].

Therefore, in this review, clinical trials of oral nutritional supplements providing increased protein levels relative to controls, administered to human patients recovering from gastrointestinal surgery, were systematically assessed with respect to clinical efficacy and cost-effectiveness.

MATERIALS AND METHODS

Search methods

The following terms were used to locate articles: "oral" or "enteral" and "postoperative care" or "post-surgical" and "proteins" or "milk proteins" or "dietary proteins" or "dietary supplements" or "nutritional supplements". In databases that allowed added limitations, results were limited to clinical trials that studied humans, and publications between 1990 and 2014. Despite these limits, multiple non-clinical trial results, non-human trials, and irrelevant studies appeared and were excluded. The search was intentionally broad as more specific searches for gastrointestinal surgery associated keywords and MeSH terms resulted in numerous missed relevant papers. Databases searched included: MEDLINE, Biosis, EMBASE, Cochrane Trials, Cinahl, and CAB. Other means of identifying records included searching reference lists of relevant papers.

Inclusion and exclusion criteria

Randomized controlled clinical trials examining protein-based oral dietary supplementation post-operatively in human gastrointestinal surgery patients were selected. Studies were excluded if: Involved immunonutrition; related to supplementation with incomplete proteins; did not specify the amount of protein supplemented; supplemented patients pre-operatively only; not strictly oral nutrition; or not published in English.

Outcomes measured

Primary outcomes included the effect of supplementation on post-operative complications, length of hospital stay, nutritional status, and weight loss. Secondary outcomes included the effect on plasma proteins, quality of life, function, and cost of care.

Data collection and analysis

Trials that met the inclusion criteria were independently assessed for eligibility by the authors (Crickmer M, O'Regan A, Dunne CP) and discrepancies were resolved

Table 1 Quality assessment tool (adapted from^[6])

Items and scores
Was the assigned treatment adequately concealed prior to allocation? 2 = method did not allow disclosure of assignment 1 = small but possible chance of disclosure of assignment or states random but no description 0 = quasi-randomized
Were the outcomes of participants who withdrew described and included in the analysis (intention to treat)? 2 = intention-to-treat analysis based on all cases randomized possible or carried out 1 = states number and reasons for withdrawal but intention-to-treat analysis not possible 0 = not mentioned or not possible
Were the outcome assessors blinded to treatment status? 2 = action taken to blind assessors, or outcomes such that bias is unlikely 1 = small or moderate chance of unblinding of assessors 0 = not mentioned
Were the treatment and control group comparable at entry? 2 = good comparability of groups 1 = confounding small 0 = large potential for confounding, or not discussed
Were care programs, other than the trial options, identical? 2 = care programs clearly identical 1 = clear but unimportant differences 0 = not mentioned or clear and important differences in care programs
Were the inclusion and exclusion criteria clearly defined? 2 = clearly defined 1 = inadequately defined 0 = not defined
Were the interventions clearly defined (including estimates of nutritional value)? 2 = clearly defined interventions are applied with a standardized protocol 1 = clearly defined interventions are applied but the application protocol is not standardized 0 = intervention and/or application protocol are poorly or not defined
Were the participants blind to assignment status following allocation? 2 = effective action taken to blind participants 1 = small or moderate chance of unblinding participants 0 = not possible, or not mentioned (unless double-blind), or possible but not done
Were the treatment providers blind to assignment status? 2 = effective action taken to blind treatment providers 1 = small or moderate chance of unblinding of treatment providers 0 = not possible, or not mentioned (unless double-blind), or possible but not done
Was the overall duration of surveillance clinically appropriate? 2 = optimal (six months or more) 1 = adequate (one up to six months) 0 = not defined, or not adequate

by discussion. Papers were read independently by the authors and themes were identified. Risk of bias was assessed by determining allocation concealment for participants, the staff and assessors. The effect of treatment was assessed relative to clinical importance and statistical significance, using *P* values of ≤ 0.05 as the cut-off point. The evaluation of the trials was guided thematically with the qualitative tool, modified from a previous Cochrane Systematic Review^[6], described in Tables 1 and 2. The characteristics of each study were tabulated and are shown in Table 3.

Where studies included both pre-and post-operative supplementation interventions, only the post-operative components are considered in this review. The numbers of trial participants per study were adjusted to reflect this.

RESULTS

Results of the search

Following PRISMA guidelines^[7], seven eligible reports

were identified (see Figure 1). Exclusions were as follows: (1) of records found *via* database searching: 358; (2) of records found by other means: 271; (3) of records screened: 629; (4) of records excluded (including removal of duplicates): 587; (5) of full text articles assessed for eligibility: 42; (6) of full text articles excluded: 35; and (7) of studies included in qualitative analysis: 7.

Assessment of studies design

All seven studies^[5,8-13] were prospective randomized controlled trials. In most cases, the patients, their carers and the assessors were not blinded. Intention to treat was not included in most studies. The control and intervention groups had similar characteristics in each trial and in all other aspects of treatment, other than the intervention. The interventions undertaken, and inclusion and exclusion criteria, were well defined in all studies. Five of the seven studies^[5,8,9,11,13] included outpatient phases that lasted between one and six months. The characteristics of the studies are outlined

Table 2 Outcomes of quality assessment, described for individual trials

	Smedley <i>et al.</i> ^[8]	Saluja <i>et al.</i> ^[10]	Beattie <i>et al.</i> ^[13]	MacFie <i>et al.</i> ^[9]	Jensen <i>et al.</i> ^[5]	Keele <i>et al.</i> ^[11]	Rana <i>et al.</i> ^[12]
Was the treatment adequately concealed prior to allocation?	2	0	2	0	0	0	2

in Table 3.

Sample sizes and patient population

Sample sizes ranged from 40 to 101. A total of 529 patients were involved, 262 of whom had an intervention. Participants were post-operative gastrointestinal surgery patients scheduled for acute or elective surgery. Nutritional status pre-operatively was variable, with some studies focused on malnourished patients^[10,13]. Patient age ranged from 18 to greater than 75, and all studies included both genders.

Interventions

All treatment group (TG) patients received post-operative nutritional supplementation in addition to their normal ward diet, while control groups (CGs) consumed only normal ward diet. In most cases, patients were encouraged to drink 200-400 mL of the supplement per day. Supplements comprised between 0.0078 g/mL and 0.06 g/mL of protein, with the most frequent value being 0.05 g/mL. They also provided between 0.6 kcal/mL and 1.5 kcal/mL of energy, with the most common inclusion being 1.5 kcal/mL. All studies, except Jensen^[5], began supplementation as soon as allowed by the surgical team, typically beginning one to six days post-operatively. Some studies focused on post-operative feeding only, while studies by Smedley *et al.*^[8] and MacFie *et al.*^[9] examined both pre-operative and post-operative feeding. Only the post-operative component of those studies is considered in this review and the numbers of trial participants has been adjusted to reflect this.

Themes

Assessment was according to the following eight themes:

Overall nutritional intake: Four of the studies quantified the difference in protein intake between treatment and CGs. Specifically, Saluja *et al.*^[10] found that protein intake was significantly higher ($P < 0.01$) in the group given supplementation in addition to ward diet. The TG consumed an average of 55.71 ± 11.63 g of protein per day during the study period, while the CG consumed 39.48 ± 11.14 g of protein per day ($P < 0.01$). These increases in protein consumption were accompanied by significant increases in the amount of carbohydrate consumed ($P < 0.01$). Jensen *et al.*^[5] calculated that the TG consumed 22% more protein than the CG and 16% more energy. It is noteworthy that supplementation in that trial started after discharge at about day 10, and was paired with dietetic advice, while in the previous trial by Saluja *et al.*^[10], supplementation began the first day following surgery. Keele *et al.*^[11] also found that the TG showed statistically significant increases in protein and energy consumption on study days one to four. No difference in protein intake was seen in the second phase of their trial, which examined intake for 4 mo following discharge. The inpatient results (improved overall nutritional intake) found by Rana *et al.*^[12] are similar to those found by Keele *et al.*^[11].

Weight: Four of five studies that measured this factor^[5,8,11,12] found reduced weight loss in normonourished patients receiving supplementation. Keele *et al.*^[11] found decreased loss both at day 3 of the trial and at discharge ($P < 0.001$). Rana *et al.*^[12] found that when patients started supplements as soon as they were allowed free fluids after surgery, they maintained their weight whereas by day 3, there was significant weight loss in the CG ($P < 0.05$). Statistically significant reduction in weight loss was also found by Smedley

Table 3 Summary details of eligible trials

Ref.	Method	Participants	Intervention	Outcomes	Conclusions/Notes
Smedley <i>et al</i> ^[8]	RCT	Undergoing elective moderate-major lower GI surgery <i>n</i> = 89; 39 patients were controls in the pre-op phase and in the TG in phase 2 making them the treatment group for this analysis. Fifty patients were controls throughout making them the control group	Included multiple groups with patients receiving pre and post-operative supplementation. This review focused on the group that received no supplements pre- and post-op, as well as the group that received no supplement pre-op and supplements post-operation (CG = Group 4, TG = Group 3) Supplementation began when patients allowed light diet or free fluids post-operation. Fortisip, nutricia used as supplement: 0.05 g/mL protein, 1.5 kcal/mL energy TG asked to drink as they desired in addition to meals	Complications: Fewer minor complications in TG (<i>P</i> < 0.05) Length of stay: No difference Weight loss: Significant reduction in patients given ONS before and after surgery and in patients given postoperative ONS only Quality of life: No difference (Short Form 36, EuroQol instruments were used) Cost: Reduced by GBPE300 (15%) per patient, however not statistically significant Post-surgery oral nutritional supplements were of benefit independently of nutritional status Adverse events: ONS well tolerated	The patients in this study had a baseline of good nutritional intake
Saluja <i>et al</i> ^[10]	PRCT	<i>n</i> = 60 (30/30) divided into BM, MM and SM using the NRI ^[26] Age: Between 20-60 yr Elective and emergency abdominal procedures (not just GI) Treatment started from day-1 post-operatively Assessment was done on admission, day 3 and at discharge	0.033 g/mL of protein or 16.66 g/500 mL drink and 500 kcal energy, in addition to ward diet. Ward diet only was provided to control group. Trial started once surgical team allowed fluids or light diet	Total protein intake: Increased in TG (<i>P</i> < 0.01) Voluntary protein intake higher though not significant Weight loss: TG = 2.15 kg <i>vs</i> CG = 4.6 kg (<i>P</i> < 0.01) Overall weight loss: TG = 5.6%, CG = 6.4% Severely Malnourished Patients: TG = 6.3%, CG = 10% (<i>P</i> < 0.01) No significant change in lymphocyte count Complications: No significant difference Length of stay: Statistically significant reduction in severely malnourished patients. No difference in other categories in length of stay No change in mid arm circumference No change in hand grip strength Treatment group felt better than control group (subjective assessment) No difference in voluntary intake in group consuming supplements	Severely malnourished patients have increased energy requirements and less oral intake, and will therefore lose lean body mass as a substrate for energy Albumin half-life is 20 d - early post-op period is too short to demonstrate a difference due to supplementation

Crickmer M *et al.* Post-operative oral protein supplementation: Systematic review of trials

Beattie <i>et al</i> ^[13]	PRCT	<p>Patients had a BMI < 20 or > 5% weight loss between hospital admission and trial inclusion, and other anthropometric criteria.</p> <p>Age: 18-80</p> <p><i>n</i> = 101, intervention = 52; control = 49</p>	<p>Oral nutritional supplement containing 0.06 g/mL protein, 1.5 kcal/mL energy. Patients encouraged to consume 400 mL/d postoperatively. In practice, patients had between 200 and 400 mL/d in addition to normal meals</p>	<p>Weight loss: CG lost an average maximum of 5.96 kg at 8 wk after admission, while TG lost a maximum of 3.4 kg on average in the first 4 wk and then gained weight (<i>P</i> < 0.001)</p> <p>Mean body weight loss = 9.8% in CG and 5.6% in treatment group</p> <p>Triceps skin fold and MAMC were higher in TG than CG (<i>P</i> < 0.001)</p> <p>Function: Improved grip strength at 10 wk (<i>P</i> < 0.001)</p> <p>Quality of life (UK SF-36): Statistically significant improvement in mental and physical health (<i>P</i> < 0.001)</p> <p>Complications: Reduced (<i>P</i> < 0.05)</p> <p>No difference in infection rates</p> <p>Length of stay: No difference</p>	<p>Support for nutritional intervention in patients with malnutrition:</p> <p>Post-operative oral nutritional supplementation improved nutritional status, quality of life and morbidity</p>
MacFie <i>et al</i> ^[9]	PRCT	<p>Major GI surgery patients <i>n</i> = 52; 27 had intervention of some kind.</p> <p>TG <i>n</i> = 27 (post op supplements), CG <i>n</i> = 25</p>	<p>Pre and post-operative phases. For this review, only the control group and post-operative supplementation group were looked at</p> <p>Fortisip, Nutricia given - 0.05 g/mL protein and 1.5 kcal energy/mL or an alternative Fortijuice, Nutricia containing 0.025 g/mL protein and 1.25 kcal/mL energy. Patients encouraged to consume 400 mL/d in addition to normal ward diet</p> <p>Supplementation commenced as soon as permitted fluids post-surgery, usually within 24 h</p> <p>CG was provided standard ward diet</p>	<p>Nutritional intake: Increased protein and energy seen (but no benefits could be seen)</p> <p>Morbidity: No difference</p> <p>Mortality: No difference</p> <p>Effect on voluntary food intake: No difference</p> <p>Nutritional status: No difference</p> <p>Functional status: No difference</p> <p>Hospital stay: No difference</p> <p>Weight Loss: No significant difference</p> <p>Serum albumin: No significant difference</p> <p>Psychological Status: No significant differences</p> <p>Return to normal activities at 6 mo: No difference</p> <p>No evidence that increased supplements decreased amount of ward diet eaten</p>	<p>Similar intakes of supplements as previous trials (Rana, Keele) that showed benefit</p> <p>Also concluded: No difference in benefit when looked at the 17 malnourished patients in the study</p> <p>Possible lack of difference due to small study numbers in each group, or in general, early return to eating post-surgery in practice along with dietician support normally at the hospital</p>
Jensen and Hesson ^[5]	RCT - Supplements given after discharge from colorectal surgery for 4 mo	<p>Elective and acute <i>n</i> = 87: 47 in CG and 40 in TG</p>	<p>Control group: Discharged without advice</p> <p>TG: Dietetic advice and a variety of supplements including protein only - aiming for 1.5 g protein/kg per day</p>	<p>Body mass: (50 d after discharge) lean body mass increase seen in TG of 1.3 kg (<i>P</i> = 0.009) and in overall body mass 2.0 kg (<i>P</i> = 0.005). 110 d after discharge: Total mass difference was +2.7 kg for TG relative to CG (<i>P</i> = 0.014), and lean body mass +1.4 kg for TG (<i>P</i> = 0.029)</p> <p>No significant difference in fat mass was seen at either stage</p> <p>Serum albumin: No difference was seen at any time</p>	<p>Initially patients in the intervention group gained LBM without fat mass; later there were gains in both types of mass</p> <p>Recommendation: Patients should increase protein intake to 1.5 g/kg per day for 2 mo post-surgery</p>

Keele <i>et al.</i> ^[11]	Short and long term (4 mo after discharge) benefits of intervention	<i>n</i> = 100 moderate-major elective GI surgery; <i>n</i> = 53 in CG and <i>n</i> = 47 in TG.	TG was given oral nutritional supplement post-operatively in addition to ward diet, which was given to the control group In-patient and out-patient phases (to 4 mo after discharge)	Inpatient phase Nutrient intake: Significant increase in protein and energy intake increase at days 1 and 2 (<i>P</i> < 0.001) and 3 (energy <i>P</i> < 0.01, protein <i>P</i> < 0.001), day 4 (<i>P</i> < 0.05) and day 7 - protein only (<i>P</i> < 0.05) No significant difference in intake of energy or protein from ward diet	Phase 1 assessment was at day 3 and discharge Clinically significant benefits with short term supplementation but not long term supplementation Both CG and TG had below requirement levels of protein as in-patients
	(There were four groups in this study: C/C had no supplementation before/after surgery; C/S had none before and supplementation after; S/C had supplementation before and none after; S/S had supplementation before and after surgery For the purposes of the review C/C were taken as CG and C/S were taken as TG)		Supplements - 200 mL cartons of Fortisip with 1.5 kcal and 0.05 g/mL (10 g protein/carton)	Energy intake 1 m after discharge: Significantly higher in TG Weight loss: Less in treatment group at day 3 and discharge (<i>P</i> < 0.001) Serious complications: Less in treatment group (<i>P</i> < 0.05) Handgrip: Significant reduction in CG at days 3 and 7; strength lost at day 3 in treatment group but regained by discharge Subjective fatigue: Increased fatigue in CG at day 3 and discharge (<i>P</i> < 0.001), no significant increase in fatigue in TG Complications: More in control group (<i>P</i> < 0.05) Giving food did not reduce voluntary food intake Outpatient phase Nutrient Intake: No significant difference in protein intake in the out-patient phase. Significantly higher energy intake was seen (<i>P</i> < 0.05) in groups consuming supplements post-discharge compared to controls No benefit was seen with supplementation post-discharge	By 1 mo, patients in both groups were eating well so supplements had little effect on well-being The rapidity of the effects of protein supplementation suggests that its effect is due to a direct action of key nutrients rather than repletion of tissue stores

Rana <i>et al.</i> ^[12]	Short term only: Started on day patients could receive free fluids until discharge	<i>n</i> = 40; 20 control and 20 supplemented	Ad libitum supplementation with oral nutritional sip feed in addition to control diet	Nutritional intake: significantly higher energy intake in the treatment group <i>P</i> < 0.004 (as well as the nutritional value of the supplements, more energy was consumed from ward diet by these patients) and protein intake (due solely to supplements)	In the CG there is a significant protein deficit by day 3 which persisted to day 7 (often the day of discharge)
		Major G-I surgery	7.8 g/L unhydrolysed protein. 1.5 kcal/mL energy density. 1.4 L is needed to provide all required nutrient as defined by United Kingdom health board	Significant weight loss in CG but not TG at day 3 and discharge	5-6 d on average elapsed between day of operation and day 1 of study period where diet was allowed. Study period began when surgical team allowed "free-fluids or light diet"
			Controls and given ward diet and allowed snacks	Grip strength difference at day 3 and discharge (<i>P</i> < 0.03) in favor of treatment group	Within 3 d of "free fluids/light diet" treatment patients were consuming 70 g protein/d and about 2000 kcal
				No difference in mid-arm circumference/triceps skin folds changes between groups	Observed increased number of calories (not protein) being eaten from ward diet in the treatment group
				Serious complications (pneumonia, wound infection) significantly higher in CG	- inference that supplementation helped to maintain appetite
				No difference in length of stay	
				Complications: Pneumonia and wound infection seen. <i>P</i> < 0.02 in favor of treatment group	
				Blood proteins: No difference in serum albumin, retinol binding albumin, prealbumin. Significant difference in retinol binding protein as CG declined while TG levels remained same. <i>P</i> < 0.05	
				Hospital stay length: No statistically significant difference	

TG: Treatment group; CG: Control group; RCT: Randomised controlled trial; PRCT: Prospective randomised controlled trial; ONS: Oral nutritional supplement; MAMC: Mid-arm muscle circumference; LBM: Lean body mass; BM: Borderline malnourished; MM: Moderately malnourished; SM: Severely malnourished; NRI: Nutritional risk index.

et al.^[8] (*P* < 0.05). In the trial by Jensen *et al.*^[5], supplementation was not started before discharge, typically around 10 d post-operatively, but at both 50 and 110 d after discharge, the intervention group had increased total and lean body mass. No other studies looked specifically at lean body mass. Conversely, however, MacFie *et al.*^[9] reported no significant difference in weight loss between control and intervention groups overall.

Studies by Saluja *et al.*^[10] and Beattie *et al.*^[13] noted reduced weight loss in the malnourished patient population investigated in their studies, but no difference was seen by MacFie *et al.*^[9] when he isolated the 17 malnourished patients from his study. More specifically, Beattie *et al.*^[13] found that controls lost an average of 5.96 kg in 8 wk, while intervention patients lost 3.4 kg on average in the first 4 wk and then gained weight (*P* < 0.001). Saluja *et al.*^[10] quantified the average weight loss in the TG as 2.15 kg compared to 4.6 kg in the CG (*P* < 0.01).

Postoperative complications: None of the studies found a difference in mortality between control and TGs. A wide variety of other complications were looked at including chest and wound infection, sepsis, cardiac arrest, pulmonary embolism, and wound dehiscence. Three of the 6 trials that investigated complications found a reduced number in the TG: Smedley *et al.*^[8] found reduced minor complications (*P* < 0.05) but no difference in major complications. Both Keele *et al.*^[11] and Rana *et al.*^[12] demonstrated significantly fewer serious complications in their short term studies (*P* < 0.05). No difference in post operative complications was found by Saluja *et al.*^[10] or MacFie *et al.*^[9]. Saluja *et al.*^[10] did find a reduction in infectious complications in severely malnourished patients, but numbers were too small for statistical significance. Similarly, Beattie *et al.*^[13] saw a reduction in complications that was not significant when adjusting for age and sex.

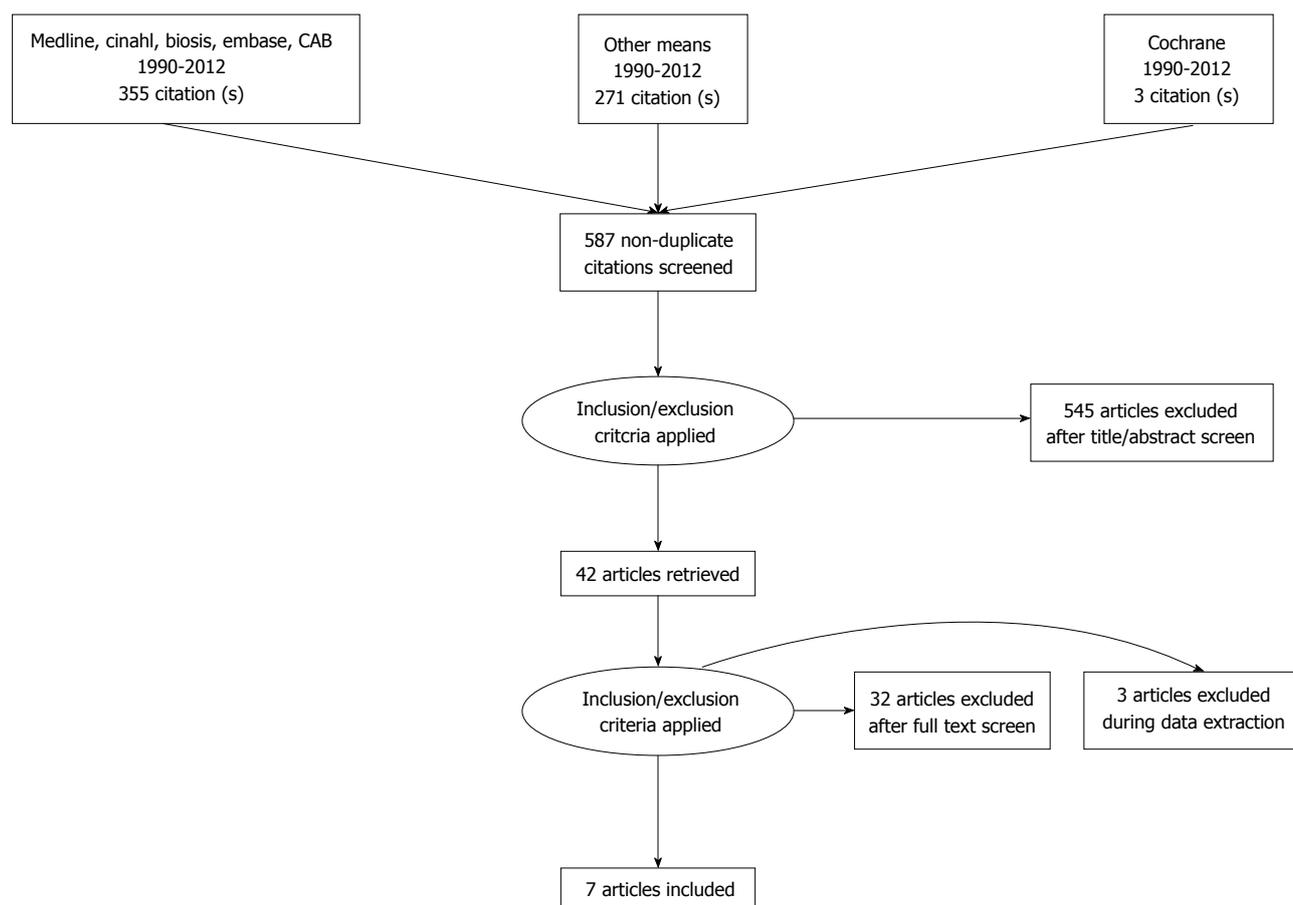

Figure 1 PRISMA guidelines.

Length of stay: The study by Saluja *et al.*^[10] determined a difference in length of stay between treatment and CGs in severely malnourished patients, but no difference in moderately or borderline malnourished patients. Beattie's study^[13], which also looked at malnourished patients, found no difference. The three studies^[8,12,13] that evaluated length of stay in normonourished patients found no difference.

Plasma proteins: Four studies investigated plasma proteins levels^[5,9,10,12], with albumin the focus of most of these studies. None of these found any significant difference in serum albumin or prealbumin. Rana *et al.*^[12] found increased retinol binding protein in the TG relative to controls at day three ($P < 0.05$).

Cost: Smedley *et al.*^[8] found that the use of oral nutritional supplementation, irrespective of when administered, decreased cost by £300 (sterling) per patient amounting to a 15% reduction compared to patients without supplementation. This was not statistically significant. No other study considered cost of care.

Grip strength: Three of five studies that investigated grip strength found reduced loss of grip strength in patients receiving oral nutritional supplements relative to controls. Keele *et al.*^[11] found that handgrip was

maintained in the intervention group and significantly reduced in controls ($P < 0.01$). Rana *et al.*^[12] found a significant difference at day three and again at discharge ($P < 0.05$). Beattie *et al.*^[13] found similar results and noted statistical significance in the differences at week 10 ($P < 0.001$). Saluja *et al.*^[10] and MacFie *et al.*^[9] detected no difference in hand grip strength after supplementation.

Quality of life and fatigue: Beattie *et al.*^[13] found increased quality of life in the TG using the short form 36 questionnaire (SF-36)^[14] in both mental and physical health ($P < 0.001$). Smedley *et al.*^[8] used SF-36 and EuroQol instruments to test quality of life and found no difference. Keele *et al.*^[11] subjectively assessed fatigue and found significant increases in control patients at study day three ($P < 0.001$), while TG increases in fatigue were not significant.

DISCUSSION

Previous reviews have concluded that oral nutritional supplements can have positive effects in terms of recovery of nutritional status post-operatively in conditions such as fractured neck of femur, colorectal surgery, and pancreaticoduodenectomy, among others^[15-17]. In these cases, the proposed benefits

could be attributed to protein supplementation (*i.e.*, the amount of orally-consumed protein that confers the greatest benefit) combined with appropriate energy intake^[18]. However, what these levels are remain unclear for patients following gastrointestinal surgery. In this review, we attempted to determine this *via* systematic review.

Our searches did not yield a single randomized controlled trial that adequately differentiated the effect of protein supplementation from carbohydrate supplementation. Therefore, analysis of the eligible reports was problematic. Limitations included the fact that protein and energy content in TG supplements were not equivalent in most of the studies. Indeed, only the study by Saluja *et al.*^[10] described using a fixed amount of supplement for daily consumption, while the remaining studies followed an "ad-libitum" approach. Arguably, the latter approach best mirrors "real-life" clinical scenarios, however it makes discerning the true effect of protein supplementation difficult. Furthermore, the characteristics of the patient cohorts were not equivalent between studies, confounding inter-study comparisons. For example, the study by Saluja *et al.*^[10] took place in Delhi and included a greater proportion of emergency surgery patients, and patients with tuberculosis, compared with the non-emergent procedures described in the Western European reports. Moreover, inadequate follow up time with control and TGs was common across studies, with some risk of bias associated with lack of blinding of participants, carers and assessors. The power of the studies was often too small, with one author conceding notably that "numbers were too small for meaningful statistical analysis"^[13] and intention to treat analysis was not used in any of the studies. Finally, the most recent of the eligible trials found in our searches was published in 2004, arguably reflecting either a shift in interest away from oral intake in favor of enteral and parenteral nutrition in this population or an emphasis placed on ordinary diet without supplement.

Despite these limitations, the authors of six of the seven studies detailed weight loss in patients receiving post-operative nutritional supplements, but to a lesser degree than the loss in control patients^[5,8,10-13]. In fact, the data suggest that this effect may be most prominent in patients malnourished initially, with statistically significant reductions in weight loss observed. While one study failed to observe this effect^[9], despite similar energy and protein intakes to other trials, the authors proposed that the lack of effect was due to a small sample size. Finally, with respect to weight gain post-operatively, it appears that weight gain commenced sooner and patients appeared to return to their preoperative weight more rapidly where supplementation was provided.

There is no evidence to suggest that nutritional supplementation post-operatively reduces mortality. While more deaths did occur in the CGs of the reported

trials, much larger samples would be needed to approach statistical significance. The topic of avoidance of both serious and minor complications is less clear. There is some precedent to suggest that post-operative supplementation decreases complications, as the effect has been documented in patients undergoing hip surgery^[15,19,20]. However, across the eligible studies here, the rate of both serious and minor complications was significantly reduced in four of the trials^[8,11-13], while no statistically significant difference was observed in two^[9,10]. This variation has been addressed somewhat by Beattie *et al.*^[13] when comparing his results to the study by MacFie *et al.*^[9] in making reference to discrepancies in defining complications. On a related topic, duration of hospitalization was reduced significantly in severely malnourished patients only^[10]. An additional study that supplemented increased amounts of protein and medium chain carbohydrates in enteral feed in gastrointestinal patients post-operatively found a 6-d reduction on average ($P < 0.05$)^[21]. However, that study had larger numbers than any of the studies considered in this review, with 229 total and 115 TG patients. It has also been suggested that length of stay is a relatively poor outcome to evaluate as it often depends on patient social circumstances and services available in addition to patient post-operative clinical condition^[12].

With respect to malnutrition, and assessment of patient incidence, low albumin has been used as a measurable indicator, but evidence suggests that it is not an effective marker of recent nutritional intake^[22]. Approximately 5% of the circulating albumin is replaced daily by the liver and, therefore, any changes in protein intake would not be evident immediately. Further, protein markers in the blood such as prealbumin, albumin and transferrin are impacted by fluid shifts and responses to injury and inflammation which complicate their use in comparisons of patients before and after major abdominal surgery, when tissue injury is present^[23]. This may explain why none of the studies in our review that monitored albumin in the early post-operative period found any disparity in albumin levels despite differences in anthropometric indicators of malnutrition (*e.g.*, triceps skin fold, mid upper arm circumference and BMI^[23]). Similarly inconsistent results were found regarding quality of life.

Evaluation of quality of life and physiological function were similarly inconsistent. For example, handgrip strength is a marker of function and results were variable across the trials. However, those variances may be explained by the use of dissimilar techniques for measurement, and confounders such as pain and fatigue post-operatively. Interestingly, the TGs in the studies conducted by MacFie *et al.*^[9] and Saluja *et al.*^[10] both described increased total body mass retention relative to CGs, but without significant increases in grip strength. Jensen *et al.*^[5] found that supplementation increased lean body mass particularly, not simply fat mass, so one could hypothesize that a functional measurement

like grip strength would also be improved, but this was not described. Previous work has documented a link between impaired muscle function and nutritionally-related complications^[24,25], but this was not consistently reflected across the eligible trials here.

The seven studies reviewed in this paper concurred that there is no difference in mortality seen with protein-inclusive nutritional supplements. There is evidence to suggest that weight reduction, nutritional intake, and nutritional status are improved, and that there may be positive cost of hospitalisation benefits, but evidence as to the effect on complications and grip strength is mixed. At present, there is some evidence to support routinely prescribed oral nutritional supplements that contain protein for gastrointestinal surgery patients in the immediate post-operative stage. However, randomized control trials using well-designed methodology to examine the optimal protein content needed to confer benefit are needed.

COMMENTS

Background

Malnutrition in hospitalized patients can negatively impact recovery; protein and energy deficiencies have been documented in gastrointestinal surgery patients and trials have demonstrated benefits of perioperative nutritional strategies, although post-operative oral nutritional supplementation have been studied to a lesser extent. The proposed benefits may be attributed to protein supplementation (*i.e.*, the amount of orally-consumed protein that confers the greatest benefit) combined with appropriate energy intake. However, what those levels may be remain unclear for gastrointestinal surgery patients.

Research frontiers

The positive impact of pre-operative nutrition has been reviewed previously and meta-analyses have demonstrated positive influence on patient outcome following gastrointestinal surgery. In the postoperative period however, the most pertinent question may be whether patients should be further supplemented. The most recent of the eligible trials found in the searches was published in 2004.

Innovations and breakthroughs

The authors' searches did not yield a single randomized controlled trial that adequately differentiated the effect of protein supplementation from carbohydrate supplementation. With only one exception, the eligible studies reviewed here involved post-operative supplements administered "ad-libitum". Although this may best mirror "real-life" clinical scenarios, it makes discerning the true effect of protein supplementation difficult. Furthermore, the characteristics of the patient cohorts were not equivalent between studies. Despite these limitations, the authors of six of the seven studies detailed weight loss in patients receiving post-operative nutritional supplements, but to a lesser degree than the loss in control patients. There is no evidence to suggest that nutritional supplementation post-operatively reduces mortality and evaluation of quality of life and physiological function were similarly inconsistent.

Applications

An intervention based on oral protein supplementation should be investigated through a double-blind randomized controlled trial.

Terminology

There are no terms used that are uncommon and that would be unfamiliar to readers.

Peer-review

The authors have made a good collation of the data to assess if there are

any benefits of post-operative protein nutritional supplementation following gastrointestinal surgery. The manuscript is well written and covers the salient points from the published studies.

Abstract

AIM: To perform a systematic review focusing on short-term outcomes after colorectal surgery in patients with previous abdominal open surgery (PAOS).

METHODS: A broad literature search was performed with the terms "colorectal", "colectomy", "PAOS", "previous surgery" and "PAOS". Studies were included if their topic was laparoscopic colorectal surgery in patients with PAOS, whether descriptive or comparative. Endpoints of interest were conversion rates, inadvertent enterotomy and morbidity. Analysis of articles was made according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

RESULTS: From a total of 394 citations, 13 full-texts achieved selection criteria to be included in the study. Twelve of them compared patients with and without PAOS. All studies were retrospective and comparative and two were case-matched. The selected studies comprised a total of 5005 patients, 1865 with PAOS. Among the later, only 294 (16%) had history of a midline incision for previous gastrointestinal surgery. Conversion rates were significantly higher in 3 of 12 studies and inadvertent enterotomy during laparoscopy

was more prevalent in 3 of 5 studies that disclosed this event. Morbidity was similar in the majority of studies. A quantitative analysis (meta-analysis) could not be performed due to heterogeneity of the studies.

CONCLUSION: Conversion rates were slightly higher in PAOS groups, although not statistical significant in most studies. History of PAOS did not implicate in higher morbidity rates.

Key words: Previous abdominal surgery; Laparoscopic surgery; Colorectal surgery; Previous abdominal surgery; Laparoscopy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: So far, there is no substantial evidence in the literature to recommend laparoscopic surgery instead of laparotomy for patients previously submitted to abdominal surgery, concerning short-term benefits, such as conversion rates and morbidity. This review, although without a meta-analysis, brings new light into this matter.

Short-term outcomes after laparoscopic colorectal surgery in patients with previous abdominal surgery: A systematic review. *World J Gastrointest Surg* 2016; 8(7): 533-540 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i7/533.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i7.533>

INTRODUCTION

In colorectal surgery, laparoscopy has been progressively accepted as a good alternative to open surgery since its first reports during the 90's^[1,2]. The main benefit attributed to laparoscopy is the associated better short-term outcomes observed in both benign and malignant colorectal diseases^[3-6]. Moreover, randomized clinical trials and meta-analysis have suggested that there is no prejudice of oncological outcomes as well^[3,7,8].

It is well recognized that the laparoscopic access to treat colorectal diseases is associated with an extended learning curve and has its own limitations. Many patient's, disease's and surgeon's factors may affect operative results, such as previous abdominal open surgery (PAOS), obesity, inflammatory conditions, pregnancy, surgical expertise and others. At the beginning of laparoscopic experience, some of these conditions were even considered contraindications for this approach^[9], due to the potential higher risk of intraoperative lesions, during trocar placement or because of visceral adhesions. In practice, these drawbacks were translated into a longer operative time and greater conversion rates. With growing expertise in laparoscopic techniques, surgeons gained confidence to perform more difficult cases and reports of laparoscopic procedures after PAOS

have been increasingly published^[10-12]. However, there is still a debate concerning the indication of laparoscopic colorectal surgery in patients with PAOS^[13,14]. Furthermore, there is no randomized study evaluating the possible benefit of laparoscopic colorectal surgery in the context of PAOS.

Thus, the aim of this study was to perform a systematic review concerning short-term outcomes after laparoscopic colorectal surgery in patients with or without PAOS.

MATERIALS AND METHODS

Incidence of conversion, inadvertent intraoperative intestinal lesions and overall morbidity were our main outcome measures.

Eligibility criteria

Studies were included if they reported results on laparoscopic colorectal surgery in patients with PAOS, whether previously open or laparoscopic, with a special interest if they were comparative. Abstracts only were not included in the systematic review, although they were taken into consideration for discussion.

Search strategy

All authors agreed regarding terms that should be used for online search. The literature search comprised the terms "colorectal", "colectomy", "PAOS", "previous surgery" and "PAOS" in different combinations. Articles were searched if published before August 2014 in the following databases: MEDLINE, EMBASE, Cochrane, Scopus, Scielo and LILACS. Initially the search was not limited by language, but only full texts in English were finally included. References in the selected articles were also searched for additional citations.

Study selection

Titles and abstracts were scanned to identify suitable articles; afterwards abstracts were reviewed to identify studies fulfilling inclusion criteria. Finally, full texts of the interested studies were selected. Two authors performed the study selection and one author was responsible for revision of this selection. There were no conflicts regarding suitability of studies selected or excluded.

Extraction and analysis of data

Two investigators were responsible to extract data from the studies to a previously designed datasheet, interesting outcomes of this study. Another investigator was responsible to review the information and to solve any conflicts. Information collected from the studies was: Overall conversion, inadvertent intraoperative lesions and morbidity. Definition of conversion was not always mentioned in the articles or differed between them. Mostly, conversion referred to unplanned incisions or size of incision in order to complete surgery. We have considered conversion as described in each study, as

Table 1 Definition of conversion in the 13 studies included in the review of patients submitted to laparoscopy with or without previous abdominal surgery

Ref.	Definition of conversion
Hamel <i>et al</i> ^[19]	“any incision unplanned, made sooner than planned or longer than 5 cm”
Kwok <i>et al</i> ^[26]	“abdominal incision exceeded 8 cm; or the incision was extended for any reasons other than division of the bowel and extraction of specimens”
Law <i>et al</i> ^[22]	N/A
Arteaga González <i>et al</i> ^[21]	N/A
Franko <i>et al</i> ^[23]	“change in operative strategy requiring exsufflation of capnoperitoneum and elongation of the surgical incision to allow direct visualization for continued dissection”
Vignali <i>et al</i> ^[14]	“abdominal incision longer than 7 cm or an abdominal incision made earlier or different from that planned at the start of the procedure”
Nozaki <i>et al</i> ^[17]	N/A
Offodile <i>et al</i> ^[25]	“final incision length longer than 7 cm (after skin closure)”
Barleben <i>et al</i> ^[16]	N/A
Fukunaga <i>et al</i> ^[24]	“performance of an unplanned incision”
Maggiori <i>et al</i> ^[18]	“any unplanned incision or a planned incision longer than 6 cm”
Naguib <i>et al</i> ^[20]	N/A

shown in Table 1.

Analysis of articles was done according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses^[15]. Forest plots were done using Review Manager (RevMan, Version 5.3. Copenhagen: The Nordic Cochrane Centre, The Cochrane Collaboration, 2012).

RESULTS

The literature search initially identified 391 articles. Search within references led us to include other 3

articles. Subject of citation did not meet the interest criteria of this study in 365 citations. Two studies were excluded because of language (Chinese and Italian) and 13 had only presented abstracts. Fourteen full-text articles were analysed and 13 studies were included in the present manuscript. One article was excluded because it did not describe nor compared laparoscopy with and without PAOS^[13,14,16-26] (Figure 1).

Regarding their characteristics, with one exception, all studies were retrospective and comparative, but only two were case-matched^[14,18]. One study was not comparative and only described a group of patients with PAOS^[16] (Table 2).

The selected studies comprised a total of 5005 patients, 1865 with PAOS. Four papers included not only open but also laparoscopic previous surgeries, and in most of them some kind of resection was done (*i.e.*, excluding diagnostic laparoscopy and bypasses), excluding one study that included a few patients submitted to a diverting stoma^[16]. In two studies^[17,23], colorectal surgery included totally laparoscopic and also hand-assisted techniques. Regarding the type of surgical procedures performed, two studies^[19,25] described only right colectomies, one included only anterior resections for upper rectum cancer^[26], while others included all types of colorectal resections. Three articles included only patients diagnosed with colorectal cancer^[17,24,26].

All but three studies^[14,18,21] included previous appendectomy. Most previous surgeries described in the studies were appendectomies, gynaecological procedures or cholecystectomies. Of 1865 patients, only 294 (16%) were cited as having had a midline incision for previous gastrointestinal surgeries, while 702 (38%) had a previous appendectomy. Although we cannot separate results of only previous gastrointestinal procedures from gynaecological procedures and cholecystectomies, these 294 cases are the object of our

Overall conversion

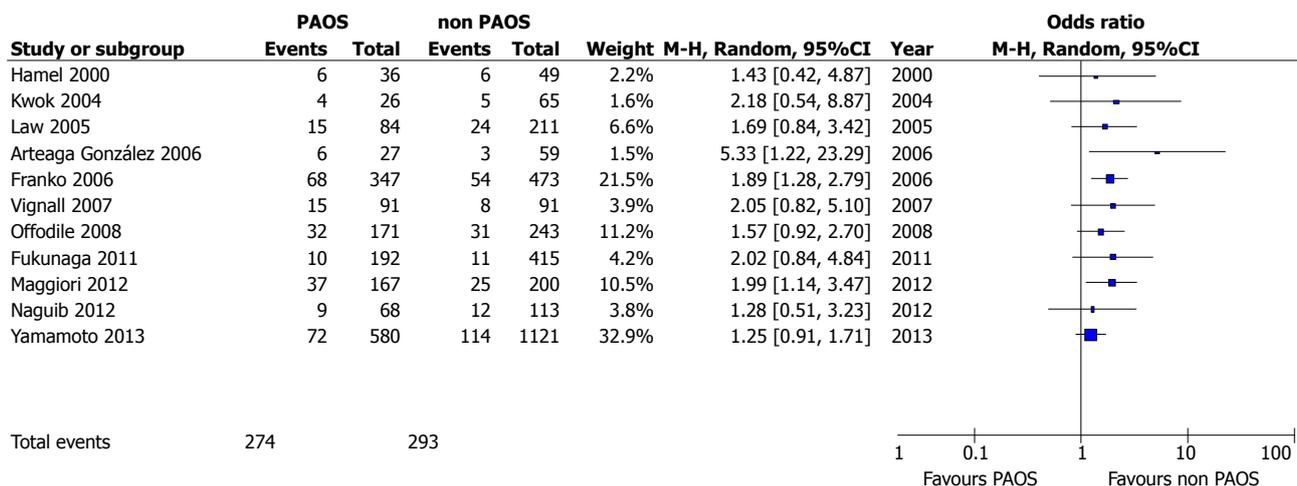

Figure 2 Forest plot showing comparison between studies regarding overall conversion.

interest in this paper.

All studies were retrospective and with great heterogeneity, so a quantitative analysis (meta-analysis) was not carried out because it would not be of value. Nonetheless, a forest plot was made in order to provide an idea of trend in the results of this review, in case data could be adequately extracted.

Conversion

Overall conversion rates were described in all 12 studies (Table 2). These rates were higher in all of the studies but only 3 of studies showed statistical significance^[18,21,23] (Figure 2). There were no conversions in one of the studies^[17].

Intraoperative inadvertent enterotomy

In 3 of 5 studies, rates of intraoperative intestinal lesions (Figure 3) were higher in the PAOS groups (not necessarily leading to conversion)^[13,23,24], while in two

studies they were similar^[20,21]. The other 8 papers did not describe such data (Table 2).

Postoperative morbidity

In the 9 studies that reported postoperative complication rates, similar rates were reported between patients with and without PAOS (Table 3). In 3 other studies the P value comparing overall morbidity rates was not available, but numbers for independent complications were summed in order to perform odds ratio analysis (Figure 4).

DISCUSSION

To date, very few studies have been devoted to evaluate the impact of PAOS on the short-term results after laparoscopic colorectal surgery. The present literature review with more than 5000 patients (including 1800 that had PAOS and 264 with previous gastrointestinal

resection by midline incision) suggests that PAOS has probably little impact on postoperative morbidity after laparoscopic colorectal surgery.

It is important to state that previous surgery away from the site of the current surgery might not interfere in short-term outcomes, for ex. previous gynaecological surgery in a patient that is going to be submitted to a

transverse colon resection should not present a problem regarding technical aspects and subsequent results.

Although conversion rates were higher in few studies (mainly because of adhesion), and the risk of inadvertent enterotomy was also slightly increased, overall postoperative morbidity was similar with or without PAOS. According to the literature, conversion

from laparoscopic to open surgery does not seem to influence directly in post-operative morbidity^[27]. In our study, although 3 studies reported higher conversion rates in the PAOS groups, morbidity was similar in both groups.

Due to the heterogeneity of the studies, it was not possible to perform a meta-analysis with qualitative results. This heterogeneity refers not only to statistical methods or study design, but also to different types of surgery (previous and actual) and diseases, as well as experience of the surgeon, which makes it hard to compare as equal.

In a pragmatic approach, laparoscopy should not be contraindicated in patients with PAOS and this is common sense for most surgeons, though it is not well established by current medical literature so far. Although surgeon and patient must be aware of the higher risk of conversion and possible accidental enterotomy, because of all the possible benefits previously demonstrated after laparoscopic colorectal surgery, laparoscopy might be attempted in most of the patients.

Short-term benefits of laparoscopic colorectal resection are clearly demonstrated by several randomized studies, including faster recovery, lower pain, earlier feeding and shorter return of normal intestinal function and shorter hospital stay^[6,28-30]. However, it remains controversial if patients still profit from laparoscopic advantages in cases of PAOS. There is no doubt that intra-abdominal adhesions may substantially impair intra and postoperative outcomes, mainly due to difficulties when performing adhesiolysis and the risks of visceral perforations. In fact, abdominal adhesions following laparotomy have been described in up to 70% to 90% of patients^[31,32], and this may reflect in a longer operative time, mainly due to adhesiolysis, even in open surgery^[33], and may lead, also in open surgery, to a higher risk of small bowel lesion in up to 20%^[34].

Conversion rates in laparoscopic colorectal surgery range between 5% and 23%^[4,35-40]. Although some studies did not find PAOS as a risk factor for higher conversion rates^[36,39,41,42], it is believed that PAOS has the potential to increase these rates. In our opinion and practice, we believe that a systematic laparoscopic approach in colorectal surgery for patients with PAOS should be done, except for those with wound dehiscence for which repair is indicated.

Our literature review about laparoscopic surgery in patients with PAOS is in accordance with our strategy: Overall postoperative morbidity was similar whether there was PAOS or not. However, it must be noticed that conversion rates are probably slightly higher in cases of PAOS (demonstrated in only 3/12 studies) mainly because of adhesions, as suggested in 5/6 studies.

We are aware that inflammatory cases (Inflammatory Bowel Disease and diverticulitis) may sometimes present as an even bigger challenge than colorectal cancer and that a learning curve is fundamental for a surgeon to achieve advanced laparoscopic skills and overcome technical difficulties. Therefore, surgeons

without significant experience in laparoscopy should carefully select PAOS cases. However, with growing experience in laparoscopic surgery, we consider that adhesion is no more a contraindication to laparoscopic surgery. Even if several minutes might be necessary in the beginning of the procedure to perform adhesiolysis, we consider that avoiding an unnecessary laparotomy may bring several advantages. First, it avoids a traumatic aggression on a previous healed abdominal incision, with the risk of long-term hernia; second, it allows keeping all the short-term advantages of laparoscopy.

In our systematic review, risk of inadvertent enterotomy seems higher with than without PAOS, but this aspect was in fact evaluated in only 5 of 12 studies, and demonstrated in only 3 of those 5 studies.

The main limitation of our review is the heterogeneity of the studies and the absence of prospective studies. For these reasons, it does not allow us to perform quantitative analysis, pooling the results together. Among the studies excluded from our review for being abstracts only, we could also perceive a trend suggesting that conversion rates in patients with PAOS is not higher than that in non PAOS groups^[43-47]. In one abstract referring to risk factors for conversion during laparoscopy in colorectal surgery, PAOS was not identified as one^[48]. Furthermore, in the context of Crohn's disease, where redo surgery is frequent, two teams have demonstrated that performing a redosurgery by laparoscopy is feasible without increased morbidity rate^[43,49], even though short-term benefits might not be the same as in first-time laparoscopies for IBD.

In conclusion, this review suggests that laparoscopic surgery in patients with PAOS is feasible and it is not associated with higher morbidity rates. Although the potential risks of conversion (due to adhesions) and inadvertent enterotomies must not be forgotten, we consider that they are not enough to contraindicate laparoscopy in these patients.

COMMENTS

Background

Laparoscopy became the standard technique in many gastrointestinal procedures. But still there is controversy when it comes to perform colorectal surgery in patients that were operated on by a previous laparotomy, since there are no definite studies in this matter. Adhesions and consequent conversion might pose a problem as well as possible higher morbidity rates derived from those. Several articles have compared patients with and without previous abdominal open surgery, but most have a small number of patients, making it harder to make definite assumptions.

Research frontiers

If the authors could consider only patients with previous gastrointestinal resections through midline incision they might bring an even better light in this subject of laparoscopy in case of previous abdominal surgery.

Innovations and breakthroughs

A systematic review concerning a theme that has not been so far elucidated by the current literature, to try to stimulate the debate and since a controlled study with such design is not probable, they might have to take the best evidence

from uncontrolled studies.

Applications

Surgeons might use a systematic revision as an extra support to the belief that previous surgery is no longer a contraindication for laparoscopy in colorectal surgery.

Peer-review

This manuscript is a satisfactorily written systemic review on this problematic subject.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Hyo K Lim, MD, PhD, Professor, Department of Radiology, School of Medicine, Samsung Medical Center, Sungkyunkwan University, Seoul 135710, South Korea

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Gallbladder cancer is the most common tumor of the biliary tract and it is associated with a poor prognosis. Unexpected gallbladder cancer is a cancer incidentally discovered, as a surprise, at the histological examination after cholecystectomy for gallstones or other indications. It is a potentially curable disease, with an intermediate

or good prognosis in most cases. An adequate surgical strategy is mandatory to improve the prognosis and an adjunctive radical resection may be required depending on the depth of invasion. If the cancer discovered after cholecystectomy is a pTis or a pT1a, a second surgical procedure is not mandatory. In the other cases (pT1b, pT2 and pT3 cancer) a re-resection (4b + 5 liver segmentectomy, lymphadenectomy and port-sites excision in some cases) is required to obtain a radical excision of the tumor and an accurate disease staging. The operative specimens of re-resection should be examined by the pathologist to find any "residual" tumor. The "residual disease" is the most important prognostic factor, significantly reducing median disease-free survival and disease-specific survival. The other factors include depth of parietal invasion, metastatic nodal disease, surgical margin status, cholecystectomy for acute cholecystitis, histological differentiation, lymphatic, vascular and perineural invasion and overall TNM-stage.

Key words: Gallbladder cancer; Laparoscopic cholecystectomy; Liver resection; Lymphadenectomy; Incidental gallbladder cancer; Unexpected gallbladder cancer

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Unexpected gallbladder cancer is diagnosed, as a surprise, after cholecystectomy for gallstones. A second surgical procedure consisting in a re-resection may be required depending on the depth of invasion. The discovery of cancer represents a challenge for the surgeon who must inform the patient many days after cholecystectomy and must evaluate the indication for a re-resection. The presence of a residual disease in the operative specimen after re-resection is the most important prognostic factor.

Clemente G. Unexpected gallbladder cancer: Surgical strategies and prognostic factors. *World J Gastrointest Surg* 2016; 8(8): 541-544 Available from: URL: <http://www.wjgnet.com>

INTRODUCTION

Gallbladder cancer (GBC) is the most common tumor of the biliary tract and it is recognized as one of the most aggressive cancers^[1]. It is generally associated with a poor prognosis with a reported 5-year survival rate of 5%^[2,3]. The delay in diagnosis is considered the main cause of the high mortality. GBC is a relatively rare disease in Western countries: In the United States an incidence of 1.2/100.000 is reported^[4] but, in some countries (Chile, Northern India), the incidence is ten times higher. Unexpected GBC (UGBC) can be defined as a cancer incidentally discovered, as a surprise, at the histological examination after cholecystectomy for gallstones or other indications. In recent years, the widespread diffusion of laparoscopic techniques has caused an increase in the number of laparoscopic cholecystectomies and therefore an increase of diagnoses of UGBC. Today, between 0.2% and 3% of patients undergoing cholecystectomy has a diagnosis of UGBC, depending on regional prevalence. In some tertiary centers such as Johns Hopkins University^[1] and the Memorial Sloan-Kettering Cancer Center^[4], UGBCs account for about half of all GBCs. Unlike the GBC, UGBC is a potentially curable disease with an intermediate or good prognosis in most cases. The adoption of an adequate surgical strategy is mandatory to improve the prognosis and an adjunctive radical resection may be required depending on the depth of invasion. However, UGBC represents a challenge for the surgeon who must inform the patient many days after cholecystectomy and must evaluate the indication for a re-resection.

DIAGNOSIS AND TREATMENT

After histological confirmation of the diagnosis, the first step is to obtain, as much as possible, all the information regarding the first surgical procedure. Circumstances and operative details of cholecystectomy must be accurately reviewed: Emergency or elective surgery, opening and emptying of the gallbladder, occurrence of bile spillage and method of gallbladder extraction (with or without bag). If possible, the original specimen could be re-reviewed by an experienced pathologist to more accurately define the exact site of the tumor, the depth of parietal invasion, the cystic duct involvement and the presence of metastatic lymph nodes. Unfortunately, as reported in a multicenter French survey, we are not always able to obtain all relevant information^[5].

In any case, if the cancer is a pTis or a pT1a, and the operation was rightly performed without loss of bile or stones, a second, revisional, surgical procedure is not mandatory. However, in these cases, a close

surveillance is still required. Unfortunately, in most cases pathology shows a muscular layer involvement (pT1b), a perimuscular tissue involvement (pT2) or a serosal involvement (pT3). A CT evaluation is required to detect any macroscopic residual disease or distant metastases; indeed, in these cases, a second surgical procedure is contraindicated. On the contrary, if any residual disease is absent, a second, radical surgical procedure can be planned. Re-resection for gallbladder carcinoma incidentally discovered after cholecystectomy is considered safe and effective^[6] and it is routinely advocated in the majority of cases^[7].

Although some authors consider unnecessary a second procedure in patients with T1b cancer, the majority performs a re-resection also in this indication. The aim of re-resection is to obtain a radical excision of the tumor and an accurate disease staging. Usually, this include a 4b + 5 segmentectomy, because a more extensive hepatectomy is not associated with a more favourable prognosis. Nevertheless, as the aim is to achieve a margin free resection, a right extended hepatectomy may be required in some cases^[8]. Lymphadenectomy should include the regional lymph nodes (gallbladder, hepatic pedicle, hepatic artery and periportal). Some topics of this surgical treatment are still under discussion: (1) the role of a preliminary laparoscopy before definitive treatment; (2) indications for CBD excision with hepatico-jejunostomy; and (3) port-sites excision. A preliminary laparoscopy could be useful in pT3 tumors to avoid an unnecessary laparotomy in cases with peritoneal carcinomatosis or liver metastases not detected by CT or MRI. The removal of the CBD with a hepatico-jejunostomy was emphasized in the past in order to obtain a more extensive lymphadenectomy. At present, there is no evidence to support prophylactic common bile duct excision^[9]. However, this maneuver, if routinely performed, increases the morbidity without any benefit on survival; therefore, it should be reserved for cases with cystic duct involvement^[10]. The routine port-sites excision is not associated with improved survival or disease recurrence^[11]. Today, this maneuver is not considered mandatory and could be reserved for cases in which the frozen-sections show residual disease on peritoneal surface at the level of the trocar-sites. However, it is advisable to excise the port-sites if the gallbladder was extracted without bag during cholecystectomy, or when this information is not available. Finally, the re-resection and lymphadenectomy can be performed by laparoscopy, as recently reported by Machado *et al*^[12]. Obviously, this approach can be pursued only in centers with extensive experience in hepatobiliary and advanced laparoscopic surgery.

PROGNOSTIC FACTORS

The operative specimens of re-resection should be examined by the pathologist to find any "residual" tumor. The "residual disease" can be found on the liver,

at the level of the gallbladder bed, on the lymph nodes or at the level of the trocar-sites excised. The presence of residual disease is found in about 50%-70% of cases and it can be predicted by the pT stage after cholecystectomy. Pawlik *et al*^[7] reported a risk of residual disease within the liver and to loco-regional lymph nodes of 0% and 12.5%, respectively, for cancers pT1, of 10.4% and 31.3% for pT2, of 36.4% and 45.5% for pT3. The residual disease is the most important prognostic factor, significantly reducing median disease-free survival and disease-specific survival^[13]. The other factors include depth of parietal invasion, metastatic nodal disease, surgical margin status (R0 resection), cholecystectomy for acute cholecystitis, histological differentiation, lymphatic, vascular and perineural invasion and overall TNM-stage^[14-16]. On the contrary, the time interval between cholecystectomy and re-resection is not significant for the prognosis^[13]. This fact allows, when the discovery of cancer occurs during the operation, to refer the re-resection to a later date. It also allows to refer the patient for re-resection in a tertiary center if the cholecystectomy was performed in a non-specialized hospital.

With regard to the prognosis after radical surgery, it is very favorable in patients with pT1b cancer with a 10-year survival up to 90%-100%^[6,17]. Re-resection significantly increases survival in patients with carcinoma pT2 and pT3. A 5-year survival rates ranging from 49.8% to 78.3% for pT2 cancers and from 0% to 23% for pT3 cancers was reported in the literature^[6,17,18]. In the same way, an increase in 5-year survival rate up to 62% for patients with pT2 cancer and up to 19% for patients with pT3 was reported in a multicenter French study^[16]. On the contrary, poor 5-year survival rates, ranging from 10% to 22%, were reported after simple cholecystectomy for pT2 cancers^[17,19]. In conclusion, radical re-resection, including liver resection and lymph node dissection, is the operation of choice for the treatment of pT2 and pT3 unexpected gallbladder cancers; it allows to obtain a significant survival benefit compared with simple cholecystectomy^[19,20].

CONCLUSION

A second, radical surgical procedure, when possible, improves prognosis in patients with UGBC. The possible occurrence of UGBC after cholecystectomy for gallstones allows some considerations. Firstly, laparoscopic cholecystectomy is a procedure that must be correctly performed in all cases, without loss of stones and bile: The occurrence of "spillage", in case of unexpected cancer, significantly worsens the prognosis. In case of acute cholecystitis, or in any technically difficult case, as in the elderly, the surgeon should be cautious and eventually can convert the laparoscopy in a traditional laparotomy rather than possibly causing a tumor dissemination with inadequate maneuvers. The patients with UGBC should be treated by an experienced surgeon, preferably in a tertiary center specialized in hepatobiliary

surgery.

Abstract

Gastric outlet obstruction (GOO) is a common problem associated with advanced malignancies of the upper gastrointestinal tract. Palliative treatment of patients'

symptoms who present with GOO is an important aspect of their care. Surgical palliation of malignancy is defined as a procedure performed with the intention of relieving symptoms caused by an advanced malignancy or improving quality of life. Palliative treatment for GOO includes operative (open and laparoscopic gastrojejunostomy) and non-operative (endoscopic stenting) options. The performance status and medical condition of the patient, the extent of the cancer, the patients prognosis, the availability of a curative procedure, the natural history of symptoms of the disease (primary and secondary), the durability of the procedure, and the quality of life and life expectancy of the patient should always be considered when choosing treatment for any patient with advanced malignancy. Gastrojejunostomy appears to be associated with better long term symptom relief while stenting appears to be associated with lower immediate procedure related morbidity.

INTRODUCTION

Gastric outlet obstruction (GOO) is a common problem associated with advanced malignancies of the upper gastrointestinal tract. Symptoms can be severe and include nausea, vomiting, malnutrition and decreased quality of life. Due to the advanced stages of the underlying malignancies causing these symptoms many patients are not candidates for curative resection. However, palliative treatment of their symptoms is an important aspect of their care. Research has shown that symptoms of advanced gastric cancer can often be effectively managed with palliative interventions. One of the main symptoms of advanced gastric cancer is GOO. Treatment for GOO includes operative and non-operative options. Traditionally, open gastrojejunostomy was the treatment modality of choice to bypass the obstruction. However, in recent years endoscopic stenting has been used more frequently. While stenting is considered less invasive and associated with a quicker return to oral intake, it is associated with several disadvantages including a high rate of re-obstruction and stent migration^[1]. In this review, we discuss the incidence and presentation of GOO, the current data regarding the goals of palliative intervention, the success of palliative treatment of gastric cancer, the techniques used to treat GOO and the outcomes of those treatments (Figure 1).

INCIDENCE OF GOO

GOO is a common complication of both benign and malignant disease of the stomach, pancreas and duodenum. It is caused by occlusion of the lumen by intrinsic or extrinsic growth^[2]. Because up to 55% of gastric cancers and up to 75% of periampullary cancers are not resectable at the time of diagnosis, they represent the most common causes of malignant gastroduodenal obstruction^[1,3]. GOO can also be caused by lymphoma, biliary disease, metastasis to the duodenum or jejunum and extrinsic compression^[1,3]. Malignant gastroduodenal obstruction is associated with limited length of patient survival. Patients, on average, live 3-6 mo^[3-7]. Malignant obstruction is a serious problem for physicians to treat because it is associated with a marked reduction in quality of life in a group of patients who are already significantly medically compromised^[4]. In the setting of patients suffering from GOO, palliative interventions are often necessary to alleviate symptoms

and improve quality of life^[5].

The stomach has a significant capacity to distend allowing GOO to go unnoticed by the patient until high grade obstruction develops^[4]. The symptoms of GOO are often incorrectly ascribed to the patient's cancer or the therapies they are undergoing (including chemotherapy, radiation therapy or both). However, the diagnosis of GOO can be made by obtaining a good history of present illness from the patient. Patients present with symptoms of nausea, vomiting, malnutrition, reflux, abdominal distension and dehydration^[3]. Patients often present with vomiting undigested food hours after eating and the vomit is often described as bilious^[4]. As a result, these patients can develop "food fear" secondary to their debilitating emesis^[3]. Patients also describe a reduced quality of life, poor condition and poor performance status^[6]. Evaluation of patients who present with symptoms of GOO may require endoscopy and upper gastrointestinal series to evaluate severity and length of the stenosis. Because of the potential of an associated biliary obstruction, it is also important that the biliary system is evaluated prior to any surgical procedure. This workup can include a liver function panel, a right upper quadrant ultrasound, or a computed tomography scan with a "pancreas protocol".

Goals of palliative intervention

Substantial variation in the definition of palliative care has complicated the understanding of the role of palliative operations^[7]. The concept of "palliation" is often used by physicians to describe: (1) a patient with limited survival; (2) procedures performed in the presence of unresectable disease; or (3) as acknowledgment that a curative procedure is not an option^[7]. This suboptimal characterization of "palliation" has perpetuated imprecise interpretations of both palliative surgical indications and outcomes^[7]. In an attempt to standardize the role of palliative care, the World Health Organization has defined palliative care as "the total active care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social, and spiritual problems is paramount. The goal of palliative care is the achievement of the best quality of life for patients and their families"^[7,8]. While these broad definitions of palliative care do provide a global understanding, they do not definitively explain the diverse goals of surgical palliation. For example, compare and contrast the patient who presents to the emergency room for an emergent laparotomy for a hemorrhagic tumor and the patient who presents to for an elective surgical biopsy to confirm advanced disease. The intent of these procedures is so dissimilar that it makes any meaningful evaluation of critical outcome measures imprecise^[7]. Even if one considers only those patients with known metastatic disease, they still present with such different clinical scenarios requiring surgery that it makes valid comparisons of outcomes difficult^[7]. In every case, ideal palliative care must emphasize the individual's specific

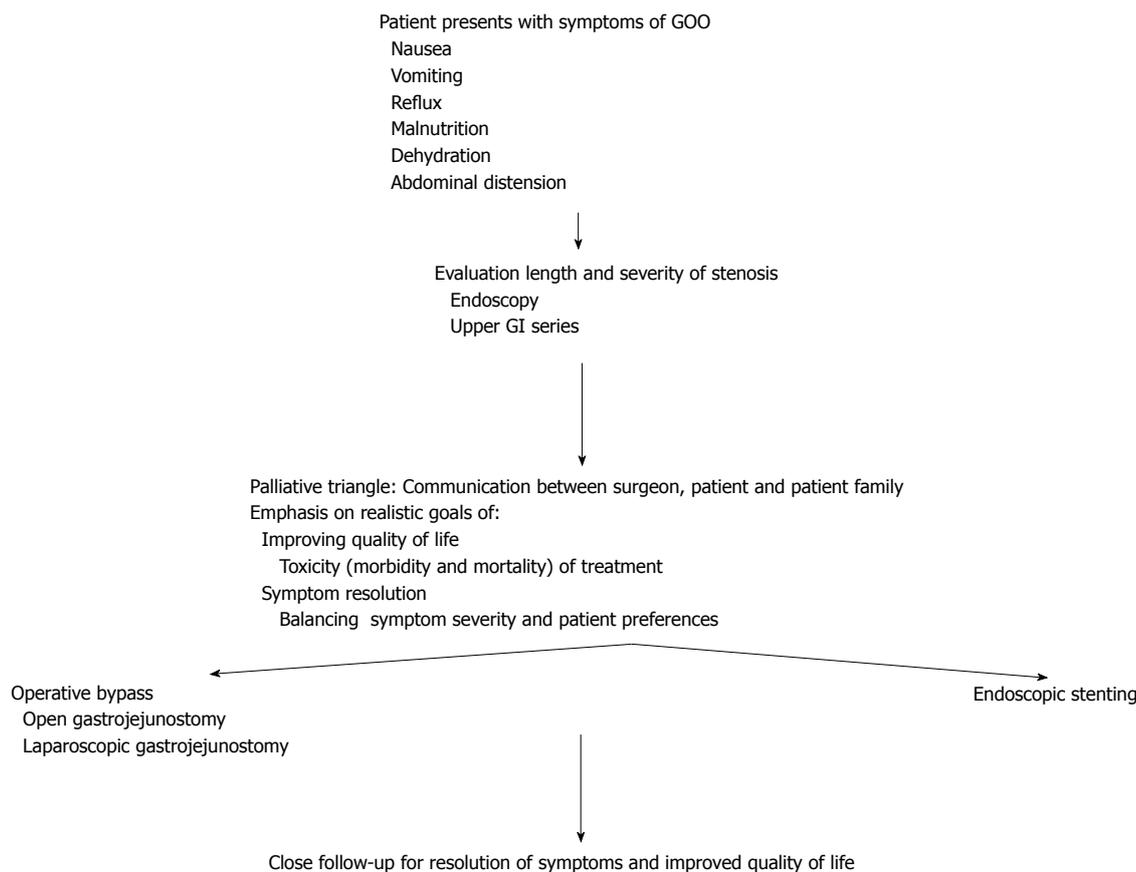

Figure 1 Flow diagram demonstrating workup and treatment for patients who present with gastric outlet obstruction from advanced malignancy. GI: Gastrointestinal; GOO: Gastric outlet obstruction.

values and needs and therefore, different indications and outcomes can be observed for essentially identical procedures^[7].

The best way to define surgical palliation of malignancy is as a procedure used with the primary intention of relieving symptoms caused by advanced malignancy or improving quality of life^[7,9-12]. It is important to note that a palliative procedure is not the opposite of curative procedure. Instead, each procedure has its own distinct goals and indications and need to be considered separately and independently. The performance status and medical condition of the patient, the extent of the cancer, the patients prognosis, the availability of a curative procedure, the natural history of symptoms of the disease (primary and secondary), the durability of the procedure, and the quality of life and life expectancy of the patient should always be considered when choosing treatment for any patient with advanced malignancy^[7,13]. The emphasis of palliative decision making should be placed on outcomes that can be realistically delivered with the goal of providing the patient with a good quality of life and symptom resolution^[10].

In order to successfully provide symptom relief at the end of life while also minimizing operative morbidity and mortality, careful patient selection is of critical importance^[14]. Appropriate decision making is enabled through effective interactions among the surgeon,

the patient, and their family members *via* a dynamic relationship described by the palliative triangle^[9,10,15]. This relationship allows the patients values, complaints, and social support to be considered against known surgical and medical alternatives^[16]. Through this triangle emphasis should be placed on outcomes that can realistically be delivered to the patient with the goal of providing: (1) symptom resolution; (2) a good quality of life; (3) technically superior palliative operations; (4) dignity; and (5) compassion. The dynamics of the palliative triangle help to moderate the different beliefs of each of its members and to guide the decision making to the best treatment for individual patient^[9,10,15]. Brown University studied the outcomes of patients with advanced malignancy that was managed by surgeons with the palliative triangle method. Patient reported symptom resolution or improvement after palliative intervention was noted in 117 of 129 procedures (90.7%) and this symptom relief occurred within 30 d after the operation. Palliative procedures were associated with 30 d postoperative mortality (3.9%) and morbidity (20.1%). Median survival was 212 d. The study suggests that palliative operations performed on patients selected using the palliative triangle approach have high rates of symptom improvement and low morbidity and mortality^[10]. It is important to note that in this study, either one or two meetings between the surgeon, the patient

and family lasting 60-90 min occurred before consensus was achieved on the appropriate palliative intervention. This fact highlights the complexity of the decision making involved when performing palliative procedures and the importance of understanding the core concepts of the palliative triangle^[10].

Excellent communication between patients, family and providers is essential to successful palliation whether surgery is performed or is not even offered^[10]. Effective communication between the patient and their doctor allows clinical problems to be identified more accurately, increases patient satisfaction with their care, improves patient compliance with treatment plans, alleviates feelings of distress and vulnerability by the patient and improves the patients overall well-being^[10]. At the end of life, patients and families are particularly vulnerable and they seek well developed interpersonal skills and communication from their physicians to guide them^[10].

PALLIATIVE INTERVENTION FOR GASTRIC CANCER-OPPORTUNITIES FOR SUCCESS

Patients with gastric cancer often present with an advanced stage and have a low cure rate, therefore palliative strategies are an essential and necessary component of gastric cancer management. Surgical palliation may include resection or bypass with or without endoscopic or percutaneous interventions. These interventions serve to eliminate potential complications (pain, obstruction, bleeding, debilitating ascites, perforation) and improve symptom control caused by the primary tumor^[7,17].

Research suggests that there may be a surgical benefit after palliative resection for patients with advanced gastric cancer^[18-20]. Keränen *et al*^[21] compared the safety, efficacy, and outcome of palliative stenting, palliative resection and gastrojejunostomy in patients with primary gastric cancer complicated by GOO. They concluded that palliative resection provides a surgical benefit and should be considered in patients suitable for surgery^[21]. A study from Memorial Sloan Kettering Cancer Center evaluated the outcomes of patients who underwent noncurative gastric resection with either palliative or nonpalliative intent^[7]. Three hundred and seven patients received a noncurative gastric resection between 1985 and 2001. Palliative operations were performed in 48% (147/307) and nonpalliative operations were performed in 52% (160/307) of patients^[7]. There was no difference in mean length of hospital stay [palliative (16.9 d) vs nonpalliative (18.9 d)], morbidity (54%) or mortality (6%) between the two groups^[7]. However, high-grade complications were less common in palliative [22% (32 of 147)] cases than in nonpalliative cases [29% (47 of 160), $P = 0.049$]^[7]. Additional palliative procedures were required in 24% (72 of 307) of patients, but their distribution was equal between the

two groups^[7]. Interestingly, many of the indications for repeat surgery were for treatment of distant disease and not for symptoms caused by the primary tumor. In both the palliative and nonpalliative groups, carcinomatosis caused gastrointestinal obstruction which required an intervention (either internal bypass, small bowel resection or colostomy) at similar rates^[7]. This study suggests that complication rates associated with noncurative procedures performed with palliative intent are lower than those performed with nonpalliative intent. Similarly, Saidi *et al*^[22] examined the role of palliative gastrectomy for patients with metastatic gastric cancer and evaluated its impact on survival. The study concludes that palliative gastrectomy with systemic therapy may improve survival in patients with stage IV gastric cancer^[22]. However, further research would need to be done to compare palliative gastrectomy plus systemic therapy to systemic therapy alone. Finally, Zhang *et al*^[23] attempted to summarize the outcome of patients undergoing palliative total gastrectomy for stage IV proximal gastric cancer. Between 1991 and 2005, clinical data of 197 patients undergoing palliative gastrectomy, 642 patients undergoing curative total gastrectomy, 102 patients undergoing explorative laparotomy, 78 patients undergoing jejunostomy and 152 nonsurgical patients, were enrolled. One-, three-, and five-year survival rates were significantly lower in the palliative gastrectomy group compared to the curative gastrectomy group^[23]. Interestingly, the median survival time in the palliative gastrectomy group was significantly longer than that in the laparotomy, jejunostomy and the no surgery. The postoperative mortality and complication rate were significantly higher in the palliative gastrectomy group compared to the curative gastrectomy group^[23]. The study concluded that palliative total gastrectomy for stage IV proximal gastric cancer is associated with prolonged survival time and decreased post-operative complications when compared to no surgery, laparotomy and jejunostomy procedures^[23]. The improvement in survival seen in the above studies may be due to the reduction in overall tumor burden^[24]. Together, this suggests that there may be a surgical benefit after palliative resection for patients with advanced gastric cancer.

Research regarding surgical treatment for advanced gastric cancer highlights the importance of appropriate patient selection. Samarasam *et al*^[25] retrospectively reviewed patients from 1999 to 2003 who underwent palliative surgery for gastric adenocarcinoma. One hundred and seven/one hundred and fifty-one (70.9%) underwent either subtotal gastrectomy (SG) or total gastrectomy (TG) to macroscopic free margins; the remaining 44/151 underwent laparotomy with or without gastrojejunostomy. All patients received adjuvant chemotherapy^[25]. Median survival was improved in resected patients (24 mo vs 12 mo, $P = 0.0003$); however the survival benefit decreased when a patient had more than one criteria for unresectability (T+, H+, P+, N+)^[25]. Median survival was similar between SG

and TG groups (24 mo and 20 mo, respectively)^[25]. This study suggests that patients with more than one criteria for unresectability may do better with less invasive procedures. Zhang *et al.*^[23] compared the clinicopathological factors and outcomes of palliative gastrectomy to exploratory laparotomy with or without bypass for noncurative gastric cancer^[26]. From 1988 to 2008, 365 patients underwent palliative gastrectomy and 151 patients underwent exploratory laparotomy or gastrojejunostomy for noncurative gastric cancer. One hundred and eighty-two of the patients were aged 70 years old and younger (group A) and 183 of the patients were older than 70 years old (group B). The overall survival of patients who underwent resection was 10.2 mo which was significantly longer than those patients who did not undergo resection (4.48 mo). Patients in the younger group (group A) were more likely to be female and had more aggressive tumors. Interestingly, the surgical morbidity was higher in both groups if the patients had comorbidities and the surgical morbidity and mortality was significantly higher in patients in the older age group (group B)^[26]. This data once again highlights the critical importance of appropriate patient selection and the terms of the palliative triangle.

While postoperative morbidity and mortality are important outcomes to consider for any surgical intervention the goals of palliative care emphasize quality of life and symptom relief. To better evaluate these important outcomes, one group performed a partitioned survival analysis, which assessed the state of health in relation to the patient's treatment, the treatment toxicity, and any patient relapse over time^[24,27]. Patient health state was defined in terms of "time without symptoms or toxicity" or (TWiST). Three hundred and seven non-curative resections were included in the analysis and 147 (48%) of them were performed with palliative intent. In the palliative group patients experienced an average of 8.5 mo in the TWiST state. Complications that reduced the time spent in TWiST included high-grade complications such as ICU admission, unplanned re-intervention, or permanent disability (2.1 mo, $P = 0.04$). Patients who presented with multiple sites of metastasis trended towards less time in the TWiST state (4.9 mo, $P = 0.08$). This data demonstrates the importance of appropriate patient selection. Pre-operative counseling between the surgeon, the patient and the family is critical in determining treatment goals and appropriate follow-up is necessary to ensure appropriate outcomes.

GASTROJEJUNOSTOMY SURGICAL TECHNIQUES

Understanding the anatomy of the stomach and small bowel in patients who have symptoms of GOO is an important aspect of choosing the right intervention.

Gastrojejunostomies can be performed in an antecolic or retrocolic fashion. The antecolic technique connects

the distal stomach to the jejunum. The retrocolic technique involves placement of the jejunal loop through the transverse colon mesentery^[28].

An incision is made in the upper midline of the abdomen. In an antecolic gastrojejunostomy the surgeon must identify a section of the distal stomach and a loop of jejunum distal to the ligament of Treitz that can be easily brought in close proximity to the stomach. Usually a location 15-20 cm distal to the ligament of Treitz is chosen. Care must be taken to identify the proximal jejunum when making a gastrojejunostomy, because anastomosing the ileum to the stomach is a rare complication associated with high morbidity. A posterior row of silk sutures is placed to connect the stomach and jejunum. Electro cautery is then used to open the jejunum and the stomach creating jejunal and gastric stomas respectively. The inner layer of the anastomosis is performed using a running full thickness absorbable suture which is carried anteriorly. Interrupted silk sutures are then placed to complete the anterior portion of the two layer gastrojejunostomy^[28].

A stapled anastomosis can also be performed in which case the enterotomy and gastrotomy are performed as described above to facilitate placement of the stapler. The opening should be large enough to allow entry of the staple device. The gastrointestinal anastomosis (GIA) stapling device is placed through the holes created in the stomach and the jejunal and the anastomosis is performed by firing the stapler. The enterotomy and gastroenterotomy are then closed together using a transanastomotic (TA) stapling device^[28].

If a retrocolic gastrojejunostomy is performed, the first step is again to identify the sites for the anastomosis of the stomach and jejunum. The transverse colon is lifted cephalad to visualize the mesentery and identify an avascular area through which the jejunal loop can pass through. A hand sewn anastomosis is performed in the same fashion described above for the antecolic approach using a two layer anastomosis with a posterior row of silk interrupted sutures. The jejunal and gastric stomas are created using electro cautery. The inner layer of the anastomosis is accomplished with a running full thickness absorbable suture. The retrocolic gastrojejunostomy is then completed using interrupted silk seromuscular sutures placed anteriorly^[28].

Similar techniques are used to perform the stapled anastomosis for a retrocolic gastrojejunostomy. The jejunal and gastric stomas are created using electro cautery. The retrocolic gastrojejunostomy is then completed using the GIA stapler and the openings created in the stomach and jejunum are closed together using a TA stapler. If a retrocolic approach is used most surgeons will loosely suture the edges of the mesentery to the jejunum to minimize the risk of herniation of the bowel loop^[28].

The midline incision is closed in the usual fashion regardless of whether an antecolic or retrocolic approach was used. A nasogastric tube is usually maintained

postoperatively on suction until bowel function returns and a diet can be initiated^[28].

LAPAROSCOPIC GASTROJEJUNOSTOMY SURGICAL TECHNIQUES

Understanding the anatomy of the stomach, liver, ligament of Treitz and esophagus are important details for the surgeon to understand before performing a laparoscopic gastrojejunostomy^[29]. It is necessary to identify the presence of hepatomegaly because a large left lateral segment may mean that the falciform ligament will need to be divided for optimal hepatic retraction and visualization^[29]. Again, accurate identification of the ligament of Treitz is imperative to ensure localization of the jejunum^[29].

Prior to surgery the patient is usually asked to undergo bowel preparation. After induction of anesthesia, a nasogastric tube (18 gauge) is placed to decompress the stomach. This will also be used during the creation of the gastrojejunostomy anastomosis and as an intraluminal stent to ensure patency of the newly created gastro-jejunal lumen. A urinary catheter is also placed to decompress the bladder.

The patient is placed in the supine position on the operating table. The arms are extended on arm boards and foot plates and safety straps are placed to secure positioning. The surgeon stands on the patient's right side while the assistant surgeon and camera operator are on the left side^[29]. The authors recommend an open Hassan technique to access the abdomen. A long 45 degree, 10 mm endoscope allows for optical visualization of the operative anatomy^[29]. Five ports are placed as follows: (1) one to the left of midline below the sternum to be used for liver retraction (an expandable liver paddle is used to bluntly retract the left lobe of the liver); (2) one to the right of midline to be used for the instrument in the surgeons left hand; (3) one to the right of the umbilicus for the instrument to be used in the surgeon's right hand; (4) one to the left of the umbilicus to be used for the camera; and (5) one in the left lower quadrant to be used for the instrument in the assistant's right hand^[30]. Laparoscopic gastrojejunostomy can be performed with a stapler or with a hand sewn technique.

For the hand sewn technique a needle driver for suturing and a left handed instrument, either blunt grasper or curved tip grasper, will be needed. To begin the construction of the gastrojejunostomy the left lobe of the liver must be fully retracted. To facilitate this, a nathanson retractor is placed in the epigastrium to elevate the liver and expose the gastro esophageal fat pad which is used to identify the gastro esophageal junction^[29,30]. The proximal end of the jejunal limb is carefully identified and brought into the upper abdomen (usually in an antecolic, antegastric manner). A running back wall suture line is created using a 2-0 Vicryl suture (approximately 20 cm in length). Two enterotomies are

made, one in the stomach and one in the jejunal limb, about 1.5 cm in length and a few millimeters away from the running back wall suture line^[30]. The suture is run from the patients left side corner to the right corner and the remaining suture and needle are saved. A second, inner running suture line is created using a 2-0 Vicryl which is started at the patients left side corner of the open enterotomy. Another 2-0 Vicryl suture is used to close the inner layer anteriorly. Prior to completion of the inner layer closure, a 34 French nasogastric (NG) or orogastric (OG) tube is passed across the anastomosis under direct visualization. The inner layer closure is completed by bringing the two sutures onto the anterior aspect of the anastomosis and tying them together. Needles are cut and removed. The previous outer layer Vicryl suture is then used to continue anteriorly to reinforce the inner layer. This can also be completed by starting a separate second suture beginning from the corner and tying in the middle of the anterior aspect gastrojejunostomy^[30].

A leak test is then performed. The patient is placed in the Trendelenburg position and the left upper quadrant is filled with normal saline to immerse the anastomosis^[30]. Air is introduced into NG tube until adequate inflation of the stomach and jejunal anastomosis is observed. A leak test can also be performed with methylene blue through the NG tube. If leakage is noticed the area is repaired with additional non absorbable sutures until no further air leak is seen^[30].

There are several of important techniques that should be used when performing a gastrojejunostomy to minimize postoperative complications. To minimize anastomotic ulcer and stricture formation, the inner layer is closed using absorbable sutures^[30]. The aperture of the anastomosis is regulated by closing the enterotomy defect over an NG or OG tube. Care must be taken to avoid suturing to the tube which can result in disruption of the closure^[30]. Back-hand suturing in the corners may allow more precise suturing if forehand stitching appears awkward in orientation^[30]. The tension on the running suture is maintained by the assistant throughout the closure process to avoid loosening of the closure and allowing potential leakage. Prior to tying the knots the entire suture must be cinched down to further eliminate potential gaps^[30].

A laparoscopic gastrojejunostomy can also be performed with stapling devices. First, the posterior wall of the stomach is cleared of adhesions and any vascular tissue with a Ligasure device. In preparation for a retrogastric anastomosis a gastrostomy is created and marked with a silk suture. An enterotomy is created in a carefully selected portion of the jejunum. A 30-mm long endoscopic gastrointestinal stapler is used to create a gastrojejunostomy by firing it across the common walls of the stomach and the jejunum for approximately 2 cm in length. Following stapling, anesthesia advances the NG tube under direct vision across the gastrojejunostomy^[29]. The gastrojejunostomy is closed over the NG tube with a running 2.0 silk suture. This layer is

carefully inspected to look for any gaps in the suture line. A second layer of 2-0 silk is paced circumferentially around the entire anastomosis. The gastrojejunostomy is tested for a leak and reinforced as appropriate. The NG tube must be advanced forward and pulled back to ensure that it has not been caught by on the sutures. The trocars are removed under direct visualization and the pneumoperitonium is released.

For both the hand sewn and stapling technique a suction drain may be left in the vicinity of the anastomosis for postoperative management. 3-0 absorbable suture is used for the subcuticular port site closure^[29]. Post operatively a nasogastric tube is usually maintained on suction until bowel function returns and a diet can be initiated^[29].

ENDOSCOPIC STENTING TECHNIQUES

It is important that the gastrointestinal stent morphology adapt to the anatomic curvature of the intestine to achieve appropriate function^[1]. There are currently two FDA approved duodenal stents and they include the Wallstent Enteral and the Wallflex Enteral duodenal Stent. The Wallstent Enteral from Boston Scientific is made from Cobalt-based alloy. It is uncovered and has a deployment diameter of 20-22 mm and a 40%-50% degree of shortening. The Wallstent Enteral features through the scope delivery and reconstrainability. The Wallflex Enteral duodenal Stent from Boston Scientific is made of Nitinol. It is uncovered and had a deployment diameter of 22 mm and a 30%-40% degree of shortening. The Wallflex Enteral duodenal Stent features proximal flaring, through the scope delivery and reconstrainability. These stents are self-expandable metal stents (SEMS)^[31]. They are both uncovered meaning that they embed into the stricture and surrounding tissue and can be placed through the working channel of a therapeutic endoscope. Uncovered SEMS are non-removable and migrate less often but tumor ingrowth frequently occurs causing a high rate of reobstruction^[31]. New stents are being developed with higher flexibility, less foreshortening and covers with the goal of reducing stent migration and tumor ingrowth. So far these stents have been found to be comparable to existing stents and may have a lower frequency of complications including decreased migration and tumor ingrowth^[4,32-36]. Other drug eluting or radioactive stents to help slow tumor growth are being developed but are currently not yet available.

Associated with GOO is sometimes so tight that it is difficult, if not impossible, to traverse the stricture with the therapeutic endoscope (the working channel of the scope needs to be greater than 3.8 mm)^[31]. In order to minimize risk of perforation, physicians should avoid attempting to aggressively dilate the stricture^[31]. However, patients with malignant duodenal obstruction are at a high risk for biliary obstruction. Therefore placing a biliary SEMS prophylactically before placing

the duodenal SEMS should be considered. Duodenal strictures are dilated (18-22 mm) only if biliary drainage is to be performed, because access to the papilla requires the use of a large diameter therapeutic duodenoscope^[31]. If, after assessing the status of the biliary tree, there is known or impending biliary obstruction an expandable metal biliary stent should be placed before the duodenal stent. To treat biliary obstruction after placement of a duodenal stent, a percutaneous transhepatic approach is usually required. Stenting of both the duodenum and the bile duct is the non-surgical equivalent of traditional double surgical bypass (gastrojejunostomy and choledochojejunostomy)^[31]. Due to these potential complications, duodenal stents generally are not used for benign disease only malignant disease.

Patients with GOO have high gastric residuals and suction of gastric contents should be performed prior to beginning the procedure to minimize aspiration risk and optimize visualization^[31]. If a patient is determined to be at high risk for aspiration then endotracheal intubation should be initiated prior to stent placement. The procedure should be performed under fluoroscopic or endoscopic guidance. Research suggests that the use of both modalities is important provide adequate visualization and get an idea of any distal obstruction^[3,37]. Patients should be in the supine or prone position to optimize fluoroscopic visualization. As mentioned above, the status of the biliary tree should always be assessed before gastro duodenal stent placement. Placement of the SEMS across the papilla will make endoscopic biliary access difficult. If the tumor is located in the proximal duodenum without involvement of the papilla a stent that is long enough to cross the lesion should be chosen but not excessively long which will prevent access to the papilla^[31]. Therefore, accurate assessment of the length and location of the malignant stricture is important^[31]. The stricture may be accessed with a standard biliary balloon catheter over a guide wire under fluoroscopic guidance. Injecting dye through the stricture may help delineate the length, geometry and extension of the structure. The selected stent should be about 4 cm longer than the stricture. Prior to patient discharge patients should be advanced to liquids and then to solids as tolerated. They should be told to avoid leafy vegetables which may result in stent occlusion.

OPEN GASTROJEJUNOSTOMY

OPERATIVE APPROACH OUTCOMES

Operative treatment options for GOO include NG placement, percutaneous gastrojejunostomy and gastrojejunostomy (open and laparoscopic).

While nasogastric and jejunostomy tubes are minimally invasive they have several disadvantages. Nasogastric tubes and gastrostomy tubes are used for decompression however they cannot be used for feeding. In contrast, jejunostomy tubes can be placed distal to the

obstruction so they can be used for hydration, enteral nutrition, and to provide medications^[4]. However these patients remain obstructed in their stomach and they often still have symptoms of nausea and vomiting. Percutaneous gastrojejunostomy tubes provide decompression of the stomach and distal enteral feeding. However these tubes can result in peritoneal leakage especially in the setting of ascites^[3]. The main disadvantage, however, of percutaneous tubes is the fact that patients are unable to resume oral feeding.

Surgical palliation is the standard treatment method for patients who present with symptoms of GOO^[38]. Gastrojejunostomy has been shown to be highly successful at relieving obstructive symptoms and allowing patients to return to oral eating^[4]. Research suggests that operative gastrojejunostomy may be preferable to endoscopic stent procedures due to its durability for providing symptom relief^[6,39,40]. However, due to the poor general condition and advanced malnutrition of these patients, surgical palliation with gastrojejunostomy can be associated with a high complication rate^[3,41]. The mortality rate associated with surgical bypass has been reported to be between 2%-36% and the complication rate to be between 13%-55%^[3,7,42,43]. The mean hospital stay is 11 to 15 d with a range of 5-80 d^[3,43,44]. Delayed gastric emptying is a common complication which has been reported to vary from 5 to 37 d^[3,38,43,45,46]. Patients who undergo palliative surgical gastrojejunostomy have been reported to have survival times between 35-293 d^[1,40,43-48]. The large range is likely due to the difference in the underlying extent of disease. There is no evidence to suggest a difference in mortality or survival between patients who undergo open surgical or endoscopic procedures^[45,46].

LAPAROSCOPIC GASTROJEJUNOSTOMY OPERATIVE APPROACH OUTCOMES

Laparoscopic gastrojejunostomy is another option for the relief of the obstructive symptoms associated with GOO^[49]. Laparoscopy is a less invasive procedure than open surgery. The hospital length of stay can be as low as 3 d and as high as 14 d^[41,42,44,50,51]. Laparoscopic procedures are associated with decreased blood loss compared to open procedures^[41,51]. However there is no research to suggest a difference in the amount of blood transfusion received^[42]. It is unclear as to whether laparoscopic gastrojejunostomy is associated with a delay in gastric emptying^[3,41]. Research shows no difference in mortality, operating time, or nonsteroidal and anti-inflammatory drug consumption between patients undergoing open vs laparoscopic bypass for GOO^[41,42]. There is inconclusive evidence regarding the difference in opiate analgesia and operative morbidity between laparoscopic and open procedures^[41,42]. The conversion to open surgery has been reported to range from 0% to 20%^[42]. The presence of malignant ascites is a relative contraindication for laparoscopic surgery.

ENDOSCOPIC STENTING APPROACH OUTCOMES

Nonoperative treatment options for the treatment of GOO include gastroduodenal stent placement. In the recent years there has been a decline in the number of patients undergoing surgical treatment of GOO because of the development of self-expanding metal stents^[4]. Stents have been found to be safe and effective in terms of palliation of symptoms especially in those patients who are too high risk to undergo surgery. Patients who have previously undergone a surgical procedure who later develop GOO are also good candidates for stent placement. However, it should be noted that because of the low durability and high re-obstruction rates of duodenal stents they are often not used for benign disease. A large systemic review found that in 6076 patients with malignant GOO, 97% underwent successful stent placement and 89% had relieve of symptoms and improvement in oral intake^[52]. Interestingly, patients who did not have relief of symptoms also suffered from side effects such as narcotic pain medication, anorexia or subsequent distal obstructive which may have been contributing to their symptoms^[52]. Advantages of stent placement include the following: less invasive, outpatient procedure, fewer complications, cost effective, rapid return to gastric emptying, shorter procedure time and improved quality of life^[3,4,45,53-55]. Patients may resume oral intake as quickly as post-operative day 1-5 of the procedure^[2-4,6,43,45,46]. It has been reported that 73%-87% of patients who have gastroduodenal stents placed resume oral food intake^[1,47]. The mean hospital discharge rate is short and has been reported to be 2.5-7.5 d. Survival has been reported to range from 63-189 d^[2,40,43,45-48]. Again, survival time is likely attributed to the advanced stages of the underlying disease.

Contraindications to stent placement include distal gastrointestinal obstruction, gastrointestinal perforation, and patients with multilevel bowel disease^[3]. The immediate complication rate of the procedure is low and has been reported to be 4%^[43]. However the rate of late adverse events has been found to be higher in patients who undergo stent placement compared to those who undergo gastrojejunostomy^[40]. The major disadvantages of stent placement include a high rate of stent migration and re-obstruction^[1,6,38,40]. Reobstruction rates have been found to occur more quickly than patients who undergo gastrojejunostomy^[40]. Another devastating complication is the concomitant or subsequent development of biliary obstruction which has been reported in up to 44% of cases^[4,56]. Other complications include bleeding and perforation^[4]. Interestingly, one study looked at the effect of endoscopic vs surgical palliative procedures for symptom relief in patients with metastatic or advanced loco regional cancer. They found that patients who underwent endoscopic procedures had fewer perioperative complications {endoscopic [18% (37/209)] vs patients who underwent operative

procedures [39% (205/522)], $P < 0.001$ }. The patients in the endoscopic group experienced a higher 30-d mortality {endoscopic [15% (38/247)]} when compared to the operative group [9% (54/576), $P = 0.017$]^[11]. Therefore, stenting is likely more beneficial for patients with a short anticipated survival, while gastrojejunostomy may provide more durable symptom improvement.

COST COMPARISON BETWEEN ENDOSCOPIC STENT AND GASTROJEJUNOSTOMY

Interestingly, one study compared the cost of stent placement and gastrojejunostomy for the treatment of malignant GOO. They found that food intake improved more rapidly after stent placement as opposed to after gastrojejunostomy. However, long term relief of obstructive symptoms was better after gastrojejunostomy. In addition they found that more major complications and more repeat interventions occurred after stent placement as opposed to after gastrojejunostomy. While the initial costs were higher for patients undergoing gastrojejunostomy there was no difference between the two procedures in follow-up costs. Total costs per patient were higher for gastrojejunostomy compared to stent placement. The incremental cost effectiveness ratio of the gastrojejunostomy compared to stent placement was 164 euros per extra day with gastric outlet obstruction scoring system adjusted for survival. They concluded that the medical effects were better after gastrojejunostomy despite the higher costs and that because the cost difference between the two groups was small that it should not play a role when deciding on the type of treatment to offer patients^[39].

CONCLUSION

Palliative treatments are offered to patients with the intent of relieving the symptoms of GOO and ultimately improving patient quality of life. Decisions regarding the use of surgical versus endoscopic procedures for GOO require the highest level of surgical judgment. Physicians must consider the individual patients quality and expectancy of life, the prognosis of the disease, the availability and the success of each treatment option^[9,14,15].

GOO can be effectively treated by both gastrojejunostomy and stenting. Gastrojejunostomy appears to be associated with better long term outcomes while stenting appears to be associated with better short term outcomes. New laparoscopic procedures and new technologies in endoscopic stents will likely continue to change the treatment recommendations for GOO. When it comes to palliative care, it is imperative that all physicians involved are adequately trained in end of life management to ensure that each patient gets the appropriate treatment for their particular circumstances.

Abstract

Restorative proctocolectomy with ileal pouch-anal

anastomosis (RP-IPAA) is the gold standard surgical treatment for ulcerative colitis. However, despite the widespread use of RP-IPAA, many aspects of this treatment still remain controversial, such as the approach (open or laparoscopic), number of stages in the surgery, type of pouch, and construction type (hand-sewn or stapled ileal pouch-anal anastomosis). The present narrative review aims to discuss current evidence on the short-, mid-, and long-term results of each of these technical alternatives as well as their benefits and disadvantages. A review of the MEDLINE, EMBASE, and Ovid databases was performed to identify studies published through March 2016. Few large, randomized, controlled studies have been conducted, which limits the conclusions that can be drawn regarding controversial issues. The available data from retrospective studies suggest that laparoscopic surgery has no clear advantages compared with open surgery and that one-stage RP-IPAA may be indicated in selected cases. Regarding 2- and 3-stage RP-IPAA, patients who underwent these surgeries differed significantly with respect to clinical and laboratory variables, making any comparisons extremely difficult. The long-term results regarding the pouch type show that the W- and J-reservoirs do not differ significantly, although the J pouch is generally preferred by surgeons. Hand-sewn and stapled ileal pouch-anal anastomoses have their own advantages, and there is no clear benefit of one technique over the other.

Core tip: Restorative proctocolectomy with ileal pouch-anal anastomosis (RP-IPAA) is the preferred surgical treatment for ulcerative colitis. However, despite the widespread use of RP-IPAA, many aspects of this treatment still remain controversial, such as the approach (open or laparoscopic), number of stages of surgery, type of pouch,

and type of construction (*e.g.*, hand-sewn or stapled ileal pouch-anal anastomosis). Few large, randomized, controlled studies have been conducted, which limits the conclusions that can be drawn regarding controversial issues associated with RP-IPAA. It is suggested that prospective, randomized studies should be conducted in the future to compare the frequency of post-operative complications, cosmetic results, short- and long-term functional outcomes, and quality of life associated with the available techniques of RT-IPAA for the treatment of ulcerative colitis.

Restorative proctocolectomy with ileal pouch-anal anastomosis for ulcerative colitis: A narrative review. *World J Gastrointest Surg* 2016; 8(8): 556-563 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i8/556.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i8.556>

INTRODUCTION

Ulcerative colitis is an inflammatory disease of the colon and rectum that affects millions of adults and children worldwide. Despite the progress of medical therapy, which has broadened the possible treatments after failure of corticosteroids, surgery is still required in 15%-35% of patients affected by ulcerative colitis^[1,2]. Surgery is indicated in the elective setting when dysplasia or cancer is present, the patient has a refractory disease, the side effects significantly impair the patient's quality of life, the patient develops steroid-dependence, or the patient is not compliant^[3,4]. In the acute setting, surgery is recommended in cases with hemorrhage, perforation, toxic megacolon, acute severe colitis, and a lack of improvement with second-line therapy. Surgeries are performed before these conditions worsen to avoid increased surgical morbidity and potential mortality^[3,4].

Since its introduction in 1978 by Parks *et al*^[5], the new gold standard surgical treatment of ulcerative colitis is restorative proctocolectomy with ileal pouch-anal anastomosis (RP-IPAA), which offers patients an unchanged body image with no stoma and a preserved anal route of defecation. It has been shown that RP-IPAA is common among older patients; one study revealed that the likelihood of requiring an end ileostomy decreased by 12% per year between 2005 and 2012 in patients aged 61 to 70 years compared with patients \leq 50 years of age [adjusted odds ratio (OR), 0.88 per year; $P = 0.021$]^[6].

However, despite the widespread use of RP-IPAA, many aspects of this treatment still remain controversial, including the type of approach (*i.e.*, open or laparoscopic), number of stages of surgery, type of pouch, and construction type (*i.e.*, hand-sewn or stapled ileal pouch-anal anastomosis) because few prospective, randomized studies have been designed

and performed.

The present narrative review aimed to define the controversies associated with the use of RP-IPAA in patients affected by ulcerative colitis. An electronic literature search of PubMed, MEDLINE, EMBASE, and the Cochrane Database of Collected Reviews was performed for the dates from January 1978 to March 2016. The search included the following terms: "Inflammatory bowel disease", "colitis", "colectomy", and "ileal pouch-anal anastomosis".

OPEN OR LAPAROSCOPIC RP-IPAA

Laparoscopic surgery in the treatment of ulcerative colitis has become very popular in the last decade. An analysis of the American College of Surgeons National Surgical Quality Improvement Program database (ACS-NSQIP, 2005-2008) for all ulcerative colitis patients who underwent a colectomy showed that the laparoscopic approach was used in 29.2% of cases, with rates increasing 8.5% each year (18.5% in 2005 to 41.3% in 2008, $P < 0.001$)^[7].

Recently, three meta-analyses^[7-9] compared open and laparoscopic RP-IPAA conducted for ulcerative colitis and familial adenomatous polyposis with respect to operative (duration of surgery, blood loss) and short-term (intraoperative mortality and post-operative complications) outcomes. One meta-analysis also compared functional outcomes (number of bowel movements in 24 h and per night, use of pads during the day and during the night, incontinence, and use of anti-diarrheal medications). As shown in Table 1, all of the meta-analyses reported that laparoscopic surgery requires a longer operative time and produces significantly less blood loss. The post-operative complications were also similar between the two procedures (with the exception of the incidence of wound infection, which was shown to be lower with laparoscopic surgery in the meta-analysis conducted by Singh *et al*^[7]). Functional outcomes were also similar between laparoscopic and open RP-IPAA in the meta-analysis of Singh *et al*^[7].

It should be noted that these meta-analyses were conducted on studies that were published many years ago (with the most recent study dated March 2012), included numerous types of interventions, and were essentially executed during the ascending phase of the learning curve of laparoscopic surgery. However, there are several more recent studies highlighted in Table 2. One of these studies showed that there was no significant difference between laparoscopic and open IPAA with respect to estimated blood loss, blood transfusions, postoperative narcotic usage, total complications, return of bowel function, length of stay, and hospital readmission rates^[10]. However, this study also reported that patients in the laparoscopic IPAA group underwent ileostomy closure an average of 24.1 d sooner than patients in the open group ($P = 0.045$).

Benlice <i>et al</i> ^[14]	Retrospective	Open: 238 LS: 119	Higher in LS		Not evaluated		Similar incidence of incisional hernia and small bowel obstruction	

¹Included patients with ulcerative colitis and familial adenomatous polyposis; ²Days to first ingestion; ³Based on a multivariate analysis: OR = 0.44 (0.27-0.70) (*P* = 0.01); ⁴Based on a multivariate analysis: OR = 0.67 (0.45-0.99) (*P* = 0.04); ⁵Number of stools per day. ^a*P* = 0.02; ^b*P* = 0.008; ^c*P* = 0.040; ^d*P* = 0.007; ^e*P* < 0.0001. LS: Laparoscopic surgery; PRT: Prospective randomized trial.

The study by Fleming *et al*^[11], which included 339 laparoscopic and 337 open IPAA procedures, showed that the laparoscopic approach was associated with a lower rate of major (OR = 0.67, 95%CI: 0.45-0.99, *P* = 0.04) and minor (OR = 0.44, 95%CI: 0.27-0.70, *P* = 0.01) complications. Accordingly, results from

the American College of Surgeons National Surgical Quality Improvement Program database (ACS-NSQIP, 2005-2008) for all ulcerative colitis patients who underwent colectomy demonstrated that a laparoscopic approach was associated with lower morbidity and mortality (IPAA complication rate: Laparoscopic =

18.2% and open = 29.9%, $P = 0.008$)^[12]. Interestingly, a prospective, randomized study comparing laparoscopic and open IPAA for the treatment of ulcerative colitis and familial adenomatous polyposis was recently conducted by German researchers^[13]. Unfortunately, the study was stopped prematurely due to insufficient patient recruitment, and data for only 21 patients in each arm were reported. The available results revealed that there was no difference in the amount of blood loss between the two groups, as well as that laparoscopic surgery was superior with respect to the length of skin incision, whereas the open approach was superior in the operative duration. However, there were no discrepancies in the length of hospital stay, postoperative pain, bowel function, and quality of life between the approaches. The retrospective cohort study (conducted from January 1992 through December 2007) by Benlice *et al.*^[14] examined 238 open and 119 laparoscopic IPAAs and showed that open and laparoscopic operations were associated with similar incidences of incisional hernia (8.4% vs 5.9%; $P = 0.40$), small-bowel obstruction requiring hospital admission (26.1% vs 29.4%; $P = 0.50$), and small-bowel obstruction requiring surgery (8.4% vs 11.8%; $P = 0.31$). The small study by Tajti *et al.*^[15] showed that there was no difference between laparoscopic and open IPAA regarding the rate of early postoperative complications, whereas the rates of intestinal obstruction (8.7% vs 45%) and sepsis (0% vs 27%) were significantly lower in the laparoscopic group. Conversely, the study by Inada *et al.*^[16], which included only 24 patients, revealed that the percentage of patients requiring a transfusion and having postoperative complications was lower in the laparoscopic group.

A cross-sectional study carried out in 3 university hospitals in the Netherlands and Belgium compared the time to first spontaneous pregnancy between 23 young patients who had undergone open RP-IPAA and 27 young patients who had undergone laparoscopic RP-IPAA. Patient characteristics were similar in both groups. Indications for surgery were ulcerative colitis in 37 patients, familial adenomatous polyposis in 12 patients, and colonic ischemia in 1 patient. A Kaplan-Meier survival analysis was conducted to assess the time to first spontaneous pregnancy and revealed a higher pregnancy rate after laparoscopic IPAA (Log-Rank test, $P = 0.023$). Similarly, a subsequent survival analysis of all the patients with ulcerative colitis showed an increased pregnancy rate in the laparoscopic group (Log-Rank test, $P = 0.033$)^[16]. This result is probably due to the reduced formation of adhesions after laparoscopic colectomy^[17].

Finally, a recent systematic review showed that the incidence of wound infection and intra-abdominal abscess is significantly lower in laparoscopy than in open emergency subtotal colectomy performed in patients with severe acute colitis^[18].

Overall, it appears that there is no clear evidence

that laparoscopic RP-IPAA offers significant advantages over open surgery. Nevertheless, more recent studies indicate that laparoscopic surgery is associated with fewer complications than open surgery. However, the scarcity of randomized, controlled trials makes any definitive conclusions impossible to draw.

ONE- VS TWO-STAGE RP-IPAA

One-stage surgery consists of RP-IPAA without ileostomy and aims to reduce the potential impact of surgery on a patient's quality of life. Many surgeons prefer to perform the entire RP-IPAA operation without the ileostomy^[19-21]. However, other surgeons consider the ileostomy to be useful and mandatory because the rate of complications and number of subsequent laparotomies is higher when diversion is not performed^[22-24].

The large retrospective study by Remzi *et al.*^[25] compared data from patients at a single institution who underwent RP-IPAA either with ($n = 1725$) or without ($n = 277$) a diverting ileostomy. They observed that there were no differences between the two groups with respect to septic complications, quality of life, and functional outcomes and concluded that in patients with stapled anastomosis, tension-free anastomosis, intact tissue rings, normal hemostasis, absence of air leaks, malnutrition, toxicity, anemia, or prolonged consumption of steroids should be considered for one-stage RP-IPAA because the one-stage procedure is safe for these patients and is associated with similar results to those of the 2-stage RP-IPAA. Conversely, a meta-analysis reviewing 17 independent studies and including a total of 1486 patients yielded different results^[26]. Essentially, the study showed that the incidence of anastomotic leakage and pouch-related sepsis was significantly greater in the group without a protective ileostomy. According to the authors of this review, the exclusion of a protective stoma may only be appropriate for specific patients undergoing RP-IPAA, such as those in whom a pouch may be technically easier to perform (*e.g.*, young women not taking corticosteroids and without comorbidities).

It appears that one-stage RP-IPAA may be safe in selected patients and that adequate, randomized studies are necessary to clarify whether protective ileostomy is needed in patients undergoing RP-IPAA.

TWO- VS THREE-STAGE RP-IPAA

Two-stage surgery consists of RP-IPAA and ileostomy during the initial operation, followed by ileostomy closure, whereas the three-stage surgery consists of a subtotal colectomy and ileostomy, proctectomy and pouch creation, and ileostomy closure. The usage rate of a 3-stage RP-IPAA is extremely variable, ranging from 19% to 69%^[27-29]. Data from the ACS-NSQIP have shown that the usage rate of a 3-stage approach remained stable in the United States between 2007 and

Table 3 Studies comparing the mortality and morbidity of 2-stage and 3-stage restorative proctocolectomy with ileal pouch-anal anastomosis

2011, with approximately 25% of patients affected by ulcerative colitis in a non-emergent setting undergoing a 3-stage RP-IPAA^[28].

The two-stage RP-IPAA has the advantages of avoiding an additional operation, a shorter hospital stay, administration of less anesthetic, and a shorter time with a stoma compared with the three-stage procedure. The three-stage procedure allows the patients to improve their nutritional status, withdraw from immunosuppressive medications, and resolve any anemia before the pelvic dissection for pouch construction and IPAA, as well as avoid a complex pelvic dissection in the setting of systemic inflammation.

All of the studies that compared 2- and 3-stage RP-IPAA are retrospective (Table 3)^[27-30]. Usually, in these studies, patients who underwent either 2- or 3-stage surgery differed significantly with respect to clinical and laboratory variables as well as the use of steroids and anti-TNF agents^[27-30]. In 1989, Nicholls *et al*^[27] reviewed data from 152 consecutive patients undergoing RP-IPAA (57 two-stage and 95 three-stage) and showed that the anastomotic leakage rate was 10.3% in the 2-stage group and 3.6% in the 3-stage group, with long-term pouch failure rates of 2% and 9%, respectively ($P < 0.05$). The frequency of defecation, frequency of night evacuation, and need for anti-diarrheal medication were reduced in patients who underwent the 3-stage procedure compared with those who underwent the 2-stage procedure. Although a higher proportion of patients in the 3-stage group had emergency surgery compared with the 2-stage group (32% vs 2.6%; $P < 0.01$), there was no advantage to the 3-stage procedure except when urgent surgery was required for the following: (1) a patient had complications of ulcerative colitis; (2) malignancy or Crohn's disease could not be

ruled out; and (3) a patient taking oral steroids with active colitis had a combination of a low hemoglobin value and low serum albumin levels. In the study by Pandey *et al*^[28], 68 ulcerative colitis patients were in the 2-stage group and 50 were in the 3-stage group. The patients in the 3-stage group were more likely to have received aggressive medical therapy, antitumor necrosis factor therapy, and systemic corticosteroids. The overall complication rates were similar between the groups, but infectious complications were significantly higher in the 2-stage group.

Conversely, in the study by Bikhchandani *et al*^[30], the records of 2002 patients (2-stage = 1452 and 3-stage = 550) from the ACS-NSQIP were reviewed, and the 30-d morbidity and mortality rates were found to be similar between the two approaches. Unfortunately, the incidence of anastomotic leakage was not reported. However, the authors reported that the rate of deep organ space infections (which were presumed to be due to a postoperative leak) did not differ between the two approaches. Interestingly, the patients who underwent a 3-stage surgery in this study had more favorable clinical features at the time of IPAA, including decreased preoperative sepsis, corticosteroid use, weight loss, and hypoalbuminemia. Finally, the study by Hicks *et al*^[29] revealed that the 3-stage procedure was associated with a higher frequency of emergency status, greater intraoperative hemodynamic instability, and a lower use of immunomodulators compared with the 2-stage procedure, but the two procedure types were similar with regard to the number of comorbidities and use of either steroids or anti-TNF agents. The patients who underwent the 2-stage surgery had a lower risk of anal stricture but a comparable risk of fistula or abscess formation or pouch failure over the long term compared

with the patients who underwent the 3-stage procedure.

One recent retrospective study showed that a modified 2-stage RP-IPAA (subtotal colectomy with end ileostomy, followed by completion proctectomy and IPAA without diverting ileostomy) compared with the conventional 2-stage RP-IPAA was associated with a significantly lower rate of anastomotic leakage following pouch creation (4.6% vs 15.7%, $P < 0.01$; multivariate analysis: OR = 0.27, 95%CI: 0.12-0.57)^[31].

TYPE OF POUCH

An IPAA can be constructed with an S-reservoir, a J-reservoir, or a W-reservoir. The J-pouch, unlike the S-pouch and W-pouch, can be formed by stapling and requires less time; for this reason, the J-pouch is generally preferred by surgeons.

The meta-analysis conducted by Lovegrove *et al.*^[32] compared the short- and long-term outcomes of J, W, and S ileal reservoirs using data from 18 studies published between 1985 and 2000, with a total of 1519 patients with ulcerative colitis and familial adenomatous polyposis (689 J-pouch, 306 W-pouch, and 524 S-pouch). There were no significant differences between the groups with regard to total postoperative complications, anastomotic leakage, anastomotic stricture, wound infection, pelvic sepsis, pouchitis, and pouch failure. However, the patients with either an S- or W-pouch had a lower frequency of defecation and a reduced need for antidiarrheal medications compared with the patients with a J-pouch, whereas patients with a J-pouch were significantly less likely to require intubation than patients with either an S- or a W-pouch.

However, two recent studies demonstrated that the J- and W-pouches have the same long-term functional results^[32,33]. In the study by Røkke *et al.*^[33], which only included patients with ulcerative colitis, the functional results of the W- and J-reservoir were similar in the middle (2.5 years) and long (11.5 years) term. Similarly, McCormick *et al.*^[34] reported that 24-h bowel movement frequency, daytime frequency, and nocturnal function did not differ between the W- and J-pouch groups at the 9-year follow-up appointments.

Some surgeons prefer the S-pouch because the efferent limb fits well into the anal canal and the body lies on the levators, whereas the blunt end of a J-pouch may be distorted because it is forced into the muscular tube of the stripped anus. In this regard, the retrospective study by Wu *et al.*^[35] showed that patients with an S-pouch, compared with patients with a J-pouch, had fewer bowel movements, less frequent pad use, and a lower fecal incontinence severity index, suggesting that, when constructing the IPAA with the hand-sewn technique, the S-pouch is preferable.

HAND-SEWN OR STAPLED ILEAL POUCH-ANAL ANASTOMOSIS

Two types of pouch-anal anastomoses can be performed

in RP-IPAA: A hand-sewn IPAA (with or without a mucosectomy) of the rectal stump and a stapled pouch-anal anastomosis with conservation of the rectal mucosa.

In 2006, two different meta-analyses were published that compared these two techniques^[36,37]. The meta-analysis by Lovegrove *et al.*^[36] included 4183 patients with ulcerative colitis and familial adenomatous polyposis who underwent formation of an ileal pouch reservoir (2699 patients with a hand-sewn pouch and 1484 patients with a stapled pouch) between 1983 and 2000. Patients with hand-sewn and stapled anastomoses showed similar early postoperative outcomes (anastomotic leak: 8.8% vs 5.2%, $P = 0.42$; pelvic sepsis: 7.2% vs 4.7%, $P = 0.21$; pouch-related fistula: 5.9% vs 2.2%, $P = 0.31$; pouchitis: 2.2% vs 5%, $P = 0.81$; stricture of the anastomosis: 18.2% vs 12.5%, $P = 0.20$; pouch failure: 5.3% vs 2.3%, $P = 0.06$). In addition, the two techniques were similar with regard to stool frequency per 24 h, defecation at night, use of antidiarrheal medication, seepage during the daytime, and daytime pad usage. However, in the hand-sewn group, seepage at night and incontinence of liquid stool occurred more frequently, and the use of pads overnight was more common. The improved nocturnal continence observed in the hand-sewn group was correlated with higher anorectal physiological measurements. Unfortunately, there were insufficient data from the included studies to perform a quantitative and comparative analysis on the incidence of dysplasia in the anal transition zone.

The meta-analysis by Schluender *et al.*^[37], which included four prospective, randomized trials published between 1994 and 2006 that included 180 ulcerative colitis and familial adenomatous polyposis patients, clearly demonstrated that there were no significant differences in functional outcomes between hand-sewn and stapled IPAA, as well as in the resting and contracting sphincter pressures. Based on these results, the authors concluded that, given the potential for persistent cuffitis and/or dysplasia/cancer development in the incompletely removed rectal mucosa after stapled IPAA, the hand-sewn IPAA appears to be preferable.

The large, retrospective study by Kirat *et al.*^[38], which included patients affected by ulcerative colitis and familial adenomatous polyposis, compared 474 hand-sewn and 2270 stapled ileal pouch-anal anastomoses performed at a single institution. Overall, patients with a stapled IPAA had better outcomes and quality of life compared with those with a hand-sewn IPAA. The frequencies of anastomotic stricture, septic complications, bowel obstruction, and pouch failure were significantly lower among the patients who received a stapled anastomosis. In addition, stapled anastomosis was associated with a lower frequency of incontinence, seepage, and pad usage, as well as reduced dietary, social, and work restrictions. Kirat *et al.*^[38] concluded that as long as there are no contraindications (dysplasia, presence of cancer in the rectum or colon), stapled anastomosis is the superior technique with respect to short-, mid-, and long-term outcomes. Nevertheless, the same study analysis

demonstrated that preservation of the anal transitional zone did not lead to the development of cancer in patients monitored for a minimum of ten years^[39].

More recently, a small retrospective study that included patients only affected by ulcerative colitis showed that postoperative complications did not differ significantly between the two pouch groups, with the exception of a greater incidence of postoperative anal fistula in the stapled group ($P = 0.03$). Functional outcomes and long-term quality of life were similar between patients who had received either hand-sewn or stapled IPAA^[40].

CONCLUSION

Regarding the use of RT-IPAA for the treatment of ulcerative colitis, there are few large, randomized, controlled studies, which makes it impossible to draw definitive conclusions regarding controversial issues such as the use of either the open or laparoscopic approach, number of stages of surgery, type of pouch, and pouch construction (*i.e.*, hand-sewn or stapled pouch). The available data from retrospective studies suggest that laparoscopic surgery has no clear advantages over open surgery and that one-stage RP-IPAA may be indicated in qualifying cases. With regard to the 2- and 3-stage RP-IPAA, the fact that patients who underwent 2- and 3-stage surgeries differed significantly with regard to their clinical and laboratory variables makes any comparison extremely difficult. Regarding pouch type, the long-term results show that W- and J-reservoirs do not differ significantly. Finally, the hand-sewn and stapled ileal pouch-anal anastomoses have their own advantages, but there is no clear benefit of one technique over the other. It is suggested that adequate prospective, randomized studies should be conducted in the near future to compare the frequency of post-operative complications, cosmetic results, short- and long-term functional outcomes, and quality of life between the available RT-IPAA techniques for the treatment of ulcerative colitis.

Currently, it is important to emphasize that the choice of the type of surgery should be based on the experience and skills of the performing surgeons in the hospital as well as on each individual case.

Abstract

This work is a topic highlight on the surgical treatment of the right colon pathologies, focusing on the literature state of art and comparing the open surgery to the different laparoscopic and robotic procedures. Different laparoscopic procedures have been described for the treatment of right colon tumors: Totally laparoscopic right colectomy, laparoscopic assisted right colectomy, laparoscopic facilitated right colectomy, hand-assisted right colectomy, single incision laparoscopic surgery colectomy, robotic right colectomy. Two main characteristics of these techniques are the different type of anastomosis: Intracorporeal (for totally laparoscopic right colectomy, single incision laparoscopic surgery colectomy, laparoscopic assisted right colectomy and robotic technique) or extracorporeal (for laparoscopic assisted right colectomy, laparoscopic facilitated right colectomy, hand-assisted right colectomy and open right colectomy) and the different incision (suprapubic, median or transverse on the right side of abdomen). The different laparoscopic techniques meet the same oncological criteria of radicalism as the open surgery for the right colon. The totally laparoscopic right colectomy with intracorporeal anastomosis and even more the single incision laparoscopic surgery colectomy, remain a technical challenge due to the complexity of procedures (especially for the single incision laparoscopic surgery colectomy) and the particular right colon vascular anatomy but they seem to have some theoretical advantages compared to the other laparoscopic and open procedures. Data reported in literature while confirming the advantages of laparoscopic approach, do not allow to solve controversies about which is the best laparoscopic technique (Intracorporeal vs Extracorporeal Anastomosis) to treat the right colon cancer. However, the laparoscopic techniques with intracorporeal anastomosis for the right colon seem to show some theoretical advantages (functional, technical, oncological and cosmetic advantages) even if all studies conclude that further prospective randomized trials are necessary.

Robotic technique may be useful to overcome the problems related to inexperience in laparoscopy in some surgical centers.

Key words: Mini-invasive right colectomy; Robotic right colectomy; Intracorporeal anastomosis; Extracorporeal anastomosis; Totally laparoscopic right colectomy

Core tip: We report a topic highlight of the mini-invasive treatment of the right colon pathologies, focusing on the Literature State of Art and comparing the open surgery *vs* the different laparoscopic and robotic procedures. We try to analyze the different current approaches to right colon cancer treatment focusing in particular light and shadows of totally laparoscopic right colectomy compared to other mini-invasive (single incision laparoscopic colectomy, laparoscopic assisted right colectomy, laparoscopic facilitated right colectomy, hand-assisted right colectomy, robotic right colectomy) and open procedure. The two main characteristics of these techniques are the different type of anastomosis: Intracorporeal or extracorporeal and the different incision (suprapubic *vs* median *vs* transverse on right side of abdomen). The different laparoscopic techniques meet the same oncological criteria of radicalism as the open surgery for the right colon. The laparoscopic techniques with intracorporeal anastomosis for the right colon remain a technical challenge but they seem to have some theoretical advantages compared to the other laparoscopic and open procedures described in our study even if further prospective randomized trials are necessary to confirm it.

INTRODUCTION

The laparoscopic treatment for benign and malignant pathologies of the left colon and rectum is actually accepted and validated. Laparoscopy advantages are widely demonstrated in term of: Post-operative pain reduction, early resumption of the intestinal function, decreasing in hospital stay, time to return to work and better cosmetic results. The oncologic outcomes are the same than open surgery^[1]. These results are also achieved thanks to the development of Kehlet "Fast-Track" recovery protocols. The laparoscopic technique for the right colon instead, had a slower diffusion probably for the complexity of right colon laparoscopic anatomy and the variability of the vascular peduncles that require a greater laparoscopic experience than left

colon and rectum surgery. For these reasons, many surgeons consider the laparoscopic approach to right colon an useless and complex waste of time^[2].

Different laparoscopic hybrid procedures developed but there are not sure evidences which is the best one and also the role of laparoscopy itself in the right colon treatment remains controversial.

The aim of the study is to critically analyze the literature state of art on right colectomy, focusing on the lights and shadows of laparoscopic and robotic approach in relation to open surgery and comparing the different laparoscopic procedures.

MINI-INVASIVE PROCEDURE FOR RIGHT COLON CANCER

Right colectomy is indicated for malignant pathologies involving the intestinal tract between the ileocecal Bahuino valve and the colonic hepatic flexure. Laparoscopic resection must respect the same oncologic criteria as the open approach including: "no-touch isolation technique", isolation and ligation of the vascular pedicles at the origin, oncologic lymphadenectomy and "distal and radial clearance" of the neoplasm from resection margins^[3,4].

Different laparoscopic procedures have been described for the treatment of right colon tumors: (1) totally laparoscopic right colectomy (TLC) which provides all steps conducted in laparoscopy including Intracorporeal ileo-colic Anastomosis (IA)^[5]; (2) single incision laparoscopic surgery (SILS) for right colon (SILC) allows to perform the intervention laparoscopically (with intracorporeal anastomosis) through larger multichannel single (about 3 cm diameter) trocar and curved instruments^[6,7]; (3) laparoscopic assisted right colectomy (LAC) which provides laparoscopic vessel ligations and right colon mobilization but the ileo-colic Anastomosis is performed extracorporeally by open incision (EA)^[8,9]; (4) laparoscopic facilitated right colectomy (LFC), a variant of laparoscopic assisted, which provides only the laparoscopic right colon mobilization while the vessels ligation and anastomosis are extracorporeally (EA)^[10]; (5) hand-assisted right colectomy (HAC) with laparoscopic mobilization of colon by hand help through a right side minilaparotomy and extracorporeal anastomosis^[11,12]; and (6) robotic right colectomy (RRC) with manual intracorporeal anastomosis^[13].

The two main characteristics of these techniques are the different type of anastomosis and minilaparotomies. The anastomosis may be performed in intracorporeal way for TLC, SILC and RRC or extracorporeally for LAC, LFC, HAC and open right colectomy. The minilaparotomy is generally performed in suprapubic region (a Pfannes-tiel of about 5-6 cm) in the TLC, SILC^[14,15] and RRC for the specimen extraction while it is performed median in periumbilical site or transverse in right side of abdomen (about 10-12 cm of length) in LAC, LFC, HAC and open surgery to extract the specimen and to make the EA.

In the SILC, the specimen extraction can also be performed through the umbilicus eventually used to make the anastomosis extracorporeally^[16].

SHORT AND LONG TERM OUTCOMES: LAPAROSCOPY VS OPEN SURGERY

Several studies including meta-analysis demonstrated the advantages of laparoscopic vs open approach for the treatment of right colon cancer in short term outcomes (Table 1): Minimal invasiveness, reduced blood loss, less postoperative pain, earlier first flatus, shorter hospital stay and reduced rate of wound infections and incisional hernias. No differences, instead, were found between the two techniques for other complications such as: pneumonia, anastomotic leaks, ileus, deep venous thrombosis or pulmonary embolism^[17]. The number of nodes taken out, the post-operative (p.o.) mortality and cancer recurrence were not statistically different in the two groups^[17-26].

In some studies, the operative time was statistically longer in laparoscopy (LS) and it is connected to the learning curve^[27].

The limits of the studies reported in literature are related to the lack of double blinded randomized clinical trials which determines selection bias, to the different experience of the Surgical Centers which cannot be judged by a single paper and to different patient's management. Consequently, more randomized clinical trials with same standardized preoperative and postoperative enhanced protocols for patient's management must be conducted by High Specialized Surgical Centers.

About long term outcomes, the study of Guerrieri *et al*^[28] reported in the open surgery group an increased risk of local recurrence, metastasis and cancer-related mortality, while a meta-analysis of Reza *et al*^[29] showed no difference between LS and open surgery (OS) groups for cancer related mortality or disease recurrence during five-year follow-up. Han *et al*^[30] confirmed the same results with no statistically difference between LS and OS groups for overall survival at 1-, 3- and 5-year follow-up for all tumor stages.

LAPAROSCOPIC COLECTOMY SHORT AND LONG TERM OUTCOMES: INTRACORPOREAL (TLC) VS EXTRACORPOREAL ANASTOMOSIS (LAC, LFC AND HAC)

A recent meta-analysis of Feroci *et al*^[31] compares the intracorporeal and extracorporeal anastomosis considering short term outcomes. The two techniques do not show significant differences in term of mortality, surgical and non surgical complications. In Fabozzi *et al*^[32] study, the TLC (with IA) group presents some advantages about post-operative recovery in particular regarding: Earlier first flatus, earlier food intake, reduced analgesic consumption, shorter hospital stay vs LAC (with EA) group (Figure 1). These better results may be explained by the less intestinal manipulation in the IA group thanks to the lesser dissection (lesser p.o. adhesions) and mobilization of transverse colon at the cost of longer operative time and higher laparoscopic experience^[32-34].

On the contrary, some authors (Table 2) reported different results: shorter operative time and hospital stay in LAC vs TLC group, remarking the necessity of further controlled studies^[9,32,33,35-38].

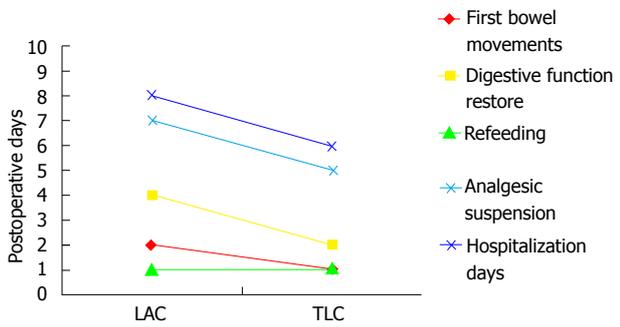

All authors, fortunately, agree about the absolute indication to TLC with IA in obese patients, who present some factors interfering with EA: Greater wall thickness, shorter and thick mesentery causing the necessity of enlarging minilaparotomy to perform the colonic resection and EA.

The goal of treatment in colon cancer outcomes should be the number of lymph nodes harvested: This is similar in TLC (IA) and LAC (EA) groups because the vessel ligation was conducted in the same intracorporeal way (Table 2). The lymph nodes removal, in fact, is influenced by the level of vessel ligation which must be performed at the origin from Superior Mesenteric Artery. This technical point explains why it is more difficult to obtain a sufficient number (at least 12) of lymph nodes through a right sided abdominal small

Fabozzi *et al.* Surg Endosc (2010)

Figure 1 Comparison between laparoscopic assisted right colectomy and totally laparoscopic right colectomy. From Fabozzi *et al*^[32].

incision of the LFC and HAC.

The right colon dissection with the median to lateral approach in TLC in fact, consents to achieve a good exposure of all colonic vessels: The ileo-colic trunk, the right colic artery, the right branch of the median colic artery (Figure 2A). The most difficult step is the nodal dissection at the origin of the median colic vein and of the Henle's trunk that could increase a risk of bleeding, so a great expertise and laparoscopic skill are requested^[39].

TLC provides a mechanical (stapled side to side anastomosis) IA (Figure 2B) while EA procedures can have a stapled or hand-sewn anastomosis. A recent Cochrane systematic review reported a lower rate of anastomotic leakage in stapled ileo-colic anastomosis compared to hand-sewn anastomosis^[40]. The safety of both types of side to side anastomosis (hand-sewn running suture anastomosis vs stapled EA) is well known but the advantages of mechanical anastomosis could be due to the standardization of anastomosis (60 mm blue cartridge) and the faster performance that do not depend from the ability of surgeon^[31].

In Fabozzi *et al*^[32] TLC has better postoperative recovery outcomes such as shorter hospital stay, faster bowel movements and also better aesthetic results thanks to the minor size and site of minilaparotomy (in suprapubic region) (Figure 2C) which also determines less post-operative pain and p.o. analgesia and less

risk of incisional hernias. The suprapubic incision (in IA procedures) in fact, is subjected to less abdominal pressure (compared to right sided abdominal incision in EA procedures) and it is not influenced by diaphragmatic movements that can increase the p.o. pain. Moreover, the pain of the right side incision (Figure 2D) can also reduce diaphragmatic and respiratory movements determining a higher risk of pulmonary infections (Table 3)^[31,32].

Other studies compare transverse vs midline incision showing better outcomes in term of p.o. morbidity, hospital stay and incisional hernia in the first one^[33,41,42].

The cost of procedures is lower in case of EA (Open, LAC, LFA) compared to IA of TLC and RRC due to longer operative time and use of instruments but the cost of drugs is significantly higher in EA than IA group related to duration of p.o. use of analgesics^[31]. The only one study published on the long term results is by Lee *et al*^[43], reporting no difference in survival and disease free survival at 3 years follow-up between the two groups (IA vs EA).

The limits of literature data depend on the large amount of non-randomized studies which leads to a bias giving preferential choice to the more difficult technique (TLC with IA).

Open questions remain the operating time that is related to the learning curve to reach the laparoscopic suture skill, and the oncological long term results connected to a correct nodal clearance for which there is lacking of high grade evidences.

SILC VS MULTIPORT LAPAROSCOPIC RIGHT COLECTOMY

Single incision laparoscopic surgery is a recently introduced mini-invasive procedure performed through single skin access of 3-4 cm using a larger multichannel port. It was first used for laparoscopic colecistectomy and appendectomy and later it has been tested for other procedures^[16]. Colorectal SILS was first performed in 2008^[44]. The umbilicus is the most common access for the SILS procedures (in particular for right colon) but some surgeons prefer to use other

From Fabozzi *et al*^[32].

sites (such as the right side of abdomen) for example when a diverting stoma is planned^[7,16]. The SILC port is generally composed by 3 or 4 channel (depending on type): 1 of 10 mm for the 30° camera, 1 of 12 mm for stapler or other instruments and other 1 or 2 channels of 5 mm for specific curved instruments to allow the inverse triangulation and to facilitate the movements in operative field^[15,16]. The specimen was generally removed through a suprapubic incision or enlarging (if necessary) the umbilical incision^[7,15,16]. Despite the experience in SILS is recently improved and many papers are appeared in literature, the technical difficulties of procedure, the prolonged learning curve and the oncological results are still object of discussion^[16,45].

Recent study of Yun *et al*^[46] reported same oncologic results in SILS compared to conventional laparoscopy for colon cancer.

A systematic review on 881 patients (389 SILC vs 492 Multiport) of Vettoretto *et al*^[47] reported no statistical difference between the two techniques in morbidity and mortality, number of lymphnodes harvested and disease free survival at 24 mo. Other outcomes such as operative time, post-operative analgesic use, blood loss, anastomotic leaks rate, first flatus and hospital stay were not analyzed due to the lack of data.

A randomized clinical trial of Poon *et al*^[48] on 25 patients reported a reduced p.o. pain and hospital stay in SILS procedure even if further randomized clinical trials are necessary.

In the SILS specimen extraction can be performed through the umbilicus, also used to make the anastomosis extracorporeally. The extracorporeal anastomosis allows shorter operative time, so some surgeons prefer it especially in their early experience. Instead, the minilaparotomy can be performed in suprapubic region to extract the specimen when intracorporeal anastomosis is made^[47].

A certain benefit of SILS is the better cosmetic result comparing to the other mini-invasive and open procedures even if some authors think that cosmetic evaluation must be made after the complete wound healing^[49].

Another metanalysis of Yang *et al*^[50] reported smaller incisions, less blood lost and more lymphnodes removed with same results in p.o. morbidity and operative time.

With the progressive diffusion of the SILS and the improvement of surgeons experience, its cost became

almost the same of conventional laparoscopy^[49].

SOMETHING ABOUT LS VS RS

The major spreading of EA techniques depends on their major feasibility compared to IA of TLC. The use of Robot (Da Vinci System™) has simplified the laparoscopic procedure allowing the surgeons who do not make laparoscopy to overcome the learning curve of minimally invasive surgery. The robotic technique plays the same steps of open surgery with the advantages of the minimally invasiveness (including the better vision) but it is easier than laparoscopy.

According to Trastulli *et al*^[13] the use of Robot facilitates an extended lymphadenectomy through a complete mesocolon excision if compared to laparoscopy.

Robotic surgery is safe and could be an effective alternative to conventional LS. Like laparoscopy, it avoids the big incision, reduces pain, allows early mobilization, and diminishes general (respiratory and circulatory) and local complications (wound infection and incisional hernia). Global morbidity and mortality rate is generally lower than all types of corresponding open interventions.

Moreover, the Da Vinci Intuitive Xi™ Robotic System could allow interventions to be more effective and reliable than traditional laparoscopic techniques and faster in terms of operative but not total time because it includes the time for system setup too. Robotic surgery, restoring the hand-eye coordination and three-dimensional view lost in laparoscopic surgery, filtering hand tremors, giving more freedom degrees to instruments and amplifying different motion scale, could allow to perform complex procedures with greater precision and better results^[51,52]. Thus, difficult laparoscopic interventions may become easier to perform, and the indications for robotic and minimal invasive surgery could be generally extended despite the long setup time.

A recent meta-analysis of Xu *et al*^[53] reports the advantages of robotic approach compared to laparoscopy in treatment of right colon cancer. In particular, RRC seems to be associated with lower blood losses, reduced p.o. complications and a faster restore of bowel functions despite a long operative time. In literature the benefits of laparoscopy vs open surgery in the treatment of colorectal surgery are well known: Smaller incision, less blood loss, less p.o. pain, early resume to normal diet and intestinal function, short hospital stay and quickly return of the patients to daily life activities. On the other side, the laparoscopic approach for the right colon shows some technical difficulties connected to the lack of fixed anatomical landmarks (as we mentioned before) and to the laparoscopy itself such as the lack of three dimensional vision, the complex dissection and suturing, so it is performed only by expert surgeons with good results. The Da Vinci Xi Robot System™ allows to overcome all laparoscopic technical difficulties (three dimensional vision, easy

Figure 2 The right colon dissection. suturing, filtering tremor movements with surgeon comfortable sitting) combining the advantages of minimally invasive surgery and open surgery^[53].

Actually, the higher costs of the robotic surgical instruments, as compared with the cost of the laparoscopic instruments, represent the real disadvantage of

this new technique.

However, the absence of a sufficient number of patient follow-up in the literature does not allow having data on long term results.

A schematic representation of the advantages or disadvantages of each technique is reported in Table

Table 4 Comparison between open right colectomy, laparoscopic assisted right colectomy, totally laparoscopic right colectomy, single incision laparoscopic Surgery for right colon and robotic right colectomy

4^[13,14,16,29,32,33,41,47,51,52].

CONCLUSION

The different laparoscopic techniques meet the same oncological criteria of radicalism as the open surgery for the right colon: Absence of tumor manipulation (“no touch techniques”), section at the origin of the right vascular peduncles and the “distal and radial clearance” of the neoplasm margins^[54]. The TLC and even more the SILC with IA remain a technical challenge due to the complexity of procedures (especially for the SILC) and the particular right colon vascular anatomy but they seem to have some theoretical advantages than the other mini-invasive and open procedures^[26,32,33,46].

Oncologic advantages

The extraction of the operative specimen by 15 cm endobag through a suprapubic incision prevents the tumor squeezing and neoplastic cells spreading (Figure 2E and G).

Technical advantages

The closure of mesentery by non-absorbable running suture (Figure 2G) especially in obese patients is easier in laparoscopic procedures with IA thanks to its better vision and exposure. The laparoscopic suturing of mesentery reduces the risks of internal hernia and avoids traction on vascular and nervous peduncles (as it could happen in case of EA) which is one of the cause of the delayed canalization.

Functional advantages

The suprapubic incision (a little Pfannestiel) for the specimen removal is smaller (about 5 cm) than other laparoscopic techniques (about 8 cm) and open technique (about 10 cm) (Figure 2C and D). The smaller dimension and the site of incision reduce the post-operative pain with less assumption of analgesic drugs, promoting early mobilization of patients and recovery of intestinal function, better respiratory exchanges,

better tissue (and anastomotic) oxygenation, faster healing and coming back to ordinary life. In fact, the major dimensions and right sided abdomen (or median) incision of non totally laparoscopic and open techniques with muscles section cause greater pain, reducing the respiratory excursions especially in the elder and favouring pulmonary complications with prolonged hospitalization and higher risk of incisional hernias as reported by some authors^[32,33,36,41,42] (Table 3).

Cosmetic advantages

The smaller dimension and the suprapubic (TLC, SILC) or umbilical (SILC) site incision determine better aesthetic results than other mini-invasive and open right colon techniques (larger incision on the right side of the abdomen).

Although some good short term outcomes, TLC and SILS with IA have the limitation of a minor tactile feedback and a steep learning curve (longer in SILS)^[16,45]. Despite advances in technologies and devices, the laparoscopic procedures require dexterity and technical skill. In a study of Tekkis *et al*^[27] the evidences demonstrated that colorectal surgeons with an experience of 0-25 procedures have a significant higher risk of conversion to open surgery respect to surgeons with over 175 procedures. Surgeons with a 25 laparoscopic colectomies experience employed a median of 180 min for procedure, while at the 175th procedure the median operating time is 115 min. To reach good results with TLC, it is mandatory to overcome specific technical steps (laparoscopic intracorporeal running suture, mechanical stapler use, correct bowel orientation) supported by expert staff assistance and advanced technology.

After these assumptions, TLC may be considered feasible and safe techniques, even if it requires a great experience not only in laparoscopy but also in open surgery to ensure better p.o. results, better comfort for the patients and similar oncological outcomes to the open surgery^[27,32,55].

The SILC may be considered a valid alternative

to TLC thanks to similar p.o. outcomes but a longer learning curve than TLC is required in addition to a great experience in laparoscopic and open surgery. It seems to report better cosmetic results, even if in TLC, the suprapubic scare would be also covered by the brief. It not clear instead, if it has an higher incisional hernia rate or p.o pain due to the median site of incision compared to suprapubic incision (of TLC) and right sided incision of other procedures^[32,36,41,42,47].

Recently, an early experience of Robotic SILC reported a longer operative time, higher conversion rate and 27% of p.o. complications rate (in particular: Wound hematomas, infections and incisional hernias of the umbilicus)^[56].

The LAC instead, could be considered an alternative to both TLC and SILC for the surgeons with early experience in laparoscopic advanced procedures or to avoid a primary open surgery of the right colon or a conversion to open surgery due to technical problems related to difficult anatomy, surgical experience or intraoperative complications untreatable in laparoscopy^[57].

Some authors report that HAC procedure has not advantages respect to LAC in term of clinical and oncological results but it could have some advantages in case of bulky tumors treatment^[11].

Data reported in literature while confirming the advantages of laparoscopic approach, do not allow to solve controversies about which is the best laparoscopic technique (IA vs EA) to treat the right colon cancer: some authors consider a mini-invasive right colectomy with IA as "a triumph of technique over the common sense" while for others is "an illogical waste of time". For these reasons, all the studies reported in literature conclude that further prospective randomized trials are necessary.

Abstract

Surgical resection is the only curative treatment modality

for colorectal cancer limited locally. Evidence for the kind of resection procedure that is effective for improving prognosis is insufficient. Prognosis improvement is expected with the no-touch isolation technique (NTIT), making it the most important resection procedure. We are conducting a multicenter randomized controlled trial (RCT) to confirm the efficacy of NTIT in patients with colorectal cancer. The present review serves as a preface to our trial, as it focuses on basic and clinical studies that support the efficacy of NTIT. The detection ratios of circulating tumor cells (CTCs) of peripheral blood indicate the progress and prognosis of colorectal cancer. In a rabbit liver tumor model, metastases increased after surgical manipulation. Also, CTCs increased during the radical excision of colorectal cancer. However, NTIT decreased the detection of CTCs of intraoperative portal vein blood in patients with colorectal cancer. Although these aforementioned results support the use of NTIT, a previous controlled prospective trial was not able to confirm the clinical benefit of NTIT, as it had an insufficient sample size and many patients were lost to follow-up. Therefore, we initiated a large-scale high-quality RCT to confirm the efficacy of NTIT for colorectal cancer.

Key words: Colorectal cancer; General surgery; No-touch isolation technique; Circulating tumor cells; Randomized controlled trial

Core tip: Currently, we are conducting a multicenter randomized controlled trial to confirm the efficacy of the no-touch isolation technique (NTIT) in patients with colorectal cancer. A previous controlled prospective trial was not able to confirm the clinical benefit of NTIT, as it had an insufficient sample size and many patients were lost to follow-up. However, basic and clinical studies have supported the use of NTIT for treating colorectal cancer. The present review serves as a preface to our

trial, as it provides background information on whether the prognosis of colorectal cancer is improved by surgery.

INTRODUCTION

Surgical resection is the only curative treatment for colorectal cancer limited locally. The purpose of surgical resection of primary colon cancer is complete removal of the tumor, major vascular pedicles, and lymphatic system of the affected colonic segment^[1]. Total mesorectal excision^[2-5] and complete mesocolic excision (CME)^[6] for colon and rectal cancers, respectively, reduce tumor recurrence after curative resection. Furthermore, Japanese D3 dissection is similar to CME^[7]. However, evidence for the kind of resection procedure that is effective for improving prognosis is insufficient. The no-touch isolation technique (NTIT) is the most important resection procedure, because prognosis improvement is expected. NTIT was first proposed in the 1950s^[8]. In this technique, central vascular ligation is the first priority, and it is followed by mobilization of the tumor-bearing segment of the colon. This technique aims to reduce cancer cells flowing from the primary tumor site into the liver and other organs by ligating the blood vessels first. A retrospective study showed improvement in prognosis with this technique^[9], but a randomized controlled trial (RCT) failed to prove its efficacy with statistical significance^[10]. Therefore, NTIT is not regarded as a standard technique in current guidelines^[1]. Currently, we are conducting a multicenter RCT to confirm the efficacy of NTIT in patients with colorectal cancer undergoing open surgery^[11]. In this trial, the conventional technique gives first priority to mobilization of the tumor-bearing segment of the colon, which is followed by central vascular ligation and ligation of other vasculature. Conversely, NTIT gives first priority to central vascular ligation, which is followed by mobilization of the tumor-bearing segment of the colon. This trial is designed to confirm the superiority of NTIT over the conventional technique in terms of disease-free survival. We hypothesize that the 3-year disease-free survival of the NTIT arm will be greater than that of the conventional technique arm (75%) by 6%. According to the method of Schoenfeld and Richter, the sample size will be 840 patients (420 patients per arm) with a one-sided alpha level of 5% and power of 80%, and 259 events are expected to occur within 3 years of accrual and 3 years of follow-up. Considering that some patients will be lost to follow-up, the total target sample size is set at 850 patients. We secured statistically sufficient cases in this

Takii Y *et al.* Review of the no-touch isolation technique

RCT, and we described the quality control of the follow-up and the surgery in the protocol. The present review serves as a preface to our trial, as it focuses on basic and clinical studies that support the benefit of NTIT for colorectal cancer.

DISCUSSION

Does the detection ratio of circulating tumor cells of peripheral blood indicate the progress and prognosis of cancer?

Numerous articles have been published about the relationship between cancer-bearing patients and circulating tumor cells (CTCs), but two meta-analyses have generalized this point well.

In the first meta-analysis^[12], five studies reported on the incidence of CTCs in lymph node involvement positive and negative groups, and three of those studies showed a statistically significant increase in the lymph node involvement positive groups compared with that in the lymph node involvement negative groups. A meta-analysis of all the studies showed a significantly higher incidence of CTCs in the lymph node involvement positive groups (50%) than in the lymph node involvement negative groups (21%). Five studies reported the rate of hepatic metastases at maximal follow-up in patients who were CTC positive and negative, and two of those studies demonstrated a statistically significant hepatic metastases rate in patients who were CTC positive compared with that in those who were CTC negative. A meta-analysis of all the studies indicated a significantly increased hepatic metastases rate of 21% in patients who were CTC positive compared with 8% in those who were CTC negative. Three studies reported the incidence of CTCs in different stages, and no study showed a significant difference between CTC positive and negative groups. A meta-analysis of all the studies showed a significantly lower incidence of CTCs in stage I and II groups (17%) than in stage III groups (32%). When stage I and stage II tumors were compared, the incidence of CTCs was higher in stage II (19%) than in stage I (12%), but this was not statistically significant. Three studies reported disease-free survival with data extracted at 1-3 years. Disease-free survival was significantly higher in the CTC negative groups than in the CTC positive groups at 1 year, 2 years, and 3 years after resection.

In the second meta-analysis^[13], 36 studies (3094 patients) were eligible for the final analyses. Pooled analyses showed that the detection of CTCs in the peripheral blood compartment was a statistically significant prognostic factor of recurrence-free survival [HR = 3.06 (95%CI: 1.74-5.38) and overall survival (OS) = 2.70 (1.74-5.38)].

Do metastases increase after surgical manipulation of the tumor?

Nishizaki *et al.*^[14] perform and experiment on liver tumors in a rabbit model and reported the results. In

this experiment, they inoculated carcinoma in a rabbit liver, and they separated the rabbits into two groups according to the presence or absence of manipulation before hepatectomy. Then they compared the number of tumors in the hepatic vein, number of metastases in the lung, and prognosis between the two groups. The incidence of vascular permeation of liver tumor cells into the hepatic vein was significantly higher in the manipulation group than in the non-manipulation group ($P < 0.01$). On the fourteenth day after tumor resection, the number of metastatic nodules in the lung was significantly increased in the manipulation group compared to that in the non-manipulation group ($P < 0.01$). The survival of rabbits after tumor resection was significantly shorter in the manipulation group than in the non-manipulation group ($P < 0.01$).

Do CTCs increase during the radical excision of colorectal cancer?

Weitz *et al.*^[15] used cytokeratin 20 reverse transcription polymerase chain reaction (RT-PCR) to detect CTCs in the peripheral vein preoperatively, intraoperatively, and postoperatively. Blood samples were taken from 65 patients who were undergoing resection of primary colorectal cancer. As the depth of tumor invasion deepened, the rate of detection of CTCs increased. Also, as the lymph node metastatic degree advanced, the rate of detection of CTCs increased. In addition, regarding the timing of the measurement, the rate of detection of CTCs was the highest intraoperatively. These data indicate that surgery enhances the release of CTCs into circulation.

Do CTCs increase during the resection of colorectal cancer liver metastasis?

Koch *et al.*^[16] also used cytokeratin 20 RT-PCR to detect CTC in the central vein preoperatively, intraoperatively, and postoperatively. Blood samples were taken from 37 patients who were undergoing resection of liver metastases. Concerning the timing of the measurement, the rate of detection of CTCs was highest intraoperatively. This was similar to the finding of colorectal cancer primary tumor surgery. When CTCs were detected during the resection of liver metastasis, the prognosis was poor.

Does NTIT decrease the detection of CTCs in intraoperative portal vein blood?

Hayashi *et al.*^[17] measured CTCs of portal vein blood using the mutant-allele-specific amplification method. They examined a ratio of CTCs of intraoperative portal vein blood by comparing the conventional technique and NTIT. For the conventional technique, CTCs were confirmed in 73% of cases, but for NTIT, CTCs were only confirmed in 14% of cases. As the use of NTIT reduces CTCs during surgical manipulation, they concluded that this technique may be effective for preventing metastases in those with colorectal cancer.

Was the clinical use of NTIT proven in the controlled prospective trial that compared NTIT and the conventional technique?

Wiggers *et al.*^[10] conducted a controlled prospective trial to assess the effect of NTIT on the treatment of colon cancers. This trial is the only RCT that has been published on this topic. Two hundred and thirty-six patients were prospectively and randomly assigned to undergo NTIT or the conventional technique. OS did not differ significantly between the two groups. This RCT failed to prove the efficacy of NTIT with statistical significance. After the results of this trial were published, NTIT was not regarded as a standard technique in current guidelines. However, there was a trend of good survival and disease-free survival in the NTIT group in the RCT. After a detailed review of the RCT, we concluded that the RCT could not show the superiority of NTIT because it had an insufficient sample size and many patients were lost to follow-up. Therefore, we initiated a large-scale RCT to confirm the efficacy of NTIT in patients with colorectal cancer^[11]. Furthermore, we considered a collateral study to obtain basic proof for this clinical trial. We thought that significant data would be needed to confirm the presence or absence of CTCs in the portal vein blood or peripheral blood intraoperatively or postoperatively. However, we were unable to establish this accompaniment study because of cost.

CONCLUSION

Although the results of basic and clinical studies support the benefit of NTIT, a previous controlled prospective trial was not able to confirm the clinical efficacy of NTIT, but it had an insufficient sample size and many patients were lost to follow-up. Therefore, we are currently conducting a large-scale high-quality RCT to confirm the efficacy of NTIT in patients with colorectal cancer.

Abstract

AIM

To evaluate the utility of hand-assisted laparoscopic restorative proctocolectomy (HALS-RP) compared with the conventional open procedure (OPEN-RP).

METHODS

Fifty-one patients who underwent restorative total proctocolectomy with rectal mucosectomy and ileal pouch anal anastomosis between January 2008 and July 2015 were retrospectively analyzed. Twenty-three patients in the HALS-RP group and twenty-four patients in the OPEN-RP group were compared. Four patients who had purely laparoscopic surgery were excluded. Restorative total proctocolectomy was performed with mucosectomy and a hand-sewn ileal-pouch-anal anastomosis. Preoperative comorbidities, intraoperative factors such as blood loss and operative time, postoperative complications, and postoperative course were compared between two groups.

RESULTS

Patients in both groups were matched with regards to patient age, gender, and American Society of Anesthesiologists score. There were no significant differences in extent of colitis, indications for surgery, preoperative comorbidities, and preoperative medications in the two groups. The median operative time for the HALS-RP group was 369 (320-420) min, slightly

longer than the OPEN-RP group at 355 (318-421) min; this was not statistically significant. Blood loss was significantly less in HALS-RP [300 (230-402) mL] compared to OPEN-RP [512 (401-1162) mL, $P = 0.003$]. Anastomotic leakage was noted in 3 patients in the HALS-RP group and 2 patients in the OPEN-RP group (13% *vs* 8.3%, NS). The rates of other postoperative complications and the length of hospital stay were not different between the two groups.

CONCLUSION

HALS-RP can be performed with less blood loss and smaller skin incisions. This procedure is a feasible technique for total proctocolectomy for ulcerative colitis.

Core tip: This is a retrospective study to evaluate the utility of hand-assisted laparoscopic restorative proctocolectomy (HALS-RP) for ulcerative colitis (UC). Fifty-one patients underwent restorative proctocolectomy, and twenty-three patients in the HALS-RP were compared with twenty-four patients in the conventional open surgery group (OPEN-RP). The mean operative time for the HALS-RP group was not different to OPEN-RP group, but blood loss was significantly less in HALS-RP compared to OPEN-RP. HALS is a feasible procedure for restorative proctocolectomy for UC with small skin incision.

Hand-assisted laparoscopic restorative proctocolectomy for ulcerative colitis. *World J Gastrointest Surg* 2016; 8(8): 578-582 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i8/578.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i8.578>

INTRODUCTION

Laparoscopic surgery (LAP) was introduced in 1991 by Jacobs *et al.*^[1] for colorectal cancer, and is now the standard of care in many colorectal operations. Numerous studies have shown the benefits of LAP for colorectal cancer including less blood loss, less postoperative pain, earlier return of bowel function, and shorter length of hospital stay^[2-4]. LAP for patients with ulcerative colitis (UC) was reported in 1992 by Peters^[5], but it has not been widely accepted because of the complexity of the surgeries and long operative times^[6]. Hand-assisted laparoscopic (HALS) was introduced in the mid-1990s as a hybrid technique^[7]. Surgeons can provide direct retraction, perform the dissection, and control bleeding with one hand placed into the abdominal space through a small incision. HALS is a minimally invasive surgery and has been reported

as an acceptable technique for total proctocolectomy (TPC). HALS is reported to be as minimally invasive as LAC^[8], but there have been few reports comparing HALS and open surgery for UC. The aim of this study was to assess the utility of hand-assisted laparoscopic restorative proctocolectomy (HALS-RP) compared with the traditional open approach (OPEN-RP) performed by colorectal surgeons for patients with UC in a single institution.

MATERIALS AND METHODS

A total of 95 patients underwent restorative TPC with mucosectomy and hand-sewn ileal-pouch anal anastomosis (IPAA) for UC in Hiroshima University Hospital from January 2008 to July 2015. Fifty-one patients who underwent a 2-staged procedure were included in this retrospective study. Those patients were divided into the HALS-RP group ($n = 23$) and the OPEN-RP group ($n = 24$) based on three surgeons' preferences. Patients diagnosed with indeterminate colitis, or those who underwent pure laparoscopic surgery ($n = 4$), were excluded. Patient's demographics, preoperative clinical information, intraoperative factors such as operative time and blood loss, postoperative complications, and postoperative course were compared. The patients were preoperatively categorized according to American Society of Anesthesiologists (ASA) classifications. Data are shown as the median with the interquartile range (IQR) in parentheses or means with standard deviations (SD) for continuous variables, and frequencies for categorical variables. Continuous data with a Gaussian distribution was showed as means and SD, and analyzed with the Student's *t* test. In the case of a non-Gaussian distribution, continuous data were expressed as median and IQR and analyzed with the Wilcoxon rank-sum test. For categorical variables, the Pearson's χ^2 test was performed, and Fisher's exact test was used when the data set was small (expected cell counts were < 5). A *P* value < 0.05 was considered statistically significant. Statistical evaluation was carried out using the JMP version11 software (SAS institute Japan).

HALS surgical technique

Transanal mucosectomy was performed in the jack-knife position. During this procedure, the anterior wall of the rectum was separated from the prostate gland or vaginal wall. The posterior wall of the rectum could be separated from the sacrum *via* transmesorectal excision. Patients were then placed in the lithotomy position. A 7-cm vertical incision below the umbilicus was made for the hand port and the wound protector was inserted. Mobilization of the right side colon and sigmoid colon was performed, and the terminal ileum was resected through the small incision under direct vision. Two trocars were placed in the upper umbilical region for the laparoscope and the left mid-abdomen for the surgeon's right hand (Figure 1). A hand-assist device (Gel Port[®] system) was assembled within the

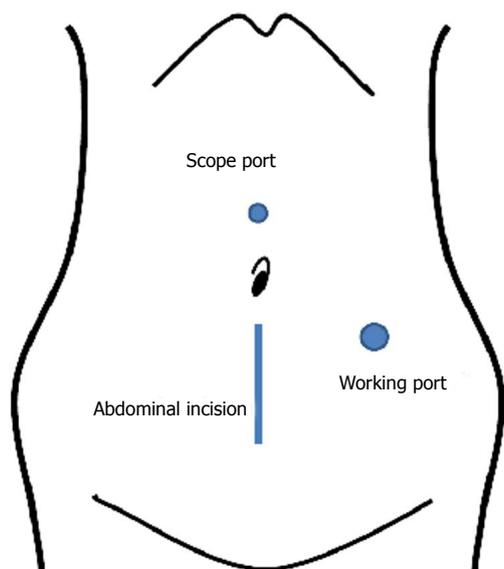

Figure 1 Skin incision for hand-assisted laparoscopic restorative proctocolectomy. A 7-cm vertical incision below the umbilicus was made for the hand port. Two trocars were placed in the upper umbilical region for the laparoscope and the left mid-abdomen for the surgeon's right hand. A hand-assist device (Gel Port® system) was assembled within the wound protector.

wound protector. Pneumoperitoneum was initiated and the greater omentum was dissected from the transverse colon. The left colon including the splenic flexure was mobilized, and the mesentery was divided outside of the marginal artery of colon. A vessel sealing system (LigaSure®; Valleylab) was used for this purpose. After pneumoperitoneum, mobilization of the rectum was performed through the incision. A J-pouch was constructed at the terminal ileum with linear staplers, and hand-sewn to the anal verge.

RESULTS

Twenty-three cases in the HALS-RP group and 24 cases in the OPEN-RP group were matched in regards to patient age, gender, and ASA score (Table 1). However, body mass index (BMI) in the HALS-RP was 20.8 ± 3.1 , which was significantly less than that of the OPEN-RP group (22.6 ± 3.3 , $P = 0.043$). There were no significant differences in extent of colitis, indications for surgery, preoperative comorbidities, and preoperative medications in the two groups. Preoperative leukocyte count was higher in the HALS-RP group than OPEN-RP group (7486 ± 478 vs 5661 ± 410 , $P = 0.002$). The amount of total-corticosteroid and C-reactive protein was also higher than the OPEN-RP group; this was not significantly different.

The operative outcomes and complications are summarized in Table 2. The mean operative time for the HALS-RP group was slightly longer, but this was not significantly different [HALS-RP 369 (320-420) min vs OPEN-RP 355 (318-421) min]. Blood loss was significantly lower in the HALS-RP group (300 (230-402) mL vs 512 (401-1162) mL, $P = 0.003$). IPAA

anastomotic leakage was noted in 3 patients in the HALS-RP group and 2 patients in the OPEN-RP group (13% vs 8.3%, NS). Rates of surgical site infection were not significantly different. Superficial and deep surgical site infections developed in 3 cases in the HALS-RP group (13.0%) and 3 cases in the OPEN-RP group (12.4%, NS). Organ space infections were noted in 5 cases in the HALS-RP group (21.7%) and 4 in the OPEN-RP group (16.7%, NS). Other postoperative complications such as small bowel obstruction, venous thrombosis, and neurologic bladder dysfunction were also similar.

Return of bowel function, which was estimated by bilious output from the ileostomy, was similar between the two groups (1.5 ± 0.13 d and 1.8 ± 1.4 d, $P = 0.26$). Tolerance of liquid diet was 1.3 ± 0.13 d and solid diet was 5.26 ± 0.75 d in the HALS-RP group; these were similar to the OPEN-RP group (1.29 ± 1.75 d and 3.62 ± 0.29 d). The length of hospital stay after surgery was not different between the two groups 20 (16-26) d in HALS-RP, 18 (14-29) d in OPEN-RP, $P = 0.408$.

HALS-RP: Hand-assisted laparoscopic restorative proctocolectomy; OPEN-RP: Restorative proctocolectomy with open surgery; IPAA: Ileal-pouch anal anastomosis; NS: No significance.

DISCUSSION

Laparoscopic surgery is common practice in segmental resection for colorectal disease namely because it provides a good field of view in the abdominal cavity. Furthermore, smaller skin incisions and faster recovery of bowel function are achieved using this technique. However, laparoscopic TPC for patients with UC is still not widely accepted as it is a longer and more complex surgery, and difficult to handle inflamed bowel laparoscopically without causing injury. In terms of avoidance of bowel edema, shorter operative times are preferred for ileal-pouch and anal anastomosis healing. On the other hand, patients with UC are relatively young and often prefer small skin incisions for cosmetic reasons. Recently, HALS for colorectal surgery was compared with conventional LAP, and showed that a HALS approach shortened operative time, but overall morbidity, time to return of bowel function, and length of hospital stay were similar to those of LAP^[8-10]. While we adopted HALS in 2008, there have been few studies comparing it with traditional open surgery for TPC with mucosectomy. In this study, we aimed to compare HALS-RP and traditional open surgery over the last 8 years in a single institution.

In terms of operative time, one study showed that HALS reduced time by 33 min in sigmoid/left colectomy, and 57 min in total colectomy compared with a conventional LAP technique^[9]. Aalbers *et al.*^[11] reported that the most important advantage of HALS in TPC was reduction in operating time, making the operation more efficient. In our series, HALS-RP was successfully completed without significant increase of operative time compared with OPEN-RP. Operative time of 374 min in this study series was still longer than previous studies, which reported times ranging from 210 to 356 min^[6,12-15]. We speculate that this was because we

started the trans-anal procedure with a mucosectomy in the jack-knife position and the time required for position change to modified lithotomy position was included. All told, this was approximately 70 min before the abdominal incision. Moreover, we chose a hand-sewn IPAA for all cases, which takes longer than a stapled IPAA, the most common technique reported in previous studies. HALS-RP showed significantly less blood loss than OPEN-RP. We attribute this to the good view of the splenic flexure as compared to that with open surgery.

Nakajima *et al.*^[14] reported that HALS maintains the early postoperative benefit of minimally invasive surgery as well as a totally laparoscopic approach for TPC. However, we are of the opinion that a HALS approach may hasten return of bowel function given there is direct manipulation of the intestine with the operator's hand. Accordingly, in this study, an advantage of the return of postoperative bowel function in the HALS-RP group was not shown. The median length of hospital stay in this study was also the same in both groups [20 (16-26) d in HALS-RP, 18 (14-29) d in OPEN-RP]. Although both were longer than in other studies^[6,14], diet advancement was done in a traditional step-wise fashion, and time was devoted to patient education regarding ileostomy care and medical control of diarrhea.

Total length of skin incisions for HALS-RP at our institution was 8 cm, with a 7-cm midline incision, and two 0.5 cm incisions for trocars. Laparoscopic TPC uses a total incision length of 4.1 to 8.2 cm for trocars and construction of the ileal-pouch^[11,13]. Thus, regarding total skin incision length, there are few cosmetic advantages of totally laparoscopic TPC.

Currently we use three different approaches for TPC: Open surgery, HALS, and LAP. Choice of technique is tailored to the individual patient. For young women, LAP may be appropriate. For patients with prior surgery, open surgery should be considered. HALS has the benefit of having the view of laparoscopic surgery but the time saving of open surgery, which may reduce surgeon stress.

This study has several limitations. Our case numbers are small. This is a nonrandomized comparison between two groups in a retrospective fashion. Surgical methods were not selected in accordance with any definitive criteria, but rather by surgeons' preferences, which could introduce some element of bias.

HALS for TPC affords the good operative view of laparoscopic surgery as well as the tactile feedback of open surgery. It is an acceptable alternative to conventional open surgery.

COMMENTS

Background

Total proctocolectomy (TPC) with mucosectomy for patients with ulcerative colitis (UC) is a complex, lengthy procedure. Traditional laparoscopic surgery (LAP) for UC has taken long operation time. The authors hypothesize that hand-assisted laparoscopic restorative proctocolectomy (HALS-RP) is superior to LAP for this disease.

Research frontiers

Although some study report about HALS-RP compared with LAP, there have been few studies comparing it with traditional open surgery for TPC.

Innovations and breakthroughs

This study indicated that HALS-RP is acceptable with less blood loss, and without increase of operative time and postoperative complications compared with open procedure (OPEN-RP).

Applications

HALS-RP is useful technique for TPC for UC with small skin incision and affords the operative good view.

Peer-review

This is a retrospective single-center study. Twenty-three patients in the HALS-RP group and 24 cases in the OPEN-RP group were matched in regards to patient age, gender, and anesthesiologists score. The study demonstrates that the rates of other postoperative complications and the length of hospital stay were not different between the two groups, with less blood loss and smaller skin incisions in the HALS-RP group.

Abstract

AIM

To analyse the impact of turning of our department from a low to a high volume provider of pancreaticoduodenectomy (PD) on surgical outcome.

METHODS

A retrospective collection of data was done for patients who underwent PD. According to the number of PDs undertaken per year, we categorized the volume into low volume (< 10 PDs/year), medium volume (10-24 PDs/year) and high volume (> 25 PDs/year) groups.

RESULTS

From 2002 to 2013, 200 patients underwent PD. The annual number of PD increased from 4 in 2002 to 34 in 2013. The mean operative time, operative blood loss and need for intraoperative blood transfusion decreased considerably over the volume categories ($P < 0.001$, $P < 0.001$ and $P < 0.001$, respectively). Increased procedural volume was associated with a lower morbidity ($P = 0.021$) and shorter length of hospital stay ($P < 0.001$). Similarly the rate of mortality dropped from 10% for the low volume group to 2.2% for the medium volume group and 0.0% for the high volume group ($P = 0.007$).

CONCLUSION

The transformation from a low volume to a high volume provider of PD resulted in most favourable outcomes favouring the continued centralization of this high risk procedure.

Key words: Pancreaticoduodenectomy; High volume centre

Core tip: Due to the complexity and challenging nature of pancreaticoduodenectomy, it is likely that both short- and long-term outcomes strongly depend on the cumulative number of cases performed by the surgeon as well as by the hospital. Strong evidence exists for volume-outcome relationship in which high volume centres have reduced perioperative morbidity and mortality. High volume hospitals are assumed to have structural characteristics associated with better quality of care, and providers in these hospitals are thought to improve their processes of care through experience in providing complex care. While the findings of this study are presented in terms of high, medium, and low volume periods, an important point exists regarding the volume-outcome relationship that must be emphasized. Thus for patients seeking to identify a hospital at which to have their surgery, the best strategy if all other factors are equal is to choose the hospital that performs pancreatic surgery most frequently.

Shah OJ, Singh M, Lattoo MR, Bangri SA. Pancreaticoduodenectomy: A study from India on the impact of evolution from a low to a high volume unit. *World J Gastrointest Surg* 2016; 8(8): 583-589 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i8/583.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i8.583>

INTRODUCTION

Pancreaticoduodenectomy (PD) is a complex, high risk surgical procedure usually performed for malignancy of the pancreatic head or periampullary region. Before 1980, PD has been associated with a high rate of morbidity (40%-60%) and a high mortality rate up to 20%^[1]. Since that time, the in-hospital mortality rate has decreased substantially with high-volume tertiary care centers reporting in-hospital mortality rate of 4% or less^[2,3]. Luft *et al*^[4] provided the empirical relationship between higher surgical volume and lower postoperative mortality, which led to centralization of high risk operations to improve the outcome. Various studies have demonstrated that high volume tertiary centers have significantly lower (< 5%) in-hospital mortality rates for PD than low volume centres (> 10%)^[5,6]. The majority of data regarding centralization of PD were obtained from multi-institutional comparisons and there are few studies describing the effects of increased caseload of PD within the same unit. Although the trend of centralization has been slow as demonstrated by a nationwide survey of PD in the United States^[7], no information is available regarding volume-outcome association in India.

The purpose of this study was to explore the effect of centralization of PD on perioperative outcome at a tertiary care center in Northern India during the period

2002-2013 and analyse the impact of turning our department from a low to a high volume provider of PD.

MATERIALS AND METHODS

Through retrospective collection of data from a prospectively maintained database at the Department of Surgical Gastroenterology, Sher-i-Kashmir Institute of Medical Sciences, Kashmir (India), medical records of patients who underwent PD for pancreatic or periampullary benign or malignant lesions were identified. Patient's demographics, surgical parameters and post-operative events were recorded and analysed. After performing PD (classical or pylorus preserving) with or without associated organ resection, pancreaticojejunostomy was achieved by anastomosing the pancreatic remnant to the end of the jejunal loop by either mucosa to mucosa or dunking method. All the surgical procedures were performed by the senior surgeon OJS with a senior assistant (SAB). The present study also included patients who were a part of previous publications from the department^[8-10]. Clavien-Dindo classification^[11] was used to grade the complications, and complications requiring either intervention under local or locoregional or general anaesthesia, ICU management or causing death were considered as major (grades 3-5). Besides recording the annual departmental volume, according to the number of PD performed per year we categorized the volume into low volume (< 10 PDs/year); medium volume (10-24 PDs/year); and high volume (\geq 25 PDs/year) as described earlier^[12].

Pancreatic fistula was categorized according to the International Study Group on Pancreatic Fistula criteria^[13]. Inability of a patient to return to a standard diet by the end of the first postoperative week necessitating prolonged nasogastric intubation of the patient was treated as delayed gastric emptying (DGE) as defined by the International Study Group on Pancreatic Surgery (ISGPS)^[14], bile leak was defined as bilious drain with raised bilirubin level, and culture positive purulent collection was treated as intra-abdominal abscess.

Postpancreatectomy haemorrhage (PPH) was defined according to the ISGPS based on the time of onset, site of bleeding, severity and clinical impact^[15]. Overall morbidity included all major complications including infections, cardiopulmonary and gastrointestinal complications; the primary endpoint was operative mortality defined as death occurring during the period of hospital stay or within 30 d of surgery. Secondary endpoints were postoperative morbidity rate, occurrence of pancreatic fistula, DGE and length of hospital stay. Follow-up for infection and non-infectious complications was carried out for 30 d after hospital discharge. Readmission rate (within 30 d after discharge) was also recorded.

Statistical analysis

Statistical analyses were performed using χ^2 and Fishers exact tests for categorical variables and ANOVA for

continuous variables. Post hoc tests were applied to look for inter-group differences. Statistical analyses were performed using SPSS 20 Chicago (United States). P values of 0.05 or less were considered statistically significant.

RESULTS

During the 12-year period from January 2002 to December 2013, 200 PDs were performed in the department. Across the study period, the annual average number of PD increased from 4 in 2002 to 34 in 2013 (Figure 1). The most common indications for surgery were pancreatic adenocarcinoma (n = 85, 42.5%), ampullary adenocarcinoma (n = 57, 28.5%) and distal cholangiocarcinoma (n = 23, 11.5%) (Table 1). The various demographic features between the low volume (group A), medium volume (group B) and high volume (group C) categories revealed no statistical change during the study period (Table 2). In group C, PD included portal vein resection (4 patients) and right hemicolectomy (6 patients) (Table 3).

In groups A, B and C the mean duration of surgery (246.3 ± 20.6 min, 227.7 ± 47.5 min, 125.5 ± 16.1 min, P ≤ 0.001), operative blood loss (1098.5 ± 163.8 mL, 932.3 ± 207.5 mL, 415.9 ± 82.7 mL, P ≤ 0.001), mean blood units transfused (1.3 ± 0.4 UI, 1.3 ± 0.6 UI, 0.2 ± 0.4 UI, P ≤ 0.001) and the requirement of feeding jejunostomy (75%, 59.1%, 7.4%, P ≤ 0.001)

decreased significantly with increasing hospital volume (Table 4). There was a progressive regression in the rate of overall complications across the volume groups (group A, 50.0%; group B, 45.5% and group C, 27.2%, P = 0.021).

The most common complications were DGE and occurrence of pancreatic fistula. Both these types of complications showed a significant difference in rates across the volume groups (pancreatic fistula rate of 15.0% in group A, 15.9% in group B and 3.6% in group C; P = 0.011), whereas DGE was observed at a rate of 20.0% in group A; 18.2% in group B and 5.9% in group C (P = 0.018; Table 5). The rate of PPH was 10.0% in group A; 2.2% in group B and 0% in group C (P = 0.007; Table 4). Five patients required reoperative surgery (2 postoperative haemorrhage, 2 pancreatic fistula and 1 DGE). The reoperative rate significantly decreased when comparing the volume groups (in low volume 10.0%; in medium volume 4.5% and in high volume 0.7%,

CA 19.9: Carbohydrate antigen 19.9; PPPD: Pylorus preserving pancreaticoduodenectomy.

P = 0.029). Occurrence of intraabdominal infections and rate of bile leak also decreased when comparing the volume categories, but did not reach statistical significance.

A consistent decrease in the mean length of hospital stay was noticed for the high volume group of patients and differences across groups were statistically significant (11.8 ± 3.4 d, 11.3 ± 2.9 d and 7.9 ± 1.7 d for low, medium and high volume periods, respectively; *P* ≤ 0.001). The consistency of the stepwise inverse relation between volume and in-hospital mortality was notable (0%, 2.2% and 10.0% for high, medium and low volume groups, respectively).

DISCUSSION

More than 30 years ago, Luft *et al*^[4] introduced the empirical relationship between higher surgical volume and lower postoperative mortality. This led to the concept of centralization of complex surgical procedures to improve outcome. This relationship of hospital volume and surgical mortality for complex surgical procedures including PD was amply described by Birkmeyer *et al*^[16]. Despite improvements due to regionalization, PD remains a complex procedure associated with high perioperative morbidity and potential mortality. Strong evidence exists for volume-outcome relationship where high volume centers have reduced perioperative morbidity and mortality, although the exact mechanism (surgeon

PD: Pancreaticoduodenectomy.

related factors vs system related factors) behind it remains unclear. For example, an experienced surgeon working in a low volume institution may be technically proficient at PD; however, the system support for diagnosis and treatment of postoperative complications may be inadequate. Conversely a high volume center with intensive care, interventional radiologic and gastroenterological expertise could provide superior support to a surgeon with lesser PD experience. Previous publications have clearly demonstrated that mortality, survival and overall life expectancy are improved when PD is performed in high volume centers^[17-20].

SKIMS is the only tertiary care hospital available for the population (about 10 million) of Kashmir valley. SKIMS, the regional provider, developed interest in the PD procedure and developed a focussed team dedicated to caring for these patients. This included formulation of treatment protocols and critical care ways, as well as standardizing diagnostic workups, operative details and management of postoperative complications. Further information regarding provider capabilities and surgical results were disseminated locally, regionally and nationally. This resulted in an increased number of referrals to the institution, resulting in regionalization. In the first period of the study (January 2002 to September 2006), the annual average number of PD was about 4. It went up to 14/year in the next three and a half years, and in the last phase of this study the figure was 34. There was a significant drop in the operative parameters like operative time (246.3 ± 20.6 min, 227.7 ± 47.5 min to 125.5 ± 16.1 min, *P* ≤ 0.001),

Table 5 Postoperative complications and outcome

Variable	Low volume (< 10 PDs/ yr), $n = 20$	Medium volume ($10-24$ PDs/yr), $n = 44$	High volume (≥ 25 PDs/yr), $n = 136$	<i>P</i> value

operative blood loss (1098.5 \pm 163.8 to 932.3 \pm 207.5 mL to 415.9 \pm 82.7 mL, $P \leq 0.001$), requirement and mean blood units transfused (1.3 \pm 0.4 UI to 1.3 \pm 0.6 UI to 0.2 \pm 0.4 UI, $P \leq 0.001$). Similarly the occurrence of complications like pancreatic fistula (15.0% to 15.9% to 3.6%, $P = 0.011$), DGE (20.0% to 18.2% to 5.9%, $P = 0.018$) and PPH (10% to 2.2% to 0%, $P = 0.007$) decreased significantly with the increase in procedure volume and increased experience.

Surgeon volume has been less emphasized in the literature and until more recently, it has been linked to mortality and may explain a significant part of an institution's volume effect^[21]. A learning curve in pancreatic surgery has been hypothesized and modelled, suggesting that after 60 PDs surgeons improved the perioperative outcomes of estimated blood loss, operative time and length of hospital stay in patients undergoing PD for periampullary adenocarcinoma^[22]. Few elective surgical procedures are associated with higher operative risk.

Numerous studies show a consistent trend towards hospital case volume predicting better outcome in pancreatic surgery. These studies offer the most compelling support of the hospital case volume: Better outcome concept because of their size and diversity of the study design. In 1995 Gordon *et al.*^[23] published a retrospective study on 501 patients who underwent pancreatic resection at one of 39 hospitals in Maryland. Hospital mortality rate was significantly lower at the

high-volume regional medical center compared to all other hospitals (2.2% vs 13.5%).

The persistent increase in the number of PD not only resulted in gross reduction of overall morbidity (50.0% to 45.5% to 27.2%, $P = 0.021$), but also significantly decreased the length of hospital stay (11.8 \pm 3.4 d to 11.3 \pm 2.9 to 7.9 \pm 1.7, $P = 0.001$). It is worth to mention that hospitals with 11 years of experience performing one Whipple's procedure per year have a predicted mortality rate that is lower than for very low volume hospitals with only 1 year of experience, although the difference is not statistically significant. Moreover, very low volume hospitals with 11 years of experience have a predicted mortality rate that is significantly different and almost three times higher than that for hospitals with 11 years of experience that perform 10 or more Whipple's procedures per year (9.2% vs 3.4%)^[17]. Thus experience does little to mitigate the difference in mortality observed between low and high volume hospitals. During the time of the study, the mortality rate dropped significantly from 10% to 0%. These results suggest that achieving a procedure volume of 25 PDs or more per year may be sufficient for minimizing inpatient mortality. The influence of institutional volume has also been reflected on late survival after PD for cancer. Birkmeyer *et al.*^[24] investigated this possible effect and concluded higher 3-year survival rate at high volume hospitals (37%) than at those with medium (29%), low (26%) or very low volume (25%) ($P < 0.0001$). These findings indicate that hospital volume also influences both perioperative risk and long-term survival after PD for cancer.

It has been clearly stated that the volume-outcome relationship usually is stronger for hospital volume than for surgeon volume. This has been ascribed to the "experience effect" of the whole team taking care of the patient. There are two competing explanations for the observed association between volume and outcome. The first, "practice makes perfect", hypothesizes that institutions have better outcome because their case load and experience allow them to improve their systems and techniques. The second, "selective referral", hypothesizes that institutions with better outcomes have larger volumes because their excellence is known and thus more patients come to be cared for in these institutions. Which hypothesis is correct has not been established.

This study clearly demonstrates that regionalization can benefit the population of a state through the reduction of in-hospital mortality. In spite of the fact that this study was not able to examine the functional status, quality of life or the length of survival, in-hospital mortality rate is an important objective measurement and of great interest and concern to consumers. Although this study has several possible limitations like the retrospective nature, lack of information on cancer staging, unavailability of data on quality of life and long term survival, the major strength of this

study is that volume groups were compared within the same surgical unit and this eliminates several biased variables affecting inter-hospital comparisons. Further individual patient variables and clinical course which previous volume outcome studies lack were described based on administrative data and not medical records. The results of this study support the beneficial effects of regionalization by which health care services should result in optimization of outcomes for complex, high risk elective surgeries. Further research should be directed to identify procedures for which regionalization is most likely to have a beneficial effect and to determine how best to achieve the regionalization.

COMMENTS

Background

Pancreaticoduodenectomy (PD) is a complex, high risk surgical procedure usually performed for malignancy of the pancreatic head or periampullary region. PD has been associated with a high rate of morbidity (40%-60%) and a high mortality rate up to 20%. High volume tertiary centers have significantly lower (< 5%) in-hospital mortality rates for PD than low volume centres (> 10%). This led to the concept of centralization of complex surgical procedures to improve outcome.

Research frontiers

The purpose of this study was to explore the effect of centralization of PD on perioperative outcome at a tertiary care center in Northern India during the period 2002-2013 and analyse the impact of turning the authors' department from a low to a high volume provider of PD. Although the trend of centralization has been slow as demonstrated by a nationwide survey of PD in the United States, no information is available regarding volume outcome association in India.

Innovations and breakthroughs

It has been clearly stated that the volume-outcome relationship usually is stronger for hospital volume than for surgeon volume. This has been ascribed to the "experience effect" of the whole team taking care of the patient. High volume hospitals are assumed to have structural characteristics associated with better quality of care, and providers in these hospitals are thought to improve their processes of care through experience in providing complex care. While the findings of this study are presented in terms of high, medium, and low-volume periods, an important point exists regarding the volume-outcome relationship that must be emphasized.

Application

The results of this study support the beneficial effects of regionalization by which health care services should result in optimization of outcomes for complex, high risk elective surgeries. Further research should be directed to identify procedures for which regionalization is most likely to have a beneficial effect and to determine how best to achieve the regionalization.

Terminology

PD is associated with a high morbidity and mortality and a constant effort at improving this, among many, has led to the concept of centralization. The concept of centralization stresses the importance of high volume centers that are assumed to have structural characteristics associated with better quality of care, and providers in these hospitals are thought to improve their processes of care through experience in providing complex care.

Peer-review

The majority of data regarding centralization of PD are obtained from multi-institutional comparisons and there are few studies describing the effects of increased caseload of PD within the same unit. Numerous studies show a consistent trend towards hospital case volume predicting better outcome in

pancreatic surgery. These studies offer the most compelling support of the hospital case volume: Better outcome concept because of their size and diversity of the study design. In India no information is available regarding volume outcome association.

Abstract

AIM

To compare the 3 main techniques of temporary closure of the abdominal cavity, vacuum assisted closure (vacuum-assisted closure therapy - VAC), Bogota bag and Barker technique, in damage control surgery.

METHODS

After systematic review of the literature, 33 articles were selected to compare the efficiency of the three procedures. Criteria such as cost, infections, capacity of reconstruction of the abdominal wall, diseases associated with the technique, among others were analyzed.

RESULTS

The Bogota bag and Barker techniques present as advantage the availability of material and low cost, what is not observed in the VAC procedure. The VAC technique is the most efficient, not only because it reduces the tension on the borders of the lesion, but also removes stagnant fluids and debris and acts at cellular level increasing cell proliferation and division. Bogota bag presents the higher rates of skin laceration and evisceration, greater need for a stent for draining fluids and wash-ups, higher rates of intestinal adhesion to the abdominal wall. The Barker technique presents lack of efficiency in closing the abdominal wall and difficulty on maintaining pressure on the dressing. The VAC dressing can generate irritation and dermatitis when the drape is applied, in addition to pain, infection and bleeding, as well as toxic shock syndrome, anaerobic sepsis and thrombosis.

CONCLUSION

The VAC technique, showed to be superior allowing a better control of liquid on the third space, avoiding complications such as fistula with small mortality, low infection rate, and easier capability on primary closure

of the abdominal cavity.

Core tip: The authors reviewed several manuscripts published in the last 20 years evaluating the management of the open abdomen. Several techniques have been described and the most popular ones were analyzed. The vacuum assisted closure (vacuum-assisted closure therapy), Bogota bag and Barker technique are currently the most used. The authors evaluate, for each technique, efficiency, complications, mortality and wound control.

INTRODUCTION

Throughout history surgical principles were based on anatomical repairs with the goal to make primary and definite organic repair. In the last decade, a greater importance has been given in repairing physiological features of the surgical patient. This resulted in the concept of damage control surgery with special emphasis on the need for open abdominal maintenance (laparotomy)^[1].

Laparostomy comprises a surgical approach where the abdominal wall is not sutured by plans and left open, allowing a regular inspection and drainage of intracavitary content^[2,3]. Its usage is indicated in cases of abdominal trauma, damage control surgery, sepsis of abdominal origin, severe acute pancreatitis, the need for new laparotomy, hemodynamic instability, retroperitoneal hematomas and necrotizing fasciitis, allowing a continuous evaluation of intra-abdominal pressure in order to avoid the development of abdominal compartment syndrome^[2,4-7].

According to the consensus carried out by the World Society of the Abdominal Compartment Syndrome (WSCAS - 2004), abdominal compartment syndrome is defined as a condition where organ dysfunction is caused by sustained intra-abdominal hypertension above 20 mmHg. However, it is known that values below this (> 12 mmHg) will also cause organ dysfunction, but to a lesser degree. Abdominal hypertension is divided in degrees^[2]: (1) 12-15 mmHg; (2) 16-20 mmHg; (3) 21-25 mmHg; and (4) > 25 mmHg.

In 2013, the WSACS concluded that intra-abdo-

Table 1 Etiologies for abdominal compartmental syndrome

Primary	Secondary
Abdominopelvic causes ^[5] :	Extra-abdominal causes ^[5] :
Complex abdominal trauma ^[5]	Sepsis ^[5]
Ruptured Aneurysm aorta ^[5]	Acidosis (pH < 7.2) ^[5]
Hemoperitoneum ^[5]	Hypothermia ^[5]
Pancreatitis ^[5]	Politransfused (> 10 IU of packed red blood cells in 24 h) ^[5]
Peritonitis ^[5]	Coagulopathies (platelets < 55000/mm ³ or aPTT > 2x/normal or TAP < 50% - INR > 1.5) ^[5]
Retroperitoneal bleeding ^[5]	Great chest, vascular and orthopedic trauma ^[5]
Hepatic transplants ^[5]	Great burnt ^[5]
Primary closure under tension ^[5]	Vigorous hydration (> 5 U/24 h) ^[5]

minimal pressure must be measured in patients who have at least two risk factors for hypertension, which are correlated with the pathology that triggered the abdominal injury. This pressure must be measured every 4-6 h, using preferentially the bladder and in cases of contraindication, other *via* as abdominal, rectal and vaginal may also be used^[2,5]. The compartmental syndrome may also be classified according to their etiology (Table 1)^[5].

Complications arise from the current shock, which leads to the involvement of multiple systems causing renal perfusion decrease, decline in glomerular filtration rate (oliguria and acute renal insufficiency); ischemia of the intestinal wall and its mucosa, liver failure by portal flow decrease, cerebral hypoperfusion, among others^[5].

During the period in which the abdomen is open, the aponeurosis can laterally retract and lose the possibility of closure, creating then a ventral incisional hernia. These, with subsequent formation of adhesions make future abdominal surgeries more complicated, increasing morbidity and mortality^[8]. This can be avoided by applying temporary closure techniques, such as Bogota bag, Barker technique, vacuum assisted closure therapy (VAC), among others that allow closing the abdominal cavity with less stress^[9].

The aim of this review article is to compare the 3 main techniques of temporary abdominal cavity closure, vacuum closure (VAC), Bogota bag and Barker technique, after damage control laparotomy. In this study, we analyzed efficiency, financial costs, risks and benefits for each of the most common available methods.

MATERIALS AND METHODS

This paper is a review of manuscripts published in the literature from 1996 to 2016. Search was performed in MEDLINE, PUBMED, Scielo e Lilac's with the following keywords: VAC technique, Bogota bag and Barker techniques, traumatic abdominal injuries. The papers should have addressed effectiveness of each technique,

Table 2 Comparison of the advantages of each technique

Bogota bag	Allows greater number of reviews of the abdominal cavity than the direct synthesis; better control of septic focuses by easy access; abdominal decompression; and functional restoration of the abdominal wall; has low cost; immediate availability; flexibility and high resistance; is not adhered to the tissues; does not cause allergic or inflammatory reactions; has quick and easy installation; can be used in any part of the body; allows the visualization of organs; is used in trauma, cancer surgery, and various abdominal surgeries; is a protector against water loss and heat
Barker technique	It is an inexpensive technique; uses material found in the surgical center and easily applicable; has moderate fluid control; allows closure of the abdominal wall with less tension; has low rates of complications
Vacuum-assisted closure therapy	It prevents contamination; allows dissection of the wound; protects the wound from external injuries; reduces the interstitial pressure; increases blood flow to the lesion; reduces the expression of matrix metalloproteinases in chronic wounds; promotes wound healing; removes stagnant fluids and debris; increases proliferation and cell division rates; induces granulation tissue formation; and brings greater comfort to the patient with infrequent complications. In selected cases it can be used as an outpatient procedure; allows shorter hospital stay and better quality of life

Table 3 Comparison between the disadvantages of each technique

Bogota bag	Use of more drains and rinses; presents a certain risk of eviscerations and difficulty in mobilizing the patient; it can cause skin lacerations; bowel adhesion to abdominal wall; it needs gas sterilization of the bag; there is a difficult control of the third space; leaks under the bag can wet the bed increasing the risk of hypothermia
Barker technique	In some cases, it does not allow adequate approach of the abdominal wall; it has moderate fluid control; greater difficulty in detecting complications that occur with bleeding and the maintaining of continuous pressure
Vacuum-assisted closure therapy	High cost; it can cause skin irritation due to the use of the adhesive; it can cause pain, infection and bleeding; it can lead to toxic shock syndrome (rare) and can cause thrombosis

cost, associated infections, readiness on abdominal wall reconstruction and diseases associated with the technique. Only articles in English and Portuguese and performed in humans were selected. Thirty-three articles met the selection criteria.

RESULTS

The Bogota bag technique presents as advantages (Table 2) the availability to material access, lower cost, fast and easily executed, and not dependent on a great experience from the surgeon. For allowing a great visibility and entrance in the abdominal cavity, it promotes greater control of the septic spots and enables several revisions. Moreover, it allows abdominal decompression, does not cause inflammatory reactions or allergies, being used in several parts of the organism and in any kind of surgery, from traumas to tumor removal. However, it presents higher rates of eviscerations and skin lacerations, implying greater need for abdominal drainage and wash-ups, higher rates of intestinal adhesion to the abdominal wall, difficulty in controlling the third space and leaks. Thus, it requires sterilization of the bag by gas preventing its availability (Table 3).

The technique proposed by Barker presents positive factors, such as easy assembly at a low cost, since it uses hospital material already used for other functions (Table 2). Since acquiring these materials is easy, the technique application becomes simple. The closure of the abdominal cavity is done with less stress, preventing complications associated with moderate control of the fluid produced by the body. One disadvantage is the lack of efficiency in approaching the abdominal wall when the injury is extensive and important. There is a deficiency on maintaining pressure, which must be

continuous and properly maintained in order to make the organs act in the recovery. In complicated cases with abdominal bleeding, it may take a while to detect this bleeding while draining the fluid (Table 3).

The temporary closure technique by negative pressure, the VAC, among all of them has a more effective action on closing the abdominal cavity because it reduces the tension on the injury borders and works at cellular level increasing cell proliferation and division. Furthermore, it induces the formation of granulated tissue, reducing the aspect of matrix metalloproteinase on chronic wounds (Table 2). There is an increase of blood flow at the site of the injury. At the same time protects the wound from external injuries to progress and removes stagnant fluids and debris, avoiding cavity contamination, reducing the interstitial pressure and bacterial proliferation. Thus, it promotes healing of the wound and decreases complication rates and hospital stay providing a better quality of life. Among all techniques, VAC presents a significant higher cost. It can generate irritation and contact dermatitis, when the drape is applied, in addition to pain, infection and bleeding. Among the complications, the most severe ones are toxic shock syndrome and anaerobic sepsis (Table 3).

DISCUSSION

Open abdomen as a damage control procedure has been recommended since 1979. The technique allows extensive drainage of pus through the wall opening and it also facilitates the washing of the peritoneal cavity through scheduled surgeries or on demand as required^[8]. In this procedure, the lining of the abdominal wall is not completely aligned, allowing a regular inspection on the

Figure 1 Bogota bag.

Figure 2 Barker technique.

condition of the handles and drainage of the intra-cavity content^[8]. This procedure is indicated in situations such as severe pancreatitis, severe sepsis, abdominal trauma among others.

In cases of pancreatitis, it is indicated in the presence of acute abdomen signs, entero-mesenteric infarction, presence of pancreatic necrosis and abdominal compartment syndrome. Surgical intervention comprises exploratory laparotomy with pancreatic necrosectomy, debridement and washing of the peripancreatic tissue with subsequent laparostomy, associated with antibiotic therapy in infected cases, presenting in general an unfavorable clinical course^[10].

When we refer to cases of severe sepsis of abdominal origin, this therapy is necessary in the presence of necrotizing soft tissue infections (necrotizing fasciitis), intra-abdominal abscess, infected pancreatic necrosis, intestinal infarction, fecal peritonitis, when there is no possibility of closing the abdomen due to edema of the abdominal viscera, and when the complete eradication of the infectious origin is not possible^[11].

For the open abdomen to be feasible, various techniques of temporary closure of abdominal cavity have been studied. The ideal technique needs to protect the abdominal content, prevent from evisceration (opening of the abdominal layer), preserve the fascia, minimize visceral damage, allow quantification of fluid losses to the third space allowing selective plugging, minimize domain loss, decrease bacteria amount, infection and inflammation, and keep patient dry and intact^[8].

Bogota bag

Initially described in 1984, plastic bags utilized to contain parenteral solutions were used to coat the abdominal opening on the patient for a second surgical intervention^[12]. Afterwards, the polyvinyl chloride (plastic bag) was adopted to maintain the abdomen open, technique initially called as Bogota bag or Borraez's bag^[12]. It consists of a sterilized (by gas) plastic bag used for closure of abdominal wounds, being sutured to the skin or fascia of the anterior abdominal wall^[13] (Figure 1). Variations of this treatment have already been described, and one of them is the use of a big bag,

inside the peritoneal cavity, loose and that covers all of the abdominal viscera. Afterwards, the bag is placed under the skin and another plastic bag is inserted. That avoids many handle collisions from inside the abdominal cavity, adhesions between the viscera and parietal peritoneum, diminishing the risk of lesions and enabling cavity washing and its closure^[12].

In general, it is very used in association with the polypropylene screen (as a reinforcement and contention), that is sutured to the skin, together with the edge of the collecting bag. This is done due to evisceration and difficulty in mobilizing the patient, consisting in the arising issues with the treatment^[1].

However, it is a procedure that will require a larger use of stents and wash-ups, presenting a certain risk of eviscerations and difficulty in mobilizing the patient^[12]. In addition, it generates skin lacerations, adherence of the intestine to the abdominal wall, difficulty in reproaching the abdomen and the need to gas sterilize the bag before its use, harder control of third space with minimum loss and any leak from under the bag can wet the bed increasing the risk of pneumonia^[13,14].

Vacuum-pack

The technique developed by Barker *et al*^[15] was described in 1995 using vacuum dressings for temporary closure of the abdominal cavity and since then it has been called "vacuum-pack" and became the most indicated for several conditions^[16] (Figure 2). It was developed to be used with material found in the surgical rooms, presenting low cost and simple technique^[15,17].

The vacuum-pack consists in an open polyethylene sheet between the abdominal viscera and anterior parietal peritoneum; a humid surgical dressing over the sheet with two suction drains. Then, an adhesive sheet throughout the wound, including a wide margin on the surrounding skin is placed. The stents are then connected to a suction device that enables 100-150 mmHg of continuum negative pressure^[18]. This technique prevents damage to the abdominal wall due to the absence of sutures, preserving it to future approaches or definite closure, maintaining integrity of the fascia for later closure, allowing a quick approach to the

Figure 3 Vacuum-assisted closure.

abdominal cavity. The material utilized in contact with the abdominal viscera - the polyethylene sheet - is not adherent, and the vacuum-pack allows a better control of fluid quantity produced^[17].

Regarding rates of fascial closure achieved with this technique, in 1997 a study obtained results of 61% of success. The patients, who were trauma victims and were subjected to Barker's technique, had primary fascial closure on the 2nd laparotomy, being close to the achieved average^[15]. Other studies had rates of 29%-100%^[16,19-21]. The definite closure of the abdominal cavity after the 8th post-operative day from laparotomy was associated with a higher rate of complications^[22].

Barker *et al.*^[23] showed their experience by using this technique in intestinal lesions submitted to resection in a study that lasted 11 years. There was no difference between patients who used this or other types of wound dressings regarding fistulas or leaks. Other studies reported fistula rates from 3% to 5%^[19,23-25].

A study combining trauma victims and other cases of open abdomen, reports as existing complications: Abdominal abscess/infection, abdominal compartment syndrome, dehiscence, anastomotic leakage, coagulopathy, deep venous thrombosis, fascial necrosis, gastrointestinal ischemia, intestinal fistula, intestinal obstruction, pulmonary embolism and multiple organ failure^[25]. In this study, it was not explained if these complications were directly related to the use of vacuum-pack. The complication rates related by Barker *et al.*^[15] are 15%.

VAC system

The VAC, called VAC therapy or system is also known as negative pressure therapy (TPN), or sub atmospheric pressure (PTE) or as vacuum packing (TVV). Argenta and Morykwas^[26] published an experimental work with VAC system, using acute wound in pigs, in 1997. In this work, they postulated that this system has a multimodal action mechanism. Since then, the clinical results observed in a variety of wounds were the best seen in comparison with the usual methods. The VAC therapy worked as a catalyst for the development of a series of studies^[24,26]. Its efficiency in severe traumatic wounds helped to develop an area that belonged to plastic and reconstructive surgery^[24].

To apply this type of therapy, equipment made of reticulated foam is used and placed at the region and sealed in with the use of a patch (Figure 3). This foam can be made of polyurethane or polyvinyl alcohol, which generally presents 400-600 μm pores; it is cut to adjust perfectly along the wound before getting applied. If needed, several pieces of foam can be used to cover the gaps of the wound^[24,27]. The foam is patched in with a drape that remains stuck on the skin with a 3 to 5 cm margin from the wound. In this sticker, a small 2 cm diameter hole is made in the center and a TRAC sticker (device that leads secretion to the tank) is linked to it. Then, a pump is connected to the foam (vacuum) that generates continuous sub atmospheric pressure (VAC-KCI, San Antonio, Texas, United States). Usually, putting an intermittent cycle of pressure for five minutes of suction and two minutes turned off. The pressure, in general, is adjusted to 125 mmHg and is distributed evenly throughout the wound through sponge pores. A plastic sticker is applied over the sponge to allow wound sealing^[24,27-29].

Firstly, VAC removes stagnant fluid and debris and then is constantly optimizing blood supply and matrix deposition. Therefore, the partial oxygen pressure within the tissue increases and bacterial proliferation is reduced. Secondly, VAC leads to increased local interleukin-8 and vascular endothelial growth factor concentrations, which may trigger the accumulation of neutrophils and angiogenesis. With the cyclical application of sub atmospheric pressure, VAC alters the cytoskeleton of cells in the wound bed, triggering a cascade of intracellular signals that increase the rates of cell proliferation and division, and subsequent formation of granulation tissue^[30].

The VAC system can be utilized for treatment of surgical infected wounds, trauma wounds, pressure ulcers, bone wounds and exposed hardware, diabetic foot ulcers and venous stasis ulcers. In addition, it can be used in reconstructing wounds, allowing elective planning of definite reconstructive surgery, without compromising the wound or the result. Furthermore, it increased significantly the success rate for skin graft when utilized as a cushion over the grafted wound^[27].

Complications of VAC therapy are not frequent when the system is used correctly. Complication rates mostly described in literature are due to patient's comorbidities and skin irritation caused by the drape. Other complications such as pain, infection or bleeding are not easily seen. Severe complications, such as toxic shock syndrome, anaerobic sepsis or thrombosis are described as well but rare^[27].

The timing of primary conclusion with the vacuum assisted closure therapy is not always the fastest because it depends on each case, with the exception for patients with cardiovascular disease and/or diabetes. A portable VAC system (VAC freedom) is available in the market and it's a regular size bag that has helped treating wounds carefully at home; this shows that VAC therapy improves quality of life because it reduces the

length of hospital stay^[31].

The total cost for VAC therapy is not significantly lower than the others; however, after analyzing time involvement and costs with nursing team, there is a considerable cut. Comfort for patients and nursing team are described in many cases as a relevant factor for choosing this therapy^[31].

Comparison between the different techniques for damage control surgery

Comparing the use of VAC to other methods for temporary closure of the abdominal cavity, several studies showed that VAC performs better. A prospective study conducted by Batacchi *et al.*^[32] in 2009 compared patients who were abdominal trauma victims treated with the Bogota bag and VAC, during the abdominal cavity temporary closure. The VAC treatment was more effective in controlling intra-abdominal pressure ($P < 0.01$), normalization of serum lactate ($P < 0.001$), as well as less time needed for ventilation, faster abdominal closure and consequently shorter time at the intensive care unit and hospital stay. The results of the "Sequential Organ Failure Assessment" and mortality rate were not significantly different. Another study, conducted by Bee *et al.*^[33] compared polyglactin 910 (MESH) and VAC on temporary closure of the abdominal cavity after damage control surgery or compartment abdominal syndrome on a randomized study. In their results, VAC presented a 31% rate against 26% for the MESH group of late primary closure. The fistulas rates on the VAC group were 26% while on MESH, it was 5%. The differences presented in this study were not statistically different.

Kaplan *et al.*^[13] in 2005 concluded that VAC is the one to supply the ideal material for temporary closure on with greater satisfaction. From the 17 articles evaluated that had as object of study the 3 alternatives discussed in this article, the Bogota bag exhibited mortality rates of 53%, the vacuum-pack and VAC, 31% and 30%, respectively. Regarding complications such as fistulas, the VAC presented a rate of 2.6% against 7% of vacuum-pack and 13% of Bogota. Fascial closure was reached in 79% of patients subjected to VAC, while 58% was reached in vacuum-pack and Bogota bag reached only 18%^[13].

Regarding intra-abdominal pressure (PIA), control Batacchi *et al.*^[32] in 2009, comparing the Bogota bag and VAC system, concluded that VAC was more effective on PIA control ($P < 0.01$) and on serum lactate ($P < 0.001$) during the first 24 h after surgical decompression^[30]. The patients subjected to VAC had a faster abdominal closure and consequently stayed a shorter time at the intensive care unit; nevertheless, mortality rates were not different between the two groups.

Cheatham *et al.*^[25] in a 2013 study that compared VAC and vacuum-pack showed that both techniques present similar complication rates such as the development of abdominal compartment syndrome (8%) and fistulas (4%). VAC was associated with a bigger

rate for primary fascial closure longer than 30 d (73% against 27% of vacuum-pack) and smaller mortality rate on the same period for patients who needed open abdomen for at least 48 h. The difference in mortality between VAC and vacuum-pack increased significantly during the first 30 d due to the posterior development of multiple organ failure subjected to vacuum-pack and due to better peritoneal fluid removal rich in cytosines (increases organ dysfunction) through VAC^[25]. Bruhin *et al.*^[34], in a recent study compared several techniques looking at contamination, fistula, and mortality rates, among others. Higher rates of primary fascial closure after VAC application in combination with "dynamic closure" technique (using traction, suture of dynamic retention or ABRA) were obtained. Moreover, patients who were not contaminated had a closure rate of 81%, followed by the exclusive use of VAC with rates of 72% and home-made (Barker technique) of 58%, taking into account that the Bogota bag data were inadequate^[32]. Contaminated lesions were noticed, and resulted on higher rates of abdominal closure (74.6%), followed by its exclusive use (48%), Barker technique (35%) and Bogota bag (27%). In relation to the presence of fistulas and the mortality rate, the VAC technique had the lowest rate, being the highest value (40% of mortality rate) obtained by the Barker technique^[32].

In conclusion, the treatment for open abdomen patients has evolved greatly in the last decades, with great improvement of the existing techniques and the emerging of new ones. Its main objective is to maximize tissue perfusion and to minimize potential intra-abdominal complications, such as fistulas and hernias, enabling early closure of the abdominal cavity. VAC therapy showed to be superior in relation to the other techniques, such as Bogota bag and vacuum-pack, allowing a better control of the third space fluid, avoiding complications such as fistula; it has lower mortality and infection rates, and better capacity in primary closure of the abdominal cavity. On the other hand, the Bogota bag technique was the least efficient, even though it is still very much used due to its low cost, easy access to material that is generally already present in the surgical room.

COMMENTS

Background

Laparostomy comprises a surgical approach where the abdominal wall is not sutured by plans and left open, allowing a regular inspection and drainage of intracavitary content. Its usage is indicated in cases of abdominal trauma, damage control surgery, sepsis of abdominal origin, severe acute pancreatitis, the need for new laparotomy, hemodynamic instability, retroperitoneal hematomas and necrotizing fasciitis, allowing a continuous evaluation of intra-abdominal pressure in order to avoid the development of abdominal compartment syndrome.

Research frontiers

The different techniques available for the temporary closure presents several benefits as well as limitations for its use and today there is a tendency to use the properties of negative pressure to ensure a faster recover of the patient

increasing the rate definite closure of the abdominal wall.

Innovations and breakthroughs

There are mainly three basic approaches for the maintenance of an open abdomen are: The Bogota bag technique presents as advantages the availability to material access, lower cost, fast and easily executed, and not dependent on a great experience from the surgeon. For allowing a great visibility and entrance in the abdominal cavity, it promotes greater control of the septic spots and enables several revisions. Moreover, it allows abdominal decompression, does not cause inflammatory reactions or allergies, being used in several parts of the organism and in any kind of surgery, from traumas to tumor removal. However, it presents higher rates of eviscerations and skin lacerations, implying greater need for abdominal drainage and wash-ups, higher rates of intestinal adhesion to the abdominal wall, difficulty in controlling the third space and leaks. Thus, it requires sterilization of the bag by gas preventing its availability. The technique proposed by Barker presents positive factors, such as easy assembly at a low cost, since it uses hospital material already used for other functions. Since acquiring these materials is easy, the technique application becomes simple. The closure of the abdominal cavity is done with less stress, preventing complications associated with moderate control of the fluid produced by the body. One disadvantage is the lack of efficiency in approaching the abdominal wall when the injury is extensive and important. There is a deficiency on maintaining pressure, which must be continuous and properly maintained in order to make the organs act in the recovery. In complicated cases with abdominal bleeding, it may take a while to detect this bleeding while draining the fluid. The temporary closure technique by negative pressure, the vacuum-assisted closure therapy (VAC), among all of them has a more effective action on closing the abdominal cavity because it reduces the tension on the injury boarders and works at cellular level increasing cell proliferation and division. Furthermore, it induces the formation of granulated tissue, reducing the aspect of matrix metalloproteinase on chronic wounds. There is an increase of blood flow at the site of the injury. At the same time protects the wound from external injuries to progress and removes stagnant fluids and debris, avoiding cavity contamination, reducing the interstitial pressure and bacterial proliferation. Thus, it promotes healing of the wound and decreases complication rates and hospital stay providing a better quality of life.

Applications

The treatment for open abdomen patients has evolved greatly in the last decades, with great improvement of the existing techniques and the emerging of new ones. Its main objective is to maximize tissue perfusion and to minimize potential intra-abdominal complications, such as fistulas and hernias, enabling early closure of the abdominal cavity. VAC therapy showed to be superior in relation to the other techniques, such as Bogota bag and vacuum-pack, allowing a better control of the third space fluid, avoiding complications such as fistula; it has lower mortality and infection rates, and better capacity in primary closure of the abdominal cavity.

Terminology

Laparostomy comprises a surgical approach where the abdominal wall is not sutured by plans and left open, allowing a regular inspection and drainage of intracavitary content. Abdominal compartment syndrome is defined as a condition where organ dysfunction is caused by sustained intra-abdominal hypertension above 20 mmHg. However, it is known that values below this (> 12 mmHg) will also cause organ dysfunction, but to a lesser degree. The Bogota bag technique presents as advantages the availability to material access, lower cost, fast and easily executed, and not dependent on a great experience from the surgeon. For allowing a great visibility and entrance in the abdominal cavity, it promotes greater control of the septic spots and enables several revisions. The Barker's technique presents positive factors, such as easy assembly at a low cost, since it uses hospital material already used for other functions such as surgical towels, sterile plastic bag and surgical drapes commercially available connected to the wall vacuum. The closure of the abdominal cavity is done with less stress, preventing complications associated with moderate control of the fluid produced by the body. The temporary closure technique by negative pressure, the VAC, reduces the tension on the injury boarders and works at cellular level increasing cell proliferation and division. Furthermore, it induces the formation of granulated tissue, reducing the aspect of matrix metalloproteinase on chronic wounds. At the same time protects the wound from external injuries to progress and removes stagnant fluids and debris using a continuous negative

pressure applied by the system, avoiding cavity contamination, reducing the interstitial pressure and bacterial proliferation.

Peer-review

This article is a review about three different techniques of laparostomy, a technique that is nowadays very often utilized above all during damage control surgery. The subject of the review is quite interesting for emergency and trauma surgeons.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Dr. Ansgar Michael Chromik, MD, Department of General and Visceral Surgery, St Josef-Hospital, University of Bochum, 44791 Bochum, Germany

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Acute severe ulcerative colitis (UC) is a highly morbid condition that requires both medical and surgical management

through the collaboration of gastroenterologists and colorectal surgeons. First line treatment for patients presenting with acute severe UC consists of intravenous steroids, but those who do not respond require escalation of therapy or emergent colectomy. The mortality of emergent colectomy has declined significantly in recent decades, but due to the morbidity of this procedure, second line agents such as cyclosporine and infliximab have been used as salvage therapy in an attempt to avoid emergent surgery. Unfortunately, protracted medical therapy has led to patients presenting for surgery in a poorer state of health leading to poorer post-operative outcomes. In this era of multiple medical modalities available in the treatment of acute severe UC, physicians must consider the advantages and disadvantages of prolonged medical therapy in an attempt to avoid surgery. Colectomy remains a mainstay in the treatment of severe ulcerative colitis not responsive to corticosteroids and rescue therapy, and timely referral for surgery allows for improved post-operative outcomes with lower risk of sepsis and improved patient survival. Options for reconstructive surgery include three-stage ileal pouch-anal anastomosis or a modified two-stage procedure that can be performed either open or laparoscopically. The numerous avenues of medical and surgical therapy have allowed for great advances in the treatment of patients with UC. In this era of options, it is important to maintain a global view, utilize biologic therapy when indicated, and then maintain an appropriate threshold for surgery. The purpose of this review is to summarize the growing number of medical and surgical options available in the treatment of acute, severe UC.

Key words: Acute severe ulcerative colitis; Colectomy; Corticosteroids; Infliximab; Cyclosporine; Ileal pouch-anal anastomosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The numerous avenues of medical and sur-

gical therapy have allowed for great advances in the treatment of patients with ulcerative colitis. In this era of options, it is important to maintain a global view, utilize corticosteroids and rescue therapy when indicated, and then maintain an appropriate threshold for surgery. Colectomy remains a viable and often life-saving treatment and should not be viewed as the "therapy of last resort".

Andrew RE, Messaris E. Update on medical and surgical options for patients with acute severe ulcerative colitis: What is new? *World J Gastrointest Surg* 2016; 8(9): 598-605 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i9/598.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i9.598>

INTRODUCTION

Acute severe ulcerative colitis (UC) is an exacerbation of a chronic condition characterized by inflammation of the colonic mucosa extending from the rectum proximally to varying portions of the large intestine. UC is a highly morbid condition that requires both medical and surgical management. Prior to the 1950's and the implementation of urgent colectomy and systemic steroids, mortality rates were as high as 70% in patients with severe UC^[1]. In recent years, mortality rates have dropped to less than 1% with the combination of medical therapy, rescue therapy, and timely total abdominal colectomy (TAC) when indicated^[2,3]. Despite the introduction of rescue therapies such as cyclosporine (calcineurin inhibitor) and infliximab [tumor necrosis factor (TNF) monoclonal antibody] in the treatment regimen of patients with severe UC, colectomy rates have remained stable (27%) for the past thirty years^[4].

Historically, severe UC has been defined as the passage of at least six daily bloody stools, along with any of the following signs of systemic disease: Erythrocyte sedimentation rate > 30 mm/h, temperature > 37.8 °C, pulse rate > 90/min and hemoglobin < 10.5 g/dL (true-love and witts criteria)^[5]. Lichtiger created a scoring system for severe UC based on frequency of stools, nocturnal diarrhea, blood in stool, fecal incontinence, and abdominal pain^[6]. These criteria play a significant role in the decision to escalate therapy or proceed to colectomy in patients with severe disease. Rates of TAC within the first five years of disease range from 9%-35%, even with medical therapy^[7]. With a growing number of options available to both gastroenterologists and surgeons in the management of UC, treatment is becoming more individualized and variable. The following review provides a description of current medical and surgical management of acute severe UC.

STANDARD MEDICAL THERAPY

Patients presenting with signs of acute severe UC

require immediate admission to the hospital. They must have regular monitoring of vital signs and urine output as well as a comprehensive laboratory workup. Initial tests on admission should include a comprehensive metabolic panel, pre-albumin, albumin, complete blood count, and inflammatory markers [erythrocyte sedimentation rate and C-reactive protein (CRP)]^[5]. A tuberculin skin test should also be performed on that admission in preparation for possible treatment with immunosuppressant or biologic agents. Abdominal imaging should be obtained to evaluate for colonic dilation (greater than 5.5 cm) on plain X-ray or computed tomography scan, and the patient should be monitored for fever, leukocytosis and other signs of systemic sepsis that accompany toxic megacolon^[8,9].

Stool cultures and a clostridium difficile assay must be obtained to exclude infectious pseudomembranous colitis, and the frequency and consistency of bowel movements should be recorded.

Patients should take nothing by mouth and should be fluid resuscitated to a goal of 0.5 mL/kg per hour of urine output. The administration of intravenous fluids and the correction of electrolyte imbalances prevent dehydration and worsening of colonic dysmotility and dilatation^[10]. All patients who are not bleeding should be given thromboembolic prophylaxis due to the increased risk of thrombosis in the setting of systemic inflammation. In addition, the patient should undergo flexible sigmoidoscopy to confirm the diagnosis of acute severe UC and to obtain biopsies to rule out cytomegalovirus colitis^[11].

Patients with acute severe UC require constant reassessment, with antibiotic administration in the setting of infection, total parenteral nutrition in the setting of malnutrition, and escalation of therapy to medication non-responders. Kedia *et al.*^[12] proposed an algorithm for reassessing patient steroid response at days 1, 3 and 4-7 in which incomplete responders and non-responders either advance to rescue therapy or proceed to colectomy. In this algorithm, the Oxford criteria (> 8 stools/d or > 3 stools/d with a CRP > 45 mg/L) are used to determine the need for escalation of therapy^[13]. With careful attention to the patient's physical condition and severity of illness, the appropriate medical or surgical therapy can be selected to target the individual's ever-changing disease (Figure 1).

CORTICOSTEROIDS

Corticosteroids were introduced in the management of UC in the 1950's, though the first clinical trial proving their efficacy was not published until the 1970's^[5,14]. For the past 40 years, intravenous corticosteroids (methylprednisolone 60 mg/d or hydrocortisone 100 mg/8 h) for a 7-10 d course have been a cornerstone in the treatment of acute severe UC^[4,14]. A large review and meta-analysis reported the response to IV steroids to be 67% with short term colectomy rate of 29%^[4].

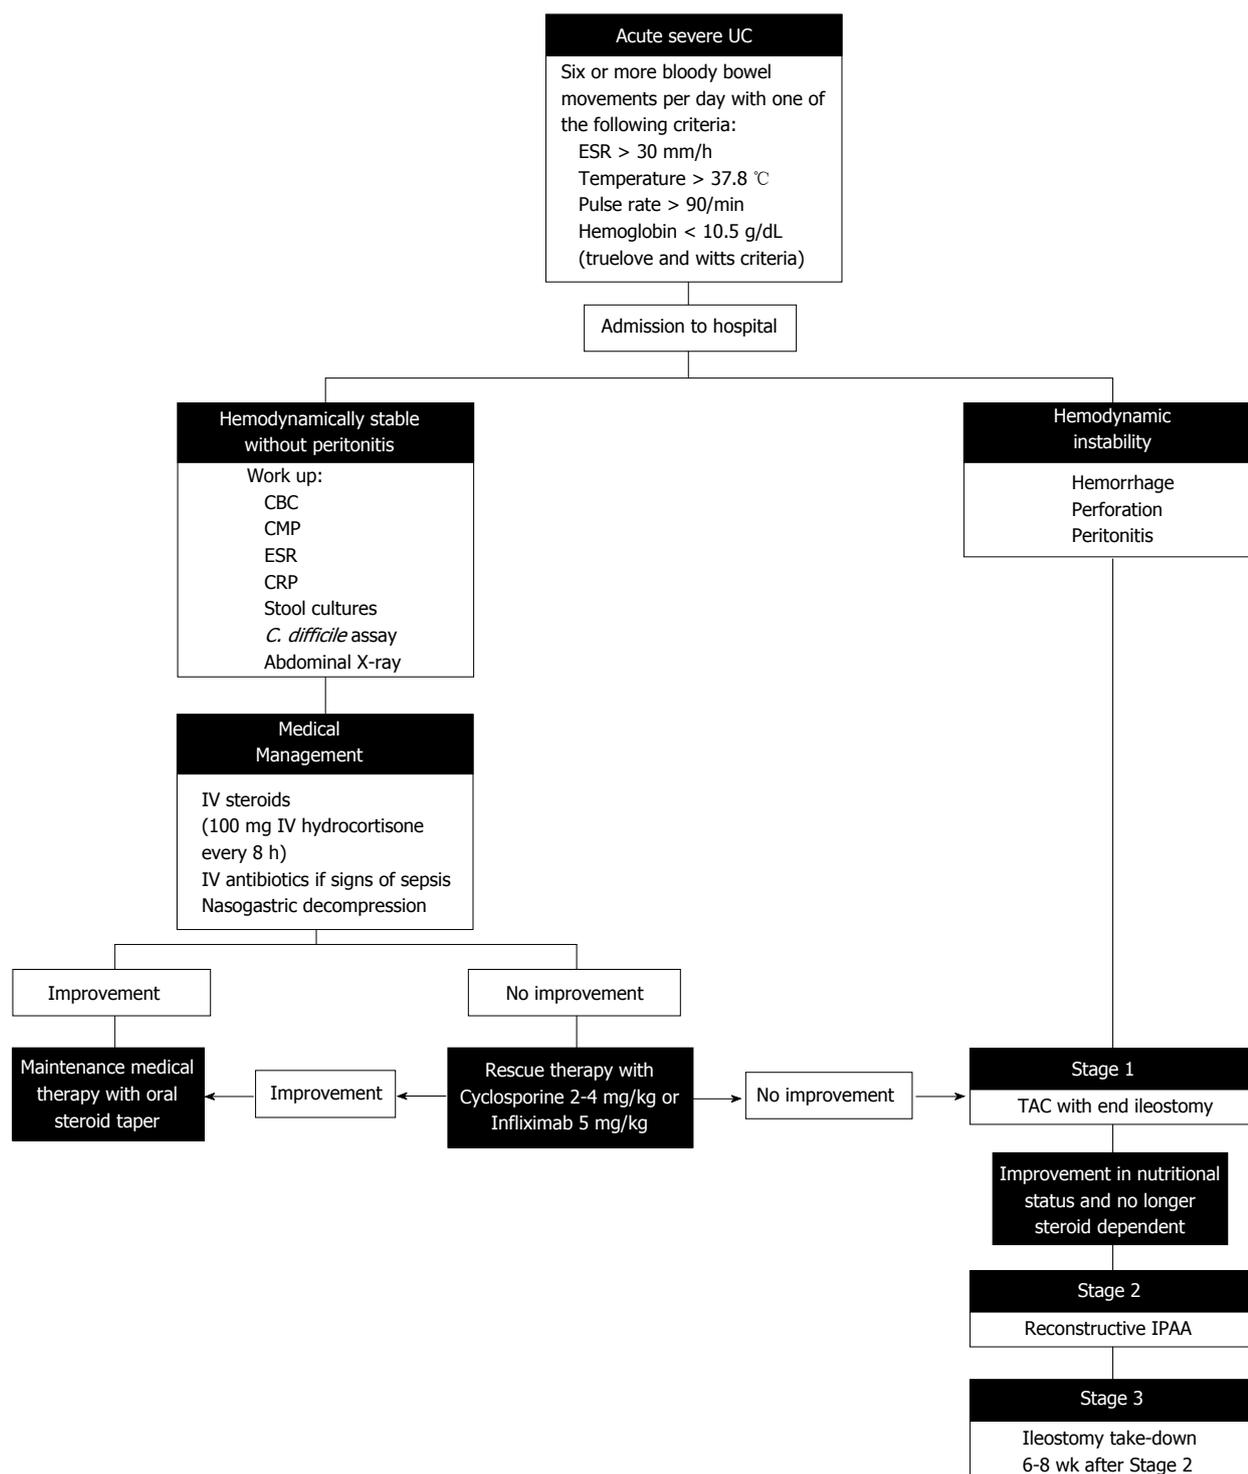

Figure 1 Algorithm for treatment of acute severe ulcerative colitis. UC: Ulcerative colitis; TAC: Total abdominal colectomy; IPAA: Ileal pouch-anal anastomosis; CBC: Complete blood count; CMP: Comprehensive metabolic panel; ESR: Erythrocyte sedimentation rate; CRP: C-reactive protein.

MEDICAL RESCUE THERAPY

Rescue therapies made their first appearance in the medical management of UC in the 1990's with the introduction of cyclosporine. Infliximab followed soon after as an alternative therapy with a different side-effect profile that could also serve as a salvage therapy in the setting of UC refractory to corticosteroids.

Cyclosporine (2-4 mg/kg) has been shown to induce

remission in 60%-80% of patients with acute severe colitis, but colectomy rates at four months remain close to 50% unless the patient is successfully bridged to maintenance therapy^[6,15,16]. The role of infliximab in the treatment of non-acute, moderate-to-severe UC has been reported in the Active Ulcerative Colitis Trials 1 and 2, with response rates between 61% and 69%^[17]. Infliximab (5 mg/kg) has also been shown to significantly decrease rate of colectomy at three months for patients with severe to

moderate attacks of UC^[18]. In an Italian trial by Kohn *et al.*^[19] there was an 85% response rate to infliximab with no colectomy in the 2 mo following hospital admission for acute severe UC and 67% at 23 mo. Multiple studies have compared infliximab and cyclosporine as rescue therapy for acute severe UC with no significant difference between the two therapies. Colectomy rates were similar at three and twelve months between patients receiving infliximab (31% and 41%) and cyclosporine (30% and 44%)^[20,21]. A recent systematic review and meta-analysis compared infliximab and cyclosporine as rescue therapy and found no significant difference in 3 or 12 mo colectomy rates among three randomized trials but reported significantly increased response to treatment and lower 12 mo colectomy rate among 12 non-randomized studies^[22].

While immunosuppressant and biologic agents have become established means of treating severe UC, there is conflicting evidence on the use of sequential therapy. Reports of the use of infliximab after failing steroids and cyclosporine have shown a 30% colectomy rate^[23]. A review of 10 studies in which rescue therapies were used sequentially for treatment of acute severe UC demonstrated colectomy rates of 28% at 3 mo and 42% at 12 mo with a 23% rate of adverse events—lower than previously reported in the literature^[24]. At this time, the selection of a rescue therapy agent, cyclosporine vs infliximab vs one agent following the other, is based primarily on physician comfort and experience, along with patient tolerance of side effects and susceptibility to infection.

IMMUNOMODULATORS

Although not currently the standard of care, vedolizumab, an integrin antibody, has been shown to induce steroid-free remission in approximately one third of UC patients who have failed anti-TNF therapy^[25]. Further investigation is required before recommendations can be made for its use in the treatment of acute severe UC.

Other agents such as thiopurines and methotrexate play a role in maintenance therapy and steroid dose reduction, but these drugs have shown no significant success as induction therapy to achieve remission in patients with active UC^[26,27].

ANTIBIOTICS

The role of antibiotics in the treatment of acute severe UC remains limited because even in severe UC there is no proven therapeutic benefit to oral or intravenous metronidazole, tobramycin, ciprofloxacin or vancomycin^[28-30]. Only in the setting of active infection or for pre-operative antibiotic prophylaxis do 2012 ECCO guidelines recommend that antibiotics be administered^[31].

SURGICAL THERAPY

Although tremendous advances have been made in the

medical treatment of UC, colectomy remains a cornerstone in the management of this disease. Overall, the rates of colectomy have not significantly changed since the addition of rescue therapies to the armamentarium of gastroenterologists. Predictors of the need for second-line treatment or colectomy are numerous, but several variables, including severity of disease, stool frequency, CRP, hypoalbuminemia (< 3 mg/dL), and radiographic evidence of colonic dilation (> 5.5 cm), all can be used in early identification of the need for escalation of therapy^[32-34]. A more recent scoring system also includes the need for blood transfusions or parenteral nutrition as predictors of need for colectomy^[35].

COLECTOMY AFTER MEDICAL RESCUE THERAPY

Due to the growing number of medical therapies for severe UC, patients are being referred for colectomy later after multiple attempts at medical salvage. These patients present in a poorer state of health, malnourished and anemic, and the delay is not without consequences.

Patients who undergo an operation after receiving high dose steroids or who are malnourished often have increased surgical complications^[36]. Post-operative complications include anastomotic leak, stricture, fistulae, and bowel obstruction. One study reported the rate of post-operative complications to be over three times higher, with the rate of sepsis being 13 times higher, in patients undergoing three-stage ileal pouch-anal anastomosis (IPAA) after treatment with infliximab^[37]. Similarly, significantly higher rates of major complications were found in patients undergoing longer duration of medical therapy (> 8 d) in a group of 80 patients with severe UC followed over the course of 7 years^[13].

The importance of continuous reassessment of the need for surgery is emphasized due to the mortality benefits of a well-timed or elective operation; mortality rates three years after elective colectomy (3.7%) are significantly lower than after admission without surgery (13.6%) or with emergent surgery (13.2%) in patients with acute severe UC^[38].

STAGED APPROACH

Surgical management of UC in the setting of failed medical therapy involves the performance of a TAC with an optional IPAA in two or three stages^[3]. In a three-stage approach, the initial operation involves a subtotal or TAC with creation of an end ileostomy. The stapled or hand-sewn rectosigmoid stump can be sutured as a mucous fistula to the distal aspect of the abdominal wall incision, may be closed and sutured to the subcutaneous tissue, or may be left unattached in the pelvis. The primary reason for creation of a mucous fistula or placement of the long rectal stump in the subcutaneous tissue is to avoid rectal stump breakdown and leakage with subsequent pelvic sepsis, especially in cases of severe

inflammation and thickening of tissue^[39]. The drawback to a mucous fistula lies in patient dissatisfaction that may occur with persistent discharge during the long-term recovery period^[40]. The manner in which the rectosigmoid is closed depends mainly upon patient anatomy and surgeon preference, but transanal rectal decompression is commonly performed following all techniques^[3]. TAC with end ileostomy as the first stage allows for immediate diversion of the fecal stream, avoids the dangers of a pelvic dissection or anastomosis in a critically ill patient, and allows for preservation of the rectum with the possible diagnosis of Crohn's colitis rather than UC.

The second stage of the procedure involves pouch formation with diverting ileostomy. Restorative proctocolectomy with IPAA is an elective operation performed in the absence of toxicity or severe malnutrition. Although proximal diversion does not prevent pelvic sepsis in the setting of IPAA, diverting ileostomy has been shown to lessen complications related to anastomotic leakage^[41,42]. The procedure can be technically challenging and involves identification of the rectal stump with full mobilization to the level of the levator ani muscles, proctectomy, and construction of a J-shaped pouch through a side-to-side anastomosis of the distal 40 cm of terminal ileum^[43]. Although several pouch designs have been promoted over the years, including the S-pouch and the W-pouch, the J-pouch has endured due to its relatively simple construction and equivalent or superior outcomes to other designs^[43,44]. The IPAA may be stapled or hand-sewn but fewer complications and better long-term quality of life have been reported in patients undergoing stapled anastomosis^[45].

The third stage of the procedure involves takedown of the diverting ileostomy and reestablishment of intestinal continuity. This final step should only be performed after water-soluble contrast enema has demonstrated patency and anastomotic integrity of the pouch.

In rare cases (5%), patients present with rectal sparing disease, and TAC with end ileostomy remains the first step to patient recovery^[46]. Only in these specific cases has ileorectal anastomosis as an alternative to pouch formation been described for reconstruction of the gastrointestinal tract^[47].

Although colectomy and pouch formation may be and are routinely performed as one procedure, this operation is reserved for UC patients who are healthy, well-nourished, off steroids and not experiencing an acute flare^[41]. Performing a three stage procedure allows for healthier, better nourished patients at the time of surgery^[48]. Some centers have attempted to abbreviate the hospital course of acute severe UC patients by performing a modified two-stage procedure (colectomy followed by IPAA and ileostomy takedown). Zittan *et al*^[49] demonstrated significantly lower rates of anastomotic leak (4.6% vs 15.7%) when comparing modified 2-stage IPAA to the traditional 2-stage procedure (colectomy with pouch formation followed by ileostomy takedown). Swenson *et al*^[50] demonstrated equivalent

patient outcomes with significantly lower hospital cost in patients with resolved severe colitis after colectomy who underwent a modified two-stage IPAA vs a three-stage procedure. The cost of medical therapy is not only affected by the operation performed but also by the timing of the procedure. In a comparison of patients with severe UC undergoing early colectomy with IPAA vs standard medical therapy, Park *et al*^[51] reported a cost analysis showing a \$90000 increase in cost to patients who received prolonged medical salvage therapy with very little improvement in quality of life.

ROLE OF LAPAROSCOPY

A laparoscopic approach to TAC in severe UC patients provides a reasonable alternative to the open approach and has been shown to be equally safe and feasible in comparison^[52]. While the laparoscopic approach has the advantage of reducing post-operative pain, time to stoma function, and overall hospital stay, it also leads to longer operative time and may be more technically demanding for the surgeon^[53,54].

LONG-TERM OUTCOMES OF IPAA

Although the ileal pouch does allow many patients to have a more normal life-style and defecation pattern, the procedure is not without enduring consequences. A recent study from the Cleveland Clinic published long-term outcomes of 74 patients who underwent IPAA and were followed over a 20-year period. Pouch-specific complications included pouchitis (45%), stricture (16%), fistula (30%), obstruction (20%), and change of diagnosis to Crohn's (28%). Long-term consequences of the procedure also included frequent stooling requiring anti-diarrheal medication (44%) and difficulty conceiving (25% and all women)^[44]. Pouch failure rates at 10 and 20 years have been reported to be 9% and 14%, although a 2016 study reported a failure rate of 2.4%, indicating that pouch outcomes may be improving^[44,55,56]. The three stage approach with proximal diversion may be associated with better outcomes as it reduces the impact that complications such as pelvic sepsis or anastomotic leak have on the ultimate quality of the pouch^[41].

While a substantial number of UC patients do elect to undergo IPAA after TAC, this procedure is not mandatory, and many choose to forgo the pouch completely. A Swedish cohort study of over 2000 patients who underwent colectomy for inflammatory bowel disease showed that less than half (43%) of the patients underwent reconstructive surgery over a ten year period^[57]. A 2015 review of UC patients with an end ileostomy or IPAA demonstrated equivalent improvement in quality of life at 1 year with the majority of the benefit related to the control of disease symptoms^[58].

CONCLUSION

The optimal treatment algorithm in the management

of severe UC remains controversial. The purpose of this review is to summarize the current medical and surgical options available in the treatment of acute, severe UC.

First line treatment for patients presenting with acute severe UC consists of intravenous steroids, but those who do not respond require escalation of therapy or emergent colectomy. The mortality of emergent colectomy has declined significantly in recent decades, but due to the morbidity of this procedure, second line agents such as cyclosporine and infliximab have been used as rescue therapy in an attempt to avoid emergent surgery. In this era of multiple medical modalities available in the treatment of acute severe UC, it is imperative that physicians consider the advantages and disadvantages of prolonged medical therapy in an attempt to avoid surgery. Colectomy remains a mainstay in the treatment of severe ulcerative colitis not responsive to corticosteroids and rescue therapy, and timely referral for surgery allows for improved post-operative outcomes with lower risk of sepsis and improved patient survival.

Options for reconstructive surgery include three-stage IPAA or a modified two-stage procedure. The three-stage procedure offers the advantage of a healthier, well-nourished patient, but the two-stage procedure offers fewer in-hospital days and decreased overall cost.

The numerous avenues of medical and surgical therapy have allowed for great advances in the treatment of patients with UC. In this era of options, it is important to maintain a global view, utilize rescue therapy when indicated, and then maintain an appropriate threshold for surgery. Colectomy remains a viable and often life-saving treatment and should not be viewed as the "therapy of last resort".

Abstract

The prevalence of subjects with colorectal cancer is expected to grow in the next future decades and surgery represents the most successful treatment modality for these patients. Anyway, currently elderly subjects undergo less elective surgical procedures than younger patients mainly due to the high rates of postoperative morbidity and mortality. Some authors suggest extensive surgery, including multistage procedures, as carried out in younger patients while others promote less aggressive surgery. In older patients, laparoscopic-assisted colectomy showed a number of advantages compared to conventional open surgery that include lower stress, higher rate of independency after surgery, quicker return to prior activities and a decrease in costs. The recent advances in chemotherapy and the introduction of new surgical procedures such as the endoluminal stenting, suggest the need for a revisitation of surgical practice patterns and the role of palliative surgery, mainly for patients with advanced disease. In this article, we discuss the current role of surgery for elderly patients with colorectal cancer.

Key words: Laparoscopy; Colorectal cancer; Elderly; Comorbidities; Colorectal surgery

Core tip: Age itself should not be considered as a risk factor for the development of complications in patients undergoing surgery for colorectal cancer. Many studies underlined that age is not a predictor of post operative complications in these patients. Therapeutic or palliative surgery should not be avoided in the elderly based exclusively on age.

INTRODUCTION

Colorectal cancer (CRC) represents the third most commonly diagnosed cancer in developed countries, with almost 694000 deaths estimated to have occurred in 2012^[1]. The prevalence of elderly subjects with CRC is expected to grow in the next future decades due to the increase of age in the general population^[2]. In fact, CRC is infrequently diagnosed before age of 40, with a highest risk around age of 70.75% of CRC are identified in patients aged 65 years or older^[3]. In both Europe and United States approximately 50% of CRC patients are older than 70 years of age and in this age group CRC is the second most common cause of cancer death^[4,5]. Thus, age could be considered as a major risk factor for the development of this cancer^[6].

Many studies showed that surgical approach represents the most successful treatment modality for patients with CRC. Over the past years it has been observed an improvement in the survival of subjects with this cancer mainly due to a reduction in operative mortality and a raising in the resection rate^[7]. However, there is significant evidence that elderly subjects undergo less elective surgical procedures than younger patients^[8] mainly due to the high rates of postoperative morbidity and mortality^[9].

IMPACT OF AGE ON CRC SURGERY

There is a lack of consensus on the impact of age on postoperative outcome after major colorectal surgery. In fact, comorbidities are higher in elderly subjects thus leading to difficult decisions whether these patients are suitable for extensive bowel resection or not. A review of the literature published in the *Lancet* in 2000 pointed out that elderly patients are less likely to have curative surgery than younger patients^[8].

In 2008, the International Society of Geriatric Oncology (SIOG) created a task force to develop guidelines for the treatment of elderly patients with CRC^[10]. The task force confirmed the paucity of clinical trial data in the elderly and pointed out that treatment for elderly CRC patients should be analogous to those of younger patients.

A registry-based study carried out by Damhuis *et al.*^[9] on 6457 patients with CRC, evaluated the influence of age and other variables on resection rates and operative risk. All subjects included in the study were enrolled from 1985 through 1992 in hospitals connected to the Rotterdam Cancer Registry. Data analysis showed that 87% of the patients underwent resection but resection

rates were lower for patients older than 89 years (67%) and for patients with rectal cancer (83%). Patients younger than 60 years had a postoperative mortality rate of 1% that constantly increased with age. Patients 80 years and older showed an operative risk of 10%. Multivariate analysis was conducted and pointed out that gender, age, cancer subsite and stage could be considered as independent prognostic factors. The authors concluded that chronological age alone should not be an exclusion criteria for performing surgery in elderly patients with CRC. Even in patients aged over 90 years, resections can be performed with acceptable risk.

Another study^[11] analysed the electronic records from the Rotterdam Cancer Registry for octogenarians and nonagenarians who underwent resection in the period 1987-2000. The results showed that for CRC, postoperative mortality rates increased from 8% in patients aged 80 to 84 years, to 13% in patients aged 85 to 89 years and to 20% in nonagenarians.

A systematic review of 28 independent studies and 34194 patients, carried out by the Colorectal Cancer Collaborative Group, analysed the results for different groups of patients aged 65-74 years, 75-84 years and 85+ years with those for patients aged < 65 years. Compared with younger subjects, elderly patients have an increased frequency of comorbid conditions, are more likely to present with later-stage disease and undergo emergency surgery^[8]. Moreover, many studies focused on the role of adjuvant chemotherapy, demonstrating that elderly are less likely to be recommended or to receive adjuvant treatment^[12].

COMORBIDITIES AND COMPLICATIONS

Traditionally, contraindications for major surgery in elderly patients include a poor functional status, associated comorbidities and impaired cognition^[13]. Anyway, in the last 30 years elderly patients with CRC took advantage of healthcare progress and a retrospective trend analysis showed a reduction of palliative procedures and a decline in operative mortality for these patients^[14].

Most elderly patients with CRC have significant comorbidities such as cardiovascular and pulmonary diseases. Such diseases increase the operative risk and the risk of postoperative morbidity and mortality^[15,16]. A study by Hermans *et al.*^[17] evaluated the impact of comorbidities on the outcome of colonic surgery in elderly patients with colon cancer.

Comorbid assessment tools provide helpful information on the impact of comorbidities at the initial diagnosis and prospective outcome of CRC patients due to their prognostic capacity on survival. According to the classification of Charlson *et al.*^[18], the evaluated comorbidities included previous malignancies, chronic obstructive pulmonary disease, cardiovascular disease, cerebrovascular disease, hypertension, diabetes, and others (rheumatoid arthritis, hyperthyroidism, hypothyroidism, and sclerodermia). Compared to younger

age, elderly subjects presented with more cardiovascular pathology and dementia and with more than one type of the previously described comorbidities. The authors concluded that the type and number of co-morbidities influence post-operative mortality and morbidity. Complications were seen in 24% of younger patients vs 50% of elderly patients. No difference was observed as regards major complications (e.g., anastomotic leakage, fascia dehiscence, or intra-abdominal abscesses). In the elderly group there was a high incidence of delirium, pneumonia, wound infections, and minor complications such as urinary tract infection, and electrolyte alterations. Other factors that may cause poor outcome of surgery in the elderly include delayed presentation and advanced stage of the disease^[19,20].

As regards preoperative factors that could influence the choice of treatment, Marventano *et al.*^[19] proposed a modified version of the Charlson comorbidity index (CCI) that was specifically developed for colorectal cancer patients. This version of CCI emphasized the importance of specific conditions to better predict the survival of the patients. Particularly, the inclusion of 6-mo weight loss $\geq 20\%$, smoking > 20 cigarettes/d, underweight condition, and cardiac arrhythmias to the other comorbid conditions tested in the CCI showed a better predictive value compared with the original CCI and other comorbidity indices (e.g., the Elixhauser method, the National Institute on Aging and National Cancer Institute comorbidity index, and the Adult Comorbidity Evaluation-27). Noteworthy, the Authors found that only moderate or severe renal disease and diagnosis of AIDS were independently associated with higher risk of death^[19].

An analysis of 31574 patients in the surveillance, epidemiology and end results-medicare database for patients diagnosed with colon cancer between 1992 and 2005 was conducted to describe patterns of surgery in patients aged > 80 years and examine outcomes with and without colectomy. The Authors demonstrated that 80% of the "oldest old" patients with colon cancer in the United States are undergoing surgical resection^[21]. In this study, 46% of subjects were diagnosed during an urgent or emergent hospital admission, with decreased 1-year overall survival (70% vs 86% for patients diagnosed during an elective admission). Older age, black race, more hospital admission, use of home oxygen, use of wheelchair, frailty and dementia were most predictive of nonoperative management. The 1-year overall survival rate for both operative and nonoperative patients was lower than the colon cancer-specific survival rate (operative patients: 78% vs 89%; nonoperative patients: 58% vs 78%)^[21].

A study by Kahn *et al.*^[22] showed that older age is not independently associated with complications after surgery for colorectal cancer. The Authors underlined the importance of clinical status and American Society of Anesthesiologists (ASA) class in patients' selection rather than age.

THERAPEUTIC OPTIONS FOR CRC IN THE ELDERLY

Different approaches to treat elderly subjects with CRC have been proposed over the past years. Some authors endorse extensive surgery, including multistage procedures, as carried out in younger patients^[23,24], while others promote less aggressive surgery^[25,26].

Most subjects with stage I or II CRC are treated by surgery, even if some patients with stage II could benefit from adjuvant therapy^[27,28]. Surgery followed by adjuvant chemotherapy is the standard treatment for stage III CRC. Subjects with metastases could benefit from chemotherapy alone or combined with targeted therapy. At this stage, surgery is indicated in selected patients. The treatment for stage IV CRC includes surgery and preoperative or postoperative, radiotherapy and/or chemotherapy.

Different factors could influence surgical outcomes in stage IV CRC, including the presence of liver metastases^[29,30] and cardiovascular disease^[31], the degree of peritoneal involvement and primary cancer resection^[32], the tumor differentiation, and age older than 75^[33].

There is still uncertainty about the effective benefit of surgery directed toward removal of the primary tumor for the management of asymptomatic patients with stage IV CRC and unresectable metastases. Palliative surgery is indicated for most patients with bowel obstruction or uncontrollable bleeding^[34].

Guidelines from the National Comprehensive Cancer Network recommend surgical treatment in stage IV CRC only in symptomatic patients at risk of obstruction, or with metastases suitable for potentially curative resection^[35].

A study by Temple *et al.*^[34] evaluated surgical practice patterns for patients over 65 years of age with stage IV CRC in a United States population-based cohort. They observed that 72% of patients received primary-cancer-directed surgery (CDS) with a 30-d postoperative mortality of 10%. CDS was less performed on patients with left-sided or rectal lesions, subjects older than 75 years, blacks, and those of lower socioeconomic status; but even among those older than age 75, the CDS rate was 69%. Chemotherapy was administered to 47% of patients that underwent CDS vs 31% of patients who did not. The resection of metastases was performed only on 3.9% of patients at any point from diagnosis to death^[34].

There is evidence that subjects with stage IV CRC could tolerate chemotherapy without requiring surgery to remove the primary tumor. In fact, a study by Tebbutt *et al.*^[36] showed that there were no differences in gastrointestinal complications (e.g., fistulas, peritonitis, obstruction) in patients who did not undergo CDS compared to those who had CDS^[36]. The recent advances in chemotherapy and the introduction of new surgical procedures (e.g., endoluminal stenting) suggest the need for a revisitation of surgical practice patterns and the role of palliative surgery for IV stage CRC patients.

Many studies underlined the importance of laparoscopic assisted colectomy (LAC) for the treatment of CRC. However the majority of them were conducted on patients younger than 65 years. In general, LAC showed a number of advantages compared to conventional open surgery that include lower stress, higher rate of independency after surgery, quicker return to prior activities and a decrease in costs^[37,38].

There are many issues related to the limited number of LAC carried out on elderly subjects requiring colectomy: First of all, the high number of comorbidities; second, the longer operative times; and third, the paucity of scientific literature assessing risks and benefits of this procedure in the elderly. A review of the literature carried out by Mutch^[37] identified 18 studies on LAC in the elderly. There is significant evidence that LAC could be performed in the elderly population safely and without significant increase in morbidity and mortality^[38].

A study by Vara-Thorbeck *et al.*^[39] represents the first report of LAC in older patients. The study was conducted on 18 patients that underwent LAC for CRC. Eleven subjects were older than 70 years. None of the cases were converted to open laparotomy, and the mortality was null. The results showed that LAC could be performed safely on both older and younger patients while maintaining the same principles of surgical technique as open colectomy. A number of more recent studies confirmed that laparoscopy-assisted colectomy in the elderly can be performed with no difference in morbidity or length of hospital stay compared with open surgery^[40-44]. Vignali *et al.*^[45], compared the outcomes of open colectomy vs LAC in a population of octogenarians. They observed that the patients undergoing LAC had a shorter hospital stay (LAC 9.8 d vs open 12.9 d), reduced morbidity (LAC 21% vs open 31%), and higher rate of independence at discharge (LAC 98% vs open 82%), thus confirming that the benefits of LAC are maintained with advancing age.

A study by Bardram *et al.*^[46] analyzed the outcomes of laparoscopy combined with a perioperative multimodal rehabilitation protocol in 50 patients of median age 81 years. After LAC, patients were treated with epidural local anaesthesia for 2 d, early mobilization and oral nutrition, with a significant improvement in recovery.

O'Connell *et al.*^[47] pointed out that in frail elderly with limited life expectancy, the benefits of cancer surgery are frequently unclear, and surgical resection of tumors is less performed as the patient ages.

A study by Finlayson *et al.*^[48] aimed to determine functional status and mortality rates after colon cancer surgery in older nursing home residents. They conclude that even when not curative, surgery for CRC may be an effective palliative procedure. Less invasive treatments, such as endoscopic treatment or embolization of bleeding tumors or the use of endoluminal stents for large bowel obstruction, may represent an alternative to surgery for individuals with limited life expectancy.

The international SIOG expert recommendations, according to the available evidence on CRC in the elderly, suggested that emergency surgery should be avoided

when possible; the use of colorectal stents should be taken into account to improve patient nutrition thus facilitating elective surgery 1-2 wk after the patient has presented as an emergency; the pathway of choice should be elective surgery with a prospective analysis of the perioperative variables and careful treatment; possible curative resection of liver metastases should be performed in healthy elderly subjects receiving a careful preoperative assessment and a high quality postoperative care^[10].

As regards rectal cancer, analysis of 991 treatments, in the 838 elderly rectal cancer patients from the Cote d'Or and Calvados tumor registries study^[49], showed 54% of patients to undergo curative resection, 7% to undergo palliative resection, 12% to undergo by-pass laparotomy, 27% to undergo no surgery, 17% to receive radiotherapy and 2% to receive chemotherapy. These data highlighted a low use of radiotherapy either combined with surgery or alone, while chemotherapy was almost never administered. Both surgery and radiotherapy are important for controlling local recurrence and therefore local failure rates. Recently the use of the surgical technique total mesorectal excision^[50] has contributed to a reduction in pelvic recurrences. A study by Kim *et al.*^[51] assessed the long-term oncological and functional outcomes of intersphincteric resection for T2 and T3 low rectal cancer. The authors observed a 5-year overall survival rates of 95.8% for T2 and of 94.7% for T3. The 5-year recurrence-free survival rates were 87.5% for T2 and 86.8% for T3 (Table 1). Radiotherapy has been shown to impact significantly on survival in resectable tumors^[52] and is critical for the management of patients with all stages of rectal tumors.

CONCLUSION

In general, there are age-related disparities in colon cancer treatment, with older patients being less likely to receive recommended therapy. According to the SIOG guidelines, elderly subjects should receive screening and earlier diagnosis; the management of CRC should be more aggressive and closer to that received by younger patients; the treatment should be the most intensive and appropriate according to the biological age and the presence of comorbidities^[10]. Many studies pointed out that age is not a predictor of post operative complications in patients with CRC^[53-56]. Age itself should not be considered as a risk factor for the development of complications in patients undergoing surgery for CRC. Thus, therapeutic or palliative surgery based solely on age should not be avoided in these patients. In the future, the surgical assessment of CRC in the elderly should take into account a multidisciplinary process before choosing the best possible therapy for each patient. There will be the need for services specialized in the care of at-risk older patients, rehabilitation and palliative care consultation. An appropriate management should also include the functional status, the grade of frailty, the life expectancy and also patient's requests.

Ref.	Year	No. of patients	Postoperative mortality	Resection rates	Comorbidities	Survival rate	Independent prognostic factors
Damhuis <i>et al</i> ⁽⁹⁾	1996	6457	1% for patients < 60 yr and steadily increased with age. The operative risk was 10% for patients > 80 yr	87% of the patients underwent resection. 67% for patients > 89 yr and 83% for patients with rectal cancer	-	-	Gender, age, subsite and stage
Damhuis <i>et al</i> ⁽¹⁰⁾	2005	2765	Increased from 8% for the age group 80-84 to 13% for those 85-89 to 20% in nonagenarian	-	-	-	-
Hermans <i>et al</i> ⁽⁷⁾	2010	207	In-hospital mortality was 16% in the elderly and 5% in the younger group ($P < 0.01$)	No differences between < 75 yr and > 75 yr: ileocecal resection (2% vs 4%); hemicolectomy right (42% vs 49%); transversum resection (1% vs 3%); hemicolectomy left (15% vs 8%); sigmoid resection (26% vs 22%); anterior resection (10% vs 9%); subtotal colectomy (3% vs 1%); double resection (1% vs 4%)	More co-morbidities > 75 yr, especially cardiovascular pathology ($P < 0.01$) and dementia ($P < 0.01$), more than one type of comorbidity according to the Charlson classification ($P < 0.05$)	5-yr survival rate in < 75 yr was 62% compared with 36% in the elderly ($P < 0.05$)	-
Neuman <i>et al</i> ⁽²¹⁾	2013	31574	30-d mortality rate of 10% after urgent/emergent admission	-	Hypertension, peripheral vascular disease, and chronic pulmonary disease were found to be associated with improved overall and cancer-specific survival	The 1-yr overall survival rate was lower than the colon cancer-specific survival rate (operative patients: 78% vs 89%, non-operative patients: 56% vs 76%)	Older age, black race, more hospital admissions, use of home oxygen, use of a wheelchair, being frail, and having dementia
Irvin ⁽²¹⁾	1988	306	The surgical mortality rates for patients > 70 yr were 6% overall, 4% after elective operations, and 16% after emergency surgery; the corresponding mortality rates for patients < 70 yr were 3%, 1%, and 20%	-	-	Crude actuarial 5-yr survival curves showed an increased death rate for patients > 70 yr after 18 mo and a significantly lower 5-yr survival ($P < 0.05$) but the age-corrected survival curves for the two groups were not significantly different	-
Temple <i>et al</i> ⁽³⁴⁾	2004	9011	The 30-d postoperative mortality was 10%. The 30-d surgical mortality was significantly greater in the no primary cancer-directed surgery (CDS) group among patients who underwent a surgical procedure, when compared with the primary CDS group (26% vs 9%, $P = 0.001$)	The rates of CDS declined with age: 76% of 65 to 69-yr-old patients received primary CDS, whereas the rate declined to 62% of patients age ≥ 85 yr	-	The overall median survival for the entire cohort was 7 mo. There were differences in survival between patients treated with CDS and no CDS exist (median, 10 mo vs 3 mo, respectively), but data are not reliably because of patient selection in the non-randomized setting	Left-sided or rectal lesions, age > 75 yr, blacks, marital status and lower socioeconomic status
Vallribera Valls <i>et al</i> ⁽⁴²⁾	2014	277: Laparoscopic group; 268: Open group	Open surgery group showed a higher mortality (6.7% vs 3.2%, $P = 0.034$). Mortality was significantly inferior in laparoscopy group in younger patients (< 75 yr, 0% vs 3%, $P = 0.038$)	-	Open surgery group showed a higher overall morbidity rate (37.3 vs 21.6%, $P = 0.001$), medical complications (16.4% vs 10.5%, $P = 0.033$), surgical complications (23.5% vs 15.5%, $P = 0.034$), the	-	-

Author	Year	Study Design	Population	Intervention	Control	Results	Conclusions
Vignali <i>et al</i> ^[45]	2005	61: Laparoscopic colectomy; 61: Open colectomy	Overall mortality rate was 2.4%. The morbidity rate was 21.5% in the laparoscopy group and 31.1% in the open group (P = 0.30)	Overall mortality rate was 2.4%. The morbidity rate was 21.5% in the laparoscopy group and 31.1% in the open group (P = 0.30)	-	Overall morbidity rate difference between open and laparoscopy approach disappeared in the oldest group (≥ 85 yrs old). Surgical site infections rate was inferior for patients < 75 yr old in laparoscopy group compared with open	-
Bouvier <i>et al</i> ^[46]	2005	1571 with colon cancer; 838 with rectal cancer	During the study period from 8.7% to 9.5% for colon and from 16.3% to 5.6% for rectum	69% in colon cancer; 54% in rectal cancer	-	Overall 3-yr survival rates were 45.2% for colon cancer and 46.2% for rectal cancer. Overall 5-yr survival rates were 40.9% and 37.3% respectively	Age, gender, period of diagnosis, treatment. A second multivariate analysis restricted to patients resected for cure and alive after the first month of follow-up showed that age between 85 and 89 was no longer a significant factor of survival
Heald <i>et al</i> ^[50]	1998	519 with rectal cancer	The operative mortality (30-d) was 3.3%	-	-	68% at 5 yr and 66% at 10 yr	-
Kim <i>et al</i> ^[51]	2016	62 with very low rectal cancer. Group I, n = 24, stage T2 Group II, n = 38, stage T3	No postoperative mortality in both groups	Temporary urinary retention (group I : 10 cases; Group II : 15 cases), postoperative paralytic ileus (group I : 2 cases; Group II : 3 cases), perineal abscess (group I : 1 case; Group II : 1 case), and anastomotic leakage (group I : 1 case; Group II : 1 case). Late complications, such as anastomotic stricture (group I : 6 cases; Group II : 10 cases), rectovaginal fistula (group I : 0 case; Group II : 1 case) after stoma closure	-	5-yr overall survival rates were 95.8% for group I and 94.7% for group II. The 5-yr recurrence-free survival rates were 87.5% for group I and 86.8% for group II	-
Schiffmann <i>et al</i> ^[54]	2008	517	30-d mortality was higher in the older age group (> 75 yr)	-	-	No differences in 30-d morbidity except in postoperative bleeding	-
Devon <i>et al</i> ^[55]	2009	898	The in-hospital mortality rate was 1% in the younger group (< 75 yr) compared with 4.2% in the older (> 75 yr) (P = 0.002)	-	-	The overall five-year survival was 68.7% and 57.3% in the younger and older groups, respectively, whereas colorectal cancer-specific five-year survival was not significantly different (74.0% vs 74.7%)	-
Paksoy <i>et al</i> ^[56]	1999	822	The postoperative (30 d) mortality was 3% in the younger group (< 65 yr) (20/565) and 7% in the older group (17/257) (difference not significant)	-	-	Five-year survival rates for older and younger patients were 33% and 45%, respectively (P < 0.05)	-

Abstract

Rubber band ligation is one of the most important, cost-effective and commonly used treatments for internal hemorrhoids. Different technical approaches were developed mainly to improve efficacy and safety. The technique can be employed using an endoscope with forward-

view or retroflexion or without an endoscope, using a suction elastic band ligator or a forceps ligator. Single or multiple ligations can be performed in a single session. Local anaesthetic after ligation can also be used to reduce the post-procedure pain. Mild bleeding, pain, vasovagal symptoms, slippage of bands, priapism, difficulty in urination, anal fissure, and chronic longitudinal ulcers are normally considered minor complications, more frequently encountered. Massive bleeding, thrombosed hemorrhoids, severe pain, urinary retention needing catheterization, pelvic sepsis and death are uncommon major complications. Mild pain after rubber band ligation is the most common complication with a high frequency in some studies. Secondary bleeding normally occurs 10 to 14 d after banding and patients taking anti-platelet and/or anti-coagulant medication have a higher risk, with some reports of massive life-threatening haemorrhage. Several infectious complications have also been reported including pelvic sepsis, Fournier's gangrene, liver abscesses, tetanus and bacterial endocarditis. To date, seven deaths due to these infectious complications were described. Early recognition and immediate treatment of complications are fundamental for a favourable prognosis.

Key words: Hemorrhoids; Rubber band ligation; Pain; Bleeding; Infection

Core tip: Rubber band ligation of hemorrhoids is a very effective non-surgical treatment for internal hemorrhoids. Different techniques were developed mainly to improve efficacy and safety. This is an overall safe procedure, although severe complications can occur, such as infections. It is very important to know these possible complications to reduce their risk and to allow early recognition and successful treatment.

Albuquerque A. Rubber band ligation of hemorrhoids: A guide for complications. *World J Gastrointest Surg* 2016; 8(9): 614-620

GENERAL CONCEPTS OF HEMORRHOIDAL LIGATION

In the 1950s, Blaisdell^[1] described a new technique for the ligation of bleeding internal hemorrhoids which can be performed in the office without the need for hospitalization. This new concept was based on the fact that internal hemorrhoids are easily accessible, practically devoid of pain and thus, suitable for outpatient treatment. In addition, during this period, injection therapy was an alternative to surgery, but without any controlled destruction of hemorrhoidal tissue. The technique of office ligation of internal hemorrhoids was later modified and simplified using rubber bands by Barron^[2] in the 1960s. Since then, rubber band ligation (RBL) was established as one of the most important, cost-effective and commonly used treatments for first- to third-degree internal hemorrhoids, causing fibrosis, retraction, and fixation of the hemorrhoidal cushions^[3].

When compared to other non-surgical methods, like sclerotherapy and infrared coagulation, RBL has better long-term efficacy, requiring fewer sessions for treatment, although with a higher rate of post-treatment pain^[4,5]. Hemorrhoidectomy showed better response rates, but it was associated with more complications, time off work and pain than RBL^[4,6]. RBL should be considered as a first-line therapy for first- to third-degree internal hemorrhoids^[4] commonly indicated for bleeding and/or prolapsing. Surgical therapy can be considered in the presence of an important external component, thrombosis or recurrence after repeated banding^[6].

There are studies that evaluated the use of combined non-surgical therapies^[7-9]. A prospective randomized trial^[7] comparing the simultaneous application of sclerotherapy and RBL (sclerotherapy of the smaller non-prolapsing hemorrhoidal piles and RBL of the larger prolapsing piles), with sclerotherapy and RBL applied separately, showed that there was no significant difference between the combination and RBL alone groups.

RBL technique can be employed using an endoscope with forward-view or retroflexion or without an endoscope, using a suction elastic band ligator or a forceps ligator. Several patient positions can be used, without the need for bowel preparation or sedation^[3] and the ligations should be performed in the area above the dentate line that is devoid of sensory nerves.

The success rate of RBL ranges from 69% to 97%^[10]. A larger number of recurrences have been described with longer follow-up periods, but recurrences can be treated with repeat sessions and time to recurrence shortened with subsequent treatment courses^[10]. Recurrence rates are variable, with 6.6% to 18% of patients submitted to RBL requiring additional treatment sessions due to the recurrent symptoms^[10].

COMPLICATIONS OF RBL

There are several complications associated with this technique, which can be classified as minor or major (severe)^[11]. Mild bleeding, pain, vaso-vagal symptoms, slippage of bands, priapism, difficulty in urination, anal fissure, and chronic longitudinal ulcers are more common and normally considered minor complications. Massive bleeding, thrombosed hemorrhoids, severe pain, urinary retention needing catheterization, pelvic sepsis, fistula and death are major complications that have been less commonly reported.

Several studies described different rates of complications following RBL, ranging from 3%^[12] to 18.8%^[13]. The most common complications are pain and bleeding.

A review of 39 studies including 8060 patients submitted to RBL revealed post-banding complications in 14% of the patients, in the form of severe pain in 5.8%, haemorrhage in 1.7%, infection in 0.05%, anal fissure and fistula in 0.4%^[14].

In a prospective study by Bat *et al*^[11], including 512 patients submitted to RBL, 37 (7.2%) patients had complications. In this study RBL was performed using the Barron applicator, with a single ligation per session, with a total of one to seven ligations per person at four-week intervals. Minor complications were reported in 4.7% (thrombosed prolapsed hemorrhoids, slippage of bands, minor rectal bleeding, chronic longitudinal ulcer, priapism, difficulty in urination, and tender induration) and severe complications, requiring admission were described in 2.5% of the patients (massive bleeding, severe thrombosis of hemorrhoids, severe pain, perianal abscess, and fistula). Severe complications were more common in right anterior hemorrhoid RBL and in patients with previous hemorrhoidectomy. Most complications occurred following the first session.

Studies do not show any significant manometric change after RBL^[15-17], namely, in the maximum resting pressure and squeeze pressure.

Bleeding

Bleeding after RBL normally occurs after 10-14 d, probably due to the sloughing of the ligated hemorrhoids^[11,18,19].

Patients taking anti-platelet and/or anti-coagulant medication have a higher risk of secondary bleeding. There are cases of massive life-threatening haemorrhage following hemorrhoidal RBL in patients on acetylsalicylic acid (ASA)^[18,20,21] and clopidogrel^[19].

In a study by Bat *et al*^[11], including 512 patients submitted to RBL, five of the six patients who had massive bleeding, developed symptoms 10 d or more after the procedure. Three patients that were transfused were taking ASA regularly.

In a retrospective study^[10] including 805 patients who had undergone RBL aiming to evaluate the efficacy and safety of this procedure, higher bleeding rates were encountered with the use of ASA /nonsteroidal anti-inflammatory drugs (NSAIDs) and warfarin. Two (25%) of eight patients taking warfarin bled, whereas three

(7.5%) of 40 patients taking ASA or other NSAIDs bled.

Marshman *et al*^[22] conducted a study, including 241 patients undergoing RBL over a five-year period and focused on complications. Three (1.2%) patients required hospitalization for complications, of these patients, two on oral anticoagulants were admitted for significant bleeding.

In a retrospective study^[23], including 364 patients submitted to RBL while on antithrombotic therapy, holding antithrombotic medication 7-10 d following the procedure, appeared to equalize the risk of bleeding to that of patients not taking antithrombotic medications. There were 23 bleeding complications, and patients on clopidogrel experienced 50% of the significant bleeding episodes and 18% of the insignificant bleeding episodes, having a higher risk for bleeding complications, but due to the small sample size, this difference did not reach statistical significance. These authors defend that not stopping the drug before the procedure reduces the risk of ischemic events and allows ligation in the first consultation. Also, the greatest risk for bleeding typically occurs from 5 to 10 d after ligation.

It is routinely recommended that patients should stop this medication for at least 1 wk prior to, and 2 wk post RBL^[18]. The risk of the hemorrhoidal bleeding against the risk of thrombotic events must be balanced.

Concerning liver cirrhosis few data are published. In a prospective study including 500 patients submitted to RBL of symptomatic internal hemorrhoids, this procedure proved to be safe in 16 patients with coagulation disorders due to liver cirrhosis^[13].

Pain

Pain is one of the most common complications of RBL. Some studies reported mild anal pain in at least 25%-50% of patients, for the first 48 h after banding^[24,25], sometimes associated with nausea, shaking, light headedness, and urinary retention^[25].

In a prospective study^[26] specifically evaluating pain and patient satisfaction following RBL of hemorrhoids, pain was the most common symptom occurring in almost 90% of patients, with the pain scores higher 4 h following the procedure. At 1 wk, 75% of patients reported themselves as being pain-free; however, 7% were still experiencing moderate-to-severe pain. A total of 65% required oral analgesia during the week following RBL, most frequently on the day of the procedure. Vaso-vagal symptoms (dizziness or fainting) occurred in 30%, more commonly at the time of the procedure and in the evening of that day. Patients requiring oral analgesia and those experiencing bleeding or vaso-vagal symptoms were significantly less likely to be satisfied with RBL.

To minimize complications, before application, the tissue should be tested and if the patient complains of discomfort following the ligation, the band should be removed immediately and reapplied^[27].

Infectious complications

Septic complications have been described after hemo-

rrhoid treatments, namely, after injection sclerotherapy, RBL, cryotherapy, hemorrhoidectomy and stapled hemorrhoidopexy^[28,29].

Several infectious complications have been reported following RBL including pelvic sepsis, Fournier's gangrene, liver abscesses, tetanus and bacterial endocarditis. Deaths due to these infectious complications were also reported.

One of hypotheses is related to the transmural necrosis or slough following banding that facilitates the development of deep infection by migration of the bowel bacterial flora, which can spread to adjacent tissues^[30-32]. Transient bacteraemias have been described following digital rectal examination, protoscopy, colonoscopy, injection sclerotherapy and hemorrhoidectomy^[33-37].

One of the most serious complications is pelvic sepsis, with several reports in the literature^[14,30,31,38-41]. Suspicion should arise in patients with pain, fever, edema and urinary retention^[28-31], normally 3-10 d following banding. To our knowledge, only one case that developed septic complications was human immunodeficiency virus (HIV) positive^[40].

A case of Fournier's gangrene in an elderly patient with diabetes following RBL was described. The patient recovered after surgical debridement and antibiotherapy^[42].

Liver abscesses associated with the treatment of hemorrhoids were first described related to hemorrhoidectomy^[43,44] and sclerotherapy^[45]. To our knowledge, there are six case reports of liver abscesses due to RBL of hemorrhoids^[20,46-50]. Most cases were male (5/6 patients), more frequently due to *Klebsiella* (4/6 patients) and multiple abscesses (5/6 patients) were normally present. All patients recovered and only in one case a right hepatectomy was necessary (Table 1).

Tetanus due to RBL was described in two patients^[51,52], both of whom survived.

There is a only a case report of patient with a ventricular septal defect that developed endocarditis leading to septic pulmonary and renal emboli following single-quadrant banding of hemorrhoids^[53]. The patient recovered after cardiac surgery.

The literature shows that all seven deaths linked to RBL were due to septic complications^[32,38,54,55]. Most cases were male (six patients) and no predisposing factors have been established. Time until symptom onset was between 3 to 10 d after banding, and the most common initial symptoms were pain and urinary retention (Table 2).

Early recognition and immediate treatment of infectious complications are fundamental. There are several authors recommending enemas, application of povidone-iodine solution and oral antibiotics before the procedure to reduce the risk, but studies supporting these recommendations are lacking.

SPECIAL SITUATIONS

There are certain conditions that have been considered a contraindication for RBL of hemorrhoids due to a higher risk of complications, namely, HIV and Crohn's disease.

In 1989, there was a case report of a 45-year-old

Table 1 Case reports of liver abscesses due to rubber band ligation of hemorrhoids

Age (yr)	Sex	Bacteria	Comorbidities	No.	Treatment	Outcome	Ref.
58	Male	Klebsiella aerogenes	Diabetes	Multiple	Antibiotics, drainage	Resolution	[20]
58	Male	Klebsiella pneumoniae	Previous pulmonary tuberculosis	Multiple	Antibiotics, drainage, right hepatectomy	Resolution	[46]
40	Male	Citrobacter freundii		Single	Antibiotics, drainage	Resolution	[47]
64	Male	Fusobacterium necrophorum	Asthma	Multiple	Antibiotics, drainage	Resolution	[48]
49	Male	Klebsiella pneumoniae	Diabetes, hypertension, dyslipidaemia, stroke, previously treated pulmonary tuberculosis	Multiple	Antibiotics	Resolution	[49]
61	Female	Klebsiella pneumoniae	Peptic ulcer, dyslipidemia	Multiple	Antibiotics, drainage	Resolution	[50]

Table 2 Deaths related to rubber band ligation

Age (yr)	Sex	Comorbidities	Time until symptom onset (d)	Symptoms	Bacteria	Ref.
38	Male	None	4	Pain, urinary retention	None	[32]
54	Male	None	10	Vomiting, urinary retention, fever	None	[32]
34	Male	None		Pain, urinary retention, fever	<i>Enterobacteriaceae</i> (abdomen fluid) <i>Escherichia coli</i> (retroperitoneum and blood)	[32]
37	Male	None	5	Pain, urinary retention	<i>Escherichia coli</i> (urine and rectal cultures)	[32]
73	Male	Not described	3	Pain, fever, urinary retention,		[38]
27	Male	Schizophrenia	4	Fever, pain, difficulty passing urine	<i>Clostridia perfringens</i> , <i>Clostridia sporogenes</i> , <i>Bacteroids</i> (pelvic muscles), <i>Escherichia coli</i> (rectal cultures)	[54]
68	Female	None	7	Anal pain, difficulty passing urine, vomiting	<i>Enterococcus</i> (perianal fluid)	[55]

HIV positive male patient who developed a supralelevator abscess after RBL^[40]. The authors concluded that this procedure is potentially dangerous in HIV patients and it should be abandoned. Although this complication was also described in HIV negative patients following RBL^[38] and, to our knowledge, this is the only infectious complication described in an HIV positive patient. In a retrospective review^[56] of asymptomatic HIV positive patients that were submitted to RBL of symptomatic hemorrhoids, this technique proved to be safe and effective. It was performed in 11 HIV positive patients and no complications were reported. Median CD4 cell count was 450 (range, 200-1000) cells/ μ L and there was a median of two (range, 1-4) bands per patient.

In a retrospective study^[57], including 42 patients with ulcerative colitis and 20 with Crohn's disease, treated both surgically and conservatively for hemorrhoids over a 41 year period, patients with ulcerative colitis had a low complication rate (4 complications after 58 courses of treatment) and Crohn's disease had a high complication rate (11 complications after 26 courses of treatment). No reference was made to RBL treatment in this study. Thus, concerning Crohn's disease and RBL very few data are published. D'Ugo *et al*^[58] published a 9-year retrospective study of 45 Crohn's disease patients treated for hemorrhoids either medically or surgically. In this series RBL was considered a surgical treatment, and in total two patients submitted to it reported no complications.

DIFFERENT TECHNICAL APPROACHES

Suction vs forceps ligation

A prospective randomized clinical trial including 100

patients with second- and third-degree hemorrhoids compared suction and forceps ligation concerning pain after the procedure, intra-procedure bleeding and other complications. The forceps group had higher pain scores immediately after ligation and at 24 h post-banding, needed higher amount of analgesia and had higher intra-procedure bleeding^[59]. Authors hypothesized that this is due to poorer visualization and forceps-induced physical trauma of the friable hemorrhoids.

Single vs multiple ligations

Initially, single ligation per session was recommended due to the belief that a higher complication rate is associated with multiple banding, namely, pain and tenesmus after the procedure^[2].

A retrospective study^[60] comparing patients with multiple banding in a single session ($n = 155$) and single banding ($n = 22$) showed that patients with multiple hemorrhoidal banding did experience more discomfort and pain (29% vs 4.5%), but that this was well tolerated and manageable with oral analgesia of limited duration. Vasovagal reactions, limited bleeding, urinary symptoms, and local swelling and oedema were also more common. There were no cases of massive bleeding or sepsis.

Randomized controlled trials comparing single and triple band ligation^[27,61] showed that triple RBL is an equally safe and effective procedure for managing internal hemorrhoid disease. Fewer treatment sessions are required for triple RBL, so this strategy is more cost-effective^[61]. Furthermore, there is a risk of possible bleeding from untreated hemorrhoids after an initial RBL for other hemorrhoids^[2].

Endoscopic vs non-endoscopic ligation

The endoscopic hemorrhoidal ligation was initially described in 1998, in the forward-view^[62] and then in retroflexion^[63,64]. Some authors favoured the retroflexed position due to easy assessment and treatment^[63].

Endoscopic ligation proved to be an effective and safe technique for treating internal hemorrhoids. In a study by Berkelhammer *et al*^[63], retroflexed endoscopic band ligation of second- and third-degree bleeding internal hemorrhoids, with a mean of three bands (range 1-6) placed in a single session, showed an excellent result in 80% of patients with second-degree hemorrhoids (better than third-degree hemorrhoids with an excellent result in 54%). Major, nonfatal complications were detected in 4% (severe pain, delayed haemorrhage requiring transfusion, urinary retention, and severe thrombosis of external hemorrhoids) of patients. In a study by Fukuda *et al*^[64], retroflexed endoscopic multiple band ligation was performed on patients with symptomatic first- to fourth-degree internal hemorrhoids, with a mean of 8 bands (range 4-14) placed per treatment session. The long-term response was excellent for 89% of the patients, without any major complications in the 82 patients included (severe pain, late-onset haemorrhage requiring transfusion, or severe thrombosis of external hemorrhoids).

Endoscopic ligation has some advantages over rigid instruments that are more difficult to manoeuvre and have limited visualization, allowing for more band placement and photographic documentation of the procedure^[62,63]. There are randomized studies comparing ligation with flexible videoendoscopes (retrograde or antegrade) and the conventional technique with rigid proctoscopes^[65,66]. These trials showed that the long-term efficacy and safety were similar, but with videoendoscopes fewer treatment sessions were needed and a higher proportion of patients treated with a single session^[65].

Local anaesthetic vs no-local anaesthetic in hemorrhoidal ligation

The use of local anaesthesia after hemorrhoidal banding in order to reduce post-procedural pain was studied. In 2015, a meta-analysis^[24] including four randomized controlled trials (387 patients in total), comparing pain and other associated symptoms in patients who received a local injection after hemorrhoidal banding and patients who did not, showed that the post-procedure pain score was significantly lower in the group of patients with local anaesthetic injection. These studies included different anaesthetic treatment protocols. Hooker *et al*^[25] randomized patients to receive a local injection of 0.5 mL of 0.5% bupivacaine with 1:200000 epinephrine, an injection of normal saline, or no injection, immediately superior to each band. In patients receiving bupivacaine within 30 min post-banding, there was a significant reduction in pain, nausea and shaking, which may be useful in the immediate period. However, bupivacaine injection did not reduce pain at 6 h or more post-banding, and did not have other benefits. In a study by

Law *et al*^[67] patients received 1-2 mL of 2% lignocaine injected into the banded hemorrhoidal segment, but no post-ligation pain reduction was reported. Kwok *et al*^[68] randomized patients to an anesthetic injection of 1 mL of 0.5% bupivacaine without adrenaline in the submucosa proximally to the rubber band site and showed that this reduced discomfort compared with no local anaesthetic by the time patients left the clinic (30 min after the procedure). Benefit beyond this period was not obtained. Authors hypothesized that local anaesthetic injection deep to the banded tissue, until a bleb large enough to encompass the "base" of the hemorrhoid was raised, would be more effective than injection into the devitalized banded tissue.

Bupivacaine effect lasts for 4 to 6 h^[25], so this could help in the short-term period following banding, but no study has thus far showed that this can be helpful beyond this period.

CONCLUSION

RBL of hemorrhoids is a very effective and safe procedure, with severe complications being uncommon. Before applying the bands, it is very important to know the patient's medical history, namely, comorbidities and medication. After RBL, patient education is mandatory, including analgesia, softening of the stools, warm sitz baths and information concerning early and late complications. If complications occur, early recognition and immediate treatment are fundamental for a successful outcome.

Abstract

Anastomotic leakage is an unfortunate complication of colo-

rectal surgery. This distressing situation can cause severe morbidity and significantly affects the patient's quality of life. Additional interventions may cause further morbidity and mortality. Parenteral nutrition and temporary diverting ostomy are the standard treatments of anastomotic leaks. However, technological developments in minimally invasive treatment modalities for anastomotic dehiscence have caused them to be used widely. These modalities include laparoscopic repair, endoscopic self-expandable metallic stents, endoscopic clips, over the scope clips, endoanal repair and endoanal sponges. The review aimed to provide an overview of the current knowledge on the minimally invasive management of anastomotic leaks.

Key words: Minimally invasive surgery; Anastomotic leak; Colorectal surgery

Core tip: Anastomotic leakage is the most feared complication of colorectal surgery, leading to significant patient morbidity and mortality. Its incidence is 3%-6%, even in experienced hands. Despite the high prevalence of this condition, there is no consensus on the proper management of anastomotic leaks. In this review, we summarize and discuss the current knowledge on minimally invasive treatment strategies for anastomotic leakage after colorectal surgery.

INTRODUCTION

Anastomotic leak (AL) following colorectal surgery is a feared complication with an incidence of 3%-6%, even

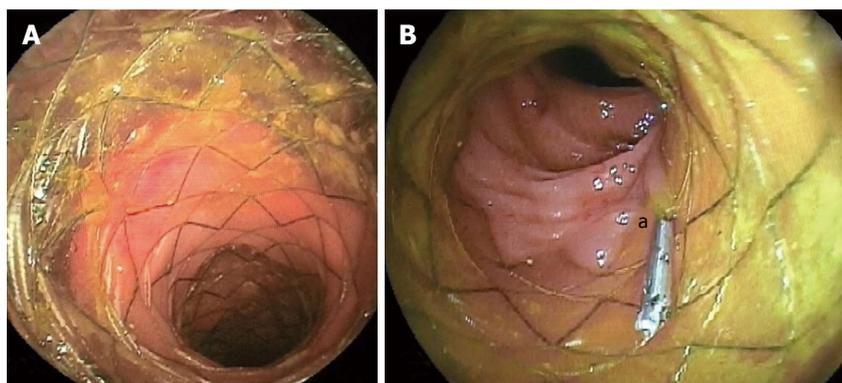

Figure 1 Self-expanding metal stent for anastomosis leakage. A: Endoscopic image after deployment of the stent; B: Stent with clip (a) at the proximal end.

in experienced hands^[1]. ALs can cause severe morbidity, cost, and affect the patient's quality of life. Moreover, major additional interventions may lead to further morbidity and mortality (with of 10%-20%)^[2]. Currently, technological developments in minimally invasive treatment modalities for ALs have caused them to be used widely. These modalities include laparoscopic repair, endoscopic self-expandable metallic stents (SEMS), endoscopic clips, over the scope clips (OTSCs), endoanal repair and endoanal sponges.

In this review, we summarize and discuss the current knowledge on minimally invasive treatment strategies for ALs after colorectal surgery.

LAPAROSCOPIC REPAIR AND MANAGEMENT

In the last two decades, there have been significant developments in the field of minimally invasive surgical procedures, including laparoscopy. Despite these advances in laparoscopic instrumentation and techniques, the laparoscopic management of AL after colorectal surgery is still under debate.

A retrospective study by Cucurullo *et al*^[3] reported that AL was the most common finding (57.1%) at laparoscopic re-intervention. In this study, 91.7% of cases were managed by anastomotic repair, peritoneal lavage and temporary diverting ostomy. Only 8.3% of ALs required a Hartmann's procedure because of gross fecal contamination. The conversion rate to open surgery was 5.6%, because of extensive colonic ischemia and generalized peritonitis. Lee *et al*^[4] also reported an 8.2% conversion rate, and all ALs were treated with ileostomy/colostomy, with or without anastomotic repair. They compared the results of open and laparoscopic management, and observed significantly shorter hospital stay, lower 30-d postoperative morbidity and complication, and improved stoma closure rate in the laparoscopic group. In other studies by Wind *et al*^[5] and Vennix *et al*^[6], the morbidity rate, hospital stay, intensive care unit admission, and incisional hernia rate were reduced in the laparoscopic re-intervention group. Furthermore, re-laparoscopy can be used as a diagnostic tool if clinical

concerns exist, despite an adjunctive diagnostic imaging with reported diagnostic accuracy between 93% and 100%^[7].

Laparoscopic re-intervention is a safe, feasible and effective technique, and can also be considered as a diagnostic option as the first therapeutic approach for evaluating suspected postoperative complications. Today, many studies encourage the use of laparoscopy for the treatment of complications following minimally invasive colorectal surgery in skilled hands.

ENDOSCOPIC SEMS, AND OTHER STENTS

The use of colonic stents has significantly evolved over the last decades as an alternative method of converting emergency surgery for obstructing colorectal cancers to safer definitive elective surgery or as palliative treatment for inoperable malignant colorectal strictures, with high success rates^[8]. Moreover, the application of colonic stents has gained increasing attention in recent years for postoperative complications following colorectal surgery, including ALs, fistulas and perforations (Figure 1). In particular, smaller ALs that are not associated with severe sepsis might benefit from colonic stenting after laparoscopic peritoneal lavage and drainage, and fashioning of stoma^[9]. By contrast, some authors considered that endoscopic stenting could be utilized in patients with or without a stoma, in combination with percutaneous drainage of infected intraabdominal collections^[10].

Several types of intestinal stent are available, such as a SEMS (uncovered, partially or fully covered), a self-expanding plastic stent, and a biodegradable stent. Colonic stent-related complications include stent migration, anorectal pain, incontinence, perforation, rectal bleeding and stent obstruction^[9,11]. The stent can only be placed across an end-to-end anastomosis, and the distal end of the stent must be no less than 5 cm proximal to the anal verge^[10-12]. Stents placed very distally in the rectum may cause increased rectal pain, tenesmus or fecal incontinence^[11-13].

The risk of stent migration is high in the lower gastrointestinal tract because of the increased intestinal motility, and has been reported in 25% to 40% of

patients^[14-16]. This rate is lower in uncovered or partially covered stents than in biodegradable and fully covered stents^[9,10,12]. Migration has been also described when large-diameter stents have been used^[11,14]. However, the use of a partially covered SEMs prevents migration and allows for tissue in-growth; however, its removal is technically difficult^[11,12]. Clips or endoscopic suturing are alternative methods to anchor the stent in place and to reduce migration risk^[14] (Figure 1B). Optimal timing of stent removal is controversial. If possible, stents should be removed after adequate healing of the dehiscence is confirmed endoscopically and following resolution of clinical signs and symptoms^[16].

A recent study found that SEMs application was successful in 86% of 22 patients with ALs following colorectal surgery^[13]. In that study, fully covered SEMs were used in 19 patients and uncovered SEMs in three patients. Stent migration occurred in only one of the 22 patients (4.5%); this patient was in the covered stent group and stent migrated 6 mo after placement. Most of the patients complained of incontinence after placement of the stent, which regressed spontaneously after an average of 14 wk.

Recent advances and innovations in stent technology have led to the development expandable polydioxanone biodegradable stents as an effective alternative treatment of AL following colorectal surgery. The biodegradable stent does not to be removed, which can decrease mucosal hyperplastic reactions and adverse events associated with stent removal, compared with metal stents^[9,10,12,14].

Based on limited data, stent placement appears to be an alternative therapeutic option for selected patients with AL after colorectal surgery when performed by skilled endoscopists. Migration and cost are the major limitations of these stents.

ENDOSCOPIC CLIPS

Application of clips to approximate the edges of the leaking anastomosis is one of the endoscopic management techniques. Standard endoclips, which are used to control small perforations and bleeding, may be used to close an AL; however, the low closure of force of these clips limit their use for more scarred, fibrotic and irradiated tissues.

The first clip was manufactured by the Olympus Corporation (Japan) in 1995. Thereafter, a disposable pre-loaded version of this clip, known as Quickclips[®] (Olympus Ltd., Tokyo, Japan), has gained popularity. Thereafter, OTSC (Ovesco Endoscopy, endoscopy, Tubingen, Germany) were introduced; and in 2011, Cook Medical from United States produced the Instinct[™] Endoscopic Hemoclip.

The OTSC is the most preferred clips to control AL. This clip is made of super-elastic nitinol, which is a biocompatible and magnetic resonance imaging-safe material, and has the benefit of a larger clip area with increased compression. Firstly, Kirschniak *et al*^[17] published their successful results using OTSC in 11 patients with bleeding or iatrogenic perforations. Application of OTSCs for leaks has since become popular. Weiland *et al*^[18] reported a general success rate of 84.6%. Arezzo *et al*^[19] used OTSCs

for colorectal surgery on 14 patients with leaks no larger than 15 mm (maximum diameter), and without luminal stenosis and abscess. Their success rate was also 86%. Occasionally, the first attempt fails, but repeated attempts will be successful in order to close the dehiscence of AL^[20].

Favorable results with OTSCs are obtained in the absence of fibrotic tissue. Closure of chronic leaks and fistulas seems to be a considerable challenge and may decrease the success rate^[21]. Contrastingly, OTSCs have significant cost benefits compared with ileostomy, and achieve full-thickness wall closure. Moreover, they require a shorter hospital stay and avoid temporary ileostomy^[19]. OTSCs can close defects up to 30 mm^[22]. Application of multiple clips may be possible for larger defects; however, there is limited experience of it^[23,24].

ENDOSCOPIC VACUUM-ASSISTED CLOSURE

Negative pressure wound therapy or vacuum-assisted closure is now a well-established treatment modality for chronic and difficult to heal wounds. Recently, this minimally invasive method has been proposed as an effective approach to manage ALs after colorectal surgery, with success rates ranging from 56.6% to 100%^[25-29]. In the original technique, after the presence of the abscess cavity is confirmed by diagnostic colonoscopy, the enteric and purulent contents are aspirated and then irrigated. Finally, an open pored, polyurethane sponge with an attached evacuation tube connected to a drainage system is inserted *via* an introducer sleeve that is fitted over an endoscope and placed through the dehiscence and into the pelvic cavity^[10,12,16,25].

The endo-sponge continuously removes secretions, improves microcirculation, and therefore induces granulation formation in the defect. It also aids closure of the pelvic cavity by the application of negative pressure of 125 mmHg^[26] (Figure 2). One disadvantage of this method is the requirement to change the sponge every 2-4 d until the abscess cavity has regressed^[25,28,29]. However, this treatment is more effective at shrinking cavities, especially when used within 6 wk after the AL^[10,30]. It should be noted that generalized peritonitis is not an indication for endo-sponge therapy^[12,25,29]; and the overall complication rates are around 20%, mainly comprising anastomosis stenosis, recidivate abscess and fistula^[26].

In 2008, a large series of endoscopic vacuum-assisted closure therapy cases was reported by Weidenhagen *et al*^[25]. In that study, definitive closure of the cavity was achieved in 28 of the 29 patients (96.6%) over a mean treatment period of 34 d (range 4-79 d). In a recent review, Strangio *et al*^[26] found that complete healing of the cavity was achieved in near 95% of cases overall, following a median of 30 d of treatment and the performance of a median of 11 sessions. The authors emphasized that endo-sponge applications might be safely performed in patients with or without a diverting ileostomy. Weidenhagen *et al*^[25] reported that four patients were treated without the construction of a divert-

F/M: Female/male; SEMS: Self-expandable metallic stent; OTSC: Over the scope clip; N/A: Data not available; VAC: Vacuum-assisted closure.

ing stoma. Similarly, Glitsch *et al*^[28] reported successful endoscopic transanal vacuum-assisted rectal drainage for AL after rectal resection in 16 of 17 patients (94.1%). They also found that the closure time was directly dependent on the cavity size, distance from anastomosis to the anal verge and the patient's age. Patients with anastomoses that were 6 cm or less from the anal verge, who were elderly (aged over 62 years), and had a cavity measuring 5 cm × 6 cm or more had considerably longer healing times.

Endoscopic vacuum-assisted closure therapy seems a safe and useful therapeutic option for the local and minimally invasive management of AL after colorectal surgery, with high success rates. However, further prospective clinical studies with randomized data and larger numbers of patients are needed to clarify the beneficial effects of endo-sponge therapy in patients with anastomotic insufficiency.

TRANSANAL REPAIR

Transanal repair is another preferred method for treatment of delayed ALs. Candidates for this method should have a documented persistent sinus or cavity diagnosed

by contrast enema, without any evidence of recurrence and co-morbidity. Transanal repair uses a primary repair or repair with flap, especially for sinus formation of AL. The flap should be prepared with skin or mucosa, although there is limited supporting data concerning this in the literature. Endorectal flap advancement is well described in ileorectal anastomotic sinuses. Blumetti *et al*^[31] published their two-center study in 2012 and reported six transanal repairs for five patients with an 80% success rate.

In 2015, Brunner *et al*^[32] reported two consecutive patients managed by transanal primary repair and irrigation of the abdominal cavity for AL after single incision laparoscopic sigmoid resection for stage II/III diverticulitis. They mentioned no residual leaks, no anastomotic strictures and normal rectal functions.

A summary of some recent successful studies managed minimally invasively after anastomotic leakage and the outcomes in SEMS, OTSC, vacuum-assisted closure and transanal repair is shown in Table 1.

CONCLUSION

Anastomotic leaks continue to be critical and life-threat-

ening events, with considerable morbidity and mortality. Patients with ALs are often critically ill, and non-operative management strategies should be the preferred first-line approach. Currently, minimally invasive treatment options are a promising alternative to surgical treatment, with satisfactory outcomes for the management of ALs. Nevertheless, there is a need for further, large, high quality, randomized, controlled trials on the long-term outcome, function and clinical efficacy of these different techniques.

Abstract

AIM

To evaluate the effectiveness of human fibrinogen-thrombin collagen patch (TachoSil®) in the reinforcement of high-risk colon anastomoses.

METHODS

A quasi-experimental study was conducted in Wistar rats ($n = 56$) that all underwent high-risk anastomoses (anastomosis with only two sutures) after colectomies. The rats were divided into two randomized groups: Control group (24 rats) and treatment group (24 rats). In the treatment group, high-risk anastomosis was reinforced with TachoSil® (a piece of TachoSil® was applied over this high-risk anastomosis, covering the gap). Leak incidence, overall survival, intra-abdominal adhesions, and histologic healing of anastomoses were analyzed. Survivors were divided into two subgroups and euthanized at 15 and 30 d after intervention in order to analyze the adhesions and histologic changes.

RESULTS

Overall survival was 71.4% and 57.14% in the TachoSil® group and control group, respectively ($P = 0.29$); four rats died from other causes and six rats in the treatment group and 10 in the control group experienced colonic leakage ($P > 0.05$). The intra-abdominal adhesion score was similar in both groups, with no differences between subgroups. We found non-significant differences in the healing process according to the histologic score used in both groups ($P = 0.066$).

CONCLUSION

In our study, the use of TachoSil® was associated with a non-statistically significant reduction in the rate of leakage in high-risk anastomoses. TachoSil® has been shown to be a safe product because it does not affect the histologic healing process or increase intra-abdominal adhesions.

Core tip: Anastomotic leakage is one of the most important complications in gastrointestinal surgery. We have performed a pioneering risk anastomosis procedure, carried out with a high risk of leakage, to test the use of thrombin and fibrinogen patch for the reinforcement and prevention of potential leakage. We obtained a significant reduction in the mortality rate without adding comorbidity. Patch application is simple and does not exceed operating time, and its use can be extremely helpful in emergency surgery or special situations that provide a high possibility of anastomosis dehiscence.

Fibrinogen-thrombin collagen patch reinforcement of high-risk colonic anastomoses in rats. *World J Gastrointest Surg* 2016; 8(9): 627-633 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i9/627.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i9.627>

INTRODUCTION

Anastomotic leakage is a severe post-operative complication that can threaten a patient's life. It has a mean incidence in the published literature of 4%-8%, and its mortality can reach up to 22%^[1,2]. Several methods have been used to attempt to reduce anastomotic leakage associated with colonic surgery, with diverse results. As some authors have reported, staplers are the only method that maintains the incidence of anastomotic leakage under 10%^[3]. Other authors have used glues and tissue sealants to reinforce the suture. Cyanoacrylates and fibrin glues are most often used, with varying results in the literature; some studies state that the use of cyanoacrylates and fibrin sealants in this kind of surgery is both efficient and advantageous^[4,5], while others have failed to demonstrate such benefits^[6]. Few studies have analyzed other materials, such as TachoSil®, a human fibrinogen and thrombin patch. TachoSil® contains human fibrinogen, human thrombin, and the following excipients: Equine collagen, human albumin, riboflavin (E101), sodium chloride, sodium citrate (E331), and L-arginine-hydrochloride. TachoSil® is indicated in adults as a supportive treatment in surgery for the improvement of hemostasis, the promotion of tissue sealing, and for suture support in vascular surgery where standard techniques are insufficient. Experimental studies have tried to assess if this product can improve the results of colonic anastomoses, with diverse results^[7-10]. An important aspect of this topic is the definition of high-risk anastomoses. Tebala *et al.*^[5] defined this kind of anastomoses as including emergency surgery, ischemic or inflammatory tissues, esophagus or extraperitoneal rectus, and immunosuppression.

We hypothesized that colonic anastomosis carried out under poor conditions can be improved with the use of TachoSil® by decreasing anastomotic leakage and its complications.

MATERIALS AND METHODS

Study design

A prospective, comparative, semi-experimental study in animals was conducted to analyze the effects of the application of a human fibrinogen-thrombin patch (TachoSil®) over high-risk anastomosis sites. The hypothesis was that this product would decrease the incidence and severity of colonic leakage. We compared the results with a control group in which there was only high-risk anastomosis. The study was carried out under the conditions established by the Helsinki statement,

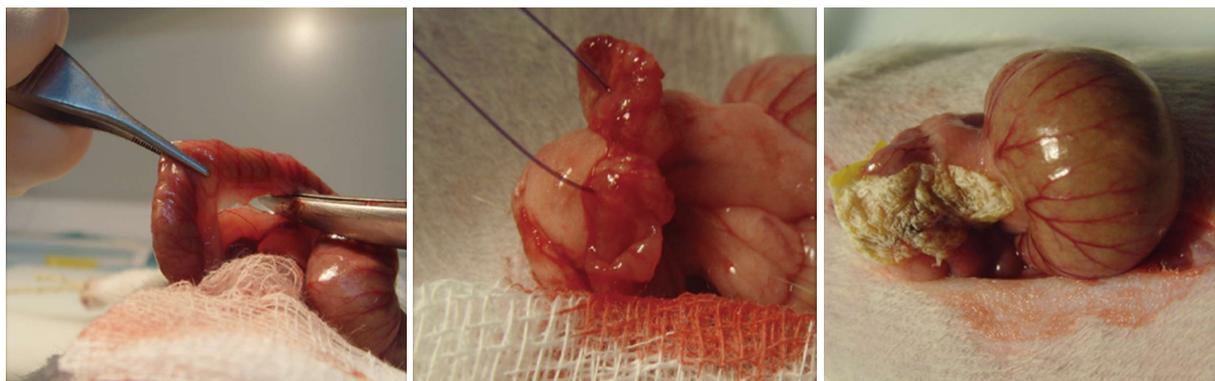

Figure 1 Surgical technique.

Table 1 Adhesive score

Adhesive score
0: No adhesions
1: Extremely soft adhesions
2: Stronger adhesions, but dissectible with dull dissection
3: Stronger adhesions only dissectible with sharpen tools
4: Stenosis

which regulates the terms and conditions for animal experiments. There was no competing interest for any of the authors. The authors did not receive any grant or sponsorship for this study. Materials were donated by the Department of Surgery of the University Hospital of Virgen del Rocío and Riotinto Hospital.

Animals

This study was performed on 56 white Wistar rats of both sexes weighing between 250 g and 350 g. Animals were divided into two groups (control group and treatment group), each consisting of 28 individuals. High-risk anastomosis was performed in all rats. A piece of fibrinogen-thrombin sealant was added that covered the entire anastomosis site in the treatment group.

Technical procedure

Anesthesia was induced with intraperitoneal ketamine (20 mg/kg), after which a laparotomy was performed. We then performed a partial colectomy of 2-3 cm just after the cecum, which was closed with an anastomosis with only two stitches of 4-0 monocryl in the mesenteric and anti-mesenteric borders of the colon. In addition, a 2 cm × 2 cm piece of TachoSil® was applied over the anastomosis, with light compression using small, wet gauze in the treatment group. Each piece was lightly wetted with 0.9% saline. The gauze was gently removed and the anastomosis site checked after 5 min to ensure the TachoSil® was in the proper location. The laparotomy was closed with 3-0 vicryl suture in a simple continuous suture for the muscle plane and 3-0 silk in a simple interrupted suture for the skin (Figure 1).

The early deceased animals underwent necropsy in order to establish the cause of death. The survivors

were euthanized at 15 and 30 d post-operatively after a randomized process. During necropsy, the formation of intra-abdominal adhesions was quantified with a numeric scale (Table 1) to compare both groups at 15 and 30 d post-operatively. In all animals, colonic anastomosis was retrieved to analyze the histopathologic healing process according to the Biert scheme (Table 2), which analyzed nine parameters. The histologic analysis, using hematoxylin and eosin staining, was performed by a pathologist blinded for the two groups.

Statistical analysis

The program used for statistical analysis was SPSS v16 for Windows, and the statistical review was performed by a biomedical statistician. Numerical results were analyzed using means and standard deviations. The Kaplan-Meier method was used to assess survival. Leakage incidence was analyzed with the χ^2 test for dichotomous variables. The intra-abdominal adhesion score was compared between groups with the Mann-Whitney test, as the variable was qualitative. The histopathologic healing process was analyzed with the Student's *t*-test, with sub-analysis performed with the Mann-Whitney test when necessary. A *P* value < 0.05 was considered significant.

RESULTS

Survival and leakage incidence

The number of events, defined as death as a consequence of colonic leakage, was 10 (35.7%) in the control group and 6 (21.4%) in the TachoSil® group. All deaths happened before the fourth post-operative day. Four animals in both groups died due to other causes, namely hemorrhage, post-anesthesia and bowel obstruction, with no relation to the experimental study. The mean survival per group was 19.5 ± 2.6 (control) and 23.7 ± 2.2 d (TachoSil®). With these results, the overall survival was 57.14% and 71.4% in the control and TachoSil® groups, respectively (*P* = 0.29) (Figure 2), with no significant differences between the groups.

Intra-abdominal adhesions

The results are shown in Table 3. We performed com-

Table 2 Histopathologic Biert' scheme

Parameters	Score			
	0	1	2	3

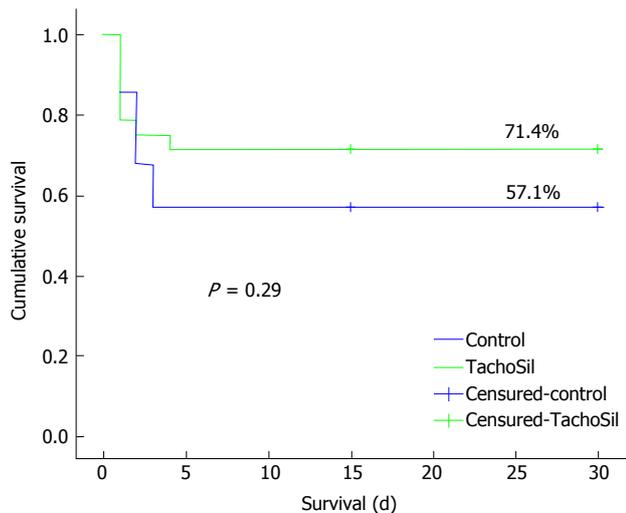

Figure 2 Survival in both groups.

parisons according to both the time (15 d vs 30 d) and group [control (16 rats) vs TachoSil® (20 rats)]. Distribution of animals sacrificed: control-15 d = 9 rats, control-30 d = 7 rats; TachoSil-7 d = 10 rats, TachoSil-15 d = 10 rats. The adhesion score was significantly different when comparing all groups according to the time, showing a much better score in animals euthanized at day 30. However, no differences were found at day 15 or day 30 when comparing groups.

Histopathologic healing process

Healing of the anastomoses was analyzed following the Biert scheme. The global results are shown in Figures 3 and 4.

Only four parameters (Table 4) showed significant

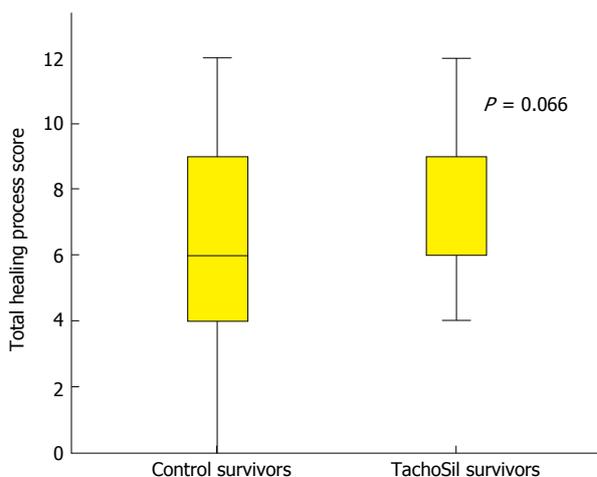

Figure 3 Healing of the anastomoses in both groups.

differences between the control and TachoSil® groups with the Student's *t*-test, and were always worse in the TachoSil® group polymorphonuclear cells 0.21 ± 0.42 vs 0.78 ± 0.64, *P* = 0.01; macrophages 0.50 ± 0.65 vs 0.89 ± 0.47, *P* = 0.026; oedema 0.43 ± 0.64 vs 0.94 ± 0.63, *P* = 0.017; and epithelium regeneration 0.64 ± 0.92 vs 1.11 ± 0.58, *P* = 0.031. The rest of parameters were similar between groups.

When we applied the total score for this analysis, defined as the sum of all values of each parameter, we found nearly significant differences between groups. Among all survivors, the control group had a mean total healing score of 6.21 ± 3.21, whereas the TachoSil® group had a mean of 8 ± 2.05 (*P* = 0.066) (Figure 3).

Sub-analysis of this total healing process score accord-

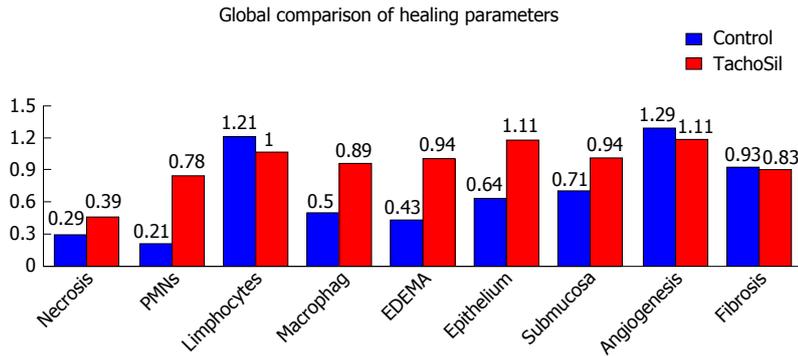

Figure 4 Global comparison of healing parameters. PMNs: Polymorphonuclear cells.

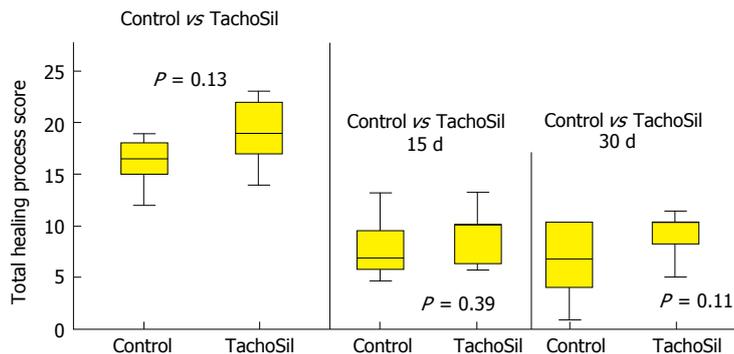

Figure 5 Healing process scores at 15 d and 30 d, and global analysis in surviving animals.

ing to the post-operative day (15 and 30 d) did not show statistically significant differences, but we did see a trend towards a worsened healing process in the TachoSil® group, especially at the end of the period. On days 15 and 30, the results were 7.5 vs 9.5 ($P = 0.39$) and 6.17 vs 9.9 ($P = 0.112$) in the control group vs the TachoSil® group, respectively (mean ranges) (Figure 5). There were no differences when the analysis was performed between groups (global analysis) (7.15 vs 10.75; $P = 0.13$).

DISCUSSION

Colonic anastomosis failure can be a life threatening complication following colonic surgery. Over time, great efforts have been made to improve the results of this procedure and define the risk factors for anastomosis failure^[1,2,11]. Systemic factors (such as diabetes and steroid use) and local factors (such as radiotherapy and tension or hemorrhage in the suture) can lead to a poor result in the healing process of the colon^[12-14]. The period in which a leak occurs is usually between days 5 and 6 post-operation. Before this period, the strength of anastomosis is mainly held by the suture, but after day 5 or 6 the healing process of the colonic wall, especially with regards to the collagen formation, is most important, as the suture material loses efficacy at that time. A variety of products^[6,15-19] have been used to reinforce intestinal anastomoses (e.g., cyanoacrylate, fibrin sealants, amniotic, collagen and dura mater membranes, and mechanical staplers), all with different results. The application of a

fibrinogen and thrombin patch over colonic anastomoses is a relatively new idea^[7]. Some authors^[19,20] used the classical cecal puncture model to define high-risk anastomosis, thereby providing the sepsis model^[20-24]. To date, there has not been any consensus regarding the definition of high-risk anastomosis and, to our knowledge, there have been few studies that have examined the application of TachoSil® over colonic anastomoses^[7-10,20-24], with only one carried out using a high-risk anastomosis^[10]. Although these studies showed the method to be safe and feasible, some results have been controversial; Ozel *et al*^[7] showed that this product increased the inflammatory reaction and led to a worsened healing process with less mechanical strength. In contrast, Stumpf *et al*^[9] found that it led to a better histopathologic healing process as a consequence of the decrease in suture material in the anastomotic line and that a suture-free anastomosis is reliable. Norden-toft *et al*^[8,22] studied this product applied over normal small-bowel anastomoses and found no differences in the mechanical strength, degree of stenosis, or healing process, with the incidence of anastomotic leakage also being similar between groups. In our study, we noted an evident reduction of anastomotic leakage incidences (31.7% vs 21.4% in control and TachoSil® groups, respectively), but these differences were not significant ($P = 0.29$). Even when a potentially injurious agent such as 5-fluorouracil is used, it has been verified that applying anastomosis TachoSil® confers greater resistance by acting as a protective agent^[24]. In a study using mice, Pantelis *et al*^[10] achieved a statistically significant difference in

the lethality and leakage rates in the group that received TachoSil[®], as well as finding that its use did not increase the formation of intra-abdominal adhesions. They did not find any differences between groups. In studies that analyzed the use of TachoSil[®] in bowel anastomoses, Nordentoft *et al*^[8] reported no differences between groups. In contrast, Ozel *et al*^[7] noted that TachoSil[®] increased the formation of peri-anastomotic adhesions. Regarding the histopathologic healing process, we found neither advantages nor disadvantages when TachoSil[®] was applied. However, when we analyzed this process with both individual and global scores, some individuals were statistically different with regards to group (control or treatment), but when the global score was compared, no differences were observed. Some authors, such as Ozel, affirmed that if TachoSil[®] is used, the neutrophilic granulocyte count can increase, and this carries a worsened prognosis for healing as a result of excessive metalloproteinases. These results were also observed by van der Ham *et al*^[21]. In contrast, Pantelis observed that if TachoSil[®] is applied in high-risk anastomosis, an improvement in the healing process can be observed. In our study, the healing process is exacerbated and inflammatory parameters were increased when TachoSil[®] was used, compared to the control group. However this does not affect the creation of useful anastomosis, only higher growth of tissue in the area where it is applied, accompanied by obvious signs of inflammation. This has not affected the result of the study and the rate of leakage has decreased, therefore we believe that a stronger healing process is useful in reinforcing the consistency of anastomosis.

We think that, despite the worsened healing in some individual parameters in the TachoSil[®] group, the improvement in leak incidence can be explained by the sealant effect of the collagen patch (*i.e.*, the mechanical sealant achieved by this sponge, which is a well-established effect of this product)^[7,8,23].

In conclusion, our study showed that the application of TachoSil[®] led to a non-statistically significant decrease in both mortality and anastomotic leakage rates. Furthermore, the use of this product did not affect the histopathologic healing process or increase the formation of adhesions, and so it can be regarded as a very safe product. We focused on the importance of the mechanical effect of TachoSil[®] in sealing the anastomosis gap. The use of TachoSil[®] is not justified in routine colonic surgery due to the low colonic anastomotic leakage rates in those procedures. Although we demonstrated that TachoSil[®] does not decrease the complication rate in high-risk anastomoses, based on the controversial data existing in the literature, we recommend that clinical studies should be performed to clarify this topic, as it may have potentially important effects in surgery.

anastomosis in rats. The hypothesis to be tested is decreasing anastomotic leaks using this product. The triple-blind comparative results confirm a decrease in leakage anastomotic.

Research frontiers

The main frontier of the study is the reduction of anastomosis leakage in anastomosis with risk factors.

Innovations and breakthroughs

Decreasing the rate of leaks in anastomosis using an absorbable sheet on the anastomosis when the procedure was performed in high-risk conditions.

Applications

The results can be applied in digestive surgery (*i.e.*, intestinal and colorectal anastomosis), especially in emergency surgeries and patients with high comorbidities.

Peer-review

This manuscript showed the potential application of TachoSil[®] in colonic sutures after surgery. The study was straight-forward and rational. The application apparently has some merits.

Abstract

AIM

To identify the current indications and outcomes of total pancreatectomy at a high-volume center.

METHODS

A single institutional retrospective study of patients undergoing total pancreatectomy from 1995 to 2014 was performed.

RESULTS

One hundred and three patients underwent total

pancreatectomy for indications including: Pancreatic ductal adenocarcinoma ($n = 42$, 40.8%), intraductal papillary mucinous neoplasms ($n = 40$, 38.8%), chronic pancreatitis ($n = 8$, 7.8%), pancreatic neuroendocrine tumors ($n = 7$, 6.8%), and miscellaneous ($n = 6$, 5.8%). The mean age was 66.2 years, and 59 (57.3%) were female. Twenty-four patients (23.3%) underwent a laparoscopic total pancreatectomy. Splenic preservation and portal vein resection and reconstruction were performed in 24 (23.3%) and 18 patients (17.5%), respectively. The 90 d major complications, readmission, and mortality rates were 32%, 17.5%, and 6.8% respectively. The 1-, 3-, 5-, and 7-year survival for patients with benign indications were 84%, 82%, 79.5%, and 75.9%, and for malignant indications were 64%, 40.4%, 34.7% and 30.9%, respectively.

CONCLUSION

Total pancreatectomy, including laparoscopic total pancreatectomy, appears to be an appropriate option for selected patients when treated at a high-volume pancreatic center and through a multispecialty approach.

Key words: Intraductal papillary mucinous neoplasms; Laparoscopic total pancreatectomy; Pancreatic ductal adenocarcinoma; Laparoscopy; Pancreas cyst; Pancreas cancer

Total pancreatectomy: Short- and long-term outcomes at a high-volume pancreas center. *World J Gastrointest Surg* 2016; 8(9): 634-642 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i9/634.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i9.634>

INTRODUCTION

In selected patients, total pancreatectomy (TP) has been established as a potential option in the treatment of pancreatic ductal adenocarcinoma (PDAC), invasive or diffuse intraductal papillary mucinous neoplasms (IPMN), multiple pancreatic neuroendocrine tumors (PNET)^[1-4]. TP is still also one of the treatment modalities in chronic pancreatitis with severe pain, pancreatic fistula or hemorrhage after pancreaticoduodenectomy (PD)^[3,5-7]. Improvement in postoperative management, including better pancreatic enzyme formula, long-acting insulin, and autologous islet cell transplantation, has made TP

a viable choice in the treatment of different pancreatic diseases^[8,9].

Although TP is performed at an increasing rate at major pancreatic centers, there is still debate regarding its indications and outcomes^[2-4]. This study aimed to analyze the indications and short- and long-term outcomes of TP in the spectrum of pancreatic resections in our high-volume center.

MATERIALS AND METHODS

We conducted a retrospective study of 103 patients who underwent TP between March 1995 and December 2014 at Mayo Clinic in Jacksonville, Florida using data collected from an institutional review board-approved prospective database.

The preoperative data, including demographic data and clinical picture, operative details, and postoperative data were collected and analyzed.

Operative strategy

The American Society of Anesthesiologists classification^[10] and Eastern Cooperative Oncology Group performance status^[11] were used for evaluation of the preoperative risk. All patients were optimized medically prior to surgery.

TP was performed either open or laparoscopic. It was done as pylorus-preserving, standard, or completion TP (of previous distal pancreatectomy or PD). The operation was done with and without splenectomy.

In cases with partial resection in pancreatic tumors, the specimen margin was analyzed by frozen section. The procedure was converted to TP if the margins showed carcinoma *in situ* or invasive carcinoma. TP was not performed for frozen section findings of moderate dysplasia or adenomatous changes at the margin. International consensus guidelines for the management of patients diagnosed with IPMN was used throughout the study time period, as appropriate. Guidelines from 2006^[12] were followed up until these were updated in 2012^[13].

The International Study Group of Pancreatic Surgery (ISGPS) classification of venous resection was used as follows^[14]: Type I: Partial venous resection with direct closure (venorrhaphy); Type II: Partial venous excision with closure by patch graft; Type III: Excision with primary end to end venous anastomosis; Type IV: Venous resection with interposition venous graft.

Histopathological data on pancreatic tumor staging were collected according to the tumor, node and metastases staging system. IPMN pathology was defined as per World Health Organization criteria into 4 categories based upon the degree of dysplasia: Adenoma, border line (low-moderate dysplasia), carcinoma *in situ* (CIS) high-grade dysplasia), or invasive carcinoma^[2]. PDAC without IPMN was considered to be de novo, but PDAC associated with IPMN was considered to be arisen from these IPMN.

Postoperative complications occurring in the first 90 d

Table 1 Demographics for 103 patients undergoing total pancreatectomy with subgroup analysis

Variable	Overall (n = 103)	PDAC (n = 42)	IPMN (n = 40)	LTP (n = 24)
Age, yr ¹	70.2 (32-84.5)	70.3 (33.3-84.5)	71.3 (42.9-81.1)	70.3 (37.3-84.5)

after surgery were graded from (0 to 5) according to the Clavien system^[15]. Grade I and II complications were considered minor and Grade III, IV and V were considered major complications. International consensus guidelines were used to evaluate specific complications^[16,17]. Major glycemic events included complications or readmissions related to severe hyperglycemia or hypoglycemia. Cardiac complications, pulmonary complications, renal insufficiency, or hepatic insufficiency were defined as temporary organ system dysfunction requiring supportive care over the usual standard postoperative measures.

The follow-up period (1-18 years) was from date of surgery. Any death during the hospital stay or within the first 90 d after surgery was defined as perioperative mortality. Readmissions to any facility were recorded for 90 d after surgery.

After analysis of results and outcomes from our previous publication in 2009^[4], patients undergoing consideration for total pancreatectomy were sent for preoperative evaluation and counseling by a nutrition and endocrine team for the anticipated exocrine and endocrine insufficiency caused by surgical intervention. Postoperatively, patients were seen and followed in the hospital setting by the inpatient nutrition and endocrine team for ongoing education and management regarding the subsequent pancreatic insufficiency. Insulin and enzyme replacement were determined according to individual patient needs. In addition, percutaneous jejunostomy feeding tube placement became a standard procedure during TP after 2009, and many patients were started on enteral tube feeds in the hospital setting and continued on after discharge to aid in avoiding readmissions for malnutrition.

Postoperatively, patients were treated on the medical-surgical floor and intensive care use was not routine unless indicated. Perioperative use of parenteral nutrition and blood product transfusion was also limited unless indicated. Based on final pathology, adjuvant

treatments including chemotherapy or radiotherapy were recommended to patients undergoing TP for periampullary adenocarcinoma.

Statistical analysis

Data were collected and analyzed by a biomedical statistician using SPSS version 21.0 (SPSS Inc., Chicago, IL, United States). A Kaplan-Meier curve was used for the analysis of survival.

RESULTS

From March 1995 to December 2014, 983 pancreatic resections were performed for benign and malignant pancreatic diseases; TP was performed in 103 patients (10.5%). The demographic and preoperative clinicopathological data are listed in Table 1. Subgroup analysis for those undergoing TP for PDAC and IPMN is shown. Indications for TP (rather than partial pancreatectomy) was multifocal disease (55 patients, 53.4%), positive margins (23 patients, 22.3%), elective completion TP for recurrence of the primary pathology (5 patients, 4.9%), or other (20 patients, 19.4%). There were no cases with emergent TP as treatment for postoperative pancreatic fistula (POPF) or hemorrhage from patients undergoing partial pancreatectomy in this study. POPF was treated with interventional radiological procedures, and in this study, all completion TP was performed in an elective fashion for pancreatic pathology.

Overall, 79 patients (76.7%) underwent an open TP. Laparoscopic TP (LTP) was attempted in 31 patients (30.1%), and conversion to open occurred in 7 patients (22.6%) due to adhesions from chronic pancreatitis in 5 patients, bleeding in 1 patient, and portal vein involvement by the tumor in 1 patient. Of the 24 patients who did not require conversion from LTP, a hand-assisted approach was used for 2 patients, and subgroup analysis is given in the tables. LTP was introduced in November

Table 2 Operative variables for 103 patients undergoing total pancreatectomy with subgroup analysis

Variable	Overall (n = 103)	PDAC (n = 42)	IPMN (n = 40)	LTP (n = 24)
Operative time (min) ¹	426 (165-930)	390 (165-636)	435 (240-930)	534 (234-770)
Estimated blood loss (mL) ¹	500 (50-18000)	500 (50-7800)	525 (50-18000)	200 (50-600)
Intraoperative pRBC transfusion (unit) ¹	1 (0%-40%)	2 (0%-30%)	1 (0%-40%)	0 (0%-2%)
Vein resection	18 (17.5%)	13 (40%)	4 (10%)	1 (4.2%)

¹Values are median (range), values in parenthesis are percentages unless otherwise indicated. IPMN: Intraductal papillary mucinous neoplasm; LTP: Laparoscopic total pancreatectomy; PDAC: Pancreatic ductal adenocarcinoma; pRBC: Intraoperative packed red blood cell.

2008, and a total of 52 patients (50.5%) had TP after this date. Of these, 28 (53.8%) underwent open surgery and 24 (46.2%) underwent LTP. Spleen-preserving TP was done in 29 patients (28.2%), four of whom underwent spleen-preserving LTP.

Operative variables are found in Table 2. LTP was found to have longer operative times, but less blood loss. Vein resection was performed in 18 patients (17.5%). The resections were conducted according to the ISGPS classification of vein resection, which included type I (lateral venorrhaphy) in 4 patients (22.22%), type II (patch graft) in 2 (11.11%; 1 from gonadal vein and 1 from bovine graft), type III (primary anastomosis) in 6 (33.33%), and type IV (interposition venous graft) in 6 (33.33%; 4 by 14 mm polytetrafluoroethylene synthetic graft, 1 from gonadal vein, and 1 from splenic vein). One patient of LTP had venous resection and laparoscopic lateral venorrhaphy.

Table 3 gives the 90-d complications and postoperative outcomes, including length of stay and readmission rate, for those undergoing TP overall and by subgroup. Major postoperative complications were found in 33 (32%) patients, and reoperation was done for 7 patients (6.8%) due to abdominal collections (4 patients), post-pancreatectomy hemorrhage (2 patients), and intestinal fistula not responding to conservative or radiological interventions (1 patient).

Pathological indications for TP are listed in Table 4. PDAC and IPMN were the most common indications for surgery. Sixty-two patients (60.2%) were found to have IPMN upon final pathology. Forty patients (38.8%) had this as the only pathologic process, while IPMN was associated with other pancreatic pathology in 22 patients (21.4%).

Twenty of 42 patients with PDAC (47.6%), had tumor recurrence; 10 (50%) had distant metastasis (mainly to the liver and lung), 3 (15%) local recurrence, and 7 (35%) had both distant and local recurrence. The mean time of recurrence was 9.5 mo (range: 2.5-27 mo).

Overall, the 90-d perioperative mortality was 7 patients (6.8%). The 1-, 3-, 5-, and 7-year total survival rate for all 103 patients were 73.7%, 61.3%, 57.5%, and 53.8%, respectively (Figure 1A). The 1-, 3-, 5-, and 7-year survival for patients without malignant tumors (50 patients) were 84%, 82%, 79.5%, and 75.9%, respectively, while in patients with malignant findings (53 patients) the survival rates were 64%, 40.4%, 34.7%,

and 30.9%, respectively. The 1-, 3-, 5-, and 7-year survival rates in patients who had PDAC (42 patients) were 59.5%, 29.2%, 21.9%, and 18.3%, respectively (Figure 1B).

The 1-, 3-, 5-, and 7-year survival rates in patients with non-invasive IPMN (44 patients) were 84.1%, 76.9%, 73.8%, and 70.1%, respectively, while in patients with invasive IPMN (18 patients) the survival rates were 77.8%, 44.8%, 37.3%, and 29.8%, respectively.

DISCUSSION

Enthusiasm for TP has varied with time. This major operation should be assessed carefully for operative risk and postoperative outcomes after the loss of the exocrine and endocrine functions of the pancreas^[1,3].

Murphy *et al*^[5] reported that there was an increase in the rate of TP in the United States between 1998 and 2006. In about a 20-year span, 50.5% of the TP on this series were performed during the last 6 years of the study. In this publication, there was increased utilization of elective TP, especially after early diagnosis of multifocal pancreatic pathologies like IPMN and multiple PNET, and the role of TP in the management of chronic pancreatitis was limited only to patients with refractory pain not responding to medical treatment.

On the other hand, there was significant decline in the use of emergency TP as in POPF and hemorrhage. This was mainly due to better use of radiologic drainage and arterial embolization which became available and preferable to relaparotomy^[6]. In our study, we had only 1 patient who underwent an emergency TP for abdominal trauma.

The recommendations of the international consensus guidelines in the management of IPMN depended on its site in the main duct or side branches and its clinical and morphological picture in preoperative imaging study. TP should be performed in patients with positive multiple surgical margins for invasive IPMN or high-grade dysplasia on frozen section^[13]. In our study, the existence of main duct IPMN as the primary pathology accounted for 38.8% of all TP performed, and IPMN associated with other tumors accounted for 21.4%, but elsewhere IPMN has been reported to encompass 22% of all TP performed^[3].

Dallemagne *et al*^[18] demonstrated the feasibility

Table 3 Postoperative outcomes and complications (90 d) for 103 patients undergoing total pancreatectomy

Variable	Overall (n = 103)	PDAC (n = 42)	IPMN (n = 40)	LTP (n = 24)
Cardiac	10 (9.7%)	5 (11.9%)	3 (7.5%)	1 (4.2%)

Length of stay, d ¹ (range)	9 (3%-71%)	9 (3%-71%)	10 (4%-67%)	8 (4%-52%)
Readmission	26 (25.2%)	12 (28.6%)	8 (20%)	3 (12.5%)

¹Values are median (range), values in parenthesis are percentages unless otherwise indicated. IPMN: Intraductal papillary mucinous neoplasm; LTP: Laparoscopic total pancreatectomy; PDAC: Pancreatic ductal adenocarcinoma.

and advantage of TP with the laparoscopic approach. They reported two cases of TP with pylorus and splenic preservation with good postoperative outcomes. Blood loss, intensive care unit length of stay, and overall hospital length of stay were shorter^[19-21]. Asbun and Stauffer also reported 11 patients with LTP^[19].

Zeh *et al.*^[22] and Buchs *et al.*^[23] reported that robotic assistance LTP can offer more advantages. Giulianotti documented five cases with laparoscopic robotic surgery, with spleen-preserving technique in two of them (Kimura technique)^[24]. Also, Boggi *et al.*^[25] showed the feasibility of robot-assisted LTP in a series of 11 patients without conversion to open surgery.

Choi *et al.*^[26] and Ferrone *et al.*^[27] reported four patients with laparoscopic-assisted pylorus and spleen-preserving TP with segmental excision of the splenic artery and vein (Warshaw's procedure), but with a small midline opening for completion of the anastomosis.

In our study, 24 patients underwent full LTP, 16 underwent pylorus-preserving LTP, and 5 underwent spleen-preserving LTP. Patients with LTP had a higher negative margins rate and significantly more lymph nodes removed than in open surgery.

There are still high postoperative complications after TP. In our study, 32% of patients had a major complication after TP. This matches with other series that had complication rates of 32%-54%^[4,28]. However,

the complications after partial resection and TP were not significantly different in one study done on 124 patients with TP^[29].

The postoperative outcomes related to exocrine and endocrine pancreatic functions may affect the enthusiasm for TP. Postoperative diabetes may be difficult to control, with reported mortality from hypoglycemia^[30,31]. In our study, no such deaths were reported. The improvements in insulin, well-trained nurses, and exposure to a diabetic care team prior to the procedure led to dramatically improved diabetic outcomes post-TP^[30,32]. Since 2008, at our institution, we have implemented a preoperative TP pathway in which patients receive glucose management, enzyme replacement, and nutritional education prior to the operation. The indications and management decisions are done through discussion at a multidisciplinary Pancreas Board that is held on a weekly basis.

Wu *et al.*^[33] reported that islet autotransplantation (IAT) is a safe modality for patients who had chronic pancreatitis and underwent TP, and a significant number of patients can achieve insulin independence for a long time after receiving enough islet equivalent per kg body weight. None of our patients who underwent TP for chronic pancreatitis were candidates for TP and IAT as all had concerns for neoplasia. Any candidate for TP and IAT are sent to those referral centers. Hence, there is a possible bias towards a small number of patients

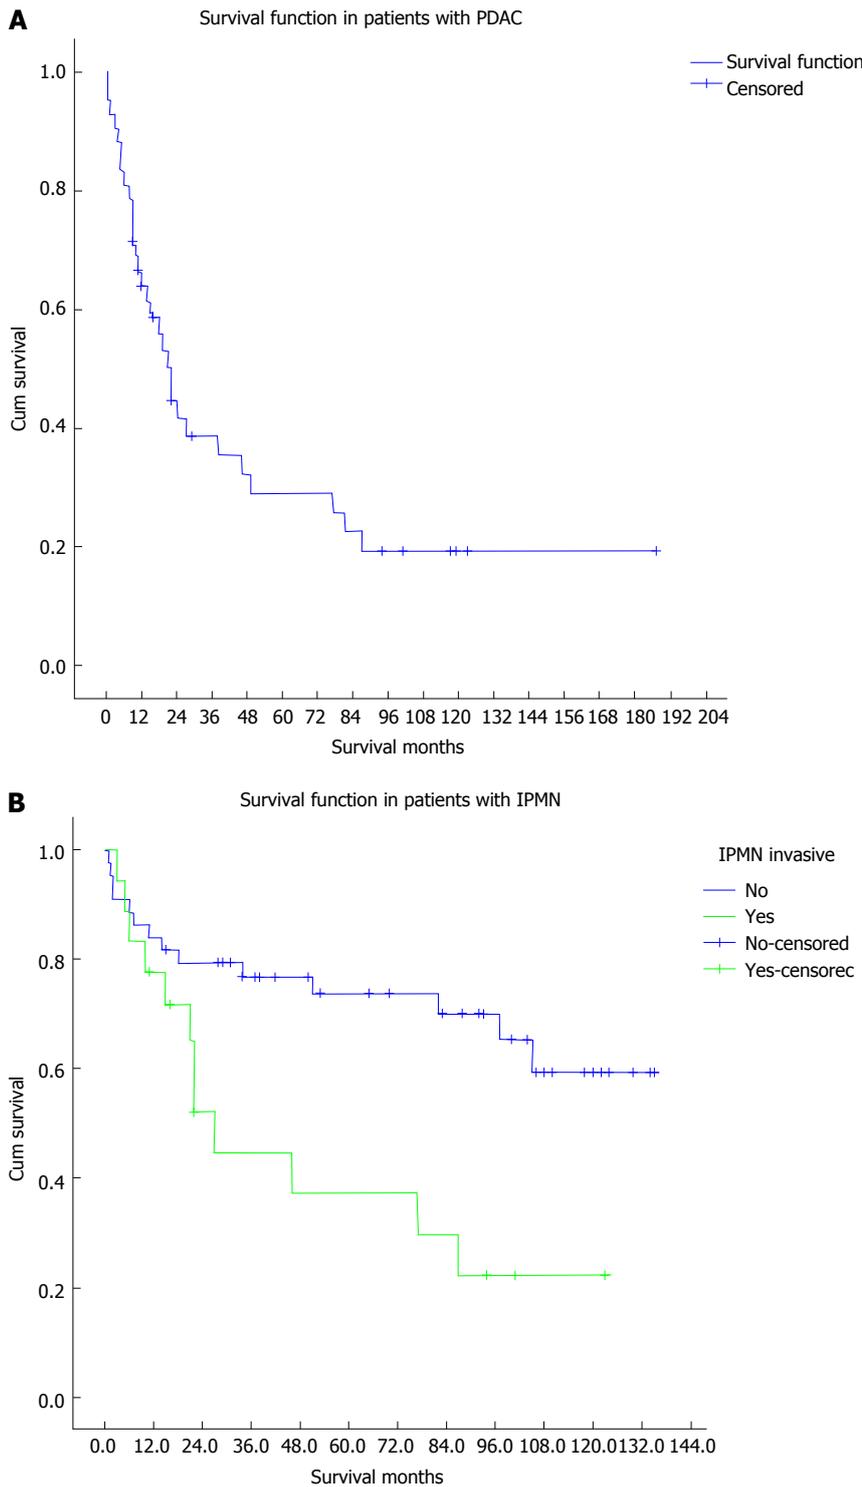

Figure 1 Kaplan Meier curve for survival. A: Survival in patients with pancreatic ductal adenocarcinoma; B: Survival in patients with intraductal papillary mucinous neoplasms. PDAC: Pancreatic ductal adenocarcinoma; IPMN: Intraductal papillary mucinous neoplasms.

undergoing TP for chronic pancreatitis at our institution.

The development of enzyme replacement formulations and the use of the duodenum-preserving TP have improved morbidity from exocrine insufficiency. However, in one study, the pylorus-preserving TP was not associated with significantly different nutritional status than the standard TP^[34].

Intraoperative frozen section analysis of the resection

margins during partial pancreatectomies is important to emphasize R0 resection. There was a significantly better survival in patients undergoing completion TP after positive margins during PD than patients undergoing R1 resection in a study done on 33 patients with PDAC^[35]. In our study, 21.4% of the patients who underwent distal pancreatectomies and pancreaticoduodenectomies also had positive resection margins in the pathological study

Table 4 Pathologic findings for 103 patients undergoing total pancreatectomy

Variable	Overall (n = 103)	LTP (n = 24)
Malignant	n = 53	n = 12
Pancreatic ductal adenocarcinoma	42 (40.8%)	5 (20.8%)
<i>De novo</i>	23 (22.3%)	3 (12.5%)
Arising from IPMN	19 (18.5%)	2 (8.3%)
Neuroendocrine	7 (6.8%)	6 (25%)
Cholangiocarcinoma with IPMN	1 (0.97%)	0
Ampullary adenocarcinoma with IPMN	1 (0.97%)	1 (4.2%)
Renal cell carcinoma	1 (0.97%)	0
Sarcoma	1 (0.97%)	0
Tumor size, cm ¹	3.5 ± 2.4 (0.5%-14%)	3.2 ± 2.5 (1.3%-10%)
Margin negative (R0)	41 (77.4%)	11 (91.7%)
Number of lymph nodes harvested ¹	23 ± 14 (1%-61%)	28 ± 11 (11%-41%)
Non malignant	n = 50	n = 12
IPMN	40 (38.8%)	11 (45.8%)
Chronic pancreatitis	8 (7.8%)	1 (4.2%)
Ampullary adenoma with IPMN	1 (0.97%)	0
Trauma	1 (0.97%)	0

¹Values are mean (range), values in parenthesis are percentages unless otherwise indicated. IPMN: Intraductal papillary mucinous neoplasm; LTP: Laparoscopic total pancreatectomy.

and required TP in the same operative sitting.

Survival of patients undergoing TP varied according to the underlying disease process. Patients with benign disease had a high survival rate whereas those with invasive IPMN or other malignant tumors had poor survival as shown in our study. Some institutions reported high operative mortality rates to be greater than 20% and associated with high morbidity, and this led these centers to stand against the role of TP^[36-38]. However, recent institution series have reported lower perioperative mortality rates to be 3%-6.1%^[4,5,32], which was near to our 90-d perioperative mortality rate of 6.8%. The improved results in recent years are likely due to improvements in perioperative support, education, and possibly, enhanced surgical technique.

In a recent study, Johnston *et al.*^[7] reported that the first month perioperative mortality after TP was 5.5%. The median survival was 15 ms, and the 1-, 3-, and 5-year overall survival rates were 60%, 22% and 13%, respectively. In multivariate analysis, the factors that affected survival were age, positive lymph nodes, positive surgical margin, tumor grade, tumor size, and adjuvant chemotherapy.

Baiocchi *et al.*^[2] and Salvia *et al.*^[39] reported that IPMN was resectable in 90%-100% of the patients. The survival rates for CIS, invasive carcinoma, and presence of nodal metastasis were 80%-90%, 50%-70% and 40%-50%, respectively.

The role of emergency TP is declining in favor of alternative interventional radiological strategies for the management of POPF and hemorrhage. Venous reconstruction in appropriately selected patients with PDAC and locally advanced tumor can be done safely

without negatively affecting recurrence or survival when compared to patients without vein involvement by the tumor. LTP appears to be a feasible and safe procedure when performed by experienced hands at a high-volume center. The significant metabolic derangements after TP may not become immediately apparent in the post-operative inpatient recovery phase, and may lead to a high rate of readmissions later on, so strict follow-up protocol should be available for these patients. A multidisciplinary approach with all-encompassing peri-operative education that includes diabetic and nutritional counseling appears to be essential in the successful management of these patients.

ACKNOWLEDGMENTS

The authors would like to acknowledge the assistance provided by Mauricia Buchanan in data collection.

COMMENTS

Background

In selected patients, total pancreatectomy (TP) has been established as a potential option in the treatment of pancreatic ductal adenocarcinoma, invasive or diffuse intraductal papillary mucinous neoplasms, multiple pancreatic neuroendocrine tumors.

Research frontiers

A single institutional retrospective study of patients undergoing total pancreatectomy from 1995 to 2014 was performed.

Innovations and breakthroughs

TP is performed at an increasing rate at major pancreatic centers, there is still debate regarding its indications and outcomes. This study aimed to analyze the indications and short- and long-term outcomes of TP in the spectrum of pancreatic resections in this high-volume center.

Applications

Total pancreatectomy, including laparoscopic total pancreatectomy, appears to be an appropriate option for selected patients when treated at a high-volume pancreatic center and through a multispecialty approach.

Terminology

The authors conducted a retrospective study of 103 patients who underwent TP between March 1995 and December 2014 at Mayo Clinic in Jacksonville, Florida using data collected from an institutional review board-approved prospective database.

Peer-review

The staff and surgeons are very experienced, presenting excellent post-operative outcome and long-term survival.

Abstract**AIM**

To compare short-term results between laparoscopic hepatectomy and open hepatectomy using a propensity score matching.

METHODS

A patient in the laparoscopic liver resection (LLR) group

was randomly matched with another patient in the open liver resection (OLR) group using a 1:1 allocated ratio with the nearest estimated propensity score. Patients of the LLR group without matches were excluded. Matching criteria included age, gender, body mass index, American Society of Anesthesiologists score, potential comorbidities, hepatopathies, size and number of nodules, preoperative chemotherapy, minor or major liver resections. Intraoperative and postoperative data were compared in both groups.

RESULTS

From January 2012 to January 2015, a total of 241 hepatectomies were consecutively performed, of which 169 in the OLR group (70.1%) and 72 in the LLR group (29.9%). The conversion rate was 9.7% ($n = 7$). The mortality rate was 4.2% in the OLR group and 0% in the LLR group. Prior to and after propensity score matching, there was a statistically significant difference favorable to the LLR group regarding shorter operative times (185 min vs 247.5 min; $P = 0.002$), less blood loss (100 mL vs 300 mL; $P = 0.002$), a shorter hospital stay (7 d vs 9 d; $P = 0.004$), and a significantly lower rate of medical complications (4.3% vs 26.4%; $P < 0.001$).

CONCLUSION

Laparoscopic liver resections seem to yield better short-term and mid-term results as compared to open hepatectomies and could well be considered a privileged approach and become the gold standard in carefully selected patients.

Key words: Laparoscopic hepatectomy; Morbidity and mortality; Hepatocellular carcinoma; Liver resection; Colorectal metastases; Open hepatectomy; Propensity score matching

INTRODUCTION

Since the development of laparoscopic cholecystectomy in 1987, the laparoscopic approach extended to several abdominal procedures. However, it took a very long time for laparoscopic liver surgery to expand.

The first non-anatomical liver resection was described by Reich *et al*^[1] in 1991 and the first anatomical hepatectomy was described by Azagra *et al*^[2] in 1996. Historically, laparoscopy was used to evaluate hepatic lesions before an open hepatectomy^[3,4] or to evaluate the carcinomatosis or peritoneal spread before the surgery and to treat cystic lesions by means of fenestrations^[5,6]. Surgical techniques were progressively developed to propose resections of benign^[2], then malignant lesions (hepatocellular carcinomas and hepatic metastases)^[7,8].

The main reasons accountable for this lack of enthusiasm for laparoscopic hepatectomies, in addition to the technical complexity of interventions, were the lack of appropriate instrumentation, the risk of gas embolism, the risks of uncontrolled bleeding, the fear of not being able to follow oncological principles with a subsequent risk of tumoral dissemination. However, some surgical teams decided to look into the possibilities of laparoscopic hepatic resections.

Indications for laparoscopic hepatectomies were defined during the first international consensus conference held in Louisville, United States^[9] in 2008 and revised in Morioka^[10] in 2014. This approach was used for patients selected with the following criteria: Location and size of lesions, liver function, and the experience of the surgical team. Although it was demonstrated that the laparoscopic approach elicits several advantages in the short- and mid-term (less postoperative pain, quicker restoration of bowel habits, less respiratory and parietal morbidity, improved quality of life, and reduced hospital stay)^[11,12], laparoscopic liver surgery remains currently limited to simple and peripheral resections, and few extensive and complex resections were reported^[13].

In the literature, such series include few patients and most monocentric series are retrospective ones with potential selection biases.

The objective of our study was to evaluate the short-term and mid-term results of laparoscopic hepatectomies as compared to open hepatectomies using a propensity score matching in order to rule out selection biases.

MATERIALS AND METHODS

From January 2012 to January 2015, data of all patients who consecutively underwent hepatectomy in two University hospital settings were collected prospectively.

All patients who required liver surgery whatever the pathology (metastasis, hepatocellular carcinoma, adenoma, neuroendocrine tumor, cholangiocarcinoma, *etc.*) were included. The laparoscopic approach did not modify the operative indications established for open surgery. Indications for laparoscopic hepatectomies were determined according to the latest recommendations^[9,10]. Exclusion criteria for the laparoscopic approach included the following: A poorly defined lesion or a lesion proximal to main vessels, decompensated cirrhosis or severe heart or respiratory failure^[14]. The following variables were analyzed: Type of liver resections (segmentectomies, bisegmentectomies, wedge resections, *etc.*), use of radiofrequency, number of resected segments, operative time, number of clampings, duration and type of clamping, rate of conversion, blood loss, number of transfusions, length of hospital stay, rate of R0 resection margins. All postoperative complications were indexed, namely respiratory (atelectasis, pneumopathy), cardiovascular (cardiac rhythm disorders, ischemia, cardiac decompression, hypertension), renal (acute renal failure, pyelonephritis, cystitis), parietal infections, deep collections, bleeding, biliary fistulas, liver failure, ascites. Liver segmentation was defined according to the Couinaud classification^[15]. Liver resections were defined according to the Brisbane classification in 2000^[16], using the following definitions: Hepatectomy was defined as major when 3 or more segments were removed. Other hepatectomies, which were limited, were performed on 2 segments or less (standard segmentectomy, bisegmentectomy or subsegmentectomy). Postoperative mortality and morbidity was defined as death or complications which occurred in the first 90 postoperative days and were graded according to the Clavien-Dindo classification^[17,18].

Complications were indexed as medical complications, including respiratory complications (atelectasis, pneumopathy), cardiovascular complications (including cardiac rhythm disorders, ischemia, cardiac decompression, hypertension), renal complications (acute renal failure, pyelonephritis, cystitis liver failure, ascites, and as surgical complications including parietal infections, deep collections, biliary fistulas, bleeding, eviscerations, parietal collections and acute digestive ischemia).

Preoperative evaluation

A complete patient evaluation included computed tomography-scan and/or magnetic resonance imaging acquired in 3 phases with a volumetric rendering. Patient personal files were discussed in a multidisciplinary meeting. Resectability was defined by the absence of extrahepatic invasion, the absence of ascites, and a normal liver function. All hepatic resections were performed by expert surgeons skilled in both laparoscopic and open hepatobiliary surgery.

Propensity score matching

All demographic and preoperative data of patients operated on using the open liver resection (OLR) group or the laparoscopic liver resection (LLR) group were compared using a univariate analysis in order to evaluate

the comparability of both groups. A propensity score matching was calculated to take into account and limit selection biases as well as confusion between the two groups. This method allows comparing the effects of the two types of intervention (open vs laparoscopy) taking into account the variables which influence the choice of the procedure type. The propensity score was assessed using logistic regression including the following variables: Age, gender, co-morbidity, American Society of Anesthesiologists (ASA) score, the use of neoadjuvant therapy, body mass index, total number of nodules, and type of resection. The choice of such variables was based on the results of the univariate analysis and/or the known influence of specific factors on the selection of the intervention type. A 1:1 balance ratio was used for propensity score matching, based on the nearest matching PS method^[19-21]. After the matching process, both groups were compared regarding their initial characteristics in order to re-evaluate the comparability of both groups. Finally, matched groups could be compared regarding the different variables of interest in the study.

Statistical analysis

Asymmetrical quantitative variables were presented as medians combined with the first and third quartiles after their distribution had been evaluated. Qualitative variables were presented as numbers and percentages. Comparison of the quantitative variables was performed using a Mann-Whitney test. Comparison of qualitative variables was performed using Pearson's χ^2 test or Fisher's exact test depending on numbers. A *P* value < 0.05 was considered as significant. Analyses were performed using the 3.2.0 version R software (R Core Team, R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Population and short-term results prior to matching

Between January 2012 and January 2015, a total of 241 consecutive hepatectomies were performed, including 169 hepatectomies using laparotomy (70.1%) and 72 laparoscopic ones (29.9%), including 8 which were performed by means of the da VinciTM robotic surgical system (*da Vinci Si*TM System; Intuitive Surgical, Inc., Sunnyvale, CA, United States).

As for patient characteristics, both groups were comparable, except for gender ratio (*P* = 0.042), the existence of a co-morbidity (67.5% of patients in the OLR group and 54.2% of patients in the LLR group, *P* = 0.0499), the existence of a hepatopathy including hepatic steatosis and cirrhotic livers (13% in the OLR group vs 36.1% in the LLR group, *P* < 0.001), and preoperative chemotherapy (59.8% in the OLR group vs 36.1% in the LLR group, *P* < 0.001) (Table 1). In addition, there were statistically more lesions in the OLR group as compared to the LLR group 3.0 (1.0-5.0) vs 1.0 (1.0-2.0); *P* < 0.001) and more major hepatectomies in the OLR group as compared to the LLR group (40.8% vs 12.5%, *P* <

OLR: Open liver resection; LLR: Laparoscopic liver resection; ASA: American Society of Anesthesiologists; COPD: Chronic obstructive pulmonary disease.

0.001). There was a significant difference concerning pathologies with 9 adenoma resections in the LLR group (12.8%), vs 3 in the OLR group (1.8%) (*P* = 0.001), 24 hepatocarcinomas in the LLR group (33.3%) vs 25 in the OLR group (14.8%), (*P* = 0.001), and 101 colorectal metastasis resections in the OLR group (59.8%) vs 18 in the LLR group (25%), *P* < 0.001 (Table 1).

Details of the procedures performed are outlined in Table 2. It can be observed that fewer segments were resected in the LLR group (median of 1 vs 2; *P* < 0.001) and that there were more segmentectomies performed in the LLR group (40.3% vs 7.1%; *P* < 0.001), fewer bisegmentectomies (13.9% vs 27.2%, *P* = 0.025), fewer right hepatectomies (4.2% vs 15.4%,

P = 0.014) and fewer associations with destruction by radiofrequency (12.5% vs 32%, *P* = 0.002) as compared to the OLR group. There was a statistically significant difference in favor of LLR concerning operative time, blood loss, and length of hospital stay. In addition, there were significantly fewer medical complications in the LLR group (4.2% vs 2.8%, *P* < 0.001), taking all types into account (Table 2).

The conversion rate was 9.7% (*n* = 7), the reason for that being the presence of several pedicular adenopathies, which required an extensive dissection in one patient, and there were difficulties of access in 6 other patients. The mortality rate was 4.2% in the OLR group and 0% in the LLR group. The reason for death

OLR: Open liver resection; LLR: Laparoscopic liver resection.

was the occurrence of multivisceral failure after a right hepatectomy in 3 ASA 3 patients including 2 who were treated for a cholangiocarcinoma and one for liver metastases of a colorectal cancer which received 3 cycles of neoadjuvant FOLFOX therapy.

Population and short-term results after matching and PS

After using the propensity score, all 72 patients of the LLR group were matched to 72 patients of the OLR group. Both groups were comparable as far as patient characteristics were concerned, except for liver diseases which were more important in the LLR group (36.1% vs 19.4%, $P = 0.026$), the type of segment resected ($P < 0.05$), and

the pathology, with more hepatocellular carcinomas in the LLR group (33.3% vs 15.3%, $P = 0.012$) and fewer colorectal metastases (25% vs 52.8% in the OLR group, $P < 0.001$), (Table 1). More bisegmentectomies were performed in the OLR group (41.7% vs 13.9%, $P < 0.001$) but more segmentectomies in the LLR group (40.3% vs 11.1%, $P < 0.001$).

There was still a significant difference in terms of operative time ($P = 0.002$), a shorter hospital stay ($P = 0.004$) in the LLR group, less blood loss ($P = 0.002$), and fewer medical complications (4.3% vs 26.4%, $P < 0.001$) in the LLR group. Other values from both groups were comparable (Table 2).

DISCUSSION

The objective of this study was to compare short-term results of hepatectomies performed using a laparoscopic and an open approach, using the propensity score in order to reduce the selection bias. After matching, it has more open resection for liver metastases of a colorectal cancer than the laparoscopic approach. Indeed in colorectal cancer, metastases are often multiple and difficult to be able to remove by laparoscopic approach. Among the population, there was a selection of indications with more limited and minor resections in the laparoscopic group with fewer resected lesions. After a matching and a propensity score were applied to the essential factors which influence morbi-mortality, a significant decrease in blood loss could be observed, as well as the length of hospital stay, operative time, and postoperative medical complications in the laparoscopic group.

Despite an increase in the number of centers which use laparoscopic hepatobiliary surgery, the use of this approach is not very widespread (5% to 30% of liver resections)^[22-27]. Only a few centers report a strong activity representing 50% to 80%^[28-30] of liver resections. Over a period of 3 years, we report 72 laparoscopic hepatectomies, out of 241 hepatectomies in total, which means that 29.9% of hepatectomies were performed laparoscopically. Our indications for laparoscopic hepatectomy are the same as for open surgery. Most often, we would decide to choose a laparoscopic approach due to the location and the size of the tumor^[9,10]. As shown in our series, laparoscopic is most often used for anterolateral resections (segments 2 to 6). Wedge resections, segmentectomies, and left lobectomies remain the best laparoscopic indications^[22,30,31]. Major hepatectomies, especially right hepatectomies, were mainly performed using an open approach due to technical difficulties^[32-36]. Resection of lesions located in segments VII, VIII, I va and I is still not properly documented due to exposure difficulties and proximity with the inferior vena cava and suprahepatic veins. Superior posterior segments can be approached using transdiaphragmatic ports^[37,38], or using a transthoracic route^[39]. In addition, laparoscopic resection is not recommended for lesions greater than 5 cm in diameter, due to manipulation difficulties with a risk of tumoral rupture and of obtaining insufficient resection margins^[22,26,29]. The hepatic pedicle is systematically controlled at the beginning of the intervention in order to perform a pedicular clamping if required (55.6% of cases in our series). We report 6 permanent clampings but this corresponds to very superficial resections. In most cases, we privileged intermittent clamping, as this allows for a better liver tolerance, especially in cirrhotic patients^[40-42], as well as a better short- and long-term prognosis^[43]. We used intermittent clamping using a laparoscopic approach systematically. Additionally, laparoscopic clamping, which is associated with pneumoperitoneum pressure, allows to decrease bleeding and almost completely eliminates the use of continuous aspiration, which is not feasible.

Average clamping time was 15 min with the LLR vs 22 min with the OLR ($P = 0.174$). Intermittent clamping was 20 min with reperfusion phases of 10 min in all patients, except for cirrhotic patients, in which clamping would not exceed 15 min.

In addition, we do not report any gas embolism in our series, a rare occurrence which has, however, previously been described in laparoscopic surgery^[22,27,28]. It has been demonstrated that in order to decrease this risk, the use of carbon dioxide (a highly soluble gas) should be privileged, as well as low insufflations pressures^[44]. We did not use Argon although it allows for a good hemostasis, because it increases the risk of gas embolism in liver surgery^[45].

After PS, our study clearly demonstrated the benefits of the laparoscopic approach. There was a decrease in intraoperative bleeding (100 mL vs 300 mL, $P = 0.002$), a reduction in the length of hospital stay^[11] with a median of 7 d vs 9 d ($P = 0.004$) and even a shorter operative time (185 min vs 247.5 min, $P = 0.002$). The same goes for postoperative outcomes which appear to be simpler with fewer medical complications, especially respiratory ones (4.3% vs 26.4%, $P < 0.001$), also described in the series by Fuks *et al.*^[46]. As for surgical complications, laparoscopy does not provide any real benefits. Some authors have reported similar results^[47-49], like Cannon *et al.*^[50] (23% vs 50%, $P = 0.004$), Simillis in his meta-analysis^[51]. In the laparoscopic group, no deaths have been recorded; the same goes for unusual complications, and less than 20% of patients were transfused during hospitalization.

The conversion rate described in the literature ranges from 5% to 15%^[22-24,30]. The 2 main reasons for conversion are: Firstly, a technical problem due to a difficult exposure, a risk of tumoral rupture dissemination for fragile lesions or a doubt concerning the sufficient resection margin. The second reason is uncontrolled bleeding. In our series, we report a conversion rate of 9.7%, the main reason for it being exposure difficulties, which make resection difficult.

The results were obtained in our series as well as in series published by surgeons with experience in liver surgery and laparoscopic surgery, and consequently these results can only be extrapolated with caution in all centers.

In conclusion, the development of liver surgery using a laparoscopic approach has been a gradual process, and some liver resections currently seem feasible and safe in patients selected in centers in which surgeons have experience in both hepatic surgery and laparoscopic surgery. This study compared the complications mainly for minor resections after matching; although bicentric study with small groups, the laparoscopic liver resections seem to produce the same results as the open approach in the short- and middle-term. It could be considered as an alternative to open surgery and become the gold standard for carefully selected patients. However, complementary studies seem necessary, especially for long-term oncological results and for major hepa-

tectomies, in order for the laparoscopic approach to become a widely used alternative to hepatectomies using laparotomy.

COMMENTS

Background

Laparoscopic surgery is a consolidate technique who is diffusing rapidly also in some subspeciality who initially were contraindicated.

Research frontiers

The aim of this paper is to evaluate the impact of short and mid-term results of laparoscopy in liver surgery.

Innovations and breakthroughs

Minimally invasive approach represents the standard of care for most digestive cancer and it has to be confirmed for liver malignancies.

Applications

The extended indication for liver malignancies are even more frequent and need to be confirmed by short, middle and long term results.

Terminology

Minimally invasive and laparoscopic approach, liver resection, and better postoperative outcome are the main subjects of the paper.

Peer-review

This article has some important information to promote introduction of laparoscopy in the hepatobiliary and pancreatic field.

Abstract**AIM**

To review clinical experience with barium appendicitis at a single institution.

METHODS

A retrospective review of patients admitted with a diagnosis of acute appendicitis, from January 1, 2013 to December 31, 2015 was performed. Age, gender, computed tomography (CT) scan findings if available, past history of barium studies, pathology, and the presence of perforation or the development of complications were reviewed. If the CT scan revealed high density material in the appendix, the maximum CT scan radiodensity of the material is measured in Hounsfield units (HU). Barium appendicitis is defined as: (1) patients diagnosed with acute appendicitis; (2) the patient has a history of a prior barium study; and (3) the CT scan shows high density material in the appendix. Patients who meet all three criteria are considered to have barium appendicitis.

RESULTS

In total, 396 patients were admitted with the diagnosis of acute appendicitis in the study period. Of these, 12 patients (3.0%) met the definition of barium appendicitis. Of these 12 patients, the median CT scan radiodensity of material in the appendix was 10000.8 HU, ranging from 3066 to 23423 HU (\pm 6288.2). In contrast, the median CT scan radiodensity of fecaliths in the appendix, excluding patients with barium appendicitis, was 393.1 HU, ranging from 98 to 2151 HU (\pm 382.0). The CT scan radiodensity of material in the appendices of patients with barium appendicitis was

significantly higher than in patients with nonbarium fecaliths ($P < 0.01$).

CONCLUSION

Barium appendicitis is not rare in Japan. Measurement of the CT scan radiodensity of material in the appendix may differentiate barium appendicitis from routine appendicitis.

Key words: Acute appendicitis; Barium appendicitis; Barium sulfate; Upper gastrointestinal imaging; Gastric cancer screening

INTRODUCTION

Acute appendicitis is one of the most common surgical problems encountered in clinical surgical practice. While the exact etiology of acute appendicitis remains unclear, an obstruction of the appendiceal lumen can result in the development of acute appendicitis^[1]. In Japan, upper gastrointestinal imaging using barium sulfate is widely used in mass screening programs for gastric cancer^[2]. Barium sulfate is not harmful to the intestinal mucosa and complications after a barium study are considered to be very rare^[2-4]. Acute appendicitis caused by residual barium is also thought to be a very rare complication after a barium study^[3-5]. General surgeons in Japan often encounter patients with acute appendicitis who have residual barium felt to be the responsible etiologic agent.

We performed a retrospective review of patients admitted with a diagnosis of acute appendicitis, and specifically reviewed those with acute appendicitis suspected to be caused by residual barium.

MATERIALS AND METHODS

Tokyo Bay Urayasu Ichikawa Medical Center is a secondary referral hospital in Chiba prefecture, Japan, providing acute surgical care. A retrospective analysis was conducted of patients seen from January 1, 2013 to December 31, 2015. Patients for review were identified based on their medical records including patients admitted with the diagnosis of acute appendicitis. Age, gender, computed tomography (CT) scan findings if available, past history of barium studies, pathology, and the presence of perforation or the development of complications were reviewed. If the CT scan revealed high density material in the appendix, the maximum CT scan radiodensity of the material is measured in Hounsfield units (HU).

Barium appendicitis is defined as: (1) patients diagnosed with acute appendicitis; (2) the patients have a history of a prior barium study; and (3) the CT scan shows high density material in the appendix. Patients who meet all three criteria are considered to have barium appendicitis.

Data were analyzed with Fisher's exact test and the Mann-Whitney *U* test. A *P*-value less than 0.05 is considered statistically significant.

RESULTS

From January 1, 2013 to December 31, 2015, 396 patients were admitted with the diagnosis of acute appendicitis, including 210 males and 186 females. The median age is 37 years, ranging from 5 to 86 years. Of these, 12 patients (3.0%) met the definition of barium appendicitis (Table 1, Figure 1), including ten males and two females, with a median age of 48 years, ranging from 37 to 62 years. Of these 12 patients, the median CT scan radiodensity of material in the appendix was 10000.8 HU, ranging from 3066 to 23423 HU (± 6288.2). According to these data, the CT scan radiodensity of residual barium is generally higher than 3000 HU. If we apply this value as a cutoff, we can identify seven more patients with suspected barium appendicitis based on CT scan radiodensity alone. According to the medical records, these seven patients had no definite history of a preceding barium study, excluding one patient who specifically denied having a barium study. The median CT scan radiodensity of fecaliths in the appendix, excluding patients with barium appendicitis, was 393.1 HU, ranging from 98 to 2151 HU (± 382.0). The CT scan radiodensity of material in patients with barium appendicitis was significantly higher than patients with non-barium fecaliths ($P < 0.01$).

Ten of 12 patients with barium appendicitis underwent laparoscopic appendectomy urgently. One patient underwent interval laparoscopic appendectomy after initially successful non-operative management. In one patient, there was obvious perforation with abscess formation and non-operative management was initially undertaken. Following this, the patient refused interval appendectomy. The interval from barium study to the diagnosis of appendicitis was variable, ranging from 2 d to 10 mo.

The pathological results in patients with barium appen-

Table 1 Patient characteristics

Age	Gender	Maximum CT density (HU)	Perforation	Appendix pathology	Interval between barium study and diagnosis	Treatment
52	M	10243	+	Phlegmonous	8 mo	Laparoscopic appendectomy
37	M	23423	-	Gangrenous	2 d	Laparoscopic appendectomy
45	M	6620	-	Gangrenous	1 mo	Laparoscopic appendectomy
49	M	15286	-	Phlegmonous	16 d	Laparoscopic appendectomy
44	M	3066	-	Gangrenous	1 mo	Laparoscopic appendectomy
62	M	18286	+	Gangrenous	Not documented	Laparoscopic appendectomy
45	M	8192	+	Chronic appendicitis	3 mo	Primary non-operative management followed by interval appendectomy
46	M	11514	-	Phlegmonous	10 mo	Laparoscopic appendectomy
60	F	3178	-	Gangrenous	Not documented	Laparoscopic appendectomy
44	M	8727	-	Gangrenous	3 mo	Laparoscopic appendectomy
45	M	7806	-	Gangrenous	5 mo	Laparoscopic appendectomy
41	F	3669	+	N/A	1 mo	Non-operative management without interval appendectomy

M: Male; F: Female; CT: Computed tomography; HU: Hounsfield units; N/A: Not analyzed.

Figure 1 Abdominal computed tomography scans with axial and coronal views. A and B: High density material is seen inside the swollen appendix (arrows); C and D: High density material is seen inside the swollen appendix and in the peritoneal cavity with a fluid collection (arrow heads). This strongly suggests a perforated appendicitis with residual barium.

ditis are available for 11 patients. Seven patients had gangrenous appendicitis and three had phlegmonous appendicitis. One patient, who underwent interval appendectomy, had chronic inflammation of the appendix. The rate of gangrenous appendicitis is 58.3% in patients with barium appendicitis and 56.4% in patients without barium appendicitis. The rate of gangrenous appendicitis is almost the same in patients with typical (unassociated with barium) appendicitis compared to patients with barium appendicitis. Four out of 12 patients had a perforation (33.3%), confirmed by intraoperative or imaging findings. The perforation rate in patients with

barium appendicitis was higher than in patients without barium appendicitis (18.8% in this study), which is not statistically significant ($P = 0.25$). Interestingly, although the rate of gangrenous appendicitis is almost the same in patients with barium appendicitis and typical appendicitis the perforation rate was higher in patients with barium appendicitis.

DISCUSSION

Barium appendicitis is a rare complication after barium examinations and was first described by Gubler *et al*^[6]

in 1954. Although retained barium in the appendix after barium studies is very common^[7], especially after colon studies, more than 90% of patients evacuate the barium within 72 h^[3,4,7]. The true pathophysiology of barium appendicitis remains unclear. The true incidence of barium appendicitis is also unknown because only a few case reports or small case series have been reported to date^[3-7]. The time interval between the barium study and the diagnosis of barium appendicitis in several previous studies ranges from four hours to four years^[5,8]. In the present study, the range is 10 d to 10 mo. The wide range of values suggests that retained barium in the appendix alone does not result in appendicitis. There would appear to be other factors that contribute to the development of acute appendicitis.

Acute appendicitis is one of the most common surgical emergencies encountered by general surgeons. Obstruction of the appendiceal lumen, often due to a fecalith, lymphoid hyperplasia, or rarely a cecal or appendiceal tumor, is generally thought to be the cause of acute appendicitis in many patients^[1,9]. Fecaliths are a cause of obstruction of the appendiceal lumen, although they are not always found at surgery. Fecaliths are composed of inspissated stool, mucus with trapped calcium phosphate and inorganic salts, which finally obstructs the appendiceal lumen^[10,11]. In this study, fecaliths were identified in 34% of patients with acute appendicitis based on imaging findings. It is unknown if the high density material in the appendix in patients with barium appendicitis is composed of only barium or if it is combined with other material such as that found in a fecalith. However, luminal obstruction of the appendix by residual barium resulted in the development of acute appendicitis. As mentioned, an additional cause of barium appendicitis may be a pre-existing fecalith in the appendix. Fecaliths not only cause appendicitis, but also are considered to be associated with appendiceal perforation^[11,12]. In this study, the perforation rate in patients with barium appendicitis was higher than in patients without barium appendicitis. Although it is not statistically significant, this suggests that residual barium may be a risk factor for appendiceal perforation, similar to a fecalith. The fact that typical appendicitis has the same rate of gangrenous inflammation in this study also supports this hypothesis.

In this study, the CT scan radiodensity of material in the appendix in patients with barium appendicitis is significantly higher than that of fecaliths in patients with typical appendicitis. These data suggest that the CT scan radiodensity of material in the appendix may differentiate barium from normal fecaliths. We acknowledge that in general, not all patients undergo CT scans to establish the diagnosis of acute appendicitis. However, during the study period, about 3% of patients presented with acute appendicitis believed to be caused by residual barium. Since acute appendicitis is one of the most common surgical emergencies, and the fact that in Japan, barium is widely used in studies screening for gastric cancer^[2], we believe that the diagnosis and recognition of barium

appendicitis as a complication of barium studies is worthwhile, especially in Japan.

According to data reporting the complications after gastric cancer screening in Japan, the total complication rate after barium studies is reported to be less than 0.04%^[13]. The most common reported complication after barium studies was aspiration, followed by allergic reaction and bowel obstruction. There have also been severe complications reported such as intestinal perforation due to residual barium^[13]. Interestingly, there were no reports of barium appendicitis^[13], although barium appendicitis occurred in 3% of patients with acute appendicitis in this study. There is an approximate 7% lifetime risk of developing appendicitis^[1,9], thus, a 3% incidence in patients with acute appendicitis is a significant number. Since acute appendicitis is often treated with appendectomy no matter what the etiology, the true incidence of barium appendicitis is likely underestimated.

Several limitations are acknowledged in this study. First, this is a single institution retrospective analysis. Second, there is no confirmation of what the high density material in the resected appendices actually was. Pathological confirmation may support the results of this study, if it is specifically checked in a prospective study.

In conclusion, barium appendicitis is not rare in Japan. Measurement of the CT scan radiodensity of material in the appendix may differentiate barium appendicitis from routine appendicitis. Since barium is widely used in Japan for gastric cancer screening, determination of the true incidence of barium appendicitis is important.

This material was presented in part at the 116th annual congress of the Japan Surgical Society (April 15th 2016, Osaka, Japan).

COMMENTS

Background

Barium appendicitis is a rare complication of gastrointestinal imaging using barium sulfate. The true incidence of barium appendicitis is unknown. However, general surgeons in Japan often encounter patients with acute appendicitis where the etiology appears to be a barolith in the appendix. The authors review their clinical experience with barium appendicitis at a single institution in Japan.

Research frontiers

The exact incidence of barium appendicitis is unknown. This study reviews their experience with appendicitis and the incidence of barium appendicitis among all patients who presented with acute appendicitis.

Innovations and breakthroughs

Barium appendicitis is thought to be a rare complication of gastrointestinal imaging. However, this study shows that barium appendicitis represents about 3% of all patients with acute appendicitis.

Applications

Measurement of the computed tomography (CT) scan radiodensity of high density material in the appendix may help to differentiate barium appendicitis from typical appendicitis. This may also help elucidate the true incidence of barium appendicitis in future studies.

Terminology

HU: Hounsfield units.

Peer-review

Barium appendicitis is a rare clinical condition. Barolith can occur due to post-examination retained barium in appendix lumen and it can cause appendicitis. CT definings in this manuscript is well-thought evidence and helps diagnose.

Abstract

Eosinophilic gastroenteritis (EGE) is a rare condition characterized by eosinophilic infiltration of the gastrointestinal tract. Depending on the dominant layer of infiltration it is classified into three types namely, mucosal, muscularis and subserosal. The most uncommon variant is the subserosal type characterized by primarily subserosal disease, eosinophilic ascites and peripheral hypereosinophilia. The clinical features are non-specific with history of atopic predisposition and allergy. Endoscopic biopsy is frequently non-diagnostic due to an uninvolved gastrointestinal mucosa rendering its diagnosis a challenge. The mainstay of diagnosis is peripheral hypereosinophilia and eosinophil-rich ascitic fluid on diagnostic paracentesis. Oral steroid therapy is usually the first line of treatment with dramatic response. Due to a propensity for relapse, steroid-sparing therapy should be considered for relapses of EGE. We report a case of subserosal EGE with diagnostic clinical features and treatment response and review the current strategy in the management of eosinophilic ascites.

Key words: Gastrointestinal; Atopy; Eosinophilic ascites; Endoscopic biopsy; Eosinophilia

Core tip: Eosinophilic gastroenteritis (EGE) is a rare condition and the diagnosis of subserosal EGE is challenging due to its nonspecific symptoms and signs and frequently non-diagnostic biopsy on gastrointestinal endoscopy. This review describes a patient with typical findings of peripheral hypereosinophilia and eosinophilic

ascites and outlines the current strategy in the diagnosis and treatment of subserosal EGE.

Agrawal S, Vohra S, Rawat S, Kashyap V. Eosinophilic ascites: A diagnostic and therapeutic challenge. *World J Gastrointest Surg* 2016; 8(9): 656-659 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i9/656.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i9.656>

INTRODUCTION

Eosinophilic gastroenteritis (EGE) is a rare and potentially fatal condition with clinico-pathologic characteristics of peripheral hypereosinophilia and eosinophilic infiltration of the gastrointestinal tract. It is classified into three pathologic types depending on the dominant gastrointestinal layer of eosinophilic infiltration^[1]. The subserosal type characterized by primarily subserosal disease and eosinophilic ascites is the rarest presentation of EGE^[2,3]. Biopsy of the mucosal layer obtained during upper gastrointestinal endoscopy frequently fails to diagnose subserosal EGE. The diagnosis of subserosal EGE is challenging because of its rarity, nonspecific clinical presentation and non-diagnostic endoscopy. This study presents the typical clinico-pathologic and radiologic findings in subserosal EGE and reviews the current diagnostic and therapeutic strategy in patients with abdominal pain, ascites and peripheral hypereosinophilia.

CASE REPORT

A 35-year-old female presented to the clinic with complaints of abdominal distension and an episode of self-limiting diarrhea three weeks ago. She admitted to the recent use of green tea and increased consumption of nuts in her diet. Past medical history was remarkable for recurrent allergic bronchitis. On examination there was no evidence of pallor, icterus or peripheral edema and abdominal examination revealed moderate distention with a doughy consistency. Abdominal ultrasonography demonstrated moderate ascites with no signs of portal hypertension, liver or renal disease. Contrast-enhanced abdominal computed tomography confirmed the presence of free peritoneal fluid, diffuse circumferential thickening of small bowel loops, distal stomach and esophagus (Figure 1). Laboratory examination revealed peripheral eosinophilic leukocytosis with 52% eosinophils (total leukocyte count 22900 cells/mm³) and no immature myeloid precursors. The C-reactive protein, erythrocyte sedimentation rate and IgE levels were within normal limits. Tumor marker CA-125 was normal. Skin prick test results for food allergens and stool examination for bacteria, ova and parasites were negative. Diagnostic paracentesis was moderately cellular with 100% eosinophils, negative for malignant cells and sterile (Figure 2). Upper endoscopy and colonoscopy demonstrated mild erythema of the gastric antrum with an unremarkable

esophagus, duodenum, colon and terminal ileum. Histology revealed a mild inflammatory infiltrate in the lamina propria of the gastric antrum and duodenum comprising of lymphocytes, plasma cells and scattered eosinophils (Figure 3). Echocardiographic findings were normal. Bone marrow aspiration and biopsy showed hypercellularity with a marked increase in mature eosinophils without blasts. The findings confirmed a diagnosis of subserosal EGE.

The patient was treated with oral prednisone 25 mg daily with rapid symptomatic improvement and normalization of the hypereosinophilia within a week of initiation of steroid therapy. Four months after the weaning of steroids, follow-up abdominal computed tomography demonstrated complete resolution of the peritoneal fluid and bowel wall thickening. Two years after completion of therapy, the patient remains asymptomatic and free of ascites or hypereosinophilia.

DISCUSSION

EGE is a rare disease with an estimated prevalence of 28/100000 in United States^[4]. Klein *et al*^[1] classified EGE into three types based on the dominant layer of eosinophilic infiltration (1) predominant mucosal disease characterized by iron deficiency anemia, protein-losing enteropathy and malabsorption; (2) predominant muscle layer disease characterized by localized or diffuse thickening of the bowel wall with features of pyloric narrowing and obstructive symptoms; and (3) predominant subserosal disease characterized by eosinophil-rich ascites^[1-5]. Mucosal EGE is the most common type (70%) followed by muscularis (20%) and subserosal (10%)^[6,7]. EGE may also present with obstructive jaundice due to biliary tract involvement or extraintestinal manifestations such as eosinophilic cystitis, eosinophilic splenitis and hepatitis^[7-9].

Talley *et al*^[10] have defined three diagnostic criteria for EGE (1) presence of gastrointestinal symptoms; (2) biopsies of the gastrointestinal tract showing eosinophilic infiltration or characteristic radiologic findings with peripheral eosinophilia or eosinophil-rich ascites with; and (3) no evidence of parasitic or extraintestinal disease. Characteristic findings of EGE on abdominal computed tomography include thickening of bowel wall or fold, layering of the bowel wall, luminal narrowing without obstruction, intra- or extra-luminal granuloma, mesenteric lymphadenopathy with peripheral rim-like enhancement or necrosis and ascites^[11]. The etiology of EGE is unclear however, an atopic predisposition is noted in patients with EGE with a history of allergy reported in 50% patients with EGE^[10]. A genetic predisposition is suspected as 16% of patients with EGE have a family member with a similar condition^[9]. The majority of the patients diagnosed with EGE are 20-50 years of age with no reported gender predisposition^[3].

The differential diagnosis of eosinophilic ascites includes parasitic infection (*Strongyloides stercoralis*, *Toxocara canis*), abdominal tuberculosis, rupture of hydatid cyst, chronic pancreatitis, vasculitis (Churg-Strauss

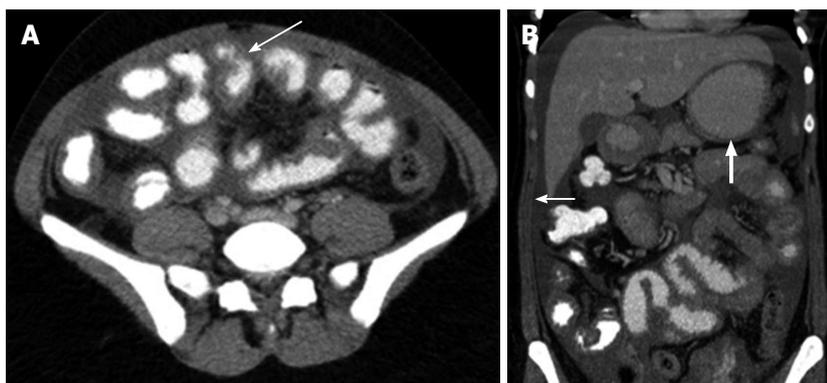

Figure 1 Findings on contrast-enhanced abdominal computed tomography. A: Sagittal section demonstrates thickened loops of small bowel (arrow); B: Coronal image demonstrates free peritoneal fluid (arrow), thickened loops of small bowel and circumferential mural thickening of the distal stomach (heavy arrow).

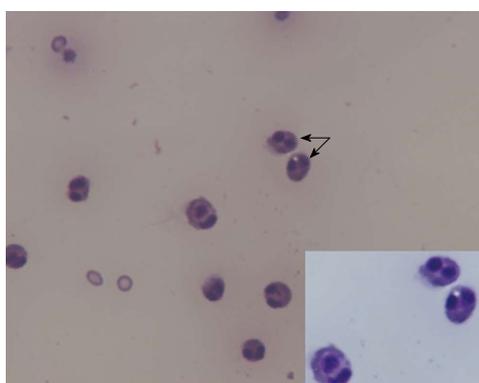

Figure 2 Diagnostic paracentesis demonstrates ascitic fluid rich in eosinophils (arrow), magnification 10 ×. Inset, eosinophils in ascitic fluid, May Grunwald Giemsa, magnification 100 ×.

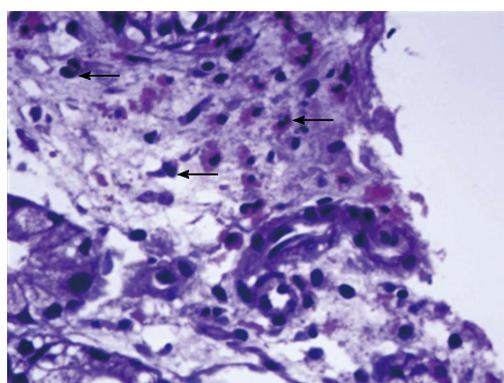

Figure 3 Endoscopic biopsy of gastric mucosa demonstrates scattered eosinophils (arrows) in the lamina propria. Hematoxylin and eosin, magnification 40 ×.

syndrome), hypereosinophilic syndrome, malignancy and Crohn’s disease^[12]. The diagnosis of subserosal EGE remains challenging because of its rarity and non-specific clinical features. The most common clinical features include abdominal pain (90.4%), nausea and vomiting (57.1%), diarrhea (52.3%) and abdominal distension (38.1%)^[13]. It should be considered in the diagnostic evaluation of patients with abdominal pain, ascites and peripheral hypereosinophilia and a high index of suspicion should be maintained by the physician^[3]. The mainstay of diagnosis of subserosal EGE is confirmation of eosinophil-rich ascitic fluid on diagnostic paracentesis and peripheral hypereosinophilia.

The overall prognosis of EGE is good with an excellent response to oral steroids comprising the first line of therapy^[2]. Prednisone 20-40 mg daily in divided doses is highly effective with symptomatic remission in 80% patients within a week and normalization of eosinophil counts within two weeks of initiation of therapy^[13]. Other medical therapy includes antihistaminic drugs, sodium cromoglycate, montelukast and ketotifen^[2,12,14,15]. Ketotifen an antihistaminic drug and mast cell stabilizer has been used to successfully treat eosinophilic ascites as the sole therapeutic intervention. Casella *et al*^[15] recommend ketotifen as the first-line approach to eosinophilic ascites because it is a relatively inexpensive and safe drug. Sur-

gical intervention is rare and reserved for patients with obstructive complications^[2,3]. The clinical course may be characterized by periods of remission and relapses usually when the steroid therapy is discontinued in up to 50% patients^[14]. Steroid-sparing therapy with antihistamines, mast cell inhibitors, leukotriene receptor antagonists, anti-interleukin drugs including ketotifen is useful in the treatment of relapses to avoid the side-effects of steroids^[12,15]. In rare cases of failure to respond to steroid therapy, total parenteral nutrition or immunosuppressive agents including oral azathioprine or cyclophosphamide may be added to the steroid regimen in patients with diffuse mucosal disease^[5].

COMMENTS

Case characteristics

A 35-year-old female presented with abdominal distension and diarrhea and was diagnosed with subserosal eosinophilic gastroenteritis (EGE). She responded to oral steroid therapy with complete resolution of the ascites and normalization of peripheral hypereosinophilia.

Clinical diagnosis

Subserosal EGE.

Differential diagnosis

Ovarian cancer, abdominal tuberculosis, vasculitis, parasitic infection, congestive

heart failure.

Laboratory diagnosis

Peripheral hypereosinophilia and eosinophil-rich fluid on diagnostic paracentesis.

Imaging diagnosis

Abdominal computed tomography demonstrated moderate ascites with diffuse wall thickening of the small bowel.

Pathological diagnosis

Mucosal biopsy of the stomach and duodenum on upper endoscopy was non-diagnostic.

Treatment

Oral steroid therapy.

Experiences and lessons

A high index of suspicion of subserosal EGE in patients with abdominal pain, ascites and peripheral hypereosinophilia. Oral steroids adequate for initial therapy and ketotifen may be considered for relapse of EGE.

Peer-review

The manuscript deals with a case report and a review on an important condition and is well written.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Tsuyoshi Konishi, MD, PhD, Doctor, Department of Gastroenterological Surgery, The Cancer Institute Hospital of JFCR, Tokyo 135-8550, Japan

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (World J Gastrointest Surg, WJGS, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Malignant neoplasms of the appendix are rare and represent less than 1% of gastrointestinal cancers. Goblet cell carcinoids (GCC) tumors are a distinctive group of heterogeneous appendiceal neoplasm that exhibit unique clinical and pathologic features. This review focuses on

the current diagnostic procedures, pathogenesis, possible signaling mechanisms and treatment options for GCC. Perspectives for future research are discussed. The tumor likely arises from pluripotent intestinal epithelial crypt base stem cells. Previous findings of Notch signaling as a tumor suppressor in Neuroendocrine tumors may have a similar role in this tumor too. Loss of Notch signaling may be the driver mutation with other successive downstream mutations likely favors them into progressing and behavior similar to poorly differentiated adenocarcinoma with minimal neuroendocrine differentiation. A multi-disciplinary approach is suggested for optimal outcomes. Surgery remains the main treatment modality. Simple appendectomy may be sufficient in early stages while right hemicolectomy is recommended for advanced tumors. Cytoreductive surgery with heated intraperitoneal chemotherapy may improve survival in a select few with metastatic peritoneal disease. These tumors have an unpredictable behavior even in early stages and local recurrence and delayed metastases may be seen. Lifelong surveillance is warranted.

Key words: Goblet cell carcinoid of the appendix; Notch-1 signaling; Immunomarkers; Math-1 signaling; Intestinal stem cells; Disease management

INTRODUCTION

Malignant neoplasms of the appendix are rare and represent less than 1% of gastrointestinal cancers. Studies evaluating data for appendiceal malignancies from seer database between 1973-2001 showed the age-adjusted incidence of cancer of appendix was 0.12 cases per 1 million people per year^[1,2]. They are further classified into colonic type adenocarcinoma, mucinous tumors, signet ring cell tumors, carcinoids [neuroendocrine tumors (NETs)] and goblet cell carcinoids (GCC). Overall five-year survival is highest for appendiceal carcinoid (83%) and lowest for signet ring cancers (18%)^[1,2]. This review focuses on GCC of the appendix. The current diagnostic procedures, pathogenesis, signaling mechanisms and possible mutations are presented. Treatment options for this neoplasm are defined and summarized, although evidence-based data are lacking. Surgery remains the treatment mainstay.

GCC tumors are a distinctive group of heterogeneous appendiceal neoplasm that exhibit unique clinical and pathologic features. These hybrid tumors have both glandular and neuroendocrine morphology and are designated with various terminologies: Adenocarcinoids, crypt cell carcinoma, mixed carcinoid-adenocarcinoma and amphicrine tumors. These various terminologies do not reflect consistent morphology, biologic behavior or accepted criteria for the diagnosis. GCC was first described by Gagné *et al*^[3] in 1969, Subbuswamy *et al*^[4] subsequently coined the term GCC in 1974. Warner *et al*^[5] in 1979 suggested a probable origin from crypt based stem cell. Isaacson *et al*^[6] in 1981 demonstrated presence of IgA, lysozyme in GCC suggestive of possible role of Paneth cells in this tumor^[3-6].

GCC exhibits clear distinction when compared to appendiceal NETs or primary adenocarcinoma in terms of demographics, biology and clinical aggressive behavior. The prognoses of GCC lays intermediate between appendiceal NETs and primary appendiceal adenocarcinoma^[1,2].

CLINICAL PRESENTATION

GCC are diagnosed in less than 1% of appendectomy specimens^[7,8]. Most commonly, patients present with abdominal pain and acute appendicitis (> 50%). They are most often diagnosed incidentally during appendectomy

or ileocecal resection and confirmed by the pathologist in post-surgical specimens. About 27% of patients may present with perforated appendicitis^[9]. Patients may also present sub-acutely in advanced stages with vague abdominal pain and mass^[7,8]. Common in Caucasians, there is equal distribution in male and females with the average age of diagnosis in the fifth decade^[1,2]. Up to 50% of patients present with metastatic disease^[8,10-12]. Similar to carcinoids a significant number of these patients may harbor a second primary malignancy^[12-14].

Morphologically the tumor circumferentially involves the appendiceal wall with transmural extension. Sub-mucosal involvement with mucosal sparing is noted. Most tumors are generally > 2 cm in size. The native appendiceal epithelium may show fibrous obliteration without adenomatous or dysplastic changes^[8,15].

GCC display a wide range of histologic patterns both in primary and metastatic sites. Common to all GCC is the presence of mucin containing goblet shaped epithelial cells arranged in clusters in the lamina propria and submucosa. These cells stain positive for mucicarmine, periodic acid-Schiff and alcian blue stains suggestive of goblet cell mucin. Extracellular pools of mucin may also be present. Also seen are cells, which demonstrate focal, inconsistent scattered immunoreactivity for neuroendocrine markers (*i.e.*, chromogranin, synaptophysin)^[8,16].

Since GCCs show a submucosal growth pattern, it has a tendency to spread to surrounding bowel. The most common metastatic sites include direct extension into the right colon and ileum, followed by spread to lymph nodes, peritoneum and omentum. The ovaries are common site of metastases in women presenting as Krukenberg tumor. Up to 80 % of women with stage 4 disease present with ovarian metastases^[8,12]. Solid organ metastases to liver, lung, bones are uncommon^[8]. A previous study reports the rate of metastases to lymph nodes increases with the T stage of the tumor T2 (0%), T3 (13%), T4 (60%)^[9].

Metastatic lesions from GCC are more aggressive tumors and often show poorly differentiated signet ring cell or undifferentiated adenocarcinoma morphology with minimal neuroendocrine features. They may not share features of primary tumor and carry poorer prognosis. Metastatic tumors usually do not stain for chromogranin A or synaptophysin and stain heavily for mucin, suggestive of degeneration into signet ring cell morphology. The population of endocrine cells and Paneth cells seem to decrease in metastatic lesions. Yan *et al*^[17] in their series of 26 patients reported that nine patients (35%) with metastatic GCC failed to stain for neuroendocrine marker. The explanation for this finding remains elusive^[17-21].

CLASSIFICATION

Currently multiple classification systems exist to describe GCC.

The 2010 World Health Organization (WHO) cla-

Classification for tumors of the appendix, classifies GCC under the category of neuroendocrine neoplasms based on differentiation and histological grading. Grade refers to the proliferative activity measured with mitotic counts and Ki-67 index. They are further sub-classified as low grade: G1 (< 2 mitosis/10 HPF and ≤ 2% Ki index), intermediate grade: G2 (2-20 mitosis/10 HPF, 3%-20% Ki index) and high grade: G3 (> 20 mitosis/10 HPF, > 20% Ki index). Differentiation refers to resemblance of tumor cells to the normal neuroendocrine cells. Carcinoids (well differentiated neuroendocrine neoplasm) generally belong to G1 and G2 categories while G3 is considered as a neuroendocrine carcinoma (NEC). Goblet cell tumors are subtyped under mixed adenoneuroendocrine carcinoma (MANEC). To qualify for this definition at least 30% of tumor should have gland forming epithelial and neuroendocrine components^[22].

The 2010 American joint commission on cancer (TNM classification) stages these tumors based on the tumor size, nodal status and metastatic disease into stages (I - IV). Stage I (T1, N0, M0), stage II (T2/T3, N0, M0), stage III (any T/N1, M0), and stage IV (any T /any N/ M1)^[23].

Tang *et al*^[8] in 2008, proposed a system of classification specific for GCC of appendix based on histologic features of the tumor at the primary site. They include the arrangement of the goblet cells, degree of atypia and desmoplasia to label these tumors into three groups. Typical GCC (group A); adenocarcinoma ex GCC, signet ring cell (group B); adenocarcinoma ex GCC, poorly differentiated (group C). Almost all patients in group C presented in advanced stages with wide metastases. This suggests that GCCs display a spectrum of histologic features with the potential to progress to an aggressive adenocarcinoma phenotype^[8].

These multiple pathologic definitions and differing terminologies have led to inconsistent reporting and difficult to characterize this disease.

MANEC per the 2010 WHO classification are tumors harboring both epithelial and neuroendocrine components. However based on this definition it requires tumors to have at least 30% representation of each component. In general this is not true for all GCC tumors. Further advanced stages of GCC losses its neuroendocrine differentiation and acquires an aggressive signet ring cell or poorly differentiated morphology.

This tumor may need further investigations to better clarify and define their heterogeneous, molecular profile and classification.

IMMUNOCHEMISTRY AND MUTATIONAL FINDINGS

GCC specimens demonstrate focal, inconsistent immunoreactivity for neuroendocrine markers. In contrast diffuse staining is observed in most classic carcinoids of the appendix. Common positive markers are synaptophysin, chromogranin A, serotonin, neuron specific enolase,

pancreatic polypeptide. Ultrastructural immunohistochemistry staining has shown tumor nests resembling normal crypts in the submucosa. Separate goblet cell and neuroendocrine cells are often located in close proximity to each other^[24] (Table 1).

In addition GCC do not exhibit mutations as conventional colorectal adenocarcinoma. These tumors are negative for KRAS, SMAD4 and BRAF mutations^[25]. They show negative staining for nuclear β-catenin and for p53. MUC2 expression is preserved^[8]. Normal colorectal and appendicular epithelium expresses MUC2 only. GCC show strong carcinoembryonic antigen, caudal type homeobox transcription factor 2, cytokeratin 7 (CK7), CK20 expression suggestive of intestinal epithelial origin while these markers remain negative in classic carcinoids^[26]. A single study showed allelic loss in chromosomes 11q, 16q, and 18q in GCC similar to ileal carcinoids^[25].

The proliferative Ki67 index remains low in typical GCC but rises with advanced stages (Tang's group C). The significance remains unknown as some groups have shown worsening survival rates with rising Ki67 index^[19,27] while other have shown no correlation^[9,28,29]. Positive staining for p53 and MUC1 with loss of MUC2 expression is suggestive of transformation to adenocarcinoma phenotype similar to colorectal adenocarcinoma^[8]. This also correlates with the rising Ki67 index as reported with Tang's *et al*'s classification.

In general patients with GCC do not present with carcinoid syndrome and urinary 5HIAA levels are within normal range^[16]. Unlike classic midgut carcinoids, serum chromogranin A levels are normal and have no value in detecting and monitoring GCC. Somatostatin expression is sparse and erratic and therefore functional scans such as 111-Indium pentetreotide scintigraphy (Octreoscan) and Gallium 68-octreotide positron emission tomography (PET) scans are usually normal in patients with GCC, and thus are of limited use^[11,19]. Fluorodeoxyglucose PET scan may be useful in advanced disease to detect peritoneal metastatic disease^[7,27,30].

GCC also express transcription factor Math-1 and HD5 (Defensins) a known marker for Paneth cells^[26]. Math-1 is a basic helix-loop-helix transcription factor essential for development of the pluripotent stem cell towards secretory stem cell lineage and may play a role in pathogenesis of GCC.

PATHOGENESIS

The pathogenesis of GCC remains unclear. Unlike adenocarcinomas of the GI tract which arises through an adenoma-carcinoma sequence GCC is thought to arise from pluripotent intestinal epithelial crypt base stem cells^[6,26].

An understanding of the embryological origin and signaling pathways associated with development of small bowel and appendix may provide clues and explain the origin and progression of GCC. The epithelial lining of

small gut consists of a single layer of columnar cells. This differentiated epithelium arises from the crypts and projects up as villi into the lumen forming the absorptive lining of the gut (Figure 1). Villi begin to form by embryonic day 15 and crypt form by invagination of intervillus pockets at post-natal day 7^[31,32]. The four main types of differentiated cells are absorptive enterocytes, goblet cells, neuroendocrine and Paneth cells. The crypt thus forms the proliferative stem cell compartment, where these cells originate, differentiate, amplify and move up into the villi akin to a system of conveyor belt in an assembly line^[33]. Paneth cells which also originate from the crypt in an exception and migrates downward into the base of the crypt. These four cell types are the main differentiated cell types found in the epithelial lining of the small intestine.

How is the stem cell niche created and defined? What molecular signaling mechanisms keep the niche intact and regulated? Information on these fundamental questions comes from mouse studies. Advances in development and stem cell biology have also occurred to generate complex three dimensional human intestinal tissues *in vitro* through directed differentiation of human pluripotent stem cells. These human intestinal organoids called mini-gut have expanded our ability to study development, genetics, intestinal pathogens and metabolic disease and cancer^[34]. Cheng and Leblond^[35,36] in 1974 were first to characterize crypt based columnar cells as intestinal stem cells. Barker *et al*^[37] identified a marker Lgr5/GPR49, a leucine rich orphan G-protein coupled receptor that labels these stem cells. Tritiated radioactive thymidine labelling experiments have confirmed that these Lgr5 cells are the multipotent stem

cells. Stem cell division occurs every 24 h and these cells are localized to the crypts. Subsequently cells migrate up from the crypt to the villus in 3-5 d^[34,38]. These stem cells by itself are not terminally differentiated and can divide without a limit. The daughter cells have to choose between committing to terminal differentiation or remain as a stem cell. The rapidly dividing groups of cells derived from the crypt stem cells that have committed to differentiation are known as transit amplifying cells. As they migrate further up the crypt they amplify according to their prospective destined fate and differentiate as enterocyte, goblet cell, neuroendocrine and Paneth cell. They cease to divide further once they reach the neck of the crypt at the crypt villous junction^[31,33].

Thus this slim, columnar crypt based Lgr5 positive stem cells along with the post mitotic Paneth cells form the stem cell niche through which begins the growth and renewal of all the differentiated cells of the small intestinal epithelium.

There are two major groups of cell signaling mechanisms which govern the crypt-villus axis (Figure 1). The first is an epithelial-epithelial cell communication. The key mediators of these mechanisms are Wnt, Notch, Eph-ephrin and Math 1 signaling pathways. Together and sequentially they are primarily responsible for maintaining the gut stem cells in a proliferative state, differentiation into secretory or absorptive lineage and establish boundaries between these clones of cells. Mutation in these critical pathways has been implicated with excessive uncontrolled, ectopic crypt formation, adenomas, excessive goblet cell or neuroendocrine cells and other risks for colorectal malignancies.

The second major group of cellular signaling comprises

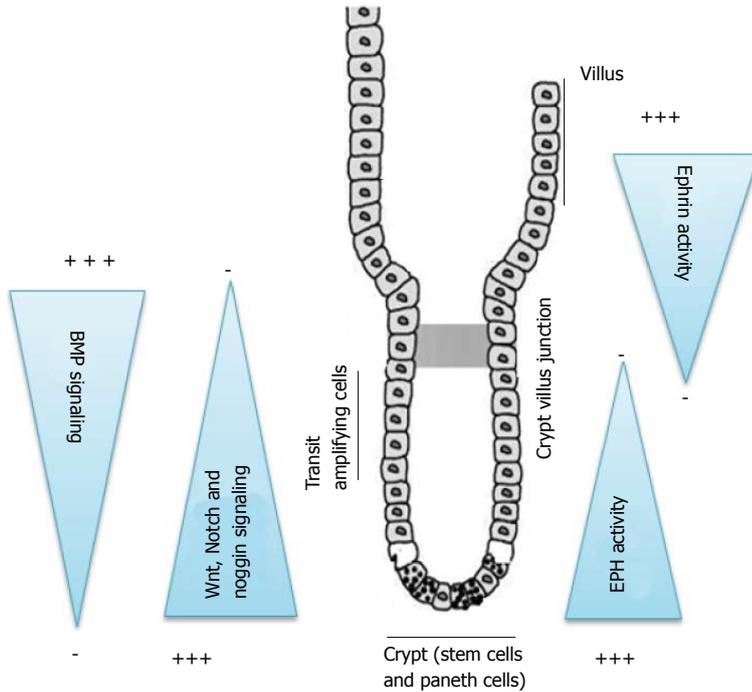

Figure 1 Schematic diagram of crypt-villus axis. The initial signaling mechanisms in a crypt-villus axis begin with Wnt and Notch pathways. The Wnt pathways maintain the gut stem cell compartment. The Paneth cell which constitutes part of the stem cell niche generates Wnt signals that act over a short range and keep cells in the crypt in a proliferative state. There exists a gradient in Wnt, Notch and noggin signaling which is highest in the crypt base and diminishes towards the crypt-villus junction. BMP signaling is low in the crypt and higher in the crypt villus junction. A definitive gradient exists for Eph-ephrin pathways too. The cells acquiring a differentiated fate switch off the expression of Eph-B and switch on the expression of Ephrin B ligands which progressively increases as they migrate up the axis.

of epithelial-mesenchymal (EMT) communications and the mediators in these pathways consist of hedgehog, BMP and PDGAF signaling pathways. The essential function of EMT pathways is to maintain a proper spacing between one crypt and the next. They are negative regulators of crypt formation. Hedgehog signaling increases the expression of BMP in the mesenchyme which further represses the Wnt signaling. Noggin, a BMP inhibitor is expressed in the crypts to maintain unsuppressed Wnt activity in the crypt epithelium (Figure 1). Mutation in these pathways or inhibition of BMP signaling by overexpression of its inhibitors, Noggin or inactivation of its receptor BMPRIA lead to excessive and ectopic crypt formation as seen with juvenile polyposis syndrome due to BMP knock out mutations^[39].

We will limit our discussion to the epithelial-epithelial signaling mechanisms which may hold clues to the pathogenesis of GCC.

The initial signaling mechanisms in a crypt-villus axis begin with Wnt and Notch pathways in the crypts (Figure 1). Both the development of small intestine and its homeostasis require canonical Wnt signaling. The Wnt pathways maintain the gut stem cell compartment. The Paneth cell which constitutes part of the stem cell niche generates Wnt signals that act over a short range and keep cells in the crypt in a proliferative state^[31,33]. There exists a gradient in Wnt signaling which is highest in the crypt base and diminishes towards the crypt-villus junction (Figure 1). Wnt signaling further drives the expression of Notch pathway. Notch pathway through its ligands such as Delta and jagged and effectors such as Hes and NF- κ B transcription factors mediate lateral inhibition within the Wnt activated cell population thus driving cells towards different fates. Delta expressing cells escape Notch activation (Wnt⁺, Notch⁻) and commit to secretory

fate through the downstream Math-1 signaling pathways and exit into a committed fate^[32,33,40]. Meanwhile (Wnt⁺/Notch⁺) cells continue to migrate up the crypt and divide, generating daughter cells and diversify till they lose Wnt activation as they move up the villus and differentiate as absorptive enterocytes. Inactivation of Notch pathway by deletion of Hes 1 or nonsense mutation of Delta ligands leads to excessive formation of goblet cells and neuroendocrine cells^[32,33,40]. Further studies have shown that inhibiting transcription factors in the Notch pathways by deletion of RBP-jk or by use of γ -secretase inhibitors prevents proteolytic cleavage and the release of notch intracellular domain complex. This result in epithelial cells composed exclusive of goblet cells^[41]. Conversely experiments have shown that increased Notch activity results in severe reduction of differentiated secretory cells, suggesting a tumor suppressor role of Notch signaling in neuroendocrine tumors^[42].

In addition to Wnt-Notch signaling another significant pathway in the crypt-villus axis known to play a role in maintaining cellular boundaries, segregation and establish migratory path are the Eph-ephrin molecules (Figure 1). Expression of Eph B receptors and the Ephrin-B ligands within the intestine is regulated *via* the β -catenin-TCF transcription complex through the Wnt pathway. A definitive gradient exists with proliferative cells in the crypt expressing higher density of Eph-B receptors and progressively decreases at the crypt villus axis. The cells acquiring a differentiated fate switch off the expression of Eph-B and switch on the expression of Ephrin B ligands which progressively increases as they migrate up the axis. Paneth cells express only Eph receptors and therefore remain at the crypt base. In general cells expressing Eph receptors are repelled by contact with cells expressing ephrins on their surface.

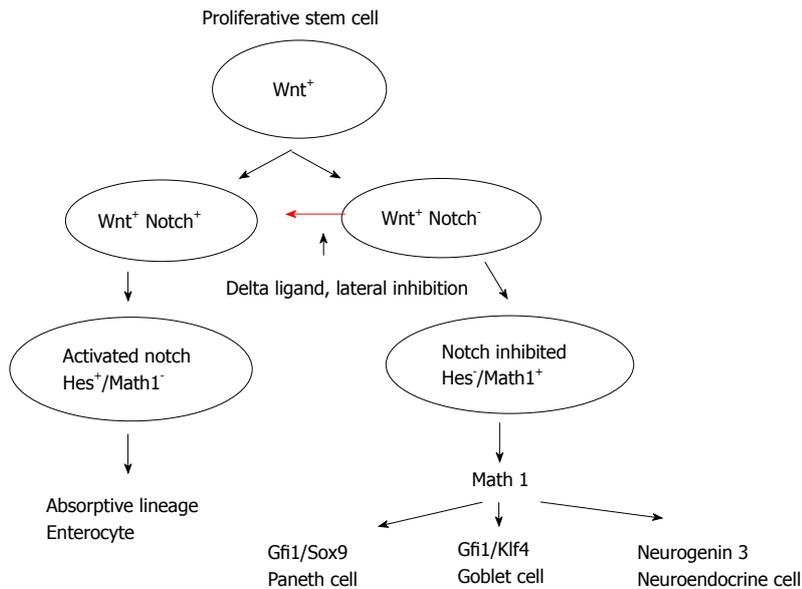

Figure 2 Intestinal stem cell signaling (Wnt, Notch, Math-1 pathways, lateral inhibition).

These mechanisms keep the cells segregated in their respective niches. Dysregulation of the eph-ephrin axis leads to cellular derangement with proliferating cells are not restricted to the bottom of the crypt and abnormally scattered along the crypt-villus axis^[33]. Eph B mediated compartmentalization restricts the spreading of Eph B expressing tumor cells into ephrin B1-positive territories *in vitro* and *in vivo*. Loss of EphB-mediated compartmentalization may lead to invasiveness of the tumor cells^[43].

All three secretory cell types derive from a precursor expressing Math-1 (mouse atonal homologue 1), also known as Atoh1, Hath-1 (humans) (Figure 2). As explained earlier Delta expressing cells escape Notch activation (Wnt^+ , $Notch^-$) and commit to secretory fate through the downstream Math-1 signaling pathways^[32,33,40]. It is a basic helix-loop-helix transcription factor that is required for secretory cell lineage through downstream Neurogenin 3 for neuroendocrine cells, Gfi1 and Klf4 for goblet cells, β -catenin and sox9 for Paneth cells and subsequent cell cycle exit^[31,32,44,45]. Mice deficient in Math1 lack goblet cells and the epithelial cells continue to maintain their proliferative state^[32,40]. Overexpression of Math1 results in ectopic secretory cells^[46]. The immunohistochemical expression of Math-1 in GCC suggests that this transcription factor is essential for normal development of the pluripotent stem cell towards secretory stem cell lineage and may play a role in its pathogenesis. Possible somewhere along its differentiation a mutation occurs with altered signaling pathways which causes excessive clones of goblet cells and neuroendocrine cells and may explain the hybrid nature of this tumor^[18,26].

NETs including GCC appear to be heterogeneous group of tumors with varying signaling mechanisms and gene expressions in different tissue of origin. A number of questions remain to be answered. Is there a Notch signaling dysfunction or inhibition leading to loss of Hes regulated inhibition of Math-1? Studies have confirmed

the potential oncogenic role of Notch signaling and its transcription factor in certain solid organ abdominal, lung, breast, and genitourinary, neural and hematological malignancies^[47]. However Notch signaling also appears to have a tumor suppressor role in gastrointestinal, thyroid and pulmonary neuroendocrine tumors^[42,48,49]. In another recent study of 31 ileal carcinoids, Notch signaling was uniformly absent in ileal neuroendocrine tumors suggestive of loss of tumor suppressive role^[50]. Is the loss of Notch signaling, the driving mutation and occurs after the first stem cell division at the level of transit amplifying cells with subsequent progeny showing dysfunction? Could there be a concurrent Eph-ephrin pathway mutation along with loss of notch signaling, leading to loss of compartmentalization of cells and portending invasiveness^[43]?

Why does metastatic GCC show minimal neuroendocrine expression and more of signet ring cell and poorly differentiated morphology? Are there further successive mutations downstream in the Math-1 signaling pathway? Are there subsequent epigenetic modifications, chromatin remodeling and inactivation of tumor suppressor genes which further amplify the carcinogenesis?

Further investigations at these levels are needed that may lead to our understanding of the pathogenesis of these tumors and may have therapeutic implications. Targeted therapies to activate Notch signaling with varying concentrations for metastatic GCC may have potential benefits. The origin of goblet cells carcinoid and its transformation from typical GCC and to advanced signet ring cell, poorly differentiated adenocarcinoma could be due to spontaneous, sporadic mutation in the mentioned crypt-villus architecture and or the surrounding mesenchyme and is yet to be successfully identified. Characterizing the levels of expression of Notch pathway components in tumor samples from patients with GCC could serve as a tumor marker. This reinforces the need to further investigate the presence of these mutations in larger cohorts and in institutions

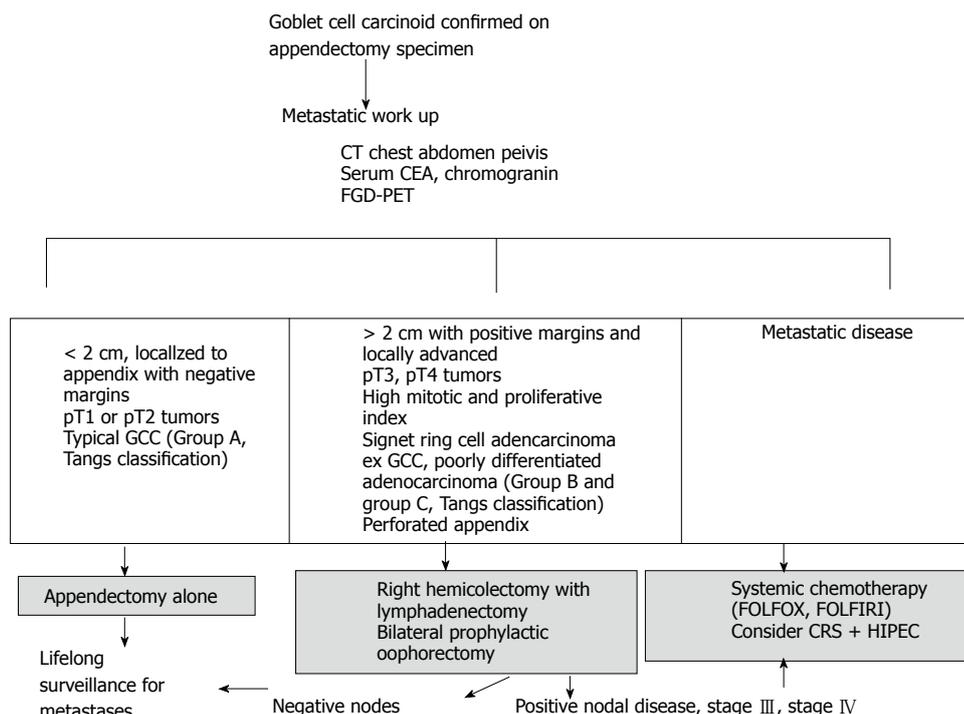

Figure 3 Treatment algorithm for goblet cell carcinoid. FDG-PET: Fluorodeoxyglucose positron emission tomography; GCC: Goblet cell carcinoids.

treating patients with GCC and appendiceal NETs.

TREATMENT

Most patients typically present with acute appendicitis and undergo appendectomy. The dilemma arises after GCC is diagnosed and confirmed, whether simple appendectomy is adequate or further oncologic resection is required (Figure 3). A multi-disciplinary evaluation is recommended for the optimal treatment. Both European and North American Neuroendocrine tumor societies guidelines recommend right hemicolectomy after appendectomy due to the high rate of metastases and its impact on prognosis^[30,51]. However other authors have argued against right hemicolectomy in their series^[8,13,52,53]. In a meta-analysis evaluating 13 studies with 100 patients, the authors concluded no benefits of right hemicolectomy in all patients. Selective criteria were recommended^[53]. In another recent retrospective analysis of a larger number of appendiceal NETs, GCC and signet ring cell adenocarcinoma from seer database showed a benefit of right hemicolectomy and statistically improved survival only for signet ring cell cancer when compared to appendectomy alone ($P = 0.01$). There was no significant difference in survival for typical NETs ($P = 0.21$) or GCC ($P = 0.94$) based on type of surgery^[54]. Based on Tangs classification the histology of the tumor in the appendectomy specimens and not the size of the tumor should determine the extent of oncologic resection^[8]. In patients who fulfill all the following criteria: Tumor less than 2 cm localized to appendix with negative margins, pT1 or pT2 tumors, and typical GCC histology group A (Tang *et al*^[8] classification) tumors, an

appendectomy alone may be sufficient as the definitive treatment^[13]. Right hemicolectomy is recommended in tumors greater than two centimeters, locally advanced, positive margins, T3, T4 tumors and histology suggestive of group B, group C (Tangs classification) in the appendectomy specimens^[8,11,12,55].

The impact of perforated appendicitis in patients with GCC remains unclear. In a meta-analysis of 18 cases of GCC diagnosed upon perforated appendicitis showed no impact on survival and prognosis^[56]. In another retrospective series of 20 GCC patients with perforated appendicitis, a lower rate of peritoneal metastases was observed in the perforated group (15%) compared to the non-perforated group (42%) with no difference in peritoneal relapse between the two groups^[9].

A complication of GCC of the appendix is their propensity to spread to the ovaries. GCC of the appendiceal origin express elevated MUC2 and MUC5AC. In contrast mucinous tumors arising from ovarian primaries express only MUC5AC^[57]. This could be of benefit in differentiating the origin of these tumors in females with primary ovarian mucinous malignancy^[58]. In postmenopausal female patients with GCC prophylactic bilateral oophorectomy, although not evidence based should be considered^[7,8,12]. In female patients with mucinous ovarian and pelvic malignancies an appendectomy should always be performed in staging laparotomy as these may represent metastatic GCC^[12,19,57].

Adjuvant systemic chemotherapy is prescribed for stage III and stage IV diseases and disease recurrence. Due to rarity of GCC a randomized control trial cannot be accomplished. Data is available from scattered anecdotal reports and small series of GCC and therefore guidelines

for choice of chemotherapy is lacking. Since metastatic GCC shows clinical and histological resemblance to colorectal adenocarcinoma and not metastatic carcinoids the choice of adjuvant therapy in GCC is similar to colorectal adenocarcinoma. 5-fluorouracil (5-FU) and leucovorin based FOLFOX (5-FU, leucovorin, oxaliplatin) and FOLFIRI (5-FU, folic acid, irinotecan) chemotherapy are standard regimens recommended^[11,30].

With locally advanced or recurrent peritoneal disease, cytoreductive surgery with hyperthermic intraperitoneal mitomycin and systemic chemotherapy (CRS+ HIPEC) may improve median survival^[11,12,17,59,60]. In a recent study of 45 patients with GCC and peritoneal metastases who received CRS+ HIPEC, the therapy was successfully completed in 71% of patients and 3 years, overall survival (OS) was 63.4 %^[60]. Another study on 26 patients report median survival of 51 mo and an overall five-year survival of 43%^[17]. However a recent retrospective study on 25 patients who received CRS plus HIPEC therapy reports no reduction in relapse rates or improvement in disease free survival in either stage I and II compared to stage III and IV^[9].

The other treatment options generally available for metastatic carcinoids such as interferon, somatostatin analogues (octreotide), targeted agents such as everolimus and sunitinib and radionuclide targeted therapy is not useful for metastatic GCC due to the absence of adequate uptake on Octreoscan or Gallium 68 PET scan and no confirmed mechanistic target of rapamycin or vascular endothelial growth factor pathway dysregulation.

PROGNOSIS

The overall disease specific survival for all GCC subtypes is 40%-80% depending on different series^[7-9,11,12,54]. The five-year survival for localized, regional and distant metastatic disease based on Tang's classification of group A, B, C are 100%, 36% and 0% respectively. This correlates with the AJCC (TNM) staging system where reported five-year survival with stage I (100%), stage II (76%), stage III (22%), stage IV (14%), respectively.

CONCLUSION

GCC are a separate entity from carcinoids and adenocarcinoma. The pathogenesis is unclear however the tumor likely arises from pluripotent intestinal epithelial crypt base stem cells. Successive mutations likely favor them into progressing and behavior similar to poorly differentiated adenocarcinoma with minimal neuroendocrine differentiation. Metastatic lesions differ from the primary appendiceal site in terms of histology and tumor aggressiveness. A multidisciplinary approach is suggested for optimal outcomes. Surgery remains the main treatment modality. Due to its heterogeneity, this tumor should not be classified according to a single system and a combination of size of the tumor (T classification), grade and mitotic index (WHO classification) and arrangement of the goblet cells, degree of atypia

and desmoplasia (Tang *et al*^[8]'s histopathologic classification) should dictate further definitive therapy. Simple appendectomy may be sufficient in early stages while right hemicolectomy is recommended for advanced tumors. CRC with HIPEC may improve survival in a select few with metastatic peritoneal disease. These tumors have an unpredictable behavior even in early stages and local recurrence and delayed metastases may be frequently seen. Therefore lifelong surveillance is warranted.

Abstract

Over the last two decades, advances in laparoscopic surgery and minimally invasive techniques have

transformed the operative management of neonatal colorectal surgery for conditions such as anorectal malformations (ARMs) and Hirschsprung's disease. Evolution of surgical care has mainly occurred due to the use of laparoscopy, as opposed to a laparotomy, for intra-abdominal procedures and the development of trans-anal techniques. This review describes these advances and outlines the main minimally invasive techniques currently used for management of ARMs and Hirschsprung's disease. There does still remain significant variation in the procedures used and this review aims to report the current literature comparing techniques with an emphasis on the short- and long-term clinical outcomes.

Key words: Neonatal surgery; Laparoscopy; Anorectal malformation; Colorectal surgery; Hirschsprung's disease

Core tip: This review describes the recent evolution of neonatal colorectal surgery. It details the advances and current techniques since the introduction of laparoscopic surgery and minimally invasive approaches to the surgical management of anorectal malformations and Hirschsprung's disease. This review focuses on the various surgical options available and the benefits of these different techniques, outlining the current literature reporting the short- and long-term outcomes for these procedures.

INTRODUCTION

The application of minimal access techniques within

paediatric surgery has evolved considerably in the last thirty years since the advent of laparoscopic surgery in the late 1980s. Advances in laparoscopic techniques and the development of new entirely transanal procedures has transformed the operative management of paediatric colorectal conditions, in particular Hirschsprung's disease and anorectal malformations (ARMs). Improving technology and refinement of techniques over the last decade has allowed these minimally invasive approaches to be used in increasingly challenging cases.

ARMS

History and evolution of technique

The posterior sagittal anorectoplasty (PSARP), a perineal approach to the correction of ARMs, has been standard practice since it was first described by Peña in the 1980s^[1]. Laparoscopy in the operative management of ARMs was first described in 1998. The laparoscopic-assisted anorectal pull-through (LAARP) was popularised in 2000^[2]. Proponents advocated this approach to avoid a laparotomy to ligate a high fistula and aimed to reduce post-operative pain and recovery time.

The LAARP is beneficial for recto-bladder neck fistulae and it may facilitate clear identification of the levator muscles so the surgeon can be sure of the correct position of the anus, avoiding the risks of sagittal dissection^[3]. It was hoped this small perineal wound, opening only in the centre of the muscle complex, would improve functional outcomes by its relative preservation of the sphincter muscles^[4].

Indications and use of laparoscopy initially expanded rapidly due to the benefit of avoiding extensive perineal dissection which was postulated to reduce soft tissue rectal scarring and lead to improved rectal compliance. However, the management of low anorectal malformation in males (recto-perineal and retro-bulbar fistulae) *via* a laparoscopic approach has resulted in an increased risk of urethral injury due to a difficult and extensive pelvic dissection as well as injury to the rectal nerves and pelvic plexus. This results in poor bowel function and therefore laparoscopy in these cases is unwarranted^[5,6].

CURRENT TECHNIQUES

Single or staged laparoscopic procedure?

ARMs with a recto-urethral fistula have been traditionally managed with colostomy formation in the newborn period, followed by definitive anorectoplasty at a later stage. Good positioning of the colostomy is vital to avoid problems in mobilizing the rectum^[3]. There is an argument in favour of the use of laparoscopy for stoma formation to ensure that it is appropriately sited and also to allow for fistula assessment and consideration of primary repair^[7]. Laparoscopy has therefore allowed surgeons to treat patients with recto-

bladder neck fistula ARMs with a single procedure without an initial colostomy. Small case series have shown that this is feasible and without the presumed difficulties of abdominal distension when the patient is operated within 48 h after birth^[7]. Though the rectum may be dilated with meconium, it has been shown to be feasible with laparoscopic manipulation to perform the dissection safely. Initial concerns about handling of friable bowel leading to injuries have not been seen in the published series reporting this technique^[7].

LAARP

We prefer a three stage operation in case of high ARMs with or without fistula. Following stoma formation, a colostogram is performed to identify the presence and level of fistula^[4]. Laparoscopic assisted pull-through is usually performed at 3 mo of age^[4].

In recto-bladder neck fistula, the fistula is located approximately 2 cm below the peritoneal reflection, and the rectum communicates with the urinary tract in a T fashion, which means that there is a minimal common wall between the distal part of the rectum and the urinary tract. The laparoscopic approach provides an excellent view of the peritoneal reflection, the ureters and the vas deferens, which must be visualised to prevent injury when dividing a recto-bladder neck fistula^[2].

The operation is begun by dividing the peritoneum around the distal rectum to create a plane of dissection to be followed distally. The dissection should occur on the rectal wall. The rectum rapidly narrows as it reaches its communication with the bladder neck. Dividing the fistula as close to the urinary tract as possible is required to prevent the formation of a diverticulum in the future^[8]. This can be confirmed by noting that the rectum has narrowed sufficiently to allow the 3 mm Maryland laparoscopic instrument to completely clamp across the fistula. A suture with 3/0 PDS is used to ligate the fistula. A submucosal dissection plane to create a mucosal tube of the distal rectum has been advocated as this facilitates easier ligation, further limiting the amount of fistula tissue left attached to the urethra^[9]. Initial reports described clip or endoloop ligation of the fistula but later studies have shown that simple sharp ligation flush with the bladder is the best technique^[10,11].

The distal rectum is then mobilized by dividing feeding vessels until there is enough length to pull the rectum comfortably down to the perineum. If the colostomy was created too distal in the sigmoid it may prevent this mobilisation.

The pubococcygeus muscle is then identified by inspection of the pelvic floor. A hiatus is located along the anterior surface of the two muscle bellies just posterior to the urethra which is the anatomical landmark where the rectum will be delivered from the pelvic side of the dissection^[2,5].

Various techniques have been described for creation

of the pull-through channel at the optimal site. The laparoscopic Peña electrostimulator has been used to identify accurately the centre of the muscle complex in the perineum^[10,12]. This can be particularly useful in cases of immature and unclear levator muscles^[3,13]. The positioning of the channel can be further guided with perineal and endoscopic ultrasound which can also serve as a useful tool for ensuring that the dissection is not risking injury to genitourinary structures^[14,15].

Entry into the pelvis from below can be facilitated under laparoscopic vision with a Verees needle and serial dilatation until a 10-12 mm trocar can be placed to allow the bowel to be pulled through and the anoplasty completed^[4,9].

Robotic assistance has been used to perform these operations in a limited series. The increased range of movement added with 3D vision technology aims to make the pelvic dissection easier for the surgeon. Currently this is hampered by the size of these infants but, as these technology advances, robotic assistance may prove a valuable tool in minimally invasive pull-through surgery for ARMs^[16].

As with other laparoscopic procedures, surgeons aiming for improved cosmesis have reported successful completion of LAARP using single-port techniques but such techniques are not commonplace due to the technical challenges and cosmetic benefits^[17].

OUTCOMES FOR LAPAROSCOPIC REPAIR OF ARMS

Short-term outcomes

Anal stenosis is a significant complication following PSARP and remains so in case series of LAARP. Ischaemia of the pull-through and tension on the anastomosis are causes of stenosis but it can also result from non-compliance with the postoperative dilatation regimes^[10].

Initial pitfalls encountered with the laparoscopic approach have been bladder/urethral injuries, bladder/urethral diverticulum and rectal prolapse but as the technique has become more established these problems do not appear to be encountered any more frequently in this group^[18].

There is evidence of reduced operating times, post-operative stay and blood loss in the LAARP group compared with open PSARP for high ARMs but again in these case series no clinical outcome difference was found^[19,20].

Long-term outcomes

It has been well documented that constipation is a major problem for patients that have undergone corrective surgery for high ARMs^[21]. Reviews have indicated a 80%-100% constipation rate following corrective surgery for recto-vesical fistulae^[22,23]. Some degree of soiling has been shown to occur in 42%-63% of cases of recto-vesical fistula^[23]. It has been noted that the majority of these patients experience resolution of constipation

by the time they have progressed through puberty^[24]. Long term follow up suggests that approximately half of patients managed with PSARP for high anorectal malformation have an excellent functional result by adulthood^[25]. It remains to be seen whether LAARP will improve this figure.

Outcome data for patients that have had LAARP remains limited to small series with relatively short follow up. The incidence of the most commonly described outcomes after PSARP and LAARP are shown in Table 1. These rates are calculated from pooled data used in a meta-analyses^[26]. An increase in preserved recto-anal relaxation reflex has been shown in patients undergoing LAARP compared to PSARP by performing follow up anorectal manometry^[27]. MRI imaging has revealed less peri-rectal fibrosis and sphincter asymmetry in these patients. However, neither of these measures has shown a correlation with a significant clinical improvement in the studies to date^[26-29].

It has been shown that the objective feedback using a continence evaluation questionnaire is significantly better at 3-4 years post-op in the LAARP group compared to PSARP, however this significance did not persist in patients that had been followed up for 5 years or more^[30]. The possible significance of this data remains limited by its small numbers.

Currently the main benefit of the laparoscopic approach is to replace the laparotomy in cases of recto-bladder neck and recto-prostatic urethra fistula. Other potential benefits remain to be confirmed^[18,31]. Attempts to review and combine the data of existing studies to ascertain if there are significant benefits have been unsuccessful due to the lack of standardisation of outcome measures reporting between paediatric surgical centres^[26,29].

HIRSCHSPRUNG'S DISEASE

History and evolution of technique

The surgical management of Hirschsprung's disease has evolved since the basic principles of repair described by Swenson *et al*^[32] in 1948. Progression occurred from a two- or three-stage procedure to a primary operation in the early 1980s^[33]. In the single stage primary operation, a laparotomy is used to mobilise the colon followed by an endorectal pull-through. Three main endorectal pull-through techniques are popularly used: Swenson, Soave and Duhamel.

The laparoscopic-assisted primary pull-through was first described by Georgeson *et al*^[34] in 1995. Following this, surgeons quickly began to replace the laparotomy for the transabdominal portion of each of the different pull-through procedures with laparoscopy^[35,36]. Subsequently, the entirely transanal endorectal pull-through emerged in 1998^[37].

More recent technical advances have also been described in conjunction with the pull-through procedure. Single-incision laparoscopic surgery has been used safely

Table 1 Comparison of outcomes of the open posterior sagittal anorectoplasty and the laparoscopic-assisted anorectal pull-through for management of anorectal malformations, subdivided into high and low malformations

	Open PSARP			LAARP		
	High	Low	All	High	Low	All
Short-term outcomes						
Mucosal prolapse (%)	10.7	21.2	16.4	9.8	2.9	6.2
Long-term outcomes						
Defecation dysfunction (%)	33.3	41.8	40.3	36.4	27	29.2
Rectoanal inhibitory reflex positive (%)	-	-	57.4	-	-	72.7

Rates extrapolated from pooled data from a meta-analysis comparing the different techniques^[26]. PSARP: Posterior sagittal anorectoplasty; LAARP: Laparoscopic-assisted anorectal pull-through.

to compliment the transanal endorectal pull-through and the Duhamel's procedure^[38-40]. One series used robotic assistance for the Swenson pull-through in 7 cases. They hypothesize that the increased dexterity as compared to laparoscopic surgery may improve the accuracy of the endorectal dissection and thus improve future outcomes, however this is as yet unproven^[41].

Main current techniques

The majority of patients with Hirschsprung's disease are suitable for a definitive primary procedure, using either the laparoscopic-assisted or the primary transanal approach^[42]. Both of these techniques can be performed at any age and are routinely performed within the first few months of life^[43,44].

Relative contraindications for a primary procedure include severe dilatation of the proximal bowel, significant clinical deterioration due to enterocolitis or long segment Hirschsprung's disease^[42]. These patients may be more appropriately managed with an initial levelling colostomy, which can be achieved with a laparoscopic approach, and a definitive pull-through procedure performed at a later stage. Laparoscopy offers the advantage of visualising the entire bowel, allowing for identification of the transition zone and biopsies prior to creating a stoma at the appropriate level.

Long segment Hirschsprung's disease is defined as a transition zone proximal to the mid-transverse colon. The most common type is total colonic aganglionosis, which can involve a portion of the terminal ileum. Although any of the three pull-through techniques can be used, the laparoscopic assisted Duhamel's procedure is favoured in these patients.

Laparoscopic-assisted endorectal pull-through

Laparoscopy is first used to take intra-operative frozen section levelling biopsies in order to identify normal ganglionated bowel. The bowel is inspected to identify the transition zone. A seromuscular biopsy is taken from above the transition zone in what appears to be normal bowel. Any perforation or bleeding at this site can be closed with a braided suture (Figure 1). If ganglion cells are absent or there is evidence of thickened nerve fibres then biopsies should be continued proximally until

normal ganglionated colon is identified. No dissection of the mesentery or rectum should be started until the level of normal bowel has been confirmed.

At this stage, in those patients found to have a long Hirschsprung's segment, it may be preferred to create a stoma above the suspected transition zone and delay the definitive procedure to a later stage, in order to await formal histology results.

Once the proximal level of the pull-through has been established, mobilisation of the colon with dissection of the mesocolon and mobilisation of the rectum below the peritoneal reflection can be continued laparoscopically (Figure 2). This is usually achieved with hook diathermy or the harmonic scalpel in older children. The transanal dissection of the surgeon's choice then follows. This involves a trans-anal endorectal dissection of the rectum starting 2-3 mm above the dentate line until the rectum and colon is completely free. In a Soave procedure, the first part of the dissection includes only the mucosa and submucosa, leaving a muscular cuff of aganglionated rectum. The posterior wall of this cuff should be incised in order to prevent stenosis. At this stage the pneumoperitoneum can be re-instated, using the laparoscope to visualise the mobilised aganglionic rectum and colon as it is pulled through. This ensures that the bowel has not been kinked or rotated during this process and there is sufficient mobilisation of the colon to prevent tension on the anastomosis. The mesenteric defect or window should then be closed to prevent the risk of an internal hernia. The aganglionated segment is excised and anastomosis of the colon to the rectal mucosa is performed, followed by closure of the laparoscopic port sites^[45].

Laparoscopic Duhamel procedure

The procedure for the initial levelling biopsies for the laparoscopic Duhamel procedure is the same as for the laparoscopic-assisted endorectal pull-through, as described above.

After the level of normal ganglionated bowel has been identified, the colon needs to be mobilised adequately and the mesentery of the distal aganglionated bowel can be divided. Once dissection has reached the peritoneal reflection, the rectum is closed to create the rectal

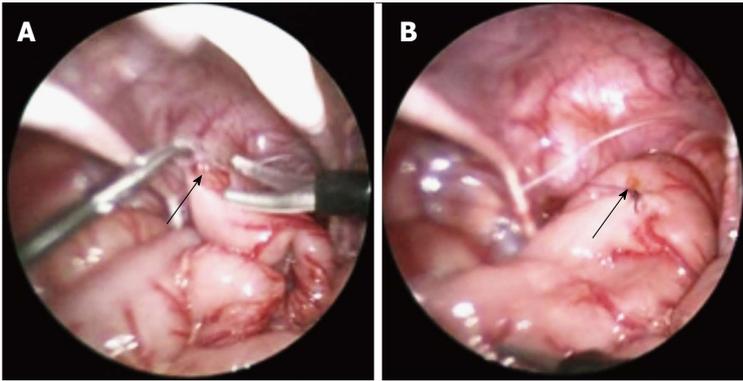

Figure 1 Photographs demonstrating a laparoscopic colonic biopsy taken in the sigmoid colon. A: Maryland grasper holding the sigmoid colon, while scissors are used to take the biopsy specimen; B: The biopsy site is then sutured closed. Arrow indicates the biopsy site.

pouch, either by oversewing the bowel or using an automatic stapler. Following this, the posterior rectum is then incised transanally, approximately 1 cm proximal to the dentate line. This creates an opening for the pull-through. A tunnel behind the rectum is created with a smooth dissector and dilated up to an adequate size with Hegar dilators. The proximal colon is pulled through the tunnel using a traction suture under laparoscopic vision. The colon is then anastomosed to the posterior wall of the rectum at the incision site. This can be completed with an automatic stapler to remove the wall between the rectal stump and the colon. Correct positioning of the pulled-through colon, without twisting or tension, is then confirmed using the laparoscopic view prior to closure^[46,47].

Primary trans-anal endorectal pull-through

The totally trans-anal endorectal pull-through was derived from the laparoscopic-assisted endorectal pull-through. It excludes the initial biopsies and proceeds directly to the trans-anal endorectal dissection, assuming that if the infant is responding to rectal wash-outs there is a classic Hirschsprung’s disease, with the transition zone at the recto-sigmoid colon. Either a lonestar retractor or retracting sutures are placed between the perianal skin and the dentate line. The rectal mucosa dissection begins 2-3 mm above the dentate line. In a Soave procedure, the dissection then proceeds submucosally until the peritoneal reflection at the level of the pouch of Douglas is reached. At this point the bowel can be dissected full-thickness after separating the sero-muscular plane 360

degrees. The muscular cuff should be vertically split posteriorly to avoid stenosis. The dissection continues along the rectal wall until a clear difference in calibre is noted, representing the transition zone. Alternatively in the Swenson procedure, the dissection of the rectum is full thickness from the beginning, leaving no muscular cuff. Once the peritoneal reflection has been reached the colon will be pulled through and the mesentery is divided trans-anally. Care must be taken to avoid rotating the bowel as the dissection progresses. Biopsies can be taken and sent as frozen section during the procedure to confirm the level of the transition zone. Once normal bowel has been reached the aganglionic segment can be excised and the anastomosis performed^[37,44].

The trans-anal pull-through has gained popularity due to its simplicity. It avoids the intra-peritoneal dissection and the need for laparoscopic expertise and equipment, which may be particularly important in low-income countries. However, in cases where the transition is proximal to the sigmoid colon mobilisation of the descending colon is usually required in order to perform an anastomosis without tension. This can be achieved laparoscopically if necessary.

The main benefit of using the laparoscopic-assisted approach over the primary trans-anal approach is early identification of the transition zone prior to dissection of the mesentery so that long segment Hirschsprung’s can be identified and dealt with appropriately. Laparoscopy also allows full mobilisation of the colon on a mesocolic pedicle to minimise tension on the anastomosis, and reduces the risk of rotational abnormalities during the

Table 2 Comparison of short-term and long-term outcomes of various approaches to the pull-through procedure for Hirschsprung's disease

	Open pull-through		Laparoscopic-assisted pull-through		Transanal endorectal pull-through
	Swenson/soave	Duhamel	Endoanal	Duhamel	
Short-term outcomes

Faecal incontinence (%)	26	11	35	4	20

Rates taken from pooled data from meta-analyses comparing the different techniques^[52,57,60].

pull-through^[48]. Additionally, it reduces the need for a lengthy trans-anal dissection resulting in less dilatation of the anal sphincter, a factor that may be associated with faecal incontinence in the long-term^[49].

OUTCOMES

Short-term outcomes

Quoted benefits of laparoscopic surgery over traditional open techniques include reduced post-operative pain, quicker recovery of bowel function, shorter length of stay and improved cosmesis^[43,46,50]. On the contrary, the disadvantage is thought to be a longer operative time^[46,50]. Reported operative time for the open approach ranges from 91.3-297 min, laparoscopic approach from 150-257 min, and trans-anal approach from 43.5-258 min. Meta-analyses directly comparing these techniques demonstrated a shorter operating time in laparoscopic procedures and trans-anal procedures^[51,52]. Reported length of stay for open procedures range from 6.9 to 18.7 d, laparoscopic-assisted procedures from 3.6 to 10.4 d and trans-anal endorectal procedures from 2.6 to 9.8 d. Two studies comparing laparoscopic vs open procedures showed a significantly shorter average length of stay with laparoscopic procedures; 4 d following the laparoscopic endorectal pull-through, 7 d with the laparoscopic Duhamel pull-through and 10 d after an open Duhamel pull-through^[46,53]. When compared to the transabdominal approach, both the laparoscopic-assisted pull-through and the trans-anal endorectal pull-through have been shown to have a shorter length of stay^[51,52].

Conversion of a laparoscopic to an open procedure usually occurs for technical reasons and conversion rates range between 1%-2.5%^[39,43,54].

Recognised early post-operative complications of the pull-through procedure for Hirschsprung's disease include bleeding, anastomotic leak, perforation, adhesive bowel obstruction and post-operative enterocolitis. Late complications include anastomotic stenosis, enterocolitis, need for re-do surgery. These have all been described in association with the minimally-invasive techniques^[39,43,54-56]. Rates of these post-operative complications are comparable in laparoscopic and open approaches and may favour laparoscopic procedures. Although no individual comparative study has shown any

significant difference in complication rates, pooled data from a meta-analysis demonstrated fewer complications in the laparoscopic operations^[51]. A meta-analysis comparing laparoscopic vs open Duhamel procedure showed lower rates of further surgery in the laparoscopic group, with 14% compared to 25% of patients after the open procedure. The incidence of post-operative enterocolitis is 10% after the laparoscopic Duhamel's procedure and 15% after the open procedure, however this did not reach significance^[57].

A large cohort study investigating the transanal endorectal pull-through suggested lower rates of early complications compared to the transabdominal approach^[58]. The reported incidence of enterocolitis following the transanal endorectal pull-through ranges from 4.6%-54%, with a systematic review suggesting an incidence of 10.2%^[59]. Comparison with both the transabdominal approach and laparoscopic-assisted approaches have not demonstrated any difference in the rates of post-operative enterocolitis^[52,60].

Long-term outcomes

Functional outcomes after surgery for Hirschsprung's disease relate to impaired bowel function. Both severe constipation and faecal incontinence are experienced by these patients even into adulthood, although bowel function has been demonstrated to improve with increasing age^[61]. The rate of severe constipation does decrease by young adulthood^[62]. Additionally, faecal incontinence, impacting on quality of life, was reported less frequently with longer follow-up. It seems that puberty is the critical age for this improvement as bowel function in late adolescence and adulthood remains similar^[63].

Investigation of the long-term outcomes of Hirschsprung's disease managed with minimally invasive techniques has been carried out, with on average up to 5 years of follow-up. There have been 3 meta-analyses undertaken comparing different techniques; laparoscopic to open Duhamel procedure, trans-anal endorectal approach to transabdominal approach, and trans-anal endorectal approach to laparoscopic endoanal approach^[52,57,60]. Unfortunately, the data has a significant degree of heterogeneity, both in terms of the actual surgical techniques used and in how

the outcomes, constipation and faecal incontinence, were defined. The incidence of the most commonly described outcomes across the different techniques is demonstrated in Table 2. These rates are calculated from pooled data used in the meta-analyses.

Meta-analysis comparing the laparoscopic Duhamel to the open Duhamel procedure indicated that the incidence of faecal incontinence seems to be significantly lower with the laparoscopic approach (4% and 11% respectively; $P = 0.02$), while the incidence of severe constipation does not seem differ (30% and 23% respectively; $P = 0.12$)^[57]. Another study suggested lower constipation rates and better continence at 1-year follow-up for the laparoscopic-assisted endoanal pull-through over the Duhamel procedure^[53].

Initial early evidence with the transanal endorectal pull-through raised concerns about higher rates of faecal incontinence^[49]. This was hypothesized to be related to overstretching of the anal sphincter muscles during the neonatal procedure. Recently comparison of the transanal endorectal approach to the trans-abdominal approach suggested reduced rates of incontinence and constipation^[52]. While a comparison between the transanal endorectal approach to the laparoscopic-assisted endoanal approach demonstrated no difference in outcome^[60].

Currently it remains too early to fully evaluate the longer term outcomes into adulthood of minimally invasive techniques vs the traditional open procedures^[63].

CONCLUSION

Over the past two decades, there has been significant evolution in the surgical management of neonatal colorectal conditions. Advances in the technology and understanding of minimally invasive surgery have allowed these techniques to be adapted for use in small infants for correction of ARMs and Hirschsprung's disease. Laparoscopy and minimally invasive techniques are now safely and routinely used in the management of these major congenital anomalies. As experience grows, these techniques will be used for increasingly complex and challenging cases.

Benefits of minimally invasive surgery have been demonstrated, in terms of shorter hospital stay and improved cosmesis, and other potential benefits are hypothesized. Major improvements in functional outcomes remain as yet unproven. Significant variation does still exist in the specific operative techniques. High quality data investigating different techniques and comparing both short-term and long-term outcomes is still needed to determine which procedures are most effective for our patients.

Abstract

AIM

To highlight the rising trend in hospital presentation of foreign bodies retained in the rectum over a 5-year period.

METHODS

Retrospective review of the cases of retained rectal foreign bodies between 2008 and 2012 was performed. Patients' clinical data and yearly case presentation with data relating to hospital episodes were collected. Data analysis was by SPSS Inc. Chicago, IL, United States.

RESULTS

Twenty-five patients presented over a 5-year period with a mean age of 39 (17-62) years and M: F ratio of 2:1. A progressive rise in cases was noted from 2008 to 2012 with 3, 4, 4, 6, 8 recorded patients per year respectively. The majority of the impacted rectal objects were used for self/partner-eroticism. The commonest retained foreign bodies were sex vibrators and dildos. Ninety-six percent of the patients required extraction while one passed spontaneously. Two and three patients had retrieval in the Emergency Department and on the ward respectively while 19 patients needed examination under anaesthesia for extraction. The mean hospital stay was 19 (2-38) h. Associated psychosocial issues included depression, deliberate self-harm, illicit drug abuse, anxiety and alcoholism. There were no psychosocial problems identified in 15 patients.

CONCLUSION

There is a progressive rise in hospital presentation of impacted rectal foreign bodies with increasing use of different objects for sexual arousal.

Key words: Rectal foreign bodies; Rigid sigmoidoscopy;

Eroticism; Examination under anaesthesia; Psychosocial issues

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: There is a progressive rising incidence of retained rectal foreign bodies with increasing use of different designed and improvised objects for sexual arousal. The clinicians in the emergency settings must be well informed about the approach to the care of the patients with foreign bodies retained in the rectum.

INTRODUCTION

Hospital presentation with foreign bodies retained in the rectum is no longer rare although concrete epidemiological data are still lacking^[1,2]. The earliest report of rectal foreign body dates back to the sixteenth century^[3]. There have been recent reports to suggest an increasing incidence and hospital presentations with foreign bodies retained within the rectum^[1-6]. Our prediction is that it is very much likely that such increasing hospital presentations shall continue to rise with the use of different objects for anal sexual fantasy. Objects retained in the rectum are mainly encountered in the adults following either intentional or non-intentional insertion. Occasionally, the retained objects may result from accidental or deliberate ingestion which had travelled through the whole of the gastrointestinal tract only to be impacted in the rectum^[1-3,6,7].

These patients usually present to the Emergency Department (ED) due to anorectal, pelvic or lower abdominal pain^[1,4]. Typically, the patients have delayed hospital presentation after several failed attempts at retrieving the object^[1-7]. The delayed presentation, particularly due to the perceived shame and/or associated embarrassment, presents both diagnostic and management challenges to the emergency staff^[1,2]. The fact that significant numbers of these patients are often reluctant to volunteer the truth about the circumstances surrounding their presentation in the ED further contributes to the diagnostic delay. Therefore, the care of the patients with foreign bodies retained within the rectum requires a methodical approach for diagnosis, retrieval of the foreign body and post-extraction clinical observation^[1,2]. The desired ultimate outcome for every case is a safe and successful per anum extraction of foreign body, in a manner as to respecting the patients' right to dignity, privacy and confidentiality.

We present our experience with retained rectal

foreign bodies to highlight a rising trend in presentation over a 5-year period and the approach to management.

MATERIALS AND METHODS

We retrospectively reviewed the cases of all retained rectal foreign bodies that were managed in our hospital over a 5-year period, 2008 to 2012. Patients coded on the hospital Patient Administrative System (PAS) with a diagnosis of rectal foreign bodies were identified. Patient and clinical related data were collected from the hospital records right from the ED presentation through to the admission episode until discharge. Data collected relate to patients' demography, clinical presentation, types of the objects, circumstance relating to insertion, the time from insertion to presentation, physical examination findings, investigations and treatment offered. The yearly case presentation, types of retained rectal foreign bodies, length of hospital stay, associated complications and psychosocial problems were recorded.

RESULTS

A total of 25 patients presented to our ED and treated for retained rectal foreign bodies over the 5 years study period. The mean age was 39 (17-62; SD 13.98) years with 17 males and 8 females giving a gender ratio of 2 to 1. We noted a progressive rise in the number of cases that presented per year from 2008 to 2012 with 3 recorded cases in 2008 and rising to the highest level of 8 cases in 2012 (Figure 1). Various objects impacted in the rectum and the reasons for insertion are shown in Tables 1 and 2 respectively. The presenting complaint were anorectal pain^[4], failure to self-retrieve the object, persistent vibration and anorectal pain^[2], anorectal pain and failure to retrieve the object^[3] and anorectal pain and rectal bleeding^[2]. The mean period between rectal object insertion and the visit to the ED was 14 (1-72; SD 14.6) h. Fifty-two percent (13/25) of the patients volunteered having had previous anorectal insertion of the same object ranging from 2 to 5 episodes with no problem.

Physical examination findings were completely normal in 11 while elicited clinical findings were tender lower abdomen in 3, palpable rectal foreign bodies on digital rectal examination (DRE) in 10 and blood in the rectum with palpable object in 1. Plain abdominal and pelvic X-ray were performed in all patients and erect chest X-ray was selectively performed only in 4 cases where indicated to exclude any free peritoneal gas under the diaphragm. Plain X-ray film confirmed the presence of retained rectal foreign objects in all cases but in one patient with apple in the rectum where it was not so obvious on the plain film. There was no specific indication for computerised tomography (CT) scan in any these patients and therefore this investigation was not done.

Extraction of the retained rectal objects was required

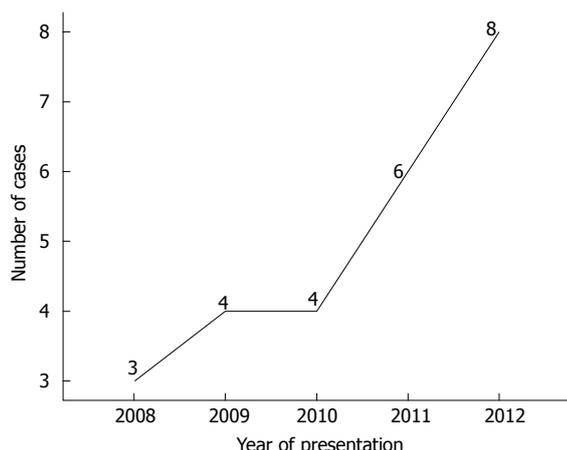

Figure 1 Line chart showing progressive rise in the number of cases over a 5-year period.

in 24 of the 25 patients. One patient passed the object spontaneously while waiting to be taken to the operating theatre. Two patients whose retained foreign bodies were easily palpable had the objects retrieved in the ED by digital manipulation and discharged. Three patients underwent digital removal of the retained rectal foreign bodies on the surgical assessment ward and were kept for a period of observation. Nineteen patients needed examination under anaesthesia (EUA) and extraction of retained foreign bodies in the operating theatre. Of the 19 patients, 15 had the objects extracted with grasping forceps with the aid of a proctoscope and/or a rigid sigmoidoscope, 2 were retrieved using small Keilland's forceps, 1 was digitally removed and one patient with impacted apple in the rectum was broken down and removed piecemeal. Rigid sigmoidoscopy was performed in 19 of 25 patients post extraction to exclude anorectal injury with the status of the anal sphincters assessed and recorded in each case. Two patients sustained anorectal mucosal tear, one of which developed significant bleeding per rectum post extraction; in one patient the sex toy had broken in ano; otherwise there was no complication recorded in 22 patients. There was no evidence of perforation identified in any of our patients in this series either during the EUA and/or following the period careful in hospital clinical observation.

The mean length of hospital stay was 19 (2-38; SD 9.56) h. All our patients had successful per anum extraction of the object with no one requiring a laparotomy or laparoscopy. Identified psychosocial issues in some of the patients included depression and deliberate self-harm in 3, illicit drug abuse in 2, anxiety in 2, depression in 1 and excess alcohol consumption in 2. There were no psychosocial problems identified in 15 patients. There was no correlation between the presence of psychosocial issues and either repeat insertion or number of previous insertions of rectal foreign bodies.

DISCUSSION

Rectal insertion of objects and retention are commonly

Table 1 Table showing types of retained rectal foreign bodies

Retained rectal objects	Frequency	Percentage (%)
Apple fruit	1	4
Glass jar	2	8
Nail varnish bottle	1	4
Sex toy (dildo)	5	20
Sex vibrator	12	48
Denture (accidentally ingested and retained in the rectum)	1	4
Roll on deodorant bottle	2	8
Ceramic candle holder	1	4

Table 2 Reasons for retained rectal foreign bodies

Reasons for insertion of retained rectal foreign body	Frequency	Percentage (%)
Self erotism	9	36
Partner erotism	13	52
Self-massage of rectal prolapse	1	4
Self-harm	1	4
Accidental ingestion of denture	1	4

seen in the adults. These are either used in the majority of cases for anal sexual stimulation or sometime for criminal intent^[1-9]. Occasionally, retained rectal foreign body may have resulted from self-treatment of anorectal conditions, attempts at concealment of illicit drugs or weapons and accidental ingestion of objects which eventually get impacted in the anorectum as in one of our patients^[1,2,4,8,10-13]. There is a wide range of objects finding their ways into the rectum and we and other authors have previously predicted a possible rise in the incidence and presentations in the ED following the of various objects for erotic fantasy^[1-4,6,8].

The current study shows a progressive increase in the number of cases that presented over a 5-year period from 2008 through to 2012 from a single centre. This outlook confirmed what we and some other authors have predicted previously^[1-4,6,8]. This most recent study has demonstrated a significant rise in the number of cases per year compared with studies by Safioleas *et al*^[5] who reported 34 patients over a 25-year period, Coskun *et al*^[6] with a report of 15 patients over a 10-year study period (1999-2009), Rodríguez-Hermosa *et al*^[7] with 30 patients over an 8-year period (1997-2004) and our previous report of 16 cases over a 4-year period (2001-2004)^[8]. We can only expect a continuing rise in the hospital presentations of impacted foreign bodies within the rectum given the increasing fantasy with a wide variety of improvised household and designed objects. Table 3 summarises the trend in the published literature over the last few decades. The sudden surge in the incidence reported by Lake *et al*^[4] covering a 10 year study period was a data from a very large United States population and stands as the largest published data on this subject in the literature. The current data and our previous report^[8] have shown a rising trend in the ED cases of objects impacted in the rectum.

Table 3 Table showing published trend in retained rectal foreign body

Ref.	Study years	No of cases	Average cases per year	M:F ratio
Huag <i>et al</i> ^[14]	1979-2000 (21 yr)	10	0.48	10:00
Lake <i>et al</i> ^[4]	1993-2002 (10 yr)	87	8.7	17:01
Clarke <i>et al</i> ^[13]	1995-2005 (10 yr)	13	1.3	13:00
Rodríguez-Hermosa <i>et al</i> ^[7]	1997-2004 (8 yr)	30	3.75	15:01
Ayantunde <i>et al</i> ^[8]	2001-2004 (4 yr)	16	4	15:01
Safioleas <i>et al</i> ^[5]	1971-2006 (25 yr)	34	1.36	6:1
Coskun <i>et al</i> ^[6]	1999-2009 (10 yr)	15	1.5	15:00
Ayantunde <i>et al</i> ^[8]	2008-2012 (5 yr)	25	5	2:1

This study also affirmed the persistent male preponderance as it was variously reported in the published literature although there seems to be a slightly higher female population in the current study than previously reported^[1-10]. The gender ratio showed that the male population was only twice affected as female gender in the current study. This reduced male to female ratio may have been due to a significant increase in the group of female gender using objects for partner-erotism in this cohort than previously reported. The majority of our patients were young adults who were using the retained objects for either self-erotism or partner-erotism. Eighty eight percent of our patient population were using the foreign bodies for erotic stimulation and this is in agreement with the previous published reports^[1-4,7-10]. The changing pattern with increasing female gender and predominantly younger population than previously reported may likely be the emerging trend in the presentations of retained rectal foreign bodies.

Our previous work^[8] and that of Cohen *et al*^[9] have shown objects used for sexual interaction accounted for more than three-quarter of the cases impacted foreign bodies in the rectum presenting to hospitals. One patients in this study inserted an apple fruit for self-harm. This patient disclosed that he was abused as a child and became very depressed after the loss of his wife. One patient was using the object for self-massage of rectal mucosal prolapse in an attempt to reduce it while one accidentally swallowed their dentures, which later became impacted in the rectum prompting the presentation to the ED. We did not encounter any patient in the current series with retained rectal foreign bodies with history of sexual rape or other violent sexual practices as previously reported by some authors^[1,2,8,14,15].

Generally speaking, patients with rectal foreign bodies do not attend the ED early unless attempts have been made to retrieve the objects by the patient or their partners because of the perceived embarrassment and shame^[1-4,7,8,12-14]. The majority of our patients attended the ED because of failure to retrieve the foreign bodies after several attempts while few others presented with anorectal pain and/or bleeding. Two of our patients in particular presented because of persistent vibration of the powered sex toys causing them significant anorectal and lower abdominal pain. The delay in presentation may be due to the hope of a spontaneous passage of the foreign objects by the patient and the eventual failure to

pass against their expectation leads to some measure of anxiety^[1].

The initial evaluation at presentation should include a careful history, abdominal and digital rectal examinations (DRE) including the assessment of the status of the perianal region and anal sphincters with the findings clearly documented before and after the extraction of the foreign body in the clinical notes^[1-4,8,14-16]. Confirmation of the type, size, number and location of the objects should be by biplanar plain abdominal and pelvic films^[1-3,8,14]. Biplanar plain X-rays in this study showed the foreign objects in all but one of our patients. The one patient with retained apple fruit was not so obvious on the plain films. Erect chest X-ray and CT scan should only be selectively performed where indicated. Plain erect chest radiograph is recommended to exclude the presence of free peritoneal gas under the diaphragm indicating rectosigmoid perforation^[1]. There was no patient in this series with any specific indication requiring a CT scan evaluation. CT scan where indicated is excellent for localization of non-opaque foreign bodies, detection of perforation or obstruction and diagnosis of pelvic abscess^[1].

The basic approach to the management of patients with retained foreign bodies include achieving a safe per anum extraction, direct visualisation of the rectosigmoid mucosal to exclude bowel injury and a period of close clinical observation in the hospital for early detection of complications^[1-4,8,16]. Extraction of impacted rectal foreign bodies should be achieved under direct vision where possible using an anoscope or sigmoidoscope to avoid iatrogenic anorectal injury^[1-4,8,14,16].

Generally speaking, the determination of level of the retained foreign bodies in the rectosigmoid segment is important and useful for the purpose of management. Most low-lying rectal foreign objects are reachable by the examining finger and can be removed per anum whereas those higher up in the sigmoid colon can prove to be difficult to retrieve^[1,2,7,13,14]. Foreign bodies that are impacted above the rectum are usually not easily visualized and therefore transanal retrieval is difficult^[1,2,7,13,14]. Generally speaking, a foreign body located below the rectosigmoid junction that is easily palpable by the clinician's examining finger can be extracted in the ED. However, an uncooperative and anxious patient with associated anal sphincter muscles contractions will make ED extraction undesirable. The

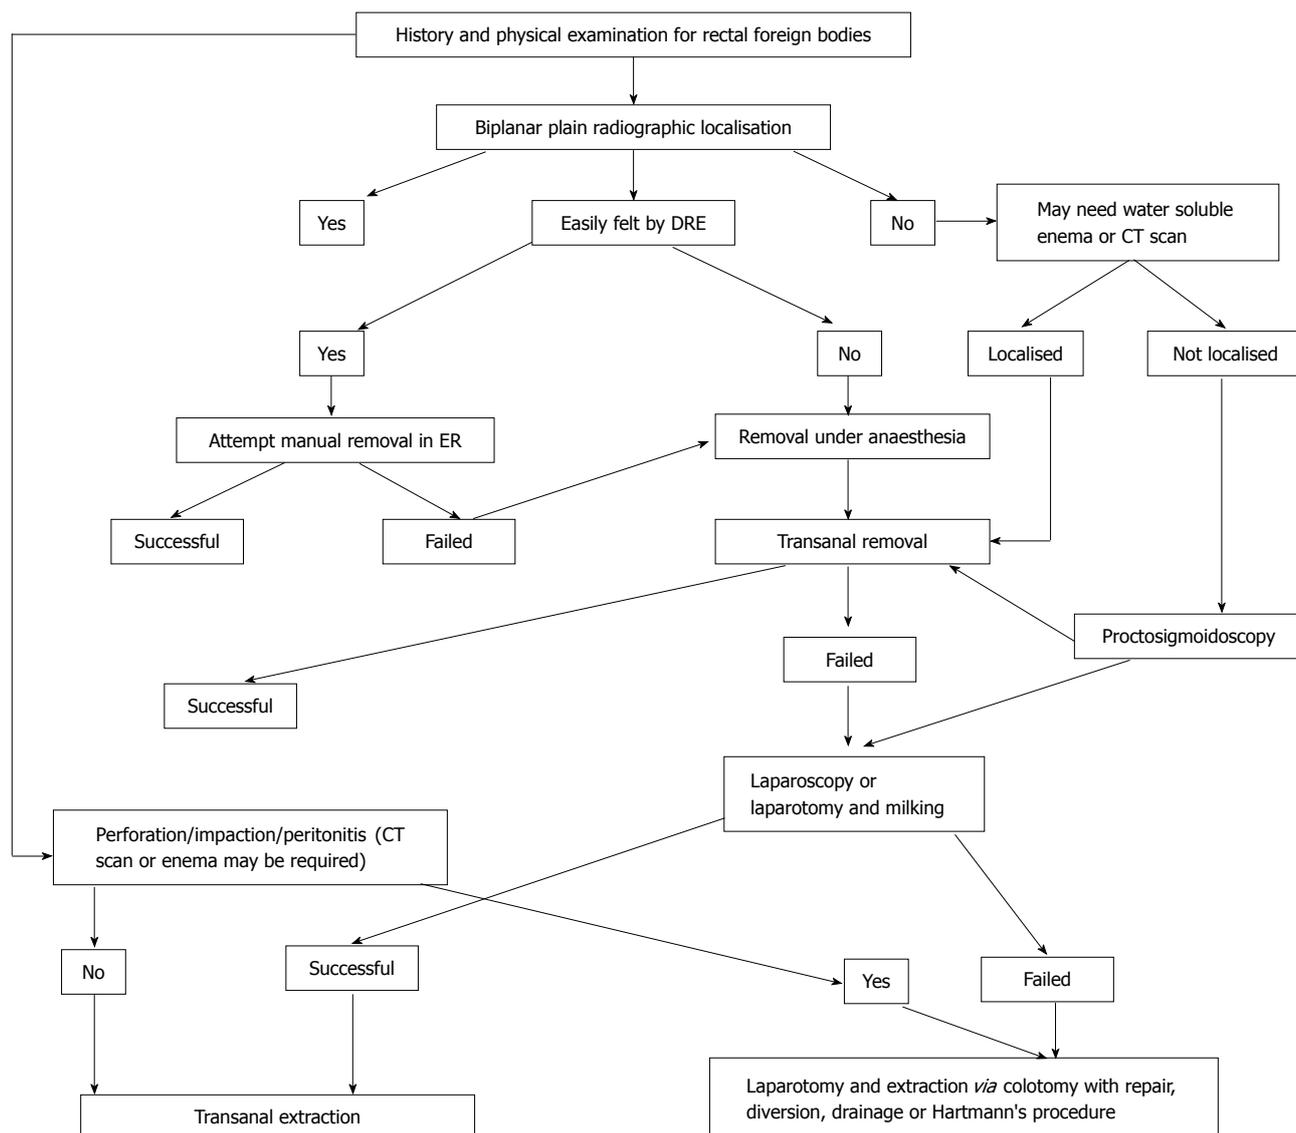

Figure 2 Algorithm for management of retained rectal foreign bodies.

use of anaesthesia in the treatment of these patients reduces anal sphincter muscles spasm and therefore improves direct visualization and good exposure with a successful chance of extraction per anum^[1,8].

There has been a significant evolution addressing the various management challenges of wide spectrum of different types of objects impacted in the rectum over the last few years^[1,2,4,8,10,14,16]. The majority of retained low-lying foreign bodies can be removed with a guided grasping forceps or a clamp introduced a proctosigmoidoscope. This approach can be aided by an initial examining finger manoeuvre to disengage the impacted object from the oedematous anorectal mucosa^[1,8]. The majority of our patients in this study required their retained rectal objects to be removed in the operating theatre under direct vision with proctosigmoidoscope using a grasping forceps or a small Keilland's forceps. All of them underwent successful transanal retrieval with no need for laparoscopy or laparotomy.

The failure of transanal retrieval of impacted foreign bodies in the rectum can be predicted preoperatively. Lake *et al*^[4] in their experience cited several factors responsible for failure of transanal removal including the impaction of a an object longer than 10 cm, hard or sharp objects, objects that have migrated upward into the sigmoid colon and those that have been impacted for more than 2 d. There are specific indications for the use of emergency laparotomy for extraction of impacted objects including failure of attempts at transanal removal, presence of perforation and/or peritonitis^[1,2,4,8,16]. The use of minimally invasive operative techniques for impacted rectosigmoid foreign bodies has been described which is a combination of laparoscopic downward milking of the object followed by per anal extraction^[1,2,17-19]. This approach however is only recommended for smooth foreign bodies and if successful, avoids the need for a full laparotomy and provides the benefit of early discharge from the hospital^[1,2,17-19]. Figure 2 is adapted from reference 1.

In conclusion, this study confirms a rising trend in the

number of patients with retained rectal foreign bodies with hospital presentations and most of these objects were used for erotic stimulation. There was also a slightly higher female population in the current study than previously reported and this may be the emerging trend of this entity. It is very much likely that the increasing trend would be encountered in most hospitals and therefore, the clinicians in the emergency settings need to be well informed about the approach to the care of patients with retained rectal foreign bodies.

COMMENTS

Background

Hospital presentation with retained rectal foreign bodies is no longer rare although concrete epidemiological data are still lacking. They are usually encountered in the adults and are either inserted intentionally or non-intentionally. The delay in the presentation and the associated patient's vague history usually lead to significant diagnostic and management challenges.

Research frontiers

There are recent anecdotal reports suggesting an increasing trend in the hospital presentations with impacted foreign bodies in the rectum. The present authors' and other authors' prediction from the previous published reports was a likelihood of an increasing presentation with the use of different objects for anorectal eroticism. Therefore, the clinicians in the emergency settings should be well familiar with the approach and the principles of care of these patients.

Innovation and breakthroughs

The authors predict that from the current study and the paucity of the available published epidemiological data that there is likely going to be an increasing trend in the incidence and presentations with the retained objects in the rectum.

Applications

The diagnosis and treatment patients presenting to hospital rectal foreign bodies should be orderly and methodical including safe retrieval and post-extraction period of observation. The desired ultimate outcome for every case is a safe and successful per anum extraction of foreign body, in a manner respecting the patients' right to dignity, privacy and confidentiality.

Terminology

Retained lower GIT foreign bodies may be located low or high based on their positions relative to the to the rectosigmoid junction. Most low-lying rectal foreign objects are easily reachable by the examining finger and can be removed per anum whereas those higher up in upper rectum or sigmoid colon may be difficult to reach and retrieved.

Peer-review

This is an interesting case series of rectal foreign bodies.

Abstract

AIM

To analyse the range of histopathology detected in the largest published United Kingdom series of cholecystectomy specimens and to evaluate the rationale for selective histopathological analysis.

METHODS

Incidental gallbladder malignancy is rare in the United Kingdom with recent literature supporting selective histological assessment of gallbladders after routine cholecystectomy. All cholecystectomy gallbladder specimens examined by the histopathology department at our hospital during a five year period between March 2008

and March 2013 were retrospectively analysed. Further data was collected on all specimens demonstrating carcinoma, dysplasia and polypoid growths.

RESULTS

The study included 4027 patients. The majority (97%) of specimens exhibited gallstone or cholecystitis related disease. Polyps were demonstrated in 44 (1.09%), the majority of which were cholesterol based (41/44). Dysplasia, ranging from low to multifocal high-grade was demonstrated in 55 (1.37%). Incidental primary gallbladder adenocarcinoma was detected in 6 specimens (0.15%, 5 female and 1 male), and a single gallbladder revealed carcinoma *in situ* (0.02%). This large single centre study demonstrated a full range of gallbladder disease from cholecystectomy specimens, including more than 1% neoplastic histology and two cases of macroscopically occult gallbladder malignancies.

CONCLUSION

Routine histological evaluation of all elective and emergency cholecystectomies is justified in a United Kingdom population as selective analysis has potential to miss potentially curable life threatening pathology.

Key words: Gallbladder; Incidental; Cholecystectomy; Histopathology; Carcinoma

Core tip: The selective use of histopathological examination of gallbladders removed during routine cholecystectomy has been advocated by several authors in the literature. We present a large single centre study demonstrating a full range of gallbladder disease from cholecystectomy specimens, including more than 1% neoplastic histology and two cases of microscopic gallbladder malignancies in macroscopically normal gallbladders. On this basis, routine histological evaluation of all elective and emergency cholecystectomies is justified in an United Kingdom population as selective analysis has potential to miss potentially curable life threatening pathology.

Incidental non-benign gallbladder histopathology after cholecystectomy in an United Kingdom population: Need for routine histological analysis? *World J Gastrointest Surg* 2016; 8(10): 685-692. Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i10/685.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i10.685>

INTRODUCTION

Cholecystectomy is among the most commonly performed surgical procedures worldwide, principally indicated in patients with symptomatic gallstone-associated disease. Approximately 5.5 million people in the United Kingdom

have gallstones^[1], with 70000 undergoing operative intervention each year in the United Kingdom^[2]. The indication for cholecystectomy is usually benign disease, though the histology can reveal incidental premalignant or malignant gallbladder pathology warranting appropriate further surgical resection.

Incidental gallbladder malignancies are rare in the United Kingdom with reported rates between 0.17%-0.81% of cholecystectomy resected specimens^[3-6]. Further revision surgery with curative intent is generally indicated in those without metastatic disease and tumour staging worse than T1a. Potentially curative resection may be offered in up to 50% of patients with incidental gallbladder malignancy post-cholecystectomy, however, some of these patients are ultimately found to have unresectable or metastatic disease at the time of laparotomy^[7,8].

Recognised premalignant conditions leading to gallbladder carcinoma include gallbladder dysplasia and those arising from adenomatous polyps^[9]. Dysplastic changes are often difficult to predict pre-operatively due to absence of macroscopic abnormalities detectable on imaging, hence emphasizing need to histologically examine all gallbladders resected^[9]. Strategies for gallbladder polyp surveillance and indications for operative management have been previously recommended, however this remains a controversial topic with widely varied practice in reality^[10,11].

Some authors have advocated selective, rather than routine, histopathological analysis of resected gallbladders, primarily due to rarity of incidental disease, financial implications and time burden on histopathology departments^[4-6,12]. Others have suggested macroscopic examination of resected gallbladders intra-operatively, to determine whether further histological analysis is required depending on presence of suspicious macroscopic lesions or significant patient risk factors for gallbladder cancer^[4].

The primary aim of this study was to review the range of histopathology detected in the largest United Kingdom series of routine cholecystectomy specimens from a single centre teaching hospital, in particular pre-malignant and malignant pathology. Secondary aims were to further analyse patients with incidental gallbladder malignancy, dysplasia and polyps and to make recommendations for future practice and necessity of routine histological examination of gallbladder specimens.

MATERIALS AND METHODS

This descriptive study was designed as a retrospective review of a database of all gallbladder specimens histopathologically examined at Cambridge University Hospital (Cambridge, United Kingdom) during a five year period between March 2008 and March 2013. This hospital is a tertiary referral centre for management of hepatopancreatobiliary malignancies. Exclusion criteria included gallbladders resected as part of another procedure (*e.g.*, Whipple's resection) and instances where malignancy was strongly suspected pre-

Table 1 Summary of histopathological findings

Histology	Subgroup	No (n = 4027)	% Total

Adenocarcinoma		6	0.15%

LGD: Low grade dysplasia; HGD: High grade dysplasia; AC: Adenocarcinoma.

operatively, including ultrasonographically suspicious lesions or polyps greater than 1 cm in size. Histology reports were retrospectively analysed for presence of gallbladder disease, including benign and malignant pathology.

Further information was obtained on gallbladders demonstrating incidental gallbladder malignancies, dysplastic changes and polypoid structures including patient demographics, pre-operative symptoms and imaging, operative details, tumour histology and post-operative clinical outcomes. In patients with incidental malignancies, extensive data was collected on staging, tumour type, further resectional surgery and survival time. Survival times were calculated from time of cholecystectomy to date of death or latest follow up. In those with detected dysplasia, additional data were collected, including type of dysplasia, presence of tumour foci and associated risk factors (*e.g.*, primary sclerosing cholangitis). For gallbladder specimens containing polyps, further information was obtained including uptake into our gallbladder surveillance programme, polyp type, size and number, preoperative ultrasonography findings and indications for surgery. Hospital electronic medical records and patient hard copy notes were used to extract relevant data.

Statistical analysis were performed using Statistical Package for the Social Sciences (SPSS Windows Version 22.0, Chicago, IL, United States) with a *P*-value less than 0.05 representing statistical significance. Continuous data analysed was described with median values accompanied with ranges [Median (range)].

RESULTS

A total of 4027 resected gallbladders from elective and emergency cholecystectomies were examined by the histopathology department at Addenbrooke's Hospital in the 5 years period studied. Overall, we report an incidental gallbladder invasive adenocarcinoma rate of 0.15% (6/4027) and one gallbladder demonstrating carcinoma-*in-situ* (0.02%, 1/4027). The majority of resected specimens exhibited gallstone or cholecystitis related disease. Table 1 displays the range of histopathological findings demonstrated from our patient sample.

Gall bladder carcinoma

Primary invasive gallbladder adenocarcinoma was identified in 6 patients with a median age of 66.5 years (range 45-71) and a female majority (5/6) (Figure 1 is an illustration of typical macroscopic and microscopic appearances of a gallbladder cancer specimen). All but one patient (5/6) had co-existing cholelithiasis on pre-operative ultrasonography, while half (3/6) had ultrasonography evident thickened gallbladder walls consistent with cholecystitis. All patients were symptomatic with right upper quadrant pain pre-operatively, however none presented with a palpable mass, clinical jaundice or weight loss. In none of these patients was gallbladder malignancy considered a potential differential diagnosis on decision to perform a cholecystectomy. Surgery in 4 of these of these cases were reported as more challenging than usual, but not in the other 2, which were both reported as macroscopically normal from histopathological examination, but microscopic examination revealed T1 disease, one T1a and the other T1b. Otherwise, tumour staging varied significantly with T3 disease the most advanced. To present date, 3 patients have died from progressive metastatic disease with a post-cholecystectomy mean survival time of 20.6 mo.

A single case of carcinoma-*in-situ* (0.02%, 1/4027) was identified in a 66-year-old gentleman with known gallstones. No lesion was identified on macroscopic examination, however microscopic analysis revealed foci of adenocarcinoma within surrounding extensive high grade dysplasia. Further details of all carcinoma patients including operation details and clinical outcome postoperatively are depicted in Table 2.

Gall bladder dysplasia

The overall incidence rate of gallbladder dysplasia was 1.37% (55/4027) with a wide spectrum of dysplastic changes as illustrated in Table 1. Median age was 53 years (range 22-82) with the majority of patients being female (85.5%, 47/55). From all 55 cases of dysplasia, 47.3% (26/55) had co-existing gallstone disease on final histology. Primary sclerosing cholangitis was pre-existent in 3.6% (2/55) patients. Four gallbladders exhibited multifocal high grade dysplasia from which half

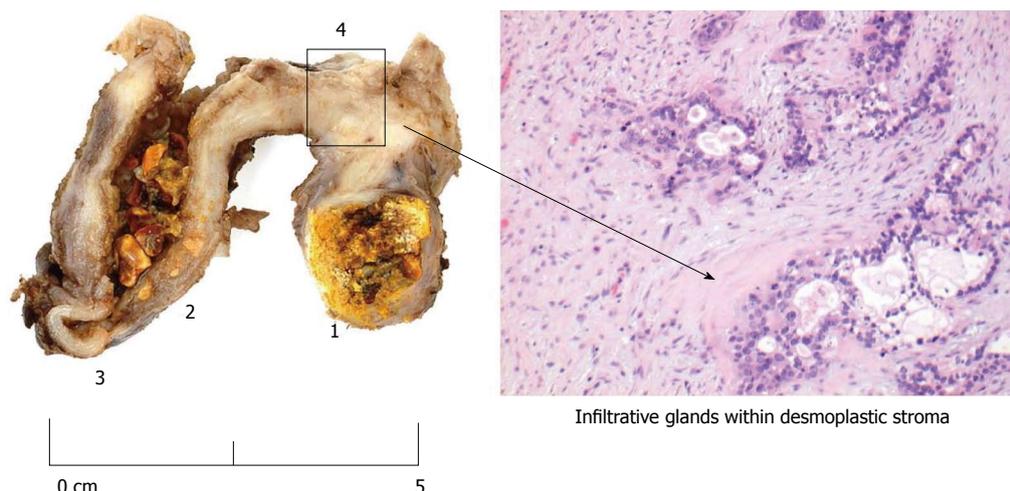

Figure 1 Typical macroscopic and microscopic appearances of gallbladder cancer. 1: Cholesterol gallstones, impacted; 2: RA sinuses containing impacted stones; 3: Chronic cholecystitis; 4: Ruptured gallbladder carcinoma.

Table 2 Pre- and post-operative characteristics of cases with incidental gallbladder adenocarcinoma							
Age	Sex	Pre-operative imaging	Operation details	Operative findings	Tumour type/staging	Further management	Survival (mo)
71	F	USS: Multiple gallstones	Lap	Smooth GB wall with multiple calculi	T1a N0 M0, Adenocarcinoma	No further operation, surveillance CT scans	Alive (64)
68	F	USS: Multiple stones, dilated CBD; CT: Multiple stones, no mass seen	Open	Large GB calculi, no CBD stones on CBD exploration	T2 N0 M0, Adenocarcinoma (MD)	Not fit for further resection (known chronic leukaemia – already on chemotherapy)	Alive (22)
45	F	USS: Stones, thickened GB wall; CT: Inflammatory changes on GB wall	Lap converted to open	Small abscess on GB bed, gross GB wall thickening	T3 N1 M0, Adenocarcinoma (PD)	Revision operation – abandoned as nodules on umbilical port and peritoneum, palliative chemotherapy	12
70	F	USS: Grossly thickened GB wall and multiple gallstones	Lap	Thick dense adhesions with fistulous communication between GB tumour and transverse colon	T3 N1 M1, Adenocarcinoma (PD)	Chemotherapy	12
65	F	USS: Stones, cholecystitis; CT: Marked GB wall thickening, ?cholecystitis	Lap	GB wall inflamed, disintegrated with biliary spillage++	T2 N0 M0, Adenocarcinoma (MD)	Not medically fit for revision surgery; developed nodal disease but not fit for chemo; palliative therapy	37
65	M	USS: Sludge and gallstones (pancreatitis patient)	Lap	Mildly inflamed GB with calculi	T1b N0 M0, Adenocarcinoma (PD)	Revision surgery and lymphadenectomy, chemotherapy	Alive (36)
66	M	USS: Multiple small gallstones	Lap	Smooth GB wall with calculi	Tis N0 M0	No further management	Alive (54)

USS: Ultrasonography; CT: Computed tomography; GB: Gallbladder; MD: Moderately differentiated; PD: Poorly differentiated.

(2/4) exhibited foci of adenocarcinoma, both previously mentioned in our cancer cohort (Table 2). One gallbladder (1.8%, 1/55) demonstrated a tubular adenoma with surrounding focal high grade dysplastic changes. No gallbladder specimen revealed evidence of dysplasia at the cystic duct resection margin.

Gall bladder polyps

Gallbladder polyps were identified in 1.09% (44/4027). The median age was 51 years (range 28-84). Pre-operative imaging identified 77.3% (34/44) of these polyps, with a measured median size of 7.4 mm (range

2-13 mm). All but three polyps were cholesterol in nature (93.2%, 41/44). The other three polyps varied in histology including one hyperplastic polyp, one xanthomatous polyp and one tubular adenomatous polyp. None of these polyps exhibited malignant features.

DISCUSSION

This study is the largest United Kingdom series to date evaluating range of histopathology demonstrated from cholecystectomy resected gallbladder specimens. Our main findings include observed overall rates of 0.17%

incidental gallbladder adenocarcinomas and 1.37% incidental premalignant gallbladder dysplasia. The most common histology reported in our study was chronic cholecystitis (85.3%).

Incidental gallbladder malignancy identified in cholecystectomy specimens make up the majority of all diagnosed gallbladder cancers^[12]. There is a well-documented heterogeneity in the incidence of gallbladder cancer, varying according to various patient demographic factors including worldwide location, ethnicity and age^[13]. Along with most of Europe, the United Kingdom is considered a low risk area with an associated low rate of incidental gallbladder malignancies when compared to high risk areas such as India and Japan^[14]. Previous United Kingdom studies have reported incidence rates between 0.17%-0.81%, however some of these studies have included gallbladders in which tumour was suspected on preoperative imaging^[3-6]. Our study observed a 0.17% rate of incidental gallbladder malignancies. This relatively low incidence may reflect the ethnicity of our study population with a strong European-Caucasian representation as only one patient from all carcinoma and dysplasia-revealing gallbladders was non-Caucasian in ethnicity (Indian). Furthermore, those patients in whom gallbladder malignancy was strongly suspected on pre-operative imaging were strictly excluded from our study and this may have contributed further to the low incidence rate.

Chronic gallstone-related irritation is a known significant risk factor for dysplastic changes and development of carcinoma^[15]. Increased gallstone weight, number and volume have also been associated with an increased risk of gallbladder cancer^[16]. In this study, 6 out of the 7 carcinoma patients had co-existing gallstones.

In contrast, only 47.3% of dysplastic gallbladders demonstrated final histology cholelithiasis, perhaps implying other pathogenesis factors involved in development of gallbladder dysplasia. In this regard, 2 patients exhibiting high grade dysplasia had a pre-operative diagnosis of primary sclerosing cholangitis, a known risk factor for gallbladder malignancy with previous reports of up to 30% of resected gallbladders displaying dysplasia/carcinoma pathology^[17]. Consistent with this, our policy is to adopt a low threshold in recommending cholecystectomy in patients with primary sclerosing cholangitis presenting with clinical or radiological evidence of gallbladder pathology.

In our institution, routine pre-operative investigations for patients presenting with symptomatic biliary pathology includes the assessment of liver function tests alongside ultrasonographic assessment of the gallbladder and biliary tree. Should these provide any suspicious features then further assessment with cross sectional imaging (CT scan or MRCP) and endoscopic ultrasound are performed, followed by discussion in the regional multi-disciplinary meeting where decision on further management is made.

Six patients in our cohort were identified as having

gallbladder carcinoma on post-operative histology (Table 2), with a median age of 66.5 years. The youngest patient was a 45-year-old female who was found to have T3N1 disease which progressed rapidly with peritoneal spread. None of these were suspected pre-operatively. In 2 of the 6 cases, the pre-operative ultrasound identified gallstones within a thin walled gallbladder with the absence of any worrying features to necessitate further investigations. Operative findings for these 2 cases were of thin walled gallbladders (macroscopically normal) and hence gallbladder cancer was not suspected. Post-operative histology described early gallbladder carcinoma (T1a and T1b respectively), despite these microscopic findings, the histopathological examination reported these specimens as macroscopically normal looking. The remaining 4 cases, were identified on pre- and intra-operative examinations as having macroscopic abnormalities. In 3 of these cases, further pre-operative investigations with cross sectional imaging (CT scan) were performed. The CT findings were reported as inflammatory, with the absence of a mass lesion and abnormal lymphadenopathy. Operative findings were of thickened gallbladder walls, while one had an associated abscess in the gallbladder fossa. The clinical suspicion here was of severe inflammatory changes. Although the presence of gallbladder cancer in such cases is always a possibility, the clinical suspicion was low and hence standard cholecystectomy was performed. Post-operative histology identified T2 disease in 2 cases and T3 N1 disease in the remaining case.

The final case was of a 70-year-old female with pre-operative ultrasonography describing a thickened and inflamed gallbladder with calculi; at the time of surgery she was found to have dense adhesions a thickened shrunken gallbladder, as well as a fistulous communication between the gallbladder and the transverse colon. These findings were thought to be inflammatory in nature, however, the diagnosis of gallbladder carcinoma is regarded as a possibility in such cases. An intra-operative decision on whether a simple cholecystectomy or a more radical should be taken. The majority of such cases will ultimately prove to be benign and inflammatory in aetiology. Factors such as pre-operative co-morbidities and the potential stage of disease, should this turn out to be malignant, are taken into account. If clinical suspicion of cancer is high, co-morbidities are limited and the patient is suitable for a potentially curative resection, then frozen section may be performed to confirm the diagnosis and the surgical plan amended as deemed necessary. However, if the patient or tumour factors render potentially curative surgical intervention impossible then a standard cholecystectomy to achieve a tissue diagnosis may be deemed appropriate.

Several United Kingdom papers have recommended selective histopathological analysis of cholecystectomy resected specimens^[4-6,14]. This recommendation is based on the assumption that incidental gall bladder malignancy is associated with macroscopic lesions which can be identified on examination of the resected gall bladder

in the operating theatre. Our study, the largest United Kingdom series to date and the only one with over 3000 patients, demonstrates that this assumption is not reliable, as evidenced by the finding of gallbladder malignancy in macroscopically normal gallbladders, including T1b disease for which revision surgery is generally advocated, on account of published data showing a survival benefit of 3.4 years from radical resection over simple cholecystectomy^[18]. The patient with T1b disease underwent further liver segmental resection with lymphadenectomy and is disease free three years later to this day. This is the first United Kingdom series to report a patient with macroscopically occult incidental gallbladder malignancy with no preoperative or intra-operative suspicion of carcinoma who subsequently underwent successful R0 resectional surgery.

A systematic review in 2014 by Jamal *et al*^[14] examined 20 previous studies, including 6 United Kingdom studies, evaluating the necessity of routine histological analysis in macroscopically normal gallbladders. The authors concluded that in gallbladders deemed normal from macroscopic examination by the operating surgeon, selective histological analysis was feasible in the "low risk" European ethnicity under the age of 60^[14]. However, the systematic review did not include a recent histopathology paper by Hayes *et al*^[19] examining gallbladder specimens sent for histology after cholecystectomy. This study reported a striking 50% (5/10) of incidental invasive gallbladder malignancies presenting with no macroscopic abnormalities on histopathologist examination with a mean age of 54.6 years. This proportion of macroscopically occult malignancies in a "low risk" population of that age range challenges the recommendations from Jamal *et al*^[14] recent systematic review. In addition, United Kingdom Royal College of Pathologists 2005 recommendations state that all gallbladders removed for presumed benign disease warrant histological examination in order to ensure no significant subtle pathology is missed from macroscopic examination^[20].

Solaini *et al*^[3] in 2014 reported almost 3% incidental neoplastic findings from cholecystectomy gallbladders with inclusion of dysplastic changes and is one of few United Kingdom papers supporting routine histological analysis of all gallbladder specimens. The authors reported dysplasia rates of 2.3% (18/771) with a median age of 45 years in a population with strong Asian ethnicity representation (66%). Our study observed lower rates of dysplastic changes at 1.37% (55/4027) with a higher median age of 53 years, perhaps partly explained by the lack of representation of the Asian population in our study group^[21].

Whether the finding of dysplasia is of clinical significance may be debated, but our opinion is that this is not merely academic. Positive cystic duct margins and gross high grade dysplastic changes can indicate further potential pancreatobiliary disease, with further operative exploration warranted in certain circumstances. Bickenbach *et al*^[22] in 2011 reported five cases of high

grade dysplasia at the cystic duct resectional margin following cholecystectomy, all of whom subsequently underwent further resectional surgery, either with excision of cystic duct remnant or excision of extrahepatic bile duct. Of these, one patient was found to have adenocarcinoma within the resected cystic duct remnant. No gallbladders in our study demonstrated cystic duct margin positive disease, however half our cases of multifocal high grade dysplasia had associated foci of adenocarcinoma. In our practice, the finding of high grade dysplasia on the cystic duct margin would warrant further surgical exploration and frozen section of cystic duct margin to ascertain whether further radical resection would be required to ensure R0 resection.

Gallbladder polyps are common with a reported incidence rate in a recent multi-ethnic United Kingdom series of 3.3%, with higher rates observed in the Asian ethnic groups^[23]. Our series reports a 1.09% (44/4027) incidence of polypoid lesions of the gallbladder, however we excluded all polyps reported as sonographically suspicious of malignancy or more than 1 cm in size pre-study in order to focus on incidental gallbladder pathology. Our largely Caucasian study population may also reflect the observed lower polyp incidence rate. All but one polyp demonstrated benign pseudotumour characteristics, predominantly cholesterol in nature (41/44). We did however observe one true polyp adenoma (1/44, 2.3%) occurring in a 67-year-old male and of 3mm in size, which had been reported as a gallstone on preoperative sonography with biliary colic as indication for surgery. Cairns *et al*^[24] in 2013 examined a large cohort of gallbladder polyps in a United Kingdom population and observed a similar 2.2% incidence rate of adenomas as well as 0.7% adenocarcinoma rate. Although adenomas are histologically benign, there is a well-recognised adenoma-carcinoma path of carcinogenesis to gallbladder malignancy^[21]. This has led to polyp surveillance implementation in HPB centres with indications to operatively remove gallbladders displaying polypoid lesions above 1 cm, rapidly growing in size or symptomatic in nature^[24]. Marangoni *et al*^[10] surveyed United Kingdom surgeons regarding their practice of gallbladder polyp surveillance with indications for operative management and revealed significant variation and identified a need for formal national guidelines to tackle this area of conflicting opinions. Although polyp surveillance was not analysed in further detail as part of this study, it is our practice to actively monitor polyps with ultrasonography particularly with recent literature to support it is cost effective^[24].

In conclusion, our study has demonstrated a broad spectrum of histopathology from examination of cholecystectomy resected gallbladders for preoperatively diagnosed benign gallbladder disease. This is the largest United Kingdom series within the literature and observed 0.17% incidence of primary adenocarcinoma and 1.37% gallbladder dysplasia. The study is the first United Kingdom study to report cases of macroscopically normal gallbladders harbouring adenocarcinoma lesions

with subsequent successful R0 resection. We also report a single case of adenocarcinoma in a patient aged 45 years. With over 1% rate of pre-malignant and malignant disease, we conclude that routine histological evaluation of all elective and emergency cholecystectomies is justified in a United Kingdom population and that selective histological evaluation has the potential to miss life threatening gallbladder pathology amenable to subsequent curative surgery.

COMMENTS

Background

Cholecystectomy is among the most commonly performed surgical procedures worldwide. Routine histopathological examination of the resected specimens is usually performed. However, selective histopathological analysis has been proposed in the literature, primarily due to rarity of incidental disease (0.17%-0.81% in the United Kingdom), financial implications and time burden on histopathology departments.

Research frontiers

The authors aimed to analyse the range of histopathology detected in the largest published United Kingdom series of cholecystectomy specimens and to evaluate the rationale for selective histopathological analysis.

Innovations and breakthroughs

This large single centre study demonstrated a full range of gallbladder disease from cholecystectomy specimens, including more than 1% neoplastic histology and two cases of macroscopically occult gallbladder malignancies.

Applications

Routine histological evaluation of all elective and emergency cholecystectomies is justified in a United Kingdom population as selective analysis has potential to miss potentially curable life threatening pathology.

Peer-review

The authors described an incidental non-benign gallbladder histopathology after cholecystectomy in a United Kingdom population. More than 4000 cases of resected gallbladder specimens were analyzed histopathologically. Although several reports regarding incidental gallbladder cancer have been already published from high prevalence areas, studies from infrequent area such as the United Kingdom are worth publishing.

Abstract**AIM**

To investigate the epidemiology, treatment and outcomes of acute appendicitis (AA) in a large population study.

METHODS

This is a retrospective cohort study derived from the administrative dataset of the Bergamo district healthcare system (more than 1 million inhabitants) from 1997 to 2013. Data about treatment, surgery, length of stay were collected. Moreover for each patients were registered data about relapse of appendicitis and hospital admission due to intestinal obstruction.

RESULTS

From 1997 to 2013 in the Bergamo district we collected 16544 cases of AA, with a crude incidence rate of 89/100000 inhabitants per year; mean age was 24.51 ± 16.17 , 54.7% were male and the mean Charlson's comorbidity index was

0.32 ± 0.92. Mortality was < 0.0001%. Appendectomy was performed in 94.7% of the patients and the mean length of stay was 5.08 ± 2.88 d; the cumulative hospital stay was 5.19 ± 3.36 d and 1.2% of patients had at least one further hospitalization due intestinal occlusion. Laparoscopic appendectomy was performed in 48% of cases. Percent of 5.34 the patients were treated conservatively with a mean length of stay of 3.98 ± 3.96 d; the relapse rate was 23.1% and the cumulative hospital stay during the study period was 5.46 ± 6.05 d.

CONCLUSION

The treatment of acute appendicitis in Northern Italy is slowly changing, with the large diffusion of laparoscopic approach; conservative treatment of non-complicated appendicitis is still a neglected option, but rich of promising results.

Key words: Acute appendicitis; Conservative treatment; Epidemiology; Laparoscopic appendectomy; Intestinal obstruction

Core tip: Acute appendicitis is the most common surgical emergency around the world. In the Bergamo district, northern Italy its incidence is 89/100000 inhabitants per year with a negative trend during the last years. Percent of 95 patients were treated with appendectomy, 48% of whom laparoscopically; 1.3% of operated patients had an intestinal obstruction during the follow-up. Conservative treatment resulted in a reduced length of stay but 23% of patients had a relapse during follow up. Cumulative length of stays during the study period was similar for the two treatment option.

Acute appendicitis: Epidemiology, treatment and outcomes-analysis of 16544 consecutive cases. *World J Gastrointest Surg* 2016; 8(10): 693-699 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i10/693.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i10.693>

INTRODUCTION

Acute appendicitis is probably the most common surgical emergency worldwide. Since its first accurate description by Fitz^[1] in 1886 and the first appendectomy performed by Treves^[2] in England, appendectomy became the preferred treatment of acute appendicitis. Although appendicitis is a very common disease, nowadays it has a still poorly understood etiology, with a very heterogeneous clinical pattern of presentation, varying from simple uncomplicated appendicitis to generalized peritonitis due to perforation. For each clinical pattern the proposed treatment is the same: Appendectomy.

This results in an overtreatment with a described rate of negative appendectomy (a histopathological diagnosis of normal appendix) ranging from 6% to 20%^[3,4]. Appendectomy has also a complication rate ranging from 8% to 11%, depending on the surgical technique^[5]. Several reports described spontaneous resolution of uncomplicated appendicitis without the need of an operation and, since the high rate of negative appendectomy and the significative complications rate, some authors proposed and advised conservative management for uncomplicated appendicitis^[6,7]. Conservative management for appendicitis has been described in 1930 by the "Ochsen-Sherren delayed^[8] treatment", which consisted of resting and fasting followed by delayed elective appendectomy; nowadays, a conservative approach based on antibiotic therapy is gaining popularity, as documented by several randomized studies and meta-analyses that analyze this peculiar issue^[9-17]. Conservative treatment has been shown to be safe and effective as primary treatment compared to surgical treatment with a significative reduction in morbidity, even with a considerable one year recurrence rate of 23%^[17].

Despite this positive evidence, great uncertainty and skepticism remain concerning conservative treatment among surgeons.

The aim of the study was to describe the epidemiology of acute appendicitis in a large population study during the last seventeen years in order to analyze the evolution of the treatment throughout the years - appendectomy or conservative treatment, open or laparoscopic surgery - and to study the long term follow up of patients, in order to investigate the relapse rate of acute appendicitis in conservatively-treated patients and the incidence of intestinal occlusion after surgery.

MATERIALS AND METHODS

This is a retrospective analysis of patients discharged from the hospital between 1997 and 2013 with a diagnosis of acute appendicitis. Data were extracted from the administrative health care database of Bergamo's district, a large area (2723 km²) in Northern Italy with 1094062 inhabitants. This database collects all discharge records for each citizen of the district from any hospital, public and private, intra and extra-district. On the basis of this register, patients are assigned to the respective DRG, and reimbursements are supplied to the hospitals from the regional health care system.

Patients were retrieved on the basis of the concomitant presence of an unplanned hospital admission, with a ICD9-CM code of AA (ICD9-CM code 540.X, 541.X, 542.X, 543.X) in the first three diagnostic fields and with an Italian DRG code of Acute Appendicitis.

For each patient tracked, data regarding age, sex, Charlson's comorbidity index, surgical procedures (ICD9-CM code 47.X), length of hospital stay, time intervals between admission and operation and mortality were

Table 1 Distribution of patients among age categories and sex

Age category	Sex		Total	
	F	M	n	Among total
0-1	1	0	1	0.01%
1-6	239	369	608	3.68%
7-13	1673	2322	3995	24.15%
14-17	1314	1119	2433	14.71%
18-25	1904	1628	3532	21.35%
26-35	1167	1556	2723	16.46%
36-45	529	889	1418	8.57%
46-55	255	514	769	4.65%
56-65	165	352	517	3.13%
66-75	135	205	340	2.06%
76-85	89	79	168	1.02%
> 85	23	17	40	0.24%
Total	7494	9050	16544	100.00%

recorded.

For each patient further data on hospitalization related to acute appendicitis (same code) and bowel occlusion (ICD9-CM code 560.X) were collected, as well as the number of further hospitalizations, interventions, length of stay of each hospitalization and cumulative length of stay during the study period.

Continuous variables were expressed as mean \pm SD and were compared with the Mann-Whitney *U* test; association was tested with the Pearson's χ^2 test. Correlations were calculated with the Pearson's correlation test. Multivariate analyses were performed with the logistic regression method. Survivals were calculated with the Kaplan Meier method. Statistical analysis was performed with SPSS software (SPSS version 20, IBM, United States). Trends were studied with the Joinpoint model: Joinpoint regression analysis was performed using the Joinpoint software from the Surveillance Research Program of the United States National Cancer Institute (Joinpoint Regression Program, Version 4.1.1 - August 2014; Statistical Methodology and Applications Branch, Surveillance Research Program, National Cancer Institute). Trends were summarized with Average Annual Percent Change (AAPC). Calendar years started from 1997, until 2013. Crude rates are per 100000 inhabitants.

RESULTS

From 1997 to 2013 in the Bergamo district we collected 16544 cases of AA, with a crude incidence rate of

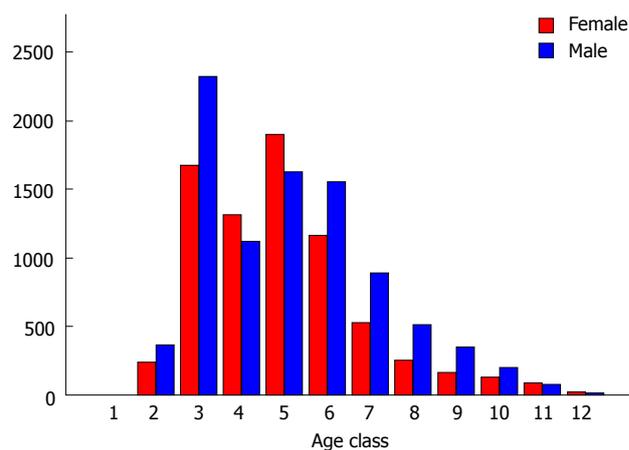

Figure 1 Age class and sex distribution. 1: 0-1; 2: 1-6; 3: 7-13; 4: 14-17; 5: 18-25; 6: 26-35; 7: 36-45; 8: 46-55; 9: 56-65; 10: 66-75; 11: 76-85; 12: > 85.

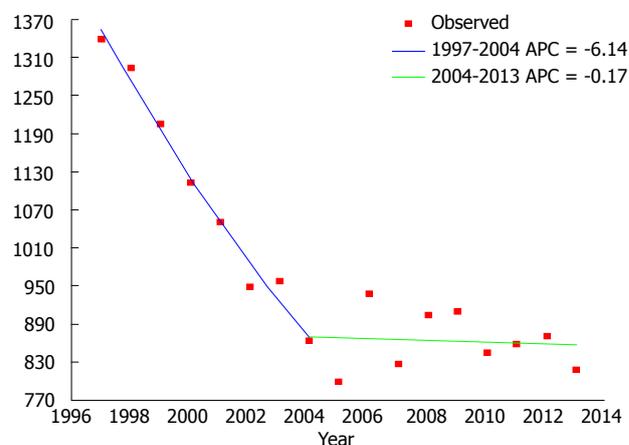

Figure 2 Number of patients discharged with acute appendicitis diagnosis during the years.

89/100000 per year; mean age was 24.51 ± 16.17 , 54.7% were male and mean Charlson comorbidity index was 0.32 ± 0.92 . Mortality was recorded for 7 patients ($< 0.0001\%$). Table 1 and Figure 1 show the distribution of age categories and sex: differences among sex in the different age categories were statistically significant ($P < 0.001$). The incidence of AA decreased during the years starting from 120/105 in 1997 to 73/105 in 2013 with a statistically significant negative value (AAPC = -2.8 , $P < 0.001$) (Figure 2).

Operative treatment

An appendectomy was performed in 94.7% of the patients: Mean age was 24.39 ± 15.98 , mean Charlson's comorbidity index was 0.31 ± 0.90 and 53.1% were male. Patients were operated after a mean of 0.85 ± 1.46 d and the mean length of stay was 5.08 ± 2.88 d with a negative trend over the considered period, starting from 6.09 ± 2.94 in 1997 to 4.58 ± 2.33 in 2013 (AAPC -1.5 , $P < 0.001$). Mortality was $< 0.0001\%$.

Data about laparoscopic procedures was available only after the year 2000: 48% of the patients were operated with the laparoscopic technique with a positive

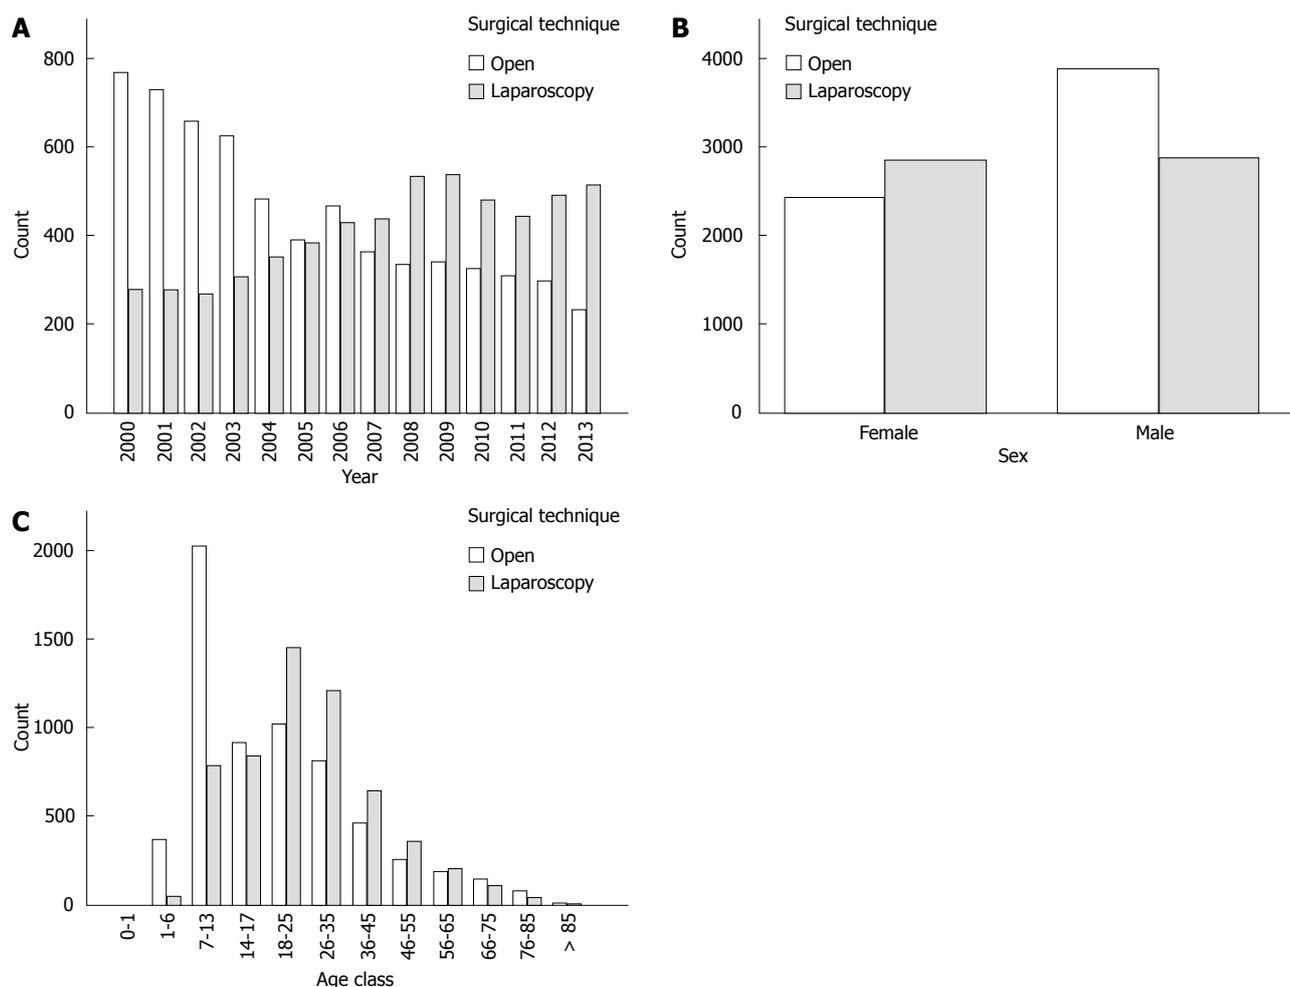

Figure 3 Surgical technique during the years (A), between sex (B) and among age classes (C).

trend during the years, starting from 26% in 2000 to 68.8% in 2013 (AAPC 5.2, $P < 0.001$) (Figure 3A) and with a mean length of stay of 4.47 ± 2.66 d (compared to 5.43 ± 2.94 with the open technique, $P < 0.001$). Laparoscopy was associated with a higher age, female sex and year in both univariate and multivariate analysis ($P < 0.0001$) (Table 2, Figure 3B and C).

The cumulative hospital stay during study period was 5.19 ± 3.36 d with a mean of 1.01 ± 0.13 hospital admissions. One hundred and ninety-two patients (1.2%) had at least one further hospitalization due intestinal occlusion after a mean of 30.53 ± 41.23 mo (median 11 mo) and 59.9% of them were operated on (Figures 4 and 5).

Conservative treatment

In general, 5.34% of the patients were treated conservatively: Mean age was 26.68 ± 19.04 ; 56.1% were male and mean Charlson's comorbidity index was 0.51 ± 1.26 ; mean length of stay was 3.98 ± 3.96 d; mortality was 0.1%. The proportion of patients treated conservatively increased during the years, from 6.1% in 1997 to 8.7% in 2013, although the trend was not significant ($P = 0.6$) (Figure 6).

Overall, relapse rate was 23.1% and a new episode of acute appendicitis occurred after a mean of 6.5 ± 15 mo (median 32 d); 89% of patients were operated on at relapse. The mean number of hospital admissions was 1.26 ± 0.47 with a cumulative hospital stay during the study period of 5.46 ± 6.05 d (Figures 4 and 5).

After univariate analysis, conservative treatment was associated with higher age, higher comorbidity index, and year of treatment ($P < 0.0001$); after multivariate analysis only Carlson's comorbidity index ($P = 0.004$) and year of treatment ($P < 0.0001$) remained significant (Table 3).

DISCUSSION

Acute appendicitis in Northern Italy has a crude rate of 89 cases per 100000 inhabitants per year, and this data is comparable to similar studies in other country worldwide^[18-21]. Surprisingly, during the study period the incidence decreased significantly, from 120 to 73 cases per 100000 inhabitants. This data contrasts with the data reported by Buckius *et al*^[20] in the United States over a similar period of time. Acute appendicitis is already a poorly understood disease and its diagnosis is still

based on clinical judgment, with great variability among surgeons. Clinical scores have been developed and proposed in the last years to help surgeons reaching a diagnosis of acute appendicitis, such as the Alvarado and the Andersson score^[22,23]. The decrease in the incidence rate could be explained by the diffusion of these scores and a consequent increased attention in the diagnosis of

acute appendicitis, in order to reduce the rate of negative appendectomies. As expected, acute appendicitis is more frequent in young and male patients (Figure 1), as reported by the literature^[18-20], with augmented incidence among patients in the 7-25 years categories. In the years categories 14-25, acute appendicitis is more frequent in females: A possible reason is the starting of childbearing ages and the sexual transmitted disorders that could mime acute appendicitis - with lower quadrant abdominal pain - and a consequent higher rate of negative appendectomies, as reported by Seetahal *et al*^[3]. Unfortunately there are no data available on the rate of negative appendectomies to confirm this hypothesis. The possibility of a diagnosis other than appendicitis in women justifies the higher frequency in this subgroup of the laparoscopic technique, which give the possibility to thoroughly explore the peritoneal cavity, as shown in Figure 3B. Laparoscopic appendectomy was performed in 48% of the cases, with an enormous increase across the years, from 26% to 69% (Figure 3). This data demonstrates the gradual diffusion of the laparoscopic technique, as shown by a similar study in the same contest for acute cholecystitis^[24]. After multivariate analysis, the laparoscopic approach was correlated to the year of treatment, female sex and older age: Figure 3C demonstrates that open appendectomy is still the

preferred technique for children.

Conservative treatment for acute appendicitis in Northern Italy is still a neglected option, with only 5% of patients treated not operatively; however, over the period of study there was a small increase in the proportion of patients treated conservatively. Despite the small number, conservative treatment seems to be an effective treatment option, showing a reduced length of stay and, notwithstanding an overall relapse rate of 23%, a similar cumulated length of stay and number of hospital admissions during the study period, with a clinically not significant difference (Figure 4). Conservative treatment, as shown in Figure 5, fails after a median of 32 d and leads to an operative treatment in the majority of cases. Factors involved in the choice of this approach are represented by the comorbidities of the patient and the year of treatment, showing that this option is slowly spreading, but still depends on the surgeon's preference. Conservative treatment resulted in 77% reduction of surgical procedures for appendicitis during the study period, maintaining a similar length of stay; moreover, appendectomy exposes patients to the risk of intestinal obstruction due to adhesions in 0.7%-10.7%^[25-27]: In our group of patients, 1.3% of the patients needed a further hospitalization due to bowel obstruction after a median of 11 mo and required a further surgical operation in 60% of cases. Laparoscopic appendectomy has been shown to reduce the risk of intestinal obstruction^[28] and our results confirm this evidence, although the clinical effect is not significant (Table 2). A cost-effectiveness study demonstrated that conservative treatment, with a failure rate of less than 40% is more cost effective than operative management: Our results on a large population study during a long period show that treating a patient with acute appendicitis conservatively could be considered the better treatment option.

The study was performed retrieving data from an administrative register that allows for a long-term follow up for each patient included; unfortunately,

administrative registries do not include data about histopathological diagnosis. Moreover, figures about failure of conservative treatment could be slightly underestimated, considering the lack of data about the immediate failure during the first hospital admission.

In conclusion the treatment of acute appendicitis in Northern Italy is slowly changing, with the large diffusion of laparoscopic approach; conservative treatment of non-complicated appendicitis is still a neglected option, but full of promising results.

COMMENTS

Background

Acute appendicitis is the commonest surgical emergency. Despite appendectomy is considered the definitive treatment there is great interest in the conservative management.

Research frontiers

Epidemiology and treatment of acute appendicitis.

Innovations and breakthroughs

The study outlines the current epidemiology of acute appendicitis giving an overview on the state of the art of the treatment's choice in the daily clinical practice.

Applications

The study gives the state of the art of the treatment of acute appendicitis and its changes during the last years.

Terminology

Conservative treatment: Medical therapy based on antibiotics administration.

Peer-review

This is a well-written article with good statistical analysis.

Abstract**AIM**

To compare a dipeptide- and tripeptide-based enteral formula with a standard enteral formula for tolerance and nutritional outcomes in abdominal surgery patients.

METHODS

A retrospective study was performed to assess the differences between a whole-protein formula (WPF) and a dipeptide- and tripeptide-based formula (PEF) in clinical outcomes. Seventy-two adult intensive care unit (ICU) patients with serum albumin concentrations less

than 3.0 g/dL were enrolled in this study. Patients were divided into two groups (WPF group = 40 patients, PEF group = 32 patients). The study patients were fed for at least 7 d, with ≥ 1000 mL of enteral formula infused on at least 3 of the days.

RESULTS

The mean serum albumin level on postoperative day (POD) 10, prealbumin levels on POD-5 and POD-10, and total lymphocyte count on POD-5 were significantly higher in the PEF group compared to those in the WPF group ($P < 0.05$). The average maximum gastric residual volume of the PEF patients during their ICU stays was significantly lower than that for WPF patients.

CONCLUSION

Dipeptide- and tripeptide-based enteral formulas are more efficacious and better tolerated than whole-protein formulas.

Key words: Dipeptides and tripeptides; Enteral nutrition; Abdominal surgery; Gastric residual volume; Absorption

Core tip: Few trials thus far have investigated the benefits of dipeptide- and tripeptide-based enteral formulas for abdominal surgery patients. The results of the present study suggest that dipeptide- and tripeptide-based enteral formulas are more efficacious and better tolerated than whole-protein formulas and could shorten the intensive care unit stays of malnourished abdominal surgery patients.

Peptide-based enteral formula improves tolerance and clinical outcomes in abdominal surgery patients relative to a whole protein enteral formula. *World J Gastrointest Surg* 2016; 8(10): 700-705 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i10/700.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i10.700>

INTRODUCTION

Malnutrition is a common finding in critically ill patients. Enteral nutrition is a preferred means of support for stimulating gut hormones, modulating immunity, and maintaining the barrier function of the intestinal mucosa. However, malabsorption, poor emptying, and hypoalbuminemia often occur in patients given enteral nutrition.

Proteins are hydrolyzed to small peptides in the intestines, which are then efficiently absorbed through a variety of specific transport mechanisms, as has been previously described^[1]. Some investigators have reported that peptide-based enteral diets are associated with better protein responses and less diarrhea compared to

intact-protein diets^[2,3]. On the other hand, others have reported that peptide-based formulas seem to offer no benefits over intact-protein diets in acutely injured, hypoalbuminemic patients^[4]. However, while previous studies have described the small peptide formulas, no particular dipeptide- or tripeptide-based formulas have been investigated.

Studies have demonstrated that dipeptides and tripeptides are the major products of proteins that are absorbed. Proteins are hydrolyzed in the intestines to small peptides, which are then efficiently absorbed through specific transport mechanisms. The major mechanism for absorption of the dipeptides and tripeptides of protein digestion products across the brush border is absorption through proton-coupled oligopeptide transporters (POTs)^[5-11]. Dietary proteins are converted into large peptides by gastric and pancreatic proteases in the gastrointestinal lumen and then undergo further hydrolysis into small peptides (80%) and free amino acids (20%) by various peptidases in the brush border membrane of the intestinal epithelium^[12]. Previously, Yoshihara *et al.*^[13] studied the absorption of a 100% free amino acids formula, a 60% dipeptides and tripeptides with 40% free amino acids mixture, a 100% dipeptides and tripeptides mixture, and a lactalbumin mixture. Absorption was evaluated by calculating the area under the curve of amino acid concentration in portal vein plasma of rats for 120 min after administration of each nitrogen source^[13]. The results indicated that the absorption was maximal upon administration of the nitrogen source when the 60% dipeptides and tripeptides with 40% free amino acids mixture was used.

Few clinical trials thus far have investigated the benefits of dipeptide- and tripeptide-based enteral formulas. In our hospital, however, critically ill patients in the intensive care unit (ICU) began receiving such a formula from July 2015. The aim of this study, then, was to compare this dipeptide- and tripeptide-based enteral formula with a standard enteral formula in terms of tolerance and nutritional outcomes in abdominal surgery patients.

MATERIALS AND METHODS

Patients

A retrospective study was deployed to investigate the effects of a dipeptide- and tripeptide-based enteral formula. Patients screened from the ICU database for abdominal surgery with serum albumin concentrations less than 3.0 g/dL were included in the study. The patients who received dipeptide- and tripeptide-based enteral formula from July 2015 to December 2015 were classified as the dipeptide- and tripeptide-based formula (PEF) group. Other patients who were fed a whole-protein formula were classified as the WPF group. These patients were generally included the study, although any patients with renal failure, hepatic

failure, or who required parenteral nutrition intervention were excluded. This study was approved by the ethics committee of Tainan Sin-Lau Hospital (Grant No. SLH 919-02). Patient information was anonymized and de-identified prior to analysis.

Enteral nutrition care

Patients in both groups received the same feeding protocol, when they were transferred to the ICU. Each patient received 18 kcal per kilogram of body weight on postoperative day (POD-) 1, 23 kcal on POD-3, and 28 kcal on POD-7. The patients were fed for at least 7 d, with ≥ 1000 mL of enteral formula infused on at least 3 of the days. The composition of the WPF (Osmolite HN, Abbott Laboratories) was 16.7% of protein, 54.3% of carbohydrate, and 29.0% of lipid. The composition of the PEF (Twinline, Otsuka Pharmaceutical Co, Ltd) was 16.0% of protein, 59.0% of carbohydrate, and 25.0% of lipid. The WPF contained only whole proteins (*e.g.*, calcium-potassium caseinate), whereas the protein source of the PEF (from enzymatically hydrolyzed milk protein) consisted of amino acids and peptides with molecular weights < 500 Da (approximately 78%), peptides with molecular weights between 500 and 1000 Da (approximately 15%), and peptides with molecular weights between 1000 and 3000 Da (approximately 7%).

On POD-1 with stable hemodynamic status, the full-strength diet was administered at 30 mL/h through a naso-gastric (NG) tube or *via* percutaneous endoscopic gastrostomy (PEG) feeding tubes, with the rate increasing as tolerated to a goal of 75-100mL/h. A gastric residual volume (GRV) of over 150 mL was the threshold for suspension of feeding^[14], which was followed by re-evaluation to reduce the feeding rate 2 h later. The GRV was calculated every 4 h by refractometry (Model N.O.W. 507-1; Nippon Optical Works, Tokyo, Japan) during each patient's stay in the ICU. A refractometer measures the "total soluble solids in solution" and a Brix value (BV) is assigned to the liquid. We examined the BV in order to measure the actual GRV^[15,16]. The GRV was recorded when volumes exceeded 150 mL. At such times, feeding of the patient was suspended for re-evaluation and reduction of the feeding rate 2 h later. No prokinetic drugs were used within 10 d in both groups.

Data collection

Demographic data obtained at the start of the study included gender, age, body mass index (BMI), APACHE II score, and major diagnoses. Additional data including the length of stay in the ICU, total enteral volume, GRV, and the prevalence of diarrhea were also collected for this study. The occurrence of diarrhea was defined as greater than three loose stools per day or greater than 300 mL/d. Serum albumin, prealbumin, C-reactive protein (CRP) and total lymphocyte count (TLC) were measured at baseline, day 5, and day 10.

Table 1 Comparison of demographic and clinical characteristics between the whole-protein formula group and the dipeptide- and tripeptide-based formula group

¹Percutaneous endoscopic gastrostomy; ²Naso-gastric tube. Values are presented as number of patients or mean \pm SD. WPF: Whole-protein formula; PEF: Dipeptide- and tripeptide-based enteral formula.

Statistical analysis

Data were analyzed using SPSS version 12.0 (SPSS, Inc). The differences between the two groups were analyzed by Student's *t*-test. Data are presented as mean \pm SD. χ^2 analysis was used for comparisons of the proportions of subjects in the two groups. A *P*-value < 0.05 was considered significant.

RESULTS

Study population

A total of 86 abdominal surgery patients with serum albumin concentrations less than 3.0 g/dL were identified who were admitted to the ICU during the study period. Seven of these 86 patients developed renal failure, one patient developed hepatic failure, and 6 patients required parenteral support; these 14 patients (WPF group = 6 patients, PEF group = 8 patients) were excluded from the study. The remaining 72 patients were divided into two groups (WPF group = 40 patients, PEF group = 32 patients), and the patient characteristics of the two groups are provided in Table 1. Colon cancer was the most common major diagnosis in both groups. Most colonic surgery patients can resume oral intake on POD-1. Some colon cancer patients were elderly, confused and had comorbid diseases such as diabetes, heart disease, and chronic obstructive pulmonary disease; thus they could not resume oral intake on POD-1. Therefore, we used an NG tube for intervention. There were no significant differences between the two groups in terms of age, APACHE II score, ventilator dependence, and BMI (Table 1).

Serum albumin, prealbumin, TLC and CRP

The patients were fed for at least 7 d, with ≥ 1000 mL of enteral formula infused on at least 3 of the days. On

POD-1 with stable hemodynamic status, a full-strength enteral formula (1.0 kcal/mL) was administered through NG or PEG. The prealbumin levels and TLCs were similar between the two groups on POD-1. There was also no significant difference between the serum albumin levels on POD-1 and POD-5 for the two groups, but the level for the PEF group was significantly higher than that of the WPF group on POD-10 (2.89 ± 0.27 vs 2.70 ± 0.30 , $P = 0.01$; Table 2). Prealbumin levels on POD-5 and POD-10 were significantly higher in the PEF group than in the WPF group ($P < 0.01$). The TLC of the PEF group was higher than that of the WPF group on POD-5, but there was no significant difference on POD-10. In critical patients protein parameters depend on inflammation. We checked the CRP levels, and there was no significant difference between the two groups.

Clinical outcomes

The prevalence of suspended feeding due to high gastric residuals and maximum caloric intake during ICU stay was similar between the two groups (Table 3). The average maximum GRV for the PEF group patients during their ICU stays was significantly lower than that for the WPF group (Table 3). There was no significant difference between the groups in terms of the caloric intake on POD-5, but the average intake for the PEF group on POD-10 was higher than that of the WPF group. There was no significant difference between the two groups in terms of the prevalence of diarrhea and pneumonia. The average length of stay in the ICU for the PEF group was 6.2 ± 0.8 d, which was significantly shorter than that for the WPF group (6.8 ± 1.5 d).

DISCUSSION

Providing enteral nutrition care for critically ill patients is challenging in general, but it is even more difficult to

Table 3 Clinical outcomes for the whole-protein formula group and the dipeptide- and tripeptide-based formula group

	WPF group	PEF group	P-value
Length of stay in the ICU ¹ (d)	6.8 ± 1.5	6.2 ± 0.8	0.047
Maximum caloric intake during ICU stay (kcal/kg)	22.5 ± 1.9	23.2 ± 2.4	0.063
Caloric intake (kcal/kg body weight/d)			
POD ² -5	20.7 ± 2.3	21.5 ± 1.7	0.116

provide such care for abdominal surgery patients. In this study, except the enteral formulas used, the care received by the two groups of patients was the same. Both groups of patients would be unable to achieve their caloric intake goals under normal circumstances. As noted above, there were no significant differences between the two groups in terms of their average caloric intakes and rates of diarrhea and pneumonia complications. The average maximum GRV recorded for each patient during ICU stay among the WPF group patients was higher than that among the PEF group patients, but there was no significant difference between the two groups in terms of the prevalence of suspended feeding due to high GRV ($P = 0.071$). It was easy and effective to calculate GRV values by refractometry. More specifically, BV measurements and the following equation were used: $(GRV \times \text{pre-dilution BV}) = (GRV + 30 \text{ mL water}) \times \text{post-dilution BV}$. We accurately grasped the GRV values to avoid the risk of aspiration pneumonia and to assess the digestion conditions. The dipeptide- and tripeptide-based enteral formula seemed to have been efficiently absorbed and resulted in better prealbumin, albumin (POD-10), and TLC (POD-5) levels in the PEF group, in addition to shortening the ICU stay. Prealbumin is a rapid-turnover protein (half-life < 48 h), which is a more sensitive indicator to assess the nutritional status than albumin (half-life 21 d). When patients' nutrition is improved, the serum prealbumin will increase rapidly (POD-5 and 10).

Four members of the POT superfamily have previously been identified, namely, PepT1 (SLC15A1), PepT2 (SLC15A2), PHT1 (SLC A4), and PHT2 (SLC A3). In humans, PepT1 expressed in the small intestine epithelium is involved in the absorption of nutritional peptides^[17,18]. Previously, the effects of PepT1 activity on a variety of pathological conditions have been studied. Ziegler *et al.*^[19] found that patients with short-bowel syndrome may experience up-regulation of the expression of colonic PepT1 adapted to malabsorption of dipeptides and

tripeptides, independent of changes in the mucosal surface area. In other studies, intestinal villous atrophy due to prolonged fasting was investigated in fasting animals, and it was observed that PepT1 expression increased during metabolic fasting phases^[20,21]. Ogiwara *et al.*^[22] showed that 4 d of starvation markedly increased the PepT1 in the jejunum, while a study by Ihara *et al.*^[23] demonstrated that starvation for 4 d and semistarvation for 10 d increased PepT1 mRNA and protein in the rat jejunum. That the cell population of PepT1 is increased in starvation may explain these results of earlier studies. In a study by Vazquez *et al.*^[24] this increase was expected to reduce the absorption of amino acids in human volunteers' jejunum after 14 d of hunger. In fact, while the absorption of amino acids was decreased, surprisingly, no significant change in the absorption of peptides was observed. In the present study of malnourished abdominal surgery patients, we conjectured that the patients' PepT1 levels would result in an increase in the absorption of dipeptides and tripeptides.

A randomized trial by Heimbürger *et al.* demonstrated that 10 d of feeding with a small-peptide diet produced slightly greater increases in serum rapid-synthesis proteins than did a whole-protein diet, especially between days 5 and 10^[25]. Our study found a similar result. The PEF group patients received the dipeptide- and tripeptide-based enteral feeding formula, and this formula was more efficacious and better tolerated than the whole-protein formula received by the patients in the other group. The present study suggests that 7 d of feeding of the dipeptide- and tripeptide-based enteral feeding formula may benefit a patient's nutritional status. Peptide formulas, however, are more expensive than whole-protein formulas, costing approximately five times more. More specifically, feeding a patient for 7 d with a peptide formula rather than whole-protein formula will cost roughly \$140 more. The mean cost of ICU is \$350 per day in Taiwan. However, peptide formulas seem to shorten the average ICU stay by about one day, and this should be factored into overall consideration of the cost and quality of care.

There were no significant differences in the prevalence of GRV, diarrhea, and pneumonia complications between the two groups, but the PEF group did exhibit a lower tendency for GRV and diarrhea than the WPF group. Two limitations of this study were its retrospective study design and low number of admitted patients. Well-designed clinical trials are needed to survey the efficacy, tolerance, and cost effectiveness of using dipeptide- and tripeptide-based enteral formulas for abdominal surgery patients.

In conclusion, the results of the present study suggest that dipeptide- and tripeptide-based enteral formulas are more efficacious and better tolerated than whole-protein formulas and could shorten the ICU stays of malnourished abdominal surgery patients.

intolerance often occurs in these patients. Few trials thus far have investigated the benefits of dipeptide- and tripeptide-based enteral formulas for abdominal surgery patients. The aim of this study, then, was to compare this dipeptide- and tripeptide-based enteral formula with a standard enteral formula in terms of tolerance and nutritional outcomes in abdominal surgery patients.

Research frontiers

The previous studies have described the small peptide formulas, but no particular dipeptide- or tripeptide-based formulas have been investigated.

Innovations and breakthroughs

The dipeptide- and tripeptide-based enteral formulas are more efficacious and better tolerated than whole-protein formulas, which shortened intensive care unit stay by about one day.

Applications

Early initiation of feeding with a dipeptide- and tripeptide-based enteral formulas for 7 d is a feasible approach in malnourished abdominal surgery patients.

Peer-review

This study is acceptable and very useful.

Abstract

AIM

To investigate the feasibility of preoperative docetaxel, cisplatin and capecitabine (DCC) in patients with resectable gastric cancer.

METHODS

Patients with resectable gastric cancer fulfilling the inclusion criteria, were treated with 4 cycles of docetaxel (60 mg/m², cisplatin (60 mg/m²) and capecitabine (1.875 mg/m² orally on day 1-14, two daily doses) repeated every three weeks, followed by surgery. Primary end point was the feasibility and toxicity/safety profile of DCC, secondary endpoints were pathological complete resection

rate and pathological complete response (pCR) rate.

RESULTS

All of the patients (51) were assessable for the feasibility and safety of the regimen. The entire preoperative regimen was completed by 68.6% of the patients. Grade III/IV febrile neutropenia occurred in 10% of all courses. Three patients died due to treatment related toxicity (5.9%), one of them (also) because of refusing further treatment for toxicity. Of the 45 patients who were evaluable for secondary endpoints, four developed metastatic disease and 76.5% received a curative resection. In 3 patients a pCR was seen (5.9%), two patients underwent a R1 resection (3.9%).

CONCLUSION

Four courses of DCC as a preoperative regimen for patients with primarily resectable gastric cancer is highly demanding. The high occurrence of febrile neutropenia is of concern. To decrease the occurrence of febrile neutropenia the prophylactic use of granulocyte colony-stimulating factor (G-CSF) should be explored. A curative resection rate of 76.5% is acceptable. The use of DCC without G-CSF support as preoperative regimen in resectable gastric cancer is debatable.

Core tip: The use of the combination of docetaxel, cisplatin and capecitabine in resectable gastric cancer has resulted in a high curative resection rate of 77%, although it also resulted in a high rate of febrile neutropenia, and in treatment related mortality.

INTRODUCTION

Although declining, gastric cancer is still ranking in the top 5 of incidence and mortality rates of malignancies in Europe^[1]. Loco-regional and metastatic recurrence rates are high and prognosis remains poor, with a 5-year survival rate of 20%-31% for stage I -III disease^[2]. Surgery is still the cornerstone of treatment for gastric cancer, although survival can be improved by adding perioperative treatment. In 2006, the results of the MAGIC trial were published showing that perioperative chemotherapy with epirubicin-cisplatin-5-fluorouracil

(FU) (ECF) improved survival compared to surgery alone (5-year survival 36% vs 23%, respectively). Although most patients assigned to the perioperative chemotherapy tolerated the preoperative chemotherapy well, only 55% of them started the postoperative chemotherapy due to postoperative complications with only 42% of the patients completing the entire regimen^[3]. These results demonstrate the problems encountered with the perioperative approach, *i.e.*, many patients do not complete the full number of post-operative chemotherapy cycles.

In an attempt to increase efficacy and tolerability of chemotherapy regimen in gastric cancer other cytotoxic agents have been explored. The combination of docetaxel, cisplatin and fluorouracil has shown to be effective in advanced gastric cancer with reported overall response rates of 37%-43% and an acceptable safety profile^[4-6]. Capecitabine, an orally substitute of 5-FU, offers a clear advantage in terms of convenience and safety without compromising efficacy^[7]. The combination of cisplatin and capecitabine showed an overall response rate of 46%-54.8% in advanced gastric cancer^[8,9]. In addition, in a phase II study using preoperative docetaxel, capecitabine and cisplatin in initially locally advanced unresectable gastric cancer a R0 resection could still be achieved in 63% of the patients with an acceptable toxicity (febrile neutropenia 4%, no treatment related mortality)^[10].

Taking these promising results into consideration we decided to conduct a one arm phase II trial investigating the feasibility of 4 cycles of preoperative chemotherapy with docetaxel, cisplatin and capecitabine in patients with resectable gastric cancer, followed by a standardized gastric resection and lymphadenectomy.

MATERIALS AND METHODS

Patient selection

Inclusion criteria were histologically proven gastric cancer [including gastro-oesophageal junction/cardia carcinoma (Siewert 2 and 3^[11])], stage I b-IVa (6th TNM classification), WHO performance state 0-1, age \geq 18 years and adequate hematologic, renal and hepatic function. All patients signed an informed consent and were expected to comply with treatment, management of toxicity and scheduled follow-up. Exclusion criteria were non-resectability, previous or current malignancies, other serious illness or medical conditions, known hypersensitivity to any of the chemotherapies used, contraindication for the use of corticosteroids, use of immunosuppressive or antiviral medication, and pregnant or lactating women. A certified ethics committee (METOPP) and the institutional review board at each centre approved the protocol. Screening included a history and physical examination, structural assessment of malnutrition, oesophagoduodenoscopy, blood sampling and CT scan of the chest and abdomen. Evaluation CT-

scans were performed after the second and fourth cycle of chemotherapy.

Treatment

Chemotherapy: Preoperative chemotherapy was administered for four cycles. Based on the described by Sym *et al.*^[10], each 3-wk cycle consisted of docetaxel 60 mg/m² IV infusion and cisplatin 60 mg/m² IV infusion on day 1, and capecitabine 1.875 mg/m² orally on days 1-14 divided into two daily doses (DCC). Prior to each cycle a full physical examination was performed, and a full blood count and chemistry was obtained. The neutrophil count had to be $\geq 1.5 \times 10^9/L$ and the platelet count $\geq 100 \times 10^9/L$. Dose reductions and delays were predefined for granulocytopenia, thrombocytopenia, and non-hematological toxicity. Secondary use of growth factors was not part of the protocol. Any adverse event was collected and registered according to Common Toxicity Criteria (CTC, version 3). A serious adverse event (SAE), defined as an event that is either fatal, life-threatening, requiring or prolonging hospitalization or resulting in persistent or significant disability or incapacity, was reported to the study coordination centre, and evaluated by the principle investigators. Furthermore, these SAE's were reported to the central medical ethics committee.

Surgery and pathology: Patients were scheduled for surgery approximately four to six weeks after the

last cycle of chemotherapy. A (partial) gastric resection and a standardized lymphadenectomy, the so-called D1extra lymphadenectomy specified to tumour location was performed by a local surgeon specialized in gastrointestinal surgery, assisted by a surgeon of the study team. The D1extra lymphadenectomy is a newly defined dissection in which lymph node stations 1-10 and/or 12 (according to the Japanese Classification^[12]) prone to metastases^[13] are removed.

Evaluation and outcome

The primary endpoint of this feasibility study was the toxicity and safety profile of 4 courses of DCC in patients diagnosed with primary resectable gastric cancer. The secondary endpoint of this study was the determination of pathological complete response (pCR) and pathological resection rate (R0). The results, *e.g.*, numbers and proportions of patients reaching the primary and secondary endpoints, will be evaluated using describing statistical analyses.

RESULTS

Patient characteristics

Between November 2008 and November 2012, 53 patients from five participating hospitals were included in the study. Two patients were classified by the monitoring committee as having distal oesophageal cancer instead of gastric cancer and were therefore excluded from the study. In Table 1 the patient characteristics are outlined. The median age was 64 years (range 34-84), and 75% of the patients exhibited an WHO performance state of 0. One patient having a WHO performance state of 2, as re-assessed later on, was not excluded because of an intention-to-treat protocol.

Feasibility

All 51 patient started preoperative chemotherapy. In total, 35 patients completed 4 cycles of chemotherapy (68.6%). In Table 2 the feasibility results are outlined. A total of 169 cycles of chemotherapy were administered. The percentage of intended dose delivered in the intention-to-treat group was 78%-79% for each drug, calculated as the percentage of dose delivered in patients eligible for chemotherapy (deceased patients were excluded). Reasons for dose reduction and discontinuation were treatment related toxicity, including two deaths and a tumour related bleeding in two patients (Figure 1).

Safety

All patients were evaluable for safety. Grade III/IV toxicity is summarized in Table 3. The most common grade III/IV toxicity was febrile neutropenia and diarrhea occurring in 10.1% and 9.5% of the cycles, in respectively 31% and 25% of patients. There were 3 chemotherapy related deaths, resulting in a mortality rate of 5.9%. In two patients, treatment-related death

was infection concomitant with grade III/IV neutropenia. One patient died after refusing further therapy of an initially successful treatment of febrile neutropenia.

Efficacy

Of the remaining 48 patients, 3 patients were considered non-evaluable for the secondary endpoints because of major protocol violation (one patient was operated one year after completion of the preoperative regimen due to myocardial infarction, one patient switched to another chemotherapy regimen, and one patient was operated in a non-participating hospital). Of the remaining 45 patients 39 patients underwent a R0 resection. Two patients developed distant metastases assessed prior to surgery, two patients had peritoneal carcinomatosis diagnosed during explorative surgery and two patients had a R1 resection. Thus, 76.5% of the intention to treat population and 86.7% of the evaluable patients had a R0 resection with curative intend. The surgical results are described elsewhere. A pCR was reported in 3 patients (5.9%).

DISCUSSION

Overall survival of gastric cancer after a curative resection can be improved with perioperative chemotherapy as shown in the MAGIC trial. The additional benefit of perioperative ECF on survival is probably for the larger part attributed to the preoperative part of the treatment^[3]. Postoperative chemotherapy in this patient category is challenging since a high percentage of the patients is not fit enough or willing to start and complete the full postoperative part of the regimen^[3]. To improve the adherence and increase the benefit of preoperative chemotherapy in resectable gastric cancer we designed this phase II study investigating the feasibility of a preoperative regimen of four cycles of docetaxel, cisplatin and capecitabine. To increase

the efficacy of the preoperative regimen, we replaced epirubicin by docetaxel, since docetaxel containing combination regimens have shown to be feasible and have good response rates in locally-advanced and metastatic gastric cancer^[4-6]. In our trial however, four courses of DCC as a preoperative regimen showed to be highly demanding for patients with primarily resectable gastric cancer. Only sixty-eight percent of the patients completed all 4 cycles of DCC, the other patients discontinued mainly due to treatment related toxicity. In comparison with results from other trials this percentage is rather low. In a German phase II trial investigating the same regimen as perioperative chemotherapy, with a higher dosage of docetaxel of 75 mg/m², 94% completed all three preoperative cycles^[14]. In the MAGIC trial, 86% completed the intended three preoperative cycles of ECF^[3]. In a French trial the rate of patients completing two cycles of preoperative chemotherapy was 87%^[15], while in an Italian study the rate of completing 4 preoperative docetaxel based cycles was 74%^[16]. Four cycles of preoperative DCC chemotherapy, therefore, might be too demanding whereas 86% and 76% of the patients in our study completed 2 and 3 cycles respectively which is comparable to the results described above. On the other hand, completing postoperative chemotherapy is even more difficult. In the aforementioned Italian study feasibility of preoperative chemotherapy was compared to the feasibility of the same regimen as postoperative chemotherapy. The rate of completing 4 postoperative cycles was 34% in this arm^[16]. In the previous mentioned German and MAGIC trials only 53% and 42% respectively completed the postoperative scheme^[3,14]. Although the rate of completing all 4 cycles was relatively low in our study, the intended delivered dose was reasonable with percentages of 78 for all drugs individually^[7,14]. Accurate

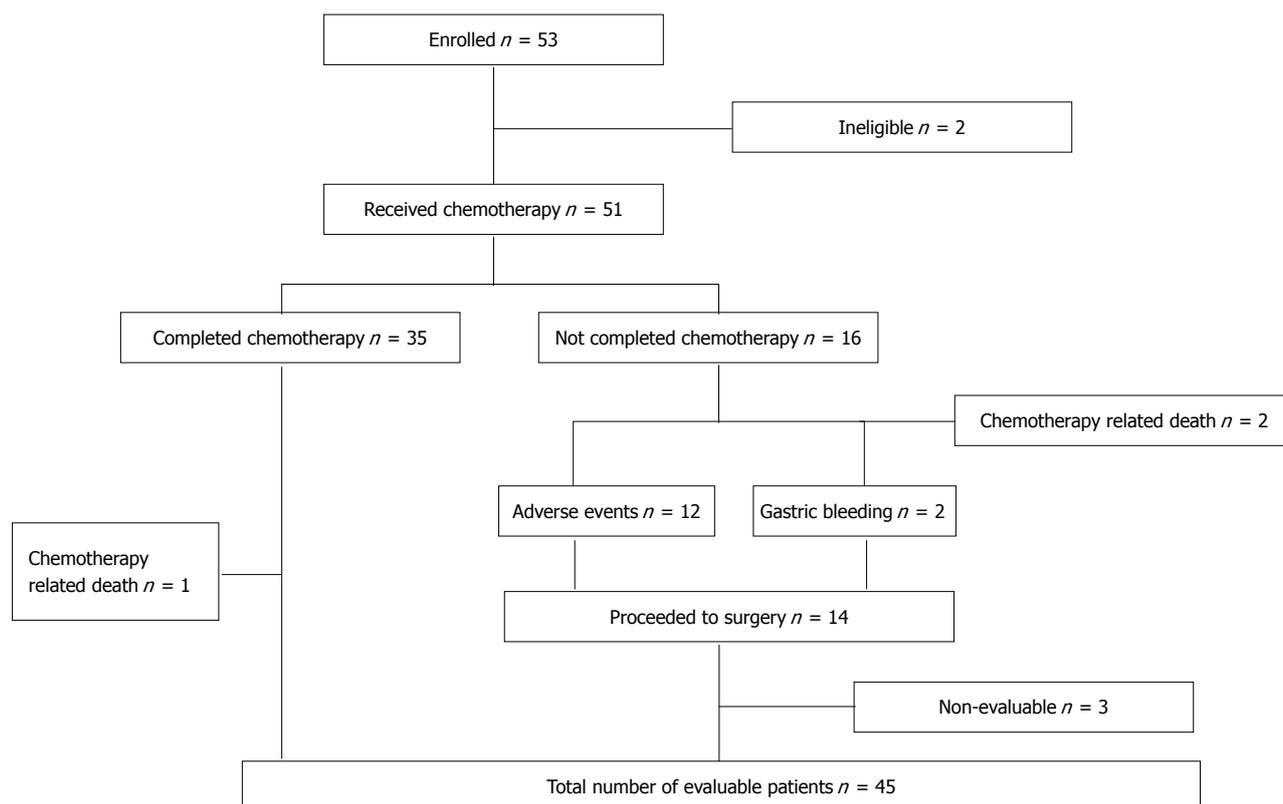

Figure 1 Flow diagram of enrolled patients.

monitoring and early intervention in case of deterioration is imperative to prevent a high amount of patients failing to complete a full chemotherapy regimen.

Treatment related mortality was 5.9% being comparable to mortality rates reported in literature (0%-6%)^[4,5,7,17]. Febrile neutropenia occurred in 10% of all cycles (vs 2%-15% found in other trials^[4,5]), being the cause of death of at least two of three patients. The prophylactic or secondary use of G-CSF was not part of the protocol as no data were available at the time of the study design about the interaction between G-CSF and capecitabine in case of simultaneous administration. In theory, the proliferative activity of bone marrow after the administration of G-CSF might increase the myelotoxicity of capecitabine. In literature, only scarce data are known about the simultaneous use of G-CSF and capecitabine. In a phase II trial in breast cancer, the use of pelfilgastrim was evaluated in a small subset of patients receiving docetaxel and capecitabine based chemotherapy regimen. Minimal grade III/IV neutropenia and no febrile neutropenia was observed^[18]. In one phase II trial in metastatic gastric cancer with a comparable DCC regimen as in our study, patients were treated successfully with G-CSF in case of febrile neutropenia and no toxicity related deaths were reported^[19]. The use of G-CSF as primary or secondary prophylaxis for (febrile) neutropenia in a docetaxel and capecitabine based chemotherapy scheme is therefore promising, and should be further investigated.

Other main toxicities we encountered were grade

III/IV hand-foot syndrome, diarrhea and anorexia. The rate of hand-foot syndrome of 7.8% in this study is acceptable compared to other studies^[7-10,17]. Many patients with gastric cancer experience difficulties with eating. With addition of the toxicity of chemotherapy gastric cancer patients are prone to anorexia and weight loss. It is therefore imperative to monitor their intake and weight to be able to act in time when this is deteriorating. A dietician should be consulted and enteral feeding should be started in an early phase^[20].

In gastric cancer, clinical tumour staging faces several difficulties. The current imaging modalities have low sensitivity rates for T- and N-stage^[21]. It is therefore difficult to clinically assess the efficacy of chemotherapy in these patients. In literature, many modalities have been used to determine response rate^[4,7,15], which makes it difficult to compare ORRs. In our study, we therefore only determined pathological response rate. A pCR was found in 3 patients (5.9%) which is lower than expected looking at other studies investigating DCF or DCC in gastric cancer in which pCRs of 6.1%^[10], 11.7%^[16] and 13.7%^[14] are reported. On the other hand, in the MAGIC trial using ECF as a treatment regimen no pCR was seen^[3].

Thirty-nine (76.5%) patients received a R0 resection. This is in line with rates found in the MAGIC trial (69.3%)^[3], although it is lower compared to other trials using a docetaxel based regimen in which a R0 resection was achieved in 84%^[15], 85%^[16], and 90.2%^[14] of patients. The long-term effects of this docetaxel based

scheme and protocolized D1extra lymphadenectomy have to be awaited.

In conclusion, in our study the benefits defined as R0 resection and complete pathological response rates of four cycles of DCC are lower than expected, although the effects on long-term results have to be awaited. Moreover, this is coupled with a high percentage of grade III/IV toxicity, especially febrile neutropenia. The use of simultaneous G-CSF and capecitabine should be further investigated to decrease toxicity-related non-adherence and mortality. According to the results of this study, the use of DCC without G-CSF support as preoperative regimen in resectable gastric cancer is debatable.

ACKNOWLEDGMENTS

We would like to acknowledge Sanofi for their support in this study.

COMMENTS

Background

Survival rates for resectable gastric cancer are still poor. Resection is the cornerstone of treatment, though the addition of perioperative chemotherapy has additional benefit. In 2006, the results of the MAGIC trial were published, comparing perioperative chemotherapy with surgery alone, which resulted in a survival benefit. Only 42% of patients completed the postoperative regimen consisting of epirubicin, cisplatin and capecitabine. Other regimens have been investigated for their effectiveness in gastric cancer, e.g., docetaxel combined with cisplatin and capecitabine, leading to promising results.

Research frontiers

Improve survival of curable gastric cancer with the use of different regimens of (neo)adjuvant chemotherapy.

Innovations and breakthroughs

At the time of study design, this was one of the first phase II studies to investigate the feasibility of a docetaxel based regimen in resectable gastric cancer. Although the R0 resection rates were high, it was accompanied by a high rate of febrile neutropenia which resulted in a mortality rate of 5.9%.

Applications

The combination of docetaxel, cisplatin and capecitabine could be used as a (neo)adjuvant regimen in the setting of resectable gastric cancer, although the role of granulocyte colony-stimulating factor (G-CSF) to prevent febrile neutropenia should be investigated.

Terminology

Docetaxel can cause neutropenia. In case of an infection, this can be fatal complication. G-CSF could prevent the development of neutropenia, thereby preventing this major complication.

Peer-review

The present study is a phase II clinical trial which had the aim to evaluate the feasibility of three-drug regimen of preoperative chemotherapy of gastric cancer, composed by cisplatin, capecitabine and docetaxel. It is a well-conducted study.

Abstract

AIM

To review the evidence for the use of different non-steroidal anti-inflammatory drugs (NSAIDs) in the treatment of biliary colic.

METHODS

The strategies employed included an extensive literature review for articles and studies related to biliary colic from electronic databases including PubMed, Science Direct, Wiley Inter Science, Medline and Cochrane from last 15 years. Keywords: "Biliary colic", "management of biliary colic", "non-steroidal anti-inflammatory drugs", "cholelithiasis" and "biliary colic management". Six randomized control trials, 1 non-randomized trial and 1 meta-analysis were included in this review. The outcomes of these studies and their significance have been reviewed in this paper.

RESULTS

Current evidence suggests there are no set protocols for biliary colic pain management. NSAIDs are potent in the management of biliary colic, not only in terms of symptom control but in disease progression as well. Apart from the studies on diclofenac and ketorolac, there are studies which have shown that intravenous tenoxicam and injectable flurbiprofen are equally effective in managing biliary colic. The efficacy of NSAIDs is superior in terms of lower number of doses and longer duration of action in comparison to other analgesic agents.

CONCLUSION

This literature review has found that NSAIDs are safe and effective for pain control in biliary colic, and reduce the likelihood of further complications.

Key words: Biliary colic; Management of biliary colic; Non-steroidal anti-inflammatory drugs; Cholelithiasis; Biliary colic management

Core tip: There are currently no set protocols for pain management in biliary colic. This literature review analyses studies from the last 15 years and shows that non-steroidal anti-inflammatory drugs (NSAIDs) provide safe

and effective pain control. It also suggests that NSAIDs play an important role in reducing the complication risk following episodes of biliary colic.

INTRODUCTION

In developed countries, including United States, United Kingdom and other European countries, 10% of adults and 20% of people aged > 65 years have cholelithiasis. It is more than twice as common in females as in males^[1]. Biliary colic is seen as a presenting symptom in 75%-80% of the patients with symptomatic cholelithiasis^[2].

This review examines the evidence for the efficacy of non-steroidal anti-inflammatory drugs (NSAIDs) and other analgesics in the management of pain in biliary colic as well as their role in the prevention of progression to complications.

MATERIALS AND METHODS

The strategies employed included an extensive literature search for articles and studies related to biliary colic from electronic databases including PubMed, Science Direct, Wiley Inter Science, Medline and Cochrane. The keywords used in electronic search were "biliary colic", "management of biliary colic", "non-steroidal anti-inflammatory drugs" and "biliary colic management". The literature searches of the last fifteen years brought up approximately 50 studies and papers in a variety of journals. However, only 6 randomized control trials (RCTs), 1 non-randomized trial and 1 meta-analysis fell within the purview of this review, which was to study the effects of NSAIDs and other pharmacological therapies on symptomatic cholelithiasis.

RESULTS

The studies were examined with the help of a questionnaire devised by the Critical Appraisal Skills Programme^[3] recommended for evaluating RCTs in evidence-based medicine.

Akriviadis *et al*^[4] designed a study investigating the effects of diclofenac in patients suffering from biliary colic. The study aimed to prove the benefits of diclofenac for pain alleviation, and also linked NSAIDs with preventing the development of complications related to cholelithiasis. The study involved 53 consenting patients who were

known to have cholelithiasis and who were diagnosed with biliary colic. One group ($n = 27$) received 75 mg of 3 mL IM diclofenac and the other group ($n = 26$) received 3 mL of saline. The patients were followed up for 3 d and the effect of each treatment was gauged by changes in pain severity and progression to complications. Satisfactory levels of analgesia were obtained in 21 patients from the diclofenac group whilst only 7 from the placebo group were relieved of pain. Nearly 50% of the patients in the placebo group progressed to the development of acute cholecystitis. It was concluded that diclofenac usage could provide cost-effective pain relief in the acute phase of biliary colic and could also prevent development of subsequent complications.

This was a randomized, double-blind and controlled study. The inclusion criteria were based on the presence of right upper quadrant and epigastric pain. These patients were further subjected to sonography to demonstrate the presence of cholelithiasis. The exclusion criteria were strictly monitored. There was a longer follow-up of 3 d in these patients, which aided the adequate monitoring of responses to treatment and the recording of any complications in a surgical ward setting, thus minimizing the chances of observer bias and maintaining uniformity of care. The study also employed the setting up of end points which were based on patient response to treatment and time taken to get relief or symptom progression. This made it a well-controlled study keeping the wellbeing of patients paramount. This is a level-II study with a sound aim and statistically significant results but the only limitation was the fallout of 28 patients from initial enrollment to the final conclusion.

Tomida *et al*^[5] conducted an extensive study on the long-term use of ursodeoxycholic Acid (UDCA) therapy in patients with known cholelithiasis. The aim of this study was to evaluate the effects of this therapy on biliary pain and development of acute cholecystitis. The study included a cohort of 527 patients with uncomplicated cholelithiasis who were either given or withheld UDCA (600 mg/d). These patients were followed for 18 years and the results analysed. It was found that UDCA therapy was associated with reduced risk of developing biliary pain in symptomatic as well as in asymptomatic patients. The risk of conversion to surgery was also reduced in symptomatic patients treated with UDCA. On the basis of these findings it was concluded that UDCA therapy might be considered as a safe option in symptomatic patients and also in patients who carry a significant surgical risk.

This was a non-randomized prospective study designed to cover a large number of patients. The strengths of this study are that it had a large sample size and that the follow-up and data collection were uniform. The inclusion and exclusion criteria were strictly monitored and the allocation of an end-point meant that the patients were given a fair chance of getting an acceptable mode of management for their symptoms. However, the absence of randomization makes this a level-III study and there is

a lack of power calculations to support the representativeness of the study, therefore increasing the likelihood of type 2 error. There is also an element of bias in this type of observational study.

Dula *et al*^[6] compared the efficacy of administering intramuscular ketorolac with intramuscular meperidine in the treatment of acute biliary colic. The study consisted of 30 patients who were divided into two groups and after the diagnosis of acute biliary colic was established, were given either meperidine 1.5 mg/kg (100 mg max.) or ketorolac 60 mg. The patients were asked to rate their pain at two time intervals; before administration and 30 min after the medication was given. This was rated on a visual analogue pain scale. The average pain score was compared between the two groups at time 0 and at 30 min. The average pain score at time 0 was 7.6 for the ketorolac group and 7.3 for the meperidine group. The visual analog scale (VAS) scores for the ketorolac group and the meperidine group were 3.8 and 3.9 at the 30-min time interval after the administration of the respective drugs. It was found that there was indeed improvement in pain control in both groups, but there was no markedly demonstrable difference in the pain relief achieved by either ketorolac or meperidine when administered intramuscularly.

This study had a definite aim and was well-designed but the size of the sample was too small to have any impact on the practice. It was a randomized, prospective and a double-blinded study. However there was an absence of power calculations, making the study less representative of the large number of cholelithiasis patients who present to emergency clinics routinely. Only 15 patients effectively got intramuscular ketorolac and this cannot constitute evidence of any consequence.

Henderson *et al*^[7] conducted a similar study on 324 patients over a 2-year period with a view to comparing analgesic efficacy and systemic tolerability of intravenous Ketorolac and Meperidine in the treatment of acute biliary colic. The patients were between the ages of 18 and 65 years with signs and symptoms consistent with acute biliary colic. Pain scores were quantified by means of a four-point verbal rating system as well as a VAS. These are validated tools for measuring patient satisfaction and drug efficacy and thus lend validity to the findings. The results did not demonstrate any significant differences in pain or drug tolerability [mean change in the VAS at 2 h was 6.2 ± 3.6 cm for the ketorolac group, compared with 6.7 ± 3.6 cm for the meperidine group ($P = 0.25$)] but revealed higher incidences of nausea and dizziness in the Meperidine group ($n = 149$). The study goes on to conclude that Ketorolac ($n = 175$) is a well-tolerated and effective analgesia for biliary colic and the fact that it showed similar efficacy as Meperidine with decreased adverse effects makes it a better alternative.

This was a prospective, randomized and a double-blinded study which included a significant sample of patients. The inclusion and exclusion criteria were strictly

monitored. The limitation of this study was that out of a sizeable number of patients initially enrolled ($n = 534$), more than 220 patients were lost for a variety of reasons such as loss of data and inappropriately filled forms. Also the employment of convenience sampling makes the study prone to potential bias. However, the presence of power calculations makes this a robust and acceptable study. There is certainly evidence collected in this study which could potentially change practice; more patients with biliary pathology could be treated with Ketorolac for effective analgesia.

Antevil *et al*^[1] undertook a trial to determine the efficacy of intravenous glycopyrrolate for the relief of pain associated with the biliary tract. At the onset 312 patients were assessed for the study but eventually only 39 were actually included in the study. The rest either declined to participate or did not meet the inclusion criteria. The initial aim of the study was to include 54 patients but due to difficulty in patient enrollment, analysis was done on only 39 patients who completed the study protocol. The initial sample size was based on power calculations to give the study a representative character, which was later lost due to the fallouts. The results of the study failed to demonstrate any significant differences in the pain relief between patients receiving glycopyrrolate and those receiving a placebo. The statistical difference in visual analogue scale for pain between the former and the latter was 3 mm vs 8 mm respectively. It was proposed that a further, larger study would be needed to underline the supremacy (if any) of glycopyrrolate in treating patients with biliary colic.

This was a randomized, prospective and a double-blind study. The randomization was computer generated and the inclusion criteria were set up keeping in view the final size of the sample based on eligibility criteria. Factors such as the selection of patients and the methods used to sample by the enrolling physicians made the study weaker and the results less relevant. The patients enrolled for the study did not all necessarily have cholelithiasis, thus making them less suitable for treatment with an anticholinergic agent like glycopyrrolate. This was highly likely to give false negative results. This study failed to achieve its aim and left a lot to be desired in terms of patient selection and the inclusion criteria.

Kumar *et al*^[2] undertook a study to compare the effects of intramuscular diclofenac with intramuscular Hyoscine-N-butyl bromide in the treatment of acute biliary colic and also to study their role in the prevention of gallstone-related complications. The study was conducted on 72 consecutive patients with biliary colic. One group ($n = 36$) received 75 mg of intramuscular diclofenac and the other group ($n = 36$) received 20 mg of intramuscular hyoscine. Pain severity was later measured on a visual analog scale at different time intervals of 30 min, 1 h, 2 h, and 4 h after the administration of the drug. Patients were followed for 72 h for signs of relapse or development of complications. It was found that diclofenac provided much

Table 1 Comparison of studies with their design and outcomes

Ref.	Design of study	Sample size	Duration of treatment	Results
Akriviadis <i>et al</i> ^[4]	Randomized controlled trial	<i>n</i> = 53 Group I (<i>n</i> = 26) (NSAID) Group II (<i>n</i> = 27) (Placebo)	3 d	Superior results from Diclofenac usage
Tomida <i>et al</i> ^[5]	Non-randomized controlled trial	<i>n</i> = 527		Ursodeoxycholic acid a safe option in symptomatic but high surgical risk patients
Dula <i>et al</i> ^[6]	Randomized controlled trial	<i>n</i> = 30 Group I (<i>n</i> = 15) (NSAID) Group II (<i>n</i> = 15) (Meperidine)	1 d	Comparable efficacy but lesser side-effects from Ketorolac
Henderson <i>et al</i> ^[7]	Randomized controlled trial	<i>n</i> = 324 Group I (<i>n</i> = 175) (NSAID) Group I (<i>n</i> = 149) (Meperidine)		Comparable efficacy but lesser side-effects from Ketorolac
Kumar <i>et al</i> ^[2]	Randomized controlled trial	<i>n</i> = 72 Group I (<i>n</i> = 36) (NSAID) Group II (<i>n</i> = 36) (Hyoscine)	3 d	Rapid symptom relief with Diclofenac and lower rate of sequelae
Antevil <i>et al</i> ^[11]	Randomized controlled trial	<i>n</i> = 39 Group I (Glycopyrrolate) Group II (Placebo)		No significant difference in analgesia between glycopyrrolate and placebo
Olsen <i>et al</i> ^[9]	Randomized controlled trial	<i>n</i> = 46 Group I (<i>n</i> = 23) (Ketorolac) Group II (<i>n</i> = 23) (Butorphanol)	1 d	Both agents provided reasonable relief of symptoms
Basurto Oña <i>et al</i> ^[10]	Meta-analysis			NSAIDs drugs of choice for symptom control and improvement of prognosis

NSAIDs: Non-steroidal anti-inflammatory drugs.

more rapid pain relief, as shown by the fact that 91.7% of such patients recorded no symptoms at the 4-h interval. Furthermore, it was noted that progression to sequelae of cholelithiasis was significantly lower in this group of patients compared with the patients treated with hyoscine.

This was a prospective, randomized, and double-blinded study with a significant sample size. There were no dropouts in terms of follow-up and the focus of the study remained unaltered. The results of this study are precise and corroborate well with the past experiences of other researchers like Todd and Sorkin^[8] in 1988. The study has, in the authors' opinion, the potential to influence practice if backed by robust statistical analysis.

Olsen *et al*^[9] carried out a prospective randomized controlled trial comparing the efficacy of ketorolac vs butorphanol for patients with suspected biliary colic in the emergency department. This was a compact study with a definite aim (though limited by a small sample size) which concluded that both agents can be considered reasonable options in patients presenting with biliary colic, especially those with a need for further investigations.

Basurto Oña *et al*^[10] conducted a systematic review and meta-analysis of randomized controlled trials involving the management of biliary colic with anti-inflammatory agents. A systematic and manual search was conducted in the literature. The authors selected 7 RCTs of 349 patients. The inclusion criteria were all the RCTs which compared the effects of NSAIDs with other interventions that were employed for treating uncomplicated biliary colic in an acute setting. The outcome measures were set up as rescue analgesia, rapidity of analgesic effect, adverse reactions and progression to complications.

The results were well analyzed and statistically significant. These were expressed in terms of confidence intervals and odds ratios, making the analysis more rigorous. The results showed a clear advantage in favour of NSAIDs because there was lower need for rescue analgesia (OR = 0.32; 95%CI, 0.16-0.61) and progression to complications (OR = 0.19; 95%CI: 0.08-0.44). This is a very robust study and can be assigned as level-I evidence. The results cannot, however, be extrapolated to the general population simply because 349 patients cannot be

representative of a pathology which affects such a large part of the adult population. In these types of studies there is a danger of publication bias in terms of selecting only the favourable trials for the analysis.

The findings of this study are also well supported by observations of Macintyre *et al.*^[11], who have termed NSAIDs as effective analgesics for the management of acute pain (level- I evidence).

DISCUSSION

The review of the above studies clearly suggests that there are no set protocols for the administration of specific analgesic agents to the patients with biliary colic (Table 1). It follows that there is strong evidence demonstrating the therapeutic and preventive potency of NSAIDs in the management of biliary colic, not only in terms of symptom control but in disease progression as well^[12]. Apart from studies on diclofenac^[4] and ketorolac^[2], there are studies^[13,14] which have shown that intravenous tenoxicam and injectable flurbiprofen (both NSAIDs) respectively are equally effective in managing biliary colic. The efficacy of NSAIDs has been proven to be superior in comparison to agents such as meperidine and hyoscine. Initial analgesic requirements may be substantial, and treatment with NSAIDs or acetaminophen (also called paracetamol) should be initiated^[15]. NSAIDs also demonstrated pharmacological superiority in terms of smaller number of doses and side effects with longer duration of action in comparison to other analgesic agents^[4]. Therefore enough qualitative evidence is available to influence practice.

A multi-centric study needs to be undertaken, aimed at identifying the reasons leading to variation in practice between the various centers after these patients are identified as having biliary colic. The evidence provided (level- I)^[10] is significant and similar studies would go a long way toward laying down strict guidelines for prescribing analgesia to patients with biliary colic.

COMMENTS

Background

Cholelithiasis is a common surgical presentation in developed countries, present in 10% of the adult population and 20% of those aged over 65 years. Biliary colic is a presenting symptom in 75%-80% of those with symptomatic cholelithiasis. Despite this, there are currently no set protocols for the pain management in biliary colic.

Research frontiers

This paper reviews extensive literature from electronic databases including PubMed, Science Direct, Wiley Inter Science, Medline and Cochrane. Six randomized control trials, 1 non-randomized trial and 1 meta-analysis were analysed from the past 15 years.

Innovations and breakthroughs

The aim in this paper was to collate evidence for non-steroidal anti-inflammatory

drugs (NSAIDs) use in biliary colic as both pain relief and with a view to preventing further complications.

Applications

This review shows NSAIDs to be both safe and effective for biliary colic pain management as well as reducing the incidence of complications arising from cholelithiasis. Practically this could have implications for increased use of NSAIDs for biliary colic as well as encouraging further study in this area to investigate the role of NSAIDs in improving complication rates.

Peer-review

The article is complete and interesting.

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Gastroesophageal reflux disease (GERD) is nowadays a highly prevalent, chronic condition, with 10% to 30% of Western populations affected by weekly symptoms. Many patients with mild reflux symptoms are treated adequately with lifestyle modifications, dietary changes, and low-dose proton pump inhibitors (PPIs). For those with refractory GERD poorly controlled with daily PPIs, numerous treatment options exist. Fundoplication is currently the most commonly performed antireflux operation for management of GERD. Outcomes described in current literature following laparoscopic fundoplication indicate that it is highly effective for treatment of GERD; early clinical studies demonstrate relief of symptoms in approximately 85%-90% of patients. However it is still unclear which factors, clinical or instrumental, are able to predict a good outcome after surgery. Virtually all demographic, esophagogastric junction anatomic conditions, as well as instrumental (such as presence of esophagitis at endoscopy, or motility patterns determined by esophageal high resolution manometry or reflux patterns determined by means of pH/impedance-pH monitoring) and clinical features (such as typical or atypical symptoms presence) of patients undergoing laparoscopic fundoplication for GERD can be factors associated with symptomatic relief. With this in mind, we sought to review studies that identified the factors that predict outcome after laparoscopic total

fundoplication.

Key words: Gastroesophageal reflux disease; Antireflux surgery; Outcome predictors; Fundoplication; Nissen; Laparoscopy; High resolution manometry; Impedance-pH monitoring

Core tip: Fundoplication is currently the most commonly performed antireflux operation for management of gastroesophageal reflux disease (GERD). Outcomes described in current literature following laparoscopic fundoplication indicate that it is highly effective for treatment of GERD. However it is still unclear which factors, clinical or instrumental, are able to predict a good outcome after surgery. Anatomical conditions seem to not be a risk factor for poor outcome. The predictability of success following laparoscopic fundoplication seems to be directly proportional to the degree of certainty that gastroesophageal reflux is the underlying cause of the patient's complaints. Thus, performing an accurate pre-operative clinical and instrumental evaluation is mandatory.

Tolone S, Gualtieri G, Savarino E, Frazzoni M, de Bortoli N, Furnari M, Casalino G, Parisi S, Savarino V, Docimo L. Pre-operative clinical and instrumental factors as antireflux surgery outcome predictors. *World J Gastrointest Surg* 2016; 8(11): 719-728 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i11/719.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i11.719>

INTRODUCTION

Gastroesophageal reflux disease (GERD) is currently a common condition; usually 10% to 30% of Western populations refer a weekly incidence of GERD symptoms. It has been recognized as a significant public health concern in the West^[1,2]. Usually, the major part of patients with mild GERD are treated effectively with dietary and lifestyle changes, and/or low-dosage proton pump inhibitors (PPIs)^[3]. For patients with GERD refractory to PPIs, different treatments can be started. In fact antireflux surgery, and endoscopic procedures exist for patients who will to undergo an operative intervention. Fundoplication is currently considered the surgical gold standard for GERD treatment. Since its first description by Rudolph Nissen in 1956^[4], the development of laparoscopy have increased the use of fundoplication worldwide. The indications for antireflux surgery in GERD patients were stated by the American Gastroenterological Association in 2013: It can be indicated in a GERD patient responsive, but not compliant to acid suppression therapy; in GERD patients who continue to experience troublesome

symptoms despite an adequate pharmacological therapy; and in GERD patient who experience persistent extraesophageal symptoms despite adequate PPI therapy^[5].

LF outcomes (as reported in current literature) point out that this technique is highly effective in GERD patients; the relief of symptoms is present in 85%-90% of subjects in the immediate post-operative period^[6,7]. Despite these encouraging data, there can be complications that can necessitate a second intervention: Re-herniation, disruption or twisting of the fundoplication, persistent dysphagia or reflux-related symptoms, gas bloat syndrome, and esophageal motor dysfunction^[8,9]. Also, it is not clear the real incidence of redo antireflux surgery, because of small sample size or are single center studies. In the 90's, Lafullarde reported an overall reoperation rate of 10% after LF^[10]. More recently, reoperation incidence is reported to be resembling 5%^[11]. A systematic review performed on elective LF documented an overall reoperation incidence approximating 0.6%^[12]. In the nationwide study from Denmark, an incidence near to 5% of redo antireflux surgery was reported in 2589 patients^[13].

Being the increasing number of GERD patients without endoscopic esophagitis that are selected for LF, there is the need to highlight the great significance of a careful selection of patients who are likely to have a successful outcome after surgery. Virtually all demographic, esophagogastric junction anatomic conditions, as well as instrumental and clinical features of patients undergoing LF for GERD can be factors associated with a good outcome. With this in mind, we sought to review studies that identified the factors that could predict outcome after LF.

DEMOGRAPHICS FACTORS (GENDER, AGE, OBESITY, COMORBIDITIES)

Some studies revealed that gender can affect the clinical manifestation of GERD. Female gender with GERD showed at pH-monitoring a minor value of esophageal acid exposure and greater symptom scores than male gender cross-matched for grades of esophagitis^[14,15]. In the same way, age seems to influence presentation, and GERD-related symptoms usually appear less severe in elderly, with a greater incidence of reflux complications^[16]. In 2009, a study investigated the impact of gender and age on 5 years outcome of LF^[17]. Authors showed that women were more likely to report a poorer outcome than men, describing heartburn, dysphagia and a lower satisfaction rate after surgery. Age, instead, did not prejudiced surgical outcome, even in presence of an higher incidence of complicated esophagitis and acid exposure in elderly than younger subjects^[18]. These results were also confirmed by two large case series from Italy that compared antireflux surgical outcome in patients younger or older than 65 years^[19,20]. Overweight and obesity are associated

with increased intraabdominal pressure, presence of hiatal hernia, increased frequency of transient sphincter relaxation, diminished lower esophageal sphincter (LES) pressure, and impaired gastric emptying, thus increasing esophageal acid exposure time (AET) and total number of reflux (TNR), which have a clear role in GERD and promoting symptoms^[21,22]. Recently, Luketina *et al.*^[23] retrospectively evaluated antireflux surgical outcomes in obese patients compared to normal weight GERD patients. Body mass index (BMI) was not associated to poorer outcome; reduction in GERD symptom score, GERD recurrence and reoperation rates were similar in both obese and normal weight patients. These data are consistent to several case-series^[24,25], whereas only few studies reported poorer outcomes after LF in obese subjects, with increased intraoperative difficulties, risk of recurrence and re-herniation^[26]. Finally, a study performed on a large cohort from North Carolina suggested that presence of pre-operative comorbidities, such as diabetes, hypertension or pulmonary disease, were unlikely to impair the outcome of LF^[27].

CLINICAL FACTORS: SYMPTOMS

Clinical presentation of GERD patients varies from typical to atypical symptoms, as well as extraesophageal symptoms and associated syndromes.

Heartburn and regurgitation are considered the hallmarks of reflux disease. Atypical reflux symptoms include non-cardiac chest pain and extraesophageal manifestations such as chronic cough, chronic asthma, chronic laryngitis, and dental erosions. Also, dyspepsia manifestations and irritable bowel syndrome symptoms can be present in up to 50% of GERD patients^[28].

Many studies were performed to verify the post-operative symptomatic gain after LF, in order to estimate its clinical effectiveness. Morgenthal *et al.*^[29] studied a cohort of 166 subjects with 11 years follow-up of; authors showed that typical symptoms presence was a predictive factor for a long term good outcome after LF. Lundell *et al.*^[30] performed a systematic review about the outcome of antireflux surgery. They found that patients did not experience heartburn substantially in the year after LF but it reappeared over time, with a certain amount of patients reporting heartburn after 10 years. Similarly, patients reporting regurgitation reported a substantial relief in the year after LF but with a recurrence 10 years after LF^[30].

Achieving atypical GERD symptoms response is challenging: In a recent review, authors did not find any sure data on the efficacy of LF in relieving these manifestations, even if the majority of studies demonstrated some degree of improvement^[31]. However, when a patient is selected on the basis of pH-impedance monitoring, LF showed a significant relief of extraesophageal symptoms but it seems to cannot improve all of the patients. Adaba *et al.*^[32] studied respiratory symptoms in patients with GERD and then

treated with LF. They stratified the study population into three groups; patients with cough only, patients with cough plus other respiratory symptoms (asthma, COPD, bronchitis, interstitial lung disease and hoarseness of voice) and patients with other respiratory symptoms only. Patients with cough only were likely to have a better symptoms improvement than patients with cough plus respiratory symptoms and respiratory symptoms only in the short and long term, even if the small number of patients represented a limitation. This trend has also been observed in other studies^[33,34]. Overall response rates were over 70% in the control of respiratory manifestations. A recent review speculated that cough and reflux may stimulate each other^[35]. Cough showed the highest preoperative scores than all extraesophageal manifestations and was referred by about 45% of the subjects.

Finally, the presence of dyspepsia-like symptoms seems to be a negative factor for outcome. In fact, several studies reported that after surgery there are subjects who will get worse or exacerbate dyspepsia-like symptoms (epigastric fullness, bloating, abdominal pain, flatulence), with worsening in GERD symptom control in up to 50% at long term follow-up^[36,37].

CLINICAL FACTORS: RESPONSE TO PPI

Acid-suppression with PPIs is the most widespread used therapy for GERD. Actually, patients who control their symptoms and resolve mucosal lesions with PPIs are referred to as "complete responders", whereas "partial responders" or "non-responders" are those increasingly numbers of patients experiencing only partial or no relief from reflux symptoms, even after optimized PPI^[38]. The LF is currently contemplated in patients with hiatus hernia and, according to some surgeons, in patients non-responsive to PPI^[39], whereas other surgeons do not consider the surgical treatment as a good option in PPI non-responders.

Several studies evaluated the clinical effectiveness of surgical treatment of GERD in PPI responders and nonresponders. According to Lundell *et al.*^[30], partial responders were the ones needing to use acid-suppressive medication and requiring surgical reintervention after LF. These results are consistent with a recent study; authors in fact showed that the pre-operative symptomatic response to PPI treatment was an excellent predictor of the subsequent response to LF^[40]. In Campos *et al.*^[41] performed a multivariate analysis, demonstrating that pre-operative PPI refractoriness was a predictive factor of poor outcome after LF. In fact, PPI non-responders patients had a significantly effectiveness from the surgical treatment but it was still less successful when matched with PPI responders. Also, other studies considered the surgical outcome in non-responders, evaluating those also affected by atypical symptoms, reflecting that surgical procedure can be ineffective to treat atypical symptoms. Hamdy *et coll.*, therefore, realized a prospective study on patients

responders and non-responders who underwent LF^[42]. The two groups were matched for endoscopic grading of esophagitis as well as no significant difference between the two groups on functional assessment on esophageal manometric study of LES pressure and pH-monitoring. According to their findings, clinical outcome was better in PPIs responders regarding disappearance of heartburn and regurgitation, while there was no difference in improvement of dysphagia between both groups. Also, overall patient satisfaction with surgery was significantly higher in the good responders. Authors concluded that patients responder to PPI have a positive predictive factor for LF outcome, whereas PPI non responders are not at risk for a contraindication. However, PPI non-responders have experienced the failure of the pharmacological therapy, evaluating the surgical treatment as the last opportunity for their relief. So that, surgeons and gastroenterologists should accurately and carefully select patients non-responders to maximize LF outcomes: PPI non responders and/or patients complaining atypical digestive symptoms should avoid a surgical procedure to treat GERD, if the real presence of GERD and a possible symptom-reflux correlation is not documented.

ANATOMICAL FACTORS: HIATAL HERNIA PRESENCE

Mechanisms of GERD are multifactorial (dysfunction of esophageal peristalsis, gastric activity, and LES continence). The presence of hiatal hernia exposes patients to increased AET, TNR and to a more severe GERD pattern^[43]. In literature in fact, is currently reported that at baseline hiatus hernia, LES resting pressure and length are significantly more compromised in patients with severe erosive reflux disease (ERD) and Barrett's esophagus (BE) compared to those with mild erosions and non erosive reflux disease (NERD).

Intuitively, GERD patients with a normal LES pressure at manometry would have less acid reflux and related symptoms at baseline; thus, they could be more likely to experience dysphagia after LF, with generally worse outcomes. On the other hand, hiatal hernia is often found in patients reporting dissatisfaction and/or undergoing reoperative antireflux surgery. Its persistence after LF is in fact a predictive factor of negative outcome^[44].

Lord *et al*^[45] demonstrated not only that the grade of GERD well links with the functional and anatomical qualities of the gastroesophageal reflux barrier, with hiatus hernia, and that a defective LES is significantly more frequent in ERD or BE patients, but also that LF, which resolves the hernia and increases the LES pressure, offers in the same way good or excellent outcomes, irrespective of the presence of mucosal inflammation, and in all degrees of GERD^[45]. Similarly, Lei *et al*^[46] study the effect of LF in treating sliding hiatal hernia. They found that at 2 years follow-up in up to

93% of subjects a normal instrumental testing was present, with a good overall satisfaction. Cowgill *et al*^[47] compared a group of patients with GERD that had a normal LES resting pressure, to a group of patients with inadequate LES, before and after LF was performed. They found that before surgery, patients with normal LES tone had symptom scores (for heartburn and regurgitation) similar to those patients with inadequate LES, and the symptom relief was also similar after LF. Inability to belch was not frequent at baseline, and its presence did not increased postoperatively. Furthermore, dysphagia scores significantly improved in patients, irrespective for inadequate and adequate LES pressure, whereas dysphagia frequency did not improve in those adequate or inadequate LES pressure at manometry.

ENDOSCOPIC FACTORS: ESOPHAGITIS, NERD AND BE

Deterioration of esophageal clearance function protracts contact of the refluxate, thus increasing mucosal damage, that can be documented during endoscopy. Therefore, GERD patients may present with a broad spectrum of endoscopic mucosal presentation (normal to esophagitis to BE).

However, a the majority of patients complaining GERD symptoms have no mucosal lesions at endoscopic imaging^[48,49], while in others gastric acid reflux may trigger ERD and causing a weakening of esophageal peristalsis^[50]. It could be expected that GERD patients without esophagitis suffer of a less symptomatic disease, and that the presence or absence of esophagitis at the endoscopic exam, could somehow influence the management of those patients, expecting that NERD patients could be treated with medical therapy whereas patients with esophagitis would need other approaches instead. Additionally, it could be thought that NERD subjects would have superior perioperative outcomes than ERD patients, but having less favorable long-term outcomes when compared to the ERDs.

Recently, there are confirmation that NERD subjects are similar to ERDs for reflux patterns, symptoms severity, and use of medical therapy^[51].

Additionally, recent reports advocate that a less aggressive therapy (cisapride, anti-H2) in NERD subjects is often ineffective, and they necessitate high-dose PPI; also, they experience relapse frequently, and a lower response rates to omeprazole when compared to ERDs^[52,53]. For these reasons, management strategies for NERD should be based on the same principles as those for ERD.

Lots of studies were taken to evaluate preoperative influence of esophagitis in GERD patients, and to evaluate how the presence of erosions would affect the outcome of surgery. The hypotheses that NERD patients would have better perioperative results with less

favorable long-term outcome than ERD is false. LF is an efficient treatment for GERD, with no significant clinical differences between patients with and without ERD at baseline. For patients with NERD, LF offers significant relief of symptoms and a marked diminution in the use of PPI^[54].

Some investigators reported relatively poorer outcomes of LF for patients with BE and suggested the use of more aggressive surgical strategies for BE developed in GERD patients^[55]. However, a study from Cowgill *et al.*^[56] compared patients with GERD with or without BE to verify the presence of differences in symptoms relative frequency and severity and in relative levels of acid reflux preoperatively and to verify symptom improvement postoperatively. Authors postulated that patients with BE would experience more severe reflux and symptoms at baseline, with poorer effects after LF than patients without BE. However, before surgery, even if BE patients showed higher DeMeester scores, symptom scores were not significantly different than patients without BE. After LF, symptoms scores improved for both group of patients. After LF, all symptoms scores significantly improved, whereas dysphagia frequency was higher in patients with BE. Similarly, Abbas *et al.*^[57] noticed that 67% of 49 BE patients after LF were asymptomatic at follow-up. Also, Oelschlagel *et al.*^[58] reported excellent outcomes in GERD and BE patients, with up to 95% of the subjects reporting a persistent symptomatic improvement after LF. Tolone *et al.*^[59] showed optimal reflux control in BE patients after LF, documenting it by the means of MII-PH monitoring; also Authors showed regression of low grade dysplasia one year after surgery.

INSTRUMENTAL FEATURES: MOTILITY

Esophageal dysmotility commonly occurs with GERD. In the study by Savarino *et al.*^[60], which combined esophageal manometry and impedance, patients with reflux esophagitis have been shown to have a significant increase in esophageal motility and bolus transit abnormalities compared to healthy controls and patients with NERD. Although the association between GERD and esophageal dysmotility is clear, GERD symptoms relief after medical therapy is not proven to be helpful in improving esophageal motility. In fact, although PPIs are able to fully resolve reflux esophagitis and are successful in the majority of patients in terms of symptom relief, it has been shown that they have no effect on the improvement of esophageal body motility^[61]. On the other hand, the surgical correction of GERD offers an improvement or a complete resolution of esophageal dysmotility^[62]. However, medical good-sense purposes a limited role for LF if esophageal dysmotility is present, fearing for postoperative dysphagia development. Coherently, successful results after LF in patients with esophageal motor dysfunction are not easy to predict^[63]. Various studies considered ineffective esophageal motility not to be a risk factor for

prolonged postoperative dysphagia after LF^[64,65]. Even if several studies reported excellent outcomes after LF in patients with manometric motor disorders, these results are not entirely shared. Dysphagia can be observed in a considerable amount (up to 20%) of GERD patients and esophageal motor abnormalities after LF^[66,67].

The study conducted from D'Alessio *et al.*^[68], showed that patients with esophageal motor dysfunction determined at manometry had adequate outcomes after LF if they were able to effectively clear a food bolus at preoperative esophagography. These patients had similar outcomes to those with normal esophageal motor function. Pizza *et al.*^[69], studied different patients divided into groups according to the motility pattern studied preoperatively with manometry. They divided a group A with impaired esophageal peristalsis, and group B without impaired peristalsis. Their study demonstrated that the two groups had a statistically significant improvement in symptom score and that preoperative defective esophageal peristalsis was not a contraindication to LF.

Another aspect to be considered is the preoperative LES resting pressure at manometry, because experience with LF in GERD patients and manometrically intact LES is limited. In the majority of GERD subjects an impaired LES competence is documented at esophageal manometry, thus reflux presence is easily argued. In those with manometrically adequate LES, several other mechanisms (transient involuntary relaxations of the LES, impaired esophageal peristalsis, decreased gastric emptying, increased intragastric or intraabdominal pressure, increased BMI, life-style habits) have been proposed to explain the occurrence of GERD.

Riedl *et al.*^[70] studied the importance of LES pressure and its hypothetic capacity to influence the outcome of LF when a normal pressure was present. In their study, they stratified 4 groups: Group I (LES with a defective intra-abdominal length and a defective pressure), group II (defective LES pressure), group III (defective LES intra-abdominal length), and group IV (normal LES). They found no significant differences among the groups regarding the quality of GERD symptoms and quality of life scores. Similar conclusions led the study of Patti *et al.*^[71] where authors studied three groups based on the preoperative LES pressure. The resolution of symptoms and incidence in the novo dysphagia was similar among the three groups, irrespective of the preoperative LES status. Also, authors found that LF was linked to a higher percentage of postoperative dysphagia than partial fundoplication, regardless the LES pressure at baseline.

Finally, a new parameter at high resolution manometry, the esophagogastric junction contractile integral, was recently used to better prove the antireflux barrier efficacy of the junction^[72]. The group from St Louis showed that this metric distinguished patients with normal AET from those with pathological values better than conventional LES parameters, and that it can be useful to evaluate the efficacy of the anti-reflux

surgery^[73].

INSTRUMENTAL FEATURES: ESOPHAGEAL ACID EXPOSURE

Outstandingly, GERD patients are really a heterogeneous population. By means of 24-h ambulatory esophageal pH monitoring, AET can be quantified and qualified depending on the body position in which it appears. According this latter feature, three reflux patterns of acid reflux at pH-monitoring are usually reported: Unique upright, unique supine, and bipositional one. The presence of abnormal supine and bipositional AET are considered classic indication for antireflux surgery^[74]. However, some investigators believe that symptom improvement and success after LF could depend upon the AET-body position pattern. It is reasonable to accept that LF outcomes can vary according to the reflux patterns. Upright reflux, for example, is cogitated to be a less severe GERD pattern, whereas bipositional reflux seems to be associated with advanced, severe disease. Although upright reflux is considered an initial form of GERD, these subjects are supposed to present a greater incidence of aerophagia and dyspepsia. Also, these patients are supposed to have worse postoperative outcomes after LF, including higher rates of postoperative gas bloating and flatus, when compared to those with supine or bipositional pathological AET^[75,76]. Consequently, some physicians have been hesitant to indicate LF in presence of isolated upright pathological AET^[77].

However, several papers are even in contrast on this matter. In fact, different studies found a similar symptoms relief in patients with pathological upright reflux and in those with pathological supine or bipositional AET^[78,79]. Only two studies evaluated objectively the outcomes of LF and demonstrated that isolated upright reflux patients had a good outcome after surgical intervention^[80,81]. Other authors have recently reopened the debate and it has been reported that poorer symptomatic improvement occurs after surgery in patients with pathological upright reflux^[82]. Cowgill *et al*^[83] studied a large cohort of GERD patients who required antireflux surgery. Authors stratified patients according to positional AET features at baseline pH-monitoring. Patient with reflux occurring in any position, even in only upright reflux, experienced similar good symptom improvement after LF; in fact, a larger percentage of patients with upright reflux defined their overall outcomes as "excellent" or "good". All symptoms improved postoperatively. Authors concluded that after LF, symptoms of GERD improved in all reflux patterns and that LF dramatically improves GERD symptoms, irrespectively of the reflux pattern; thus, antireflux surgery is encouraged. Actually, it remains debated whether upright reflux should be considered as a relative contraindication for LF, because

studies comparing long-term objective and subjective parameters are lacking.

INSTRUMENTAL FEATURES: IMPEDANCE-PH MONITORING

Combined multichannel intraluminal impedance-pH (MII-pH) monitoring can identify reflux events independently of its pH quality. In recent years, in fact, MII-pH monitoring has become a progressively adopted method in the evaluation of GERD. Because MII-pH monitoring detects retrograde movements in the esophagus regardless of an acid pH drop, it permits to document either nonacid or weakly acidic reflux events (with a pH higher than 4). This central advantage allows to evaluate GERD patients with refractory symptoms during acid-suppression therapy; in fact, recent studies have shown the capacity of MII-pH monitoring in increasing the symptom index sensitivity for patients on PPIs^[84,85].

Mainie *et al*^[86] assessed LF as a management for patients with PPI refractory symptoms associated with reflux, by means of MII-pH monitoring. Authors found that at baseline 18 of 19 patients had a positive symptom index and one, a negative symptom index. At postoperative follow-up (14 mo), 94% of patients with a positive symptom index were asymptomatic or with a marked improvement. Persistent symptoms were experienced in the patient with a negative symptom index, and one patient had recurrent symptoms after 9 mo. Authors concluded that patients resistant to PPI with a positive symptom index demonstrated by MII-pH monitoring could be managed successfully by LF.

Del Genio *et al*^[87] in 2008 verified if the MII-pH was effective to provide a correct selection of patients for LF. Authors prospectively assessed and reviewed data from 314 consecutive patients not responsive or not compliant to PPI who underwent MII-pH for GERD. One hundred fifty-three patients who underwent LF with a minimum follow-up of 1 year were included in the study. Outcomes were reported for patients with normal and ineffective peristalsis and for patients with positive pH-monitoring, negative pH-monitoring and positive total number of reflux episodes at MII, and negative pH-monitoring and normal number of reflux episodes at MII and a positive symptom index correlation with MII (hypersensitive esophagus patients). The overall patient satisfaction rate after surgery was 98.3%. No differences in patients' satisfaction and clinical postoperative symptom score were recorded between the groups as stratified by MII-pH. Authors concluded that MII-pH provided a useful objective selection of patients for LF and that LF can provide excellent outcomes in either patients with positive pH or negative pH and positive MII monitoring or symptom index association. These results were later confirmed by another Italian group that documented the positive impact of LF on reflux control in patients who

underwent MII-pH before and after surgery^[88].

CONCLUSION

The LF is a good and efficacy therapeutical option for GERD. However, due to great heterogeneity in the phenotypical appearance of GERD, it is arguable that the outcomes of LF can be affected by a great number of factors. Based on the results highlighted in literature, a correctly fashioned LF, and, more important, a correct indication to LF can provide optimal results with good patient satisfaction. Thus, in large part, the predictability of success following LF is directly proportional to the level of certainty that GERD is the underlying cause of the patient's symptoms. Pre-operative testing are mandatory, especially MII-pH, due to its ability to better stratify GERD patients and to better identify the reflux-symptom association.

Abstract

Histoacryl glue is used increasingly for the treatment of gastric and ectopic varices, and there is experience in its use for oesophageal varices. It is an effective treatment, yet numerous reports of complications have accumulated. This review of the literature describes

the technique, explores circulatory and vascular consideration unique to portal hypertension and categorises the complications into: "Embolisation", "local venous thrombosis", "fistulisation and extravascular injection", "ulceration, erosion and extrusion", and "nidus of infection". A case is then made for standardisation of the technique and the consent process.

Key words: Complications; Embolisation; Thrombosis; Sepsis

Core tip: N-butyl-2-cyanoacrylate (Histoacryl "glue") injection is of proven efficacy for the treatment of bleeding gastric varices but its utility in bleeding oesophageal varices remains unproven. Overall complication rates are 0.5%-5%, 1% being commonly quoted. Complications include pulmonary and systemic arterial embolisation, portal and mesenteric vein thrombosis, persistent sepsis, fistulisation and mucosal erosion due to extravascular injection, and late extrusion or variceal ulceration. Consent processes and injection techniques vary according to local experience, and there is a case for national/international agreement to standardise these.

Al-Hillawi L, Wong T, Tritto G, Berry PA. Pitfalls in histoacryl glue injection therapy for oesophageal, gastric and ectopic varices: A review. *World J Gastrointest Surg* 2016; 8(11): 729-734 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i11/729.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i11.729>

INTRODUCTION

Histoacryl glue therapy is licensed in the United Kingdom for emergency treatment of bleeding varices. Its chemical composition is a monomer, *n*-butyl-2-

Figure 1 Endoscopic images of a gastric varix before and after glue therapy. The varix has become smaller and is now firm when probed. The plain radiograph between demonstrates a radio-opaque deposit in the fundus of the stomach, due to lipiodol.

cyanoacrylate, which polymerises into a solid mass in contact with ionic materials including water or blood. This obturates, or fills, the vascular lumen and also encourages local thrombosis. It is used first line in gastric and ectopic varices (for emergency haemostasis and secondary prophylaxis) and second line for oesophageal varices (where banding is not possible due to degraded oesophageal tissue or previous failed banding attempts). There is a solid evidence base to support the use of glue in gastric varices with numerous case series^[1-8] and randomised controlled trials^[9-13] indicating that efficacy of haemostasis is over 80%-90%. Data comparing gastric variceal glue injection with transjugular intrahepatic portosystemic shunt (TIPSS) is relatively scarce. Lo *et al*^[14] performed a prospective case controlled trial in patients who had presented with acute GV bleeding and who had been stabilised with vasoconstrictors and endotherapy (not glue). They found long term superiority for TIPSS in terms of rebleeding at 33 mo (11% vs 38%, $P = 0.01$), but equivalent survival. A retrospective study found fewer rebleeds in the TIPSS group at 6 mo (15% vs 30%, $P = 0.005$), but again no differences in survival. A cost analysis showed far higher resource implications for TIPSS [\$4138 United States dollars (\$3009-\$8290 United States dollars)] for glue vs \$11906 United States dollars (\$8200-\$16770 United States dollars)^[15].

The use of glue in the oesophagus is more controversial, although one series by Cipolletta *et al*^[16] reported good results in 133 patients who had primary oesophageal injection of undiluted glue. Glue has also been used successfully in babies and infants less than 2 years old^[17].

TECHNIQUE

Histoacryl glue is commonly mixed with lipiodol which slows the polymerisation process, allowing more time for injection, and being radio-opaque also permits post-procedural radiological examination. Precise technique varies across units both nationally and internationally. At the authors' centre 0.5 mL glue aliquots are mixed with 1 mL of lipiodol in small syringes. Saline can be

injected into the variceal lumen initially to confirm an intra-luminal position at this point. Glue/lipiodol mixture is then injected 1.5 mL at a time, the number of syringes depending on the size of the varix. Further saline is injected which detaches the glue from the end of the needle and reduces the chance of tearing the glue through the variceal wall on removal of the needle. Some endoscopists prefer to inject glue as they leave the lumen, thus sealing the injection site and maintaining a view of the needle before withdrawing completely. The varix is observed, and it is not unusual to see some self-limiting bleeding through the injection site. Further injections are administered into different parts of the varix if necessary, the intention being to render the varix "solid". This is determined by probing with varix with an injection needle (needle withdrawn). The role of endoscopic ultrasound in facilitating injection when the view is obscured by blood in the stomach, or to provide a more accurate assessment of vascularity during and after injection, has been explored^[18]. Real-time fluoroscopy to assess for possible embolisation has also been described, but this is better suited to elective re-injection of gastric varices and less achievable in the emergent scenario^[19].

Great care should be taken by staff when preparing the glue. Any contact with the sclera or cornea can cause permanent injury, so goggles or full face masks should be used, and protocol for eye-washing well rehearsed. Patients with iodine allergies cannot receive Lipiodol. Permanent damage can also be done to the endoscope if glue polymerises in the working channel. Before the injection needle is withdrawn through the instrument the needle lumen should be flushed thoroughly. Small residues of polymerised glue may be visible on the tip of the needle, but this does not usually cause a problem.

The ideal outcome after treatment of gastric varices is illustrated in Figure 1. An 85-year-old lady who presented with haematemesis and encephalopathy was found to have a fundal gastric varix with a red sign. It was injected with 3 mL × 1.5 mL aliquots of glue/lipiodol. A plain X-ray demonstrated a well circumscribed "clot" of glue in the fundus, with additional strands in

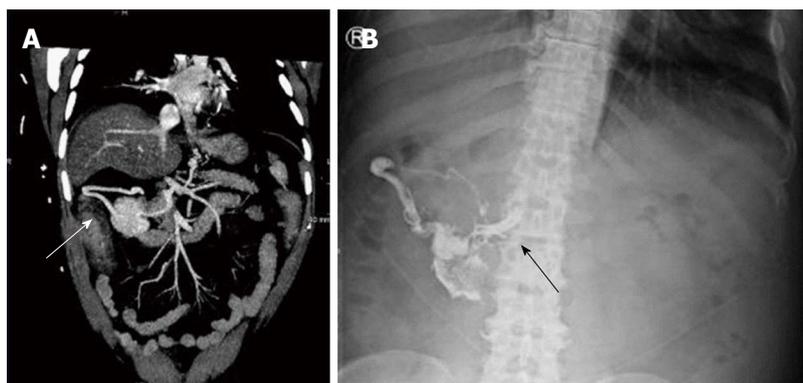

Figure 2 Duodenal varix on computed tomography and plain radiograph before and after glue injection. A: Computed tomography angiogram showing a large abdominal varix meeting the duodenum (white arrow); B: After glue injection a plain radiograph showed lipiodol/glue in the same vessel, with extension medially up to the portal vein (black arrow).

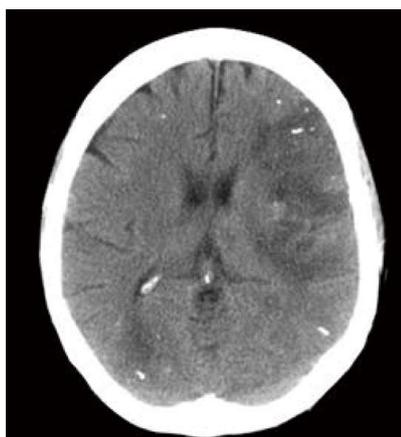

Figure 3 Computed tomogram of brain following glue/lipiodol injection. There are high signal deposits peripherally following embolisation of glue.

oesophageal vessels above. At check endoscopy 7 d later the varix was smaller and appeared "safe".

VASCULAR CONSIDERATIONS

The propensity for glue in its liquid phase to spread along vessels distal and proximal to the bleeding varix should be emphasised, as this is relevant to the phenomena of local venous thrombosis and distant embolization. Specific haemodynamic features of cirrhotic patients such as hyperdynamic circulation, presence of porto-systemic shunts and dilated pulmonary vessels may also be implicated in these events.

Figure 2 illustrates how glue can spread into feeding and draining vessels. A computed tomography (CT) angiogram (Figure 2A) performed on a cirrhotic patient who had a negative index endoscopy shows a large varix indenting the wall of the second part of duodenum, but without active extravasation. Figure 2B is a plain X-ray taken following injection of 9 mL histoacryl glue into a large, actively bleeding duodenal varix that was identified at second endoscopy several hours later. A plain abdominal X-ray delineated the extent of lipiodol/histoacryl, which filled the varix and extended towards the portal vein, probably representing a dilated pancreato-duodenal vein. This patient recovered and experienced no adverse effects.

In this review we categorise reported complications

based on published reports, and will include illustrative examples of cases that the authors have been involved with.

COMPLICATIONS

Overview and incidence

Cheng *et al*^[20], in a study focussed on complications, documented 51 adverse events in 753 treated patients (6.7%), 33 of these being early re-bleeds related to extrusion of glue within 3 mo. Overall complication related mortality was 0.53%. A study examining factors influencing outcomes ($n = 90$) found early complications in 14.4%, mostly infective and not clearly related to injection - however systemic embolisation occurred in 4.4%^[5]. The American Society for Gastrointestinal Endoscopy, in its technical evaluation report of 2013^[21], did not support the use of glue for oesophageal varices due to sporadic reports of complications. Embolisation is the most frequently mentioned complication during the consent process (author's experience), a 1% risk being commonly quoted based on reviews which are explored below, but there is little certainty regarding other types of complications. Although most studies emphasise that the technique is safe, numerous reports describe unexpected early and delayed complications some of which are fatal.

Embolisation

A retrospective review looking at 25-year experience with glue injection by Saraswat *et al*^[2] identified a risk of embolisation in the range 0.5%-4.3%. Cheng *et al*^[20]'s large review of 753 cases identified distant embolisation in 5 patients (0.7%; 1 pulmonary, 1 brain, and 3 splenic). Fatal sepsis related to splenic infarction was reported in an isolated report^[22].

Embolisation to the right atrium or pulmonary arteries has been reported by several authors^[23-25], including one fatal case^[26]. Chew *et al*^[27] describe a patient who developed sudden hypoxia 10 d after injection. In this case solid particles must have become detached from the primary mass of glue. In contrast, the patient in whose care one of the authors was involved became hypoxic during the injection procedure and suffered runs of ventricular tachycardia which self-

Figure 4 Endoscopic appearances of oesophagus following glue injection for refractory variceal haemorrhage. There is ulceration and early cavitation in the first image which progresses and is severe 5 d later.

terminated. A post-procedural X-ray demonstrated glue in the pulmonary vasculature^[23].

Cerebral embolisation has been reported several times. Upadhyay *et al*^[28] described a patient who developed cortical blindness (as well as acute myocardial infarction), attributed to glue emboli. Sée *et al*^[29] reported two cases of cerebral embolization (one fatal), and Roesch *et al*^[30] reported simultaneous pulmonary, cerebral and coronary events. An intubated and ventilated patient one of the authors treated did not wake up appropriately following injection of a gastric varix. A CT scan of the brain revealed multiple peripheral radio-opaque deposits (Figure 3). An echocardiogram revealed an atrial septal defect, the likely explanation for cross over from the portal to the systemic arterial circulation, *via* the systemic venous return. The patient succumbed to multi-organ failure secondary to decompensated liver disease. In the absence of septal defects it is not easy to explain how glue moves into the systemic arterial circulation, but Sée *et al*^[29] hypothesised that glue may travel *via* dilated pulmonary vessels which are known to develop in cirrhosis (associated with hepatopulmonary syndrome).

Local venous thrombosis

Belletrutti *et al*^[6] in their large review of patients in North America treated for gastric varices reported one case of superior mesenteric vein thrombosis. Mosca *et al*^[7] reported one case of acute splenic vein thrombosis in their series of 65 patients treated for gastric varices. Liu *et al*^[31] also reported splenic vein thrombosis in association with *Klebsiella* septicaemia. Shih *et al*^[32] presented a case of portal vein thrombosis and progressive liver atrophy after cyanoacrylate injection. Shim *et al*^[33] noted combined portal and splenic vein thrombosis in their report. Thrombosis of portomesenteric vessels is not surprising, given their proximity and intimate relation to porto-systemic collaterals that form oesophagogastric varices. Case reports have not described morbidity or mortality due to organ ischaemia secondary to vascular impingement, although experience would suggest new PVT can only be disadvantageous to cirrhosis patients.

Fistulisation and extravascular injection

Late fistulisation to a pulmonary vein following oesophageal

injection was reported by Barclay *et al*^[34]. This must have occurred following extra-vascular injection into the mediastinum. Retrogastric abscess formation following gastric variceal injection has been reported^[35]. One of the authors has seen glue in the pleural space and in the para-oesophageal tissues (unpublished). In neither of these cases were there any short or medium term adverse consequences. The use of glue in refractory oesophageal variceal bleeding is more difficult and prone to inadvertent injection through the oesophageal wall into adjacent structures. Whereas gastric varices present an easily definable vessel, and the presence of the injection needle within the lumen can be confirmed with saline injections, oesophageal varices have usually been banded already and there may be considerable ulceration and mucosal trauma. Injections may be semi-blind or intended to enter intramural feeding vessels. Glue has also been used to “seal” the edges of post-banding ulcers that are found to be oozing. A report by Kim *et al*^[36] described sinus formation after treatment for this indication.

Ulceration, erosion and extrusion

Choudhuri *et al*^[3] identified ulceration of gastric varices in 32 of 170 injected patients, but did not attribute specific morbidity to this. Sharma *et al*^[37] reported late bleeding from a glue ulcer. The authors’ experience suggests that ulceration is more troublesome after glue injection into the oesophagus, where extra-luminal injection is far more likely due to the difficulty in delineating the variceal columns. In one case, serial endoscopies identified increasing cavitation around a nidus of solid glue (Figure 4). This patient suffered ongoing decompensation and intermittent bleeding, dying from multiple organ failure two weeks after the initial treatment of bleeding. He was chronically encephalopathic and could not undergo TIPSS.

A large series ($n = 168$) reported by Wang *et al*^[38] found early re-bleeding associated with “rejection” of glue in 9 (6.2%) at less than two months, and extrusion in a further 12 (8.1% at 2–18 mo). This study appeared to suggest that extrusion of glue casts into the gastric lumen is common, almost inevitable. There were cases of late re-bleeding, although persistent obturation of the variceal lumen was confirmed in the majority. The study of over 700 patients by Cheng *et al*^[20] documented re-

bleeding associated with "early extrusion" (*i.e.*, less than 3 mo) in 33 (4.4%). One of these patients died.

Laceration of varix due to banding of an unrecognised glue deposit

One case report^[39] has described inadvertent laceration of an oesophageal varix during band ligation, due to the presence of glue from a previous treatment session. This highlights the fact that glue is permanent, and it should be noted prior to future interventions.

Stricture

A single case of oesophageal impaction^[40] following glue injection into a gastric varix was described over ten years ago.

Nidus of sepsis

There are several reports of chronic sepsis associated with glue, and a particular case reported by Wright *et al.*^[41] resulted in recurrent sepsis episodes with extended spectrum β -lactamase-producing *Escherichia* following injection of a gastric varix. Imaging showed glue deposits in the fundal varix itself, the IVC and the left renal vein. The patient required 6 wk of parenteral antibiotic therapy before the sepsis was cleared. The case of splenic vein thrombosis reported by Liu *et al.*^[31] was associated with *Klebsiella* septicaemia. Hamad *et al.*^[42] described sepsis in association the embolic events, while Chang *et al.*^[43] identified portal vein thrombosis following injection as a source of continued sepsis.

CONCLUSION

The attractions of glue therapy include an evidence base for its efficacy, the ability to learn the technique by adapting common endoscopic skills, and the option to offer haemostatic therapy to patients who would otherwise require emergency transfer to a tertiary unit for consideration of TIPSS. Sadly, many patients are not candidates for TIPSS due to co-morbidity or the severity of liver failure, which leaves glue injection as the only remaining therapeutic option. Training in glue injection therapy is ad hoc, relying on the presence of trainees when patients present as emergencies. Planned glue sessions do occur, during following after treatment of large gastric varices, but the numbers are small.

Seewald *et al.*^[44] proposed several standardised steps, including dilution ratios, aliquot volumes and injection number. Agreed standards which include indications, recommended consent details and technical approach would ensure that trainees experience some consistency, would enlarge the foundation of experience on which informed consent is based and protect practitioners in the event of adverse outcomes.

ACKNOWLEDGMENTS

Clinical observations contributing to this paper were made by the authors at Guy's and St Thomas' NHS

Foundation Trust, London; Kings College Hospital, London; Royal Free Hospital, London and Frimley Park Hospital, Surrey, all in the United Kingdom. The authors would like to thank Dr. Robert Barker, Consultant Radiologist, Frimley Park Hospital, for expert interpretation of radiological images in Figure 2.

Abstract

Minimally invasive surgery has been replacing the open standard technique in several procedures. Similar or even better postoperative outcomes have been

described in laparoscopic or robot-assisted procedures when compared to open surgery. Moreover, minimally invasive surgery has been providing less postoperative pain, shorter hospitalization, and thus a faster return to daily activities. However, the learning curve required to obtain laparoscopic expertise has been a barrier in laparoscopic spreading. Laparoscopic surgery training laboratory has been developed to aid surgeons to overcome the challenging learning curve. It may include tutorials, inanimate model skills training (box models and virtual reality simulators), animal laboratory, and operating room observation. Several different laparoscopic courses are available with specific characteristics and goals. Herein, we aim to describe the activities performed in a dry and animal-model training laboratory and to evaluate the impact of different kinds of laparoscopic surgery training courses on surgeon's performance. Several tasks are performed in dry and animal laboratory to reproduce a real surgery. A short period of training can improve laparoscopic surgical skills, although most of times it is not enough to confer laparoscopic expertise for participants. Nevertheless, this short period of training is able to increase the laparoscopic practice of surgeons in their communities. Full laparoscopic training in medical residence or fellowship programs is the best way of stimulating laparoscopic dissemination.

INTRODUCTION

Laparoscopic surgery has gained popularity in the last few decades, replacing open standard technique in several procedures from general surgery, gastrointestinal surgery, gynecology and urology. In fact, it has been considered standard of care in many cases such as cholecystectomy, appendectomy, colectomy, hysterectomy, pyeloplasty, nephrectomy, and others^[1-5]. Laparoscopic approach has been associated with decreased postoperative pain, shorter hospitalization, faster recovery, and better cosmetics^[1-5]. Although surgeons are interested in adopting laparoscopic techniques in their practices, most are lacking formal training in laparoscopy. Barriers such as new technology, inadequate training availability, concerns about complications, and willingness to negotiate learning curves make the transition to minimally invasive procedures challenging.

Currently, more realistic training opportunities involving weekend courses, video libraries, hands-on conferences, and traveling proctors are helping in laparoscopy dissemination. In addition, new generation of surgeons has been trained in laparoscopy during medical residence or fellowship programs. Inanimate models, virtual-reality simulators, and animal and cadaver laboratory have been incorporated to surgical education and are providing a positive impact on minimally invasive surgeon's performance.

Herein, we aim to describe the activities performed in a dry and animal-model training laboratory and to evaluate the impact of different kinds of laparoscopic surgery training courses on surgeon's performance.

DRY LABORATORY

Dry laboratory training comprises box models (consisting of physical inanimate materials) and virtual reality simulators (Figure 1). Similarly, there are physical and virtual reality training models available for robot-assisted laparoscopic surgery. As the fundamentals of laparoscopic surgery (*e.g.*, camera navigation, cutting, suturing, grasping) require different skills from surgeons familiarized with conventional surgery, training models begin with basic principles and can offer more sophisticated exercises, including physical or virtual simulation of complete procedures and surgeries (Figure

2). Each model has particularities regarding cost, availability and performance measures.

Evaluation of a model's validity for training includes face, content and construct validity^[6]. Face validity refers to the subjective perception of a test being able to measure what it is set out to measure, which means, in the case of training models, the impression of realism. Content validity is the extent to which a test measures and represents all relevant aspects of a given construct (*i.e.*, whether a model can thoroughly evaluate all aspects of surgical skills). Construct validity refers to the ability of a test to effectively measure what it claims to measure. A manifestation of construct validity in surgical simulators is the ability of the system to differentiate novices from experts. Evaluation of a trainee performing tasks may take into account time for completion, accuracy of movements, number of movements, and distance needed to complete a given task^[7,8]. Camera skills evaluation also takes into account percentage of time with optimal framing. For complex procedures, ability to finish a surgical step and complications within steps are also considered. A composite score is usually generated to evaluate the whole of the performance.

Box model training

Surgical box models consist of real instruments used for laparoscopy inserted into a box with a camera to simulate the human abdomen. The surgeon will manipulate targets inside the box that simulate tissues (*e.g.*, silicon models to mimic bowels or a bladder). Advantages of these models include low cost and high availability; trainees may even purchase models and practice at home. Another strength is the use of real instruments. Face validity is a shortcoming of this method, since rubber or silicon models used are limited in realism regarding aspects such as consistency and ability to simulate bleeding. Another drawback of the method is the limited repertoire of surgeries and the complexity of tasks that a single model can provide. Yet, to date, these models appear to be effective in improving basic technical skills in subjects with no previous experience in laparoscopic surgery. Studies with medical students have shown improvement in quality and speed of sutures^[9] as well as improved camera skills after training in box models^[10]. Similarly, studies have shown greater accuracy, precision and speed for cutting among novice students trained with box models^[11]. Subjects appear to develop greater speed, travel lesser distances and perform lesser movements to complete tasks after training, although these results have not been replicated in all studies^[12,13]. Trainees also seem to present lower error rates after training, although it is unclear whether box models or virtual reality simulators offer better results^[9,12,14]. Overall, despite existence of conflicting results and the difficulty in accurately assessing improvement, box model training seems to improve performance of basic skills in laparoscopy for trainees with no previous

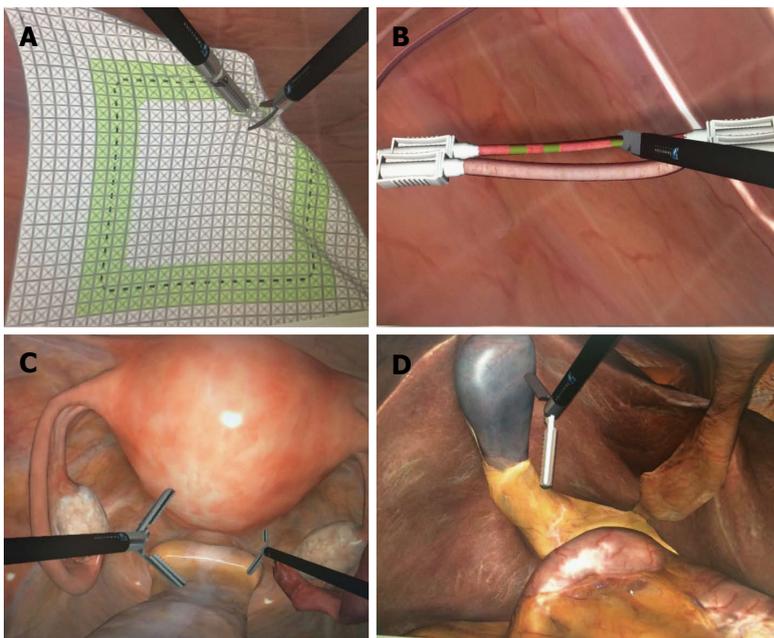

Figure 2 Virtual reality simulator. A: Cutting task; B: Clipping task; C: Hysterectomy; D: Cholecystectomy.

experience^[15].

Virtual reality simulators

Virtual reality simulators (VRS) of numerous manufacturers have been released in the market. These models consist of sophisticated softwares that generate representations of laparoscopic exercises, from simple tasks to whole surgeries (e.g., nephrectomy, colectomy). The trainee manipulates instruments that mimic those used in real laparoscopy. VRS have been

tested and validated for face, content and construct validity^[16,17]. Strengths of VRS include greater realism and the possibility of a wide range of procedures of different complexity^[18]. Furthermore, performance of an individual can be recorded, measured against objective standards and compared to other trainees. However, low availability and high prices, beginning at EUR 60000 are a limitation for the widespread use of these instruments^[19]. Studies have suggested that VRS provide comparable skill acquisition in relation to

Figure 3 Pig model for laparoscopic training.

box model training, and it has also been suggested that these 2 methods may have complementary roles in laparoscopic training^[11,20]. The individual role of VRS alone in final surgical performance is still unclear^[21].

Robotic surgery simulators

Similar to virtual simulators of conventional laparoscopy, robotic surgery simulators have been developed and validated, offering representation of surgical tasks and incorporating the technical differences between the two surgical techniques^[6,22,23]. These models share the same strengths of conventional laparoscopy VRS, especially realism and standardized evaluation. Similarly, robotic surgery simulators are of limited dispersion due to their high prices. To date, skill transfer properties of these models are still unclear^[24].

ANIMAL AND CADAVER MODEL LABORATORY

Teaching minimally invasive techniques in the operating room has become increasingly difficult due to economic and patient safety concerns. Laparoscopic surgical training includes live animal training (Figure 3), animal cadaver training, training using the box-trainer and virtual reality training. Virtual reality training has been used primarily to develop component skills, *i.e.*, diathermy, clipping, suturing. It usually does not allow the student to perform the entire procedure and does not take into consideration possible anatomic variations

that might be encountered. In addition, real laparoscopic instruments are not used, current technology has limitations, and high costs limit widespread applicability of virtual reality simulators. Yet, the combination of virtual and box-trainer with the animal model training might shorten the learning curve. La Torre *et al.*^[25] showed that the ability and time to knot-tying might be reduced if the surgeon underwent training in the virtual simulator prior to the animal model. More important, if the surgeon is exposed to repetitive animal model training, surgical time and intraoperative complications are reduced and the level of confidence and expertise measured by the global operative assessment of laparoscopic skills (GOALS) are significantly improved. Animal model training and surgeon evaluation through GOALS might be used to identify all areas of skill deficiency that require improvement. Supplementary training and mentoring can be offered to address skill deficiencies. In addition, surgeons' performances might be evaluated and compared in relation to the mean of the performances of other surgeons with the same training or those with high proficiency.

Residents usually prefer animal models for training rather than a virtual simulator model because the first are more realistic to the real scenario of operating on a patient. Tissue handling and haptic feedback are advantages compared to virtual simulators and box models. Also, intraoperative complications such as bleeding and organ lesions are only realistic in the animal model^[26,27]. Zimmerman *et al.*^[28] evaluated 36 surgical residents of a multimodality intensive laparoscopic training course who underwent a 5-d intensive training on the porcine model and found that the post-course performance scores improved by 100% to 200% with respect to the pre-course scores. The main areas with significant interest on laparoscopic training during residency are general surgery, urology, gastrointestinal surgery, and gynecology. Since Rassweiler *et al.*^[29] highlighted the importance of preclinical training on pelvic trainer and animal studies before advancing to real-time laparoscopic nephrectomy, there has been an increase in number of training models being utilized and reported in literature in regards to urological procedures. The most common models for training are the porcine or chicken models^[30]. Initially, authors studied the learning curve for ablative procedures such as total nephrectomy. Later, with the advancement in minimally invasive surgeries, the learning of complex surgical skills with multiple models were developed for partial nephrectomy, pyeloplasty, single port surgery, natural orifice transluminal endoscopic surgery, orthotopic renal transplants, and finally radical prostatectomy. More recently, 2-dimensional (2D) was compared to 3-dimensional (3D) laparoscopy during residence laboratory training^[31]. The authors found that the 3D technology facilitated the surgical performance of inexperienced surgeons during complex laparoscopic kidney procedures on a porcine model.

Although most general surgery program directors consider skills labs effective for improving operating room performance, only half of those programs have in fact an implemented skill lab training program in the residency curriculum^[32]. Torricelli *et al*^[18] have demonstrated that with a 10-wk dedicated laparoscopic training program, first-year urology residents were able to perform more than one hundred procedures with low and high complexity in the porcine model under supervision of a more experienced proctor^[18]. The improvements on laparoscopic skills lead to a high degree of familiarization with the actual operative field. Also, it shortens operative time, decreases operative complications and ultimately increases patient safety. In the same study, the authors emphasize that residents from more than one surgical specialty might train in the same laboratory. However, a cross-specialty training program is also feasible and has proved validity^[33-35]. Benefits of this arrangement for a training program comprise more frequent disposal of courses and a more effective use of training resources.

IMPACT OF LAPAROSCOPIC TRAINING COURSES

Several different laparoscopic courses are available for surgeons who aim to improve their skills in minimally invasive surgery. There are short length courses that range from 2 to 5 d well as full year fellowship programs, which are designated for senior residents interested in laparoscopic and robotic procedures. Each course has its particularities and has proved to be able of achieving specific goals.

Asano *et al*^[36] in a 2-d laparoscopic intestinal workshop including interactive discussions during live laparoscopic resection, didactic teaching, video clips and supervised hands-on practice of laparoscopic colon resection on cadaveric models reported 62.5% of participants who were not performing laparoscopic colectomies prior to the course had performed at least one 6 mo after the training. Okraanee *et al*^[37] in a 3-d course described the impact of the "fundamentals of laparoscopic surgery" (FLS) program in small group of 20 surgeons and trainees (general surgery, urology, and gynecology). FLS is an educational program developed by the Society of American Gastrointestinal and Endoscopic Surgeons for teaching the basic cognitive knowledge and technical skills required for laparoscopic surgery^[37]. It includes a didactic component presented in a standardized fashion CD-ROM, a simulation-based technical skills component (peg transfer, pattern cutting, ligating loop, extracorporeal suture, and intracorporeal suture), and an assessment component that measures both cognitive and technical skills. In this course, although the mean posttest scores were significantly higher than pretests for each FLS task and for the total normalized FLS simulator score, only two surgeons achieved a passing score on both cognitive and skills

assessment required to obtain FLS certification. This study indicates that FLS course can positively impact on surgeons' performance, however a longer period of training is probably required for surgeons obtain FLS certification^[38].

"Mini-residency" is another modality of laparoscopic training, usually performed in a 5-d period. Chou *et al*^[39] described their experience with 16 participants who had individual didactic sessions with expert faculty and skills-training sessions with inanimate models, pelvic trainers, virtual reality simulators, and the animal and cadaver laboratory. Overall, the participants did not show a statistically significant improvement in their overall laparoscopic skills scores. When subcategories (ring transfer, thread suture, cutting line, suturing) of laparoscopic skills were examined, only the task of threading suture through loops showed a statistically significant improvement after mini-residency. On the follow-up survey, two laparoscopically naive participants had performed laparoscopic nephrectomy, and of the eight participants who had prior renal-ablative laparoscopic experience, four had performed advanced reconstructive laparoscopic cases^[39]. In a similar study with 32 participants, Corica *et al*^[40] reported their experience with a 5-d mini-residency program that included inanimate model skills training, animal laboratory, and operating room observation. Eight months after mini-residency program, 26 (81%) participants were performing laparoscopic surgery. Compared with before the mini-residency program, laparoscopic radical nephrectomy ($P = 0.008$), nephroureterectomy ($P < 0.0005$), and pyeloplasty ($P = 0.008$) were performed considerably more often by participants after training. Concomitantly, participants performed hand-assisted laparoscopic surgery considerably less often ($P = 0.008$)^[40]. In a large sample including 106 urologists, Kolla *et al*^[41] reported similar findings to those described before. In a study evaluating the impact of 5-d mini fellowship program that included tutorial sessions, hands-on inanimate and animate skills training, and clinical case observations, there was also a significant increase in the laparoscopic procedures performed by the participants after the program. Of the surgeons with prior experience with laparoscopy, there was an increase in the practice of laparoscopic radical nephrectomy (88% vs 72%), nephroureterectomy (56% vs 13%), pyeloplasty (40% vs 6%) and partial nephrectomy (32% vs 6%). Of the laparoscopic naive surgeons, the take rate was 76%, 52%, 34%, and 32% for laparoscopic radical nephrectomy, nephroureterectomy, pyeloplasty and partial nephrectomy^[41]. From all these studies, it is noted that short period training can improve laparoscopic surgical skills, although most of times it is not enough to confer laparoscopic expertise for participants. But one point is clear, short period training is able to increase the laparoscopic practice of surgeons in their communities.

When evaluating the learning process in robot-assisted laparoscopic procedures, the findings are

similar to those described above. One or 2-d courses, as well as mini-fellowship training program, have proved their efficiency of improving participant's robotic skills. Moreover, these courses also are increasing the number of robot-assisted cases performed by the participants in their institutions^[42,43].

Full year laparoscopic fellowship programs are another way of improving laparoscopic skills. In a retrospective analysis including more than 4000 surgical cases, the percentage of total cases performed laparoscopically increased from 12.1% to 48.3% after integrating a fellowship-trained surgeon into an established practice. The integration of a fellowship-trained colleague into a general surgery practice resulted in a 300% increase in the proportion of appendectomies, ventral hernias, inguinal hernias, and colectomies performed laparoscopically by the other members of the practice. In this study, when surveyed, the surgeons felt that mentoring by a colleague with laparoscopic training was the most effective method for adopting minimally invasive surgery into their practice^[44].

LAPAROSCOPIC TRAINING AND LEARNING CURVE

Sandy *et al.*^[45] evaluated if laparoscopic skills could be objectively quantified by measuring specific skill parameters during training in a virtual reality surgical simulator. The authors compared the performance of ten medical students with no laparoscopic experience at all with the performance of ten urology residents with some degree of expertise in regards to basic laparoscopic skills, *e.g.*, camera handling, cutting, peg transfer and clipping skills (Immersion Lap VR, San Jose, CA, United States). They found that most individuals in both groups exhibited a significant improvement in their task completion time and error rate, proving that there was a learning curve effect on training. Moreover, the mean time taken to complete tasks was significantly shorter for the urology residents. In addition, this more experienced group of surgeons could complete the tasks with fewer errors. The authors concluded that laparoscopic skills might be objectively measured in a virtual reality surgical simulator based on quantified skill parameters, including the time spent to complete skill tasks and the associated error rate. In a subsequent study from the same group, Duarte *et al.*^[46] aimed to determine the minimal number of simulator sessions of basic laparoscopic tasks required to elaborate an ideal virtual reality training curriculum. Eleven medical students with no previous laparoscopic experience were enrolled in the study and underwent simulator training sessions starting at level 1, including sequentially camera handling, peg and transfer, clipping and cutting. Each student trained twice a week until a total of ten sessions were completed. By a non-linear regression method analysis, the authors found after 4.26

sessions all students reached the plateau of 80% of the estimated acquired knowledge. From the fifth session till the last, some students could reach 96% of the expected improvement, though the gain of knowledge was not significant.

Training is certainly crucially important for laparoscopic skills learning. However, there are other factors, which should be considered in this equation, and surgeon aptitude is one of this. Buckley *et al.*^[47] recruited twenty medical students and divided them in two groups according to their aptitude in regards to visual-spatial ability, depth perception, and psychomotor ability. All individuals were tested consecutively using the ProMIS III simulator until they reached proficiency performing laparoscopic suturing. Students with high aptitude achieved proficiency after a mean of 7 attempts, ranging from 4 to 10 trials. In converse, only 30% of subjects with low aptitude achieved proficiency after a mean of 14 attempts, ranging from 10 to 16 tries. In addition, in the group with low aptitude, 40% showed improvement but did not reach proficiency, and 30% failed to progress. The authors concluded that the fundamental ability of distinguish individuals lead to distinct learning curves for laparoscopic suturing, where high aptitude is directly related to earlier completion of the learning curve.

Another factor that has been proved to influence on the learning curve for laparoscopic training is coaching^[48,49]. Cole *et al.*^[48] compared the effects of structured coaching with an autodidactic training in simulated laparoscopic surgery. Seventeen surgically inexperienced medical students were randomized into two groups, eight being placed into an intervention group which received structured coaching, and nine being placed into a control group who received no training at all. All subjects performed ten laparoscopic cholecystectomies on a virtual reality simulator and the surgical quality of the first, fifth, and tenth operations was evaluated by two independent blinded assessors using the competency assessment tool (CAT) for cholecystectomy. They found that the coached group scored significantly higher on the CAT assessment and knowledge test of procedures one, five, and ten, with increasing disparity. The learning curve for error frequency of the coached group reached competency after operation seven, while the control group did not plateau by the last procedure. The authors concluded that structured coaching might represent a key element in the acquisition of laparoscopic surgical skills. In the same sense, Ahlberg *et al.*^[49] evaluated individual learning curves for a cohort of surgeons performing laparoscopic fundoplication and analyzed if the ProCedicus MIST-simulator (Mentice Inc., Göteborg, Sweden) could predict surgical performance. For that, twelve centers participated and each contributed with a "master" and a "pupil" surgeon. Pupils were tested in the simulator and then performed their first twenty supervised operations. All procedures were recorded

and thereafter appraised by three independent reviewers. The authors found the master to significantly affect the pupil's score and concluded that Individual learning curves varied, and the teacher was shown to be the most important factor influencing the pupil's performance score.

More recently, a technological advancement allowed for a shorter learning curve during laparoscopic training. Romero-Loera *et al.*^[50] tested the potential benefit of in-depth perception of 3D images in laparoscopic surgery. They recruited 40 individuals with no experience in laparoscopic surgery and divided them in two groups: 20 began the skills in the 2D modality and then performed them in 3D, and the other 20 began in 3D and then shifted to 2D. Each subject was used as his own control. Of all skills evaluated, there was a significant difference in time improvement between groups, being 72% in the 3D group compared to 37% in the 2D modality. In addition, the accomplishment percentage using the 3D laparoscopy was greater for both groups. Finally, subjects' preference was also evaluated and 52.5% of participants preferred 3D laparoscopy, only 15% preferred 2D, and 32.5% had no preferences. The authors concluded that 3D laparoscopic surgical training is feasible and superior to 2D, with a shorter learning curve.

Finally, the learning curve has a potential benefit in terms of cost-savings. Stefanidis *et al.*^[51] compared a group of ten medical students who trained until proficiency was achieved on five basic laparoscopic tasks with a group of ten students who received no training. After this initial step, both groups underwent a supervised training on the Fundamentals of Laparoscopic Surgery suturing model until previously reported proficiency levels were achieved and then two weeks later they were retested to evaluate their retention scores, training parameters, instruction requirements, and cost between groups. The initial performance on the simulator was better for individual with basic skills training, their suturing learning curve was shorter, and they required less active instruction. Although the overall time required to finish the curriculum was similar for both cohorts, the subjects who underwent a previous training strategy cost less, with mean savings of USD148 per student. Therefore, they determined that teaching novices basic laparoscopic skills before a more complex laparoscopic task allows substantial cost savings.

CONCLUSION

Laparoscopic surgery has been replacing the open standard technique in several procedures. However, the learning curve required to obtain laparoscopic expertise has been an issue in medical community. Laparoscopic surgery training laboratory was developed to overcome this barrier. Although a short period of training can improve laparoscopic surgical skills, full laparoscopic training in medical residence or fellowship program is the best way of stimulating laparoscopic dissemination.

Abstract

AIM

To analyse the current literature regarding the urogenital functional outcomes of patients receiving robotic rectal cancer surgery.

METHODS

A comprehensive literature search of electronic databases was performed in October 2015. The following search terms were applied: "rectal cancer" or "colorectal cancer" and robot* or "da Vinci" and sexual or urolog* or urinary or erect* or ejaculat* or impot* or incontinence. All original studies examining the urological and/or sexual outcomes of male and/or female patients receiving robotic rectal cancer surgery were included. Reference lists of all retrieved articles were manually searched for further relevant articles. Abstracts were independently searched by two authors.

RESULTS

Fifteen original studies fulfilled the inclusion criteria. A total of 1338 patients were included; 818 received robotic, 498 laparoscopic and 22 open rectal cancer surgery. Only 726 (54%) patients had their urogenital function assessed *via* means of validated functional questionnaires. From the included studies, three found that robotic rectal cancer surgery leads to quicker recovery of male urological function and five of male sexual function as compared to laparoscopic surgery. It is unclear whether robotic surgery offers favourable urogenital outcomes in the long run for males. In female patients only two studies assessed urological and three

sexual function independently to that of males. In these studies there was no difference identified between patients receiving robotic and laparoscopic rectal cancer surgery. However, in females the presented evidence was very limited making it impossible to draw any substantial conclusions.

CONCLUSION

There seems to be a trend towards earlier recovery of male urogenital function following robotic surgery. To evaluate this further, larger well designed studies are required.

Key words: Rectal neoplasms; Robotic surgical procedures; Colorectal surgery; Sexual dysfunction; Physiological; Urinary bladder; Neurogenic; Humans

Core tip: Urogenital dysfunction is a significant problem following rectal cancer surgery that significantly affects quality of life. Despite laparoscopic total mesorectal excision becoming the standard approach in much of the developed world, the incidence of post-operative urogenital dysfunction remains high. Robotic surgery allows for precision surgery in the pelvis, therefore enabling better preservation of the pelvic autonomic nerves. Current studies examining the urogenital outcomes following robotic rectal cancer surgery have several limitations, but suggest that robotic surgery may offer favourable outcomes when compared to laparoscopic and open surgery. Larger scale prospective studies are required to validate these results.

Critical analysis of the literature investigating urogenital function preservation following robotic rectal cancer surgery. *World J Gastrointest Surg* 2016; 8(11): 744-754 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i11/744.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i11.744>

INTRODUCTION

Colorectal cancer is one of the most common cancers in the developed world^[1-3] with rectal cancers making up a third of those cancers^[2-4]. The aim of rectal cancer surgery is to radically resect the cancer in order to achieve oncological cure and avoid local recurrence. During the past three decades significant improvements have been made to combat this predicament. These advances include earlier diagnosis, advanced surgical techniques and the improvement of adjuvant and neoadjuvant treatment^[4-8]. These developments were not only aimed to improve the patients' survival but also directed to improve the quality of life after cancer rectal surgery.

Urogenital function is one of the most important

aspects of quality of life and rectal cancer may have adverse effects on it^[5,9-13]. Although urogenital dysfunction is considered to be multifactorial, intra-operative damage to the pelvic autonomic nerves is the primary cause^[14-16]. This is mainly due to the close proximity of the mesorectum to the autonomic nerves, and the difficulty in identifying such small structures such as the autonomic nerves in a narrow operative space such as the pelvis^[13,17]. Damage to the sympathetic nerves results in urinary incontinence, ejaculation disorders in men and decreased orgasmic intensity in women^[13,18]. Damage to the parasympathetic nerves leads to a lack of detrusor muscle function and subsequent voiding disorder, as well as erectile problems and lubrication dysfunction in men and women respectively^[13,18]. These are significant post-operative and life changing events that jeopardise patients quality of life^[9].

It is logical to assume that better visualisation of the structures of the pelvis, such as offered from laparoscopic or robotic surgery, can aid preservation of the autonomic nerves. Nevertheless, there is a debate as to whether laparoscopic surgery offers improved urogenital functional outcomes when compared to open surgery^[19], as some studies have shown improved outcomes^[20] while other advocate the contrary^[21]. A probable reason for the disparate results is due to laparoscopic rectal surgery being technically difficult^[22], as evident from its long learning curve^[23] and the high conversion rate demonstrated in the CLASSICC and COLOR II trials^[24,25]. Existing laparoscopic instruments have a restricted range of movement compared with that of the surgeons hand and are difficult to use in confined spaces such as the pelvis^[26,27].

Robotic surgical systems were introduced to overcome the technical limitations of laparoscopic surgery^[28]. They provide a superior three dimensional view, tremor filtering and superior ergonomic instrumentation^[26,29]. These chattels enable precise dissection in narrow surgical fields such as the pelvis and help preserve the autonomic nerves. Even though multiple studies have examined the pathological, oncological and postoperative outcomes of robotic rectal surgery, there are only a few studies that have investigated the urological and sexual outcomes of robotic rectal cancer surgery and these tend to be predominantly about male patients.

Therefore the aim of this systematic review is to examine the available literature on the postoperative urogenital outcomes of robotic rectal cancer surgery on both male and female patients.

MATERIALS AND METHODS

A comprehensive literature search of electronic databases was performed in October 2015 by using the Discovery search engine tool (for more info refer to: <http://www.port.ac.uk/library/infores/discovery/>). Discovery is Portsmouth University's search engine tool and it simultaneously searches over 200 scientific

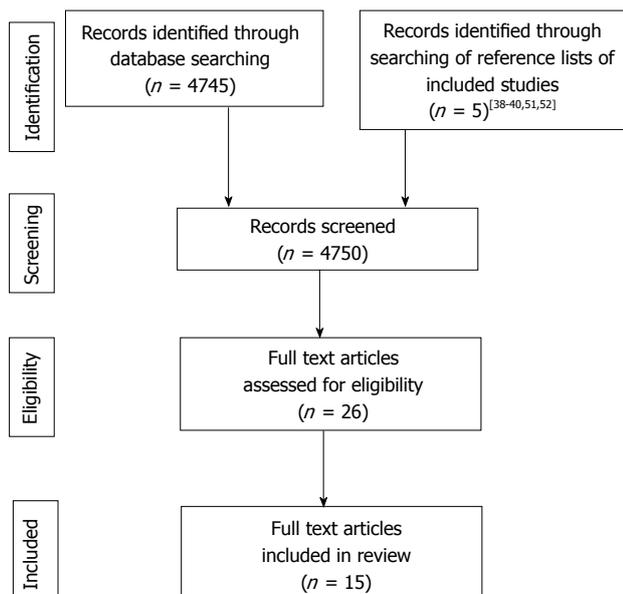

Figure 1 Selection process flow diagram.

electronic databases including MEDLINE (PubMed), Google Scholar and Science Direct. The following search terms were applied: "rectal cancer" or "colorectal cancer" and robot* or "da Vinci" and sexual or urolog* or urinary or erect* or ejaculat* or impot* or incontinence. All original studies that reported the urological and/or sexual outcomes of patients having robotic rectal cancer surgery were included. Reference lists of all retrieved articles were manually searched for further relevant articles. A flow diagram of the selection process is given in Figure 1. Abstracts were independently searched by two authors. Fifteen full text articles fulfilled the inclusion criteria.

RESULTS

Original studies

A total of 1338 patients were included in the reviewed studies (818 received robotic, 498 laparoscopic and 22 open rectal cancer surgery). The characteristics of all the original studies reporting either urinary or sexual outcomes are outlined in Tables 1 and 2. Of the 15 studies that met the inclusion criteria, 14 were cohort studies^[5,6,9,18,30-39] and one a randomised control trial^[40]. Nine of the cohort studies were comparing robotic rectal cancer surgery to either laparoscopic^[9,30-33,35,38,40] or open^[18] rectal cancer surgery.

Out of the 15 studies only six^[5,6,9,18,30,31] were specific to urogenital outcomes; the rest reported urogenital outcomes amongst a multitude of outcomes examined in those studies.

Outcome assessment

Functional questionnaire scores were used in ten^[5,6,9,18,30-33,36,37] of these studies to assess the urological and sexual function of patients. These questionnaires are validated tools that have been used in a multitude of

previous studies to access urinary and sexual function in males and females^[41-45]. Out of the 1338 patients included in this review, only 726 (54%; 442 robotic, 262 laparoscopic, 22 open) had their urogenital function assessed *via* functional questionnaires.

To assess male urological function the majority of studies used the International Prostatic Symptoms Score (IPSS) or a slight modification of it. This is a subjective scoring system examining seven categories^[41]. These include incomplete bladder emptying, frequency, intermittency, urgency, weak stream, straining and nocturia. Patients score each category and assign a higher score for increasing severity of symptoms. Alternative questionnaires used to assess urological function were the the International Consultation on Incontinence Questionnaire - Male Lower Urinary Tract Symptoms^[44], and the International Consultation on Incontinence Questionnaire - Female Lower Urinary Tract Symptoms^[45] questionnaire.

Male sexual function was assessed in ten studies by the international index of erectile function (IIEF)^[42] score. The IIEF is a 15-item score that analyses five factors: Erectile function, orgasmic function, libido, intercourse satisfaction and overall satisfaction. Unlike the IPSS score for urinary function, a high IIEF score is associated with good sexual function and the lower the IIEF score the greater the degree of sexual dysfunction.

Female sexual function was assessed in three studies^[6,30,37] *via* the Female Sexual Function Index (FSFI)^[43]. This is a validated questionnaire that is in many ways the female version of the IIEF questionnaire.

The studies that did not use validated scoring tools to assess functional outcomes simply reported the incidence of dysfunction. The limitations present in this method of reporting are the inability to quantify dysfunction and the difficulty in defining what makes a case.

Finally, one study^[31] assessed urological function by performing urodynamic studies as well as using a validated functional questionnaire, making it the only study to report urinary outcomes with both subjective and objective measurement tools.

Pre-operative assessment and follow up

The studies assessing functional outcomes *via* validated questionnaires asked their participants to fill the questionnaires pre-operatively in order to establish their baseline urogenital function. In this way post-operative scores were assessed against the pre-operative scores for each patient, allowing the change of function from baseline to be assessed. Reporting the change of function from baseline is a more accurate way of assessing the impact of the intervention, rather than reporting the postoperative functional scores alone.

It was unclear across several of the studies^[6,18,30,32] how many patients were sexually inactive pre-operatively and whether they were included in the analysis. Adding sexually inactive patients in the analysis will result in skewing of the data and it is therefore important

Table 1 Characteristics of original studies

Ref.	Country	Study design	Control group	No. of cases for urogenital outcomes	Study specifically examines urogenital outcomes
Hellan <i>et al</i> ^[34]	United States	Retrospective	No control group	39	No
Patriti <i>et al</i> ^[40]	Italy	RCT	Robot <i>vs</i> lap	29 rob <i>vs</i> 37 lap	No
Luca <i>et al</i> ^[6]	Italy	Prospective	No control group	74	Yes
Kim <i>et al</i> ^[31]	South Korea	Prospective	Robot <i>vs</i> lap	30 rob <i>vs</i> 39 lap	Yes
Park <i>et al</i> ^[39]	United States	Prospective	No control group	30	No

Park <i>et al</i> ^[32]	South Korea	Retrospective	Robot <i>vs</i> lap	14 rob <i>vs</i> 15 lap	No
D'Annibale <i>et al</i> ^[33]	Italy	Retrospective	Robot <i>vs</i> lap	30 <i>vs</i> 30	No
Stănciulea <i>et al</i> ^[37]	Romania	Retrospective	No control group	78	No
Erguner <i>et al</i> ^[38]	Turkey	Prospective	Robot <i>vs</i> lap	27 rob <i>vs</i> 37 lap	No
Park <i>et al</i> ^[9]	South Korea	Retrospective	Robot <i>vs</i> lap	32 <i>vs</i> 32	Yes
Ozeki <i>et al</i> ^[18]	Japan	Prospective	Robot <i>vs</i> open	15 rob <i>vs</i> 22 open	Yes
Cho <i>et al</i> ^[35]	South Korea	Retrospective	Robot <i>vs</i> lap	278 <i>vs</i> 278	No
Alecu <i>et al</i> ^[36]	Romania	Retrospective	No control group	79	No
Morelli <i>et al</i> ^[30]	Italy	Retrospective	Robot <i>vs</i> lap	30 <i>vs</i> 30	Yes

These include: (1) the studies country of origin; (2) the study design (prospective, retrospective or randomised control trial); (3) the control group (if present) used to compare with the robotic rectal surgery, this was either laparoscopic or open rectal surgery cases; (4) the number of cases included in each study whose urogenital outcomes were evaluated; and (5) whether the study was specifically designed to investigate the urogenital outcomes of robotic surgery or not. RCT: Randomised control trial; Robot: Robotic; lap: Laparoscopic.

to report how many patients were sexually inactive and whether they were included in the analysis or not.

In contrast to the studies applying validated functional scores, most of the studies that simply reported the incidence of urogenital dysfunction did not mention the pre-operative state of their participants. This makes it difficult to assess whether any cases of dysfunction became cases because of the intervention or not.

Follow up was fairly variable between the different studies and the follow up intervals for each study are summarised in Table 2. The majority of the studies followed up their patients in more than one occasion following surgery. The commonest follow up intervals were 3, 6 and 12 mo post-operatively.

Quality of included original studies

The Scottish Intercollegiate Guidelines Network critical appraisal tool for cohort studies was used to evaluate the original studies included in this review. However, none of the studies met the majority of the criteria for a high quality study. Most of the studies fell between the acceptable and low quality bracket (Table 2). The majority of studies were retrospective in nature, included a small number of patients, were subject to selection bias in terms of patient selection and made no adjustments for confounding factors.

The studies included in this review have significant differences in terms of outcome reporting and methodology. In addition, almost all of them are non-randomised in nature. Considering this and because of the heterogeneity of the data in these studies it was not appropriate to perform a meta-analysis. There are only a few studies whose data were homogeneous enough to permit a meta-analysis. However, this has already been performed by two previous systematic reviews^[46,47] which combined the data of three studies. We discuss these systematic reviews in our discussion.

Male urological function

Out of the 15 original studies included, 12 studies reported male urological functional outcomes. The characteristics of these studies plus a summary of their results are present in Table 3.

Validated functional scores were used in nine of the above studies. Six of those compared the scores of patients undergoing robotic surgery with those undergoing laparoscopic or open surgery. Most studies^[18,30,32,33] showed that urological function tended to deteriorate in the early postoperative phase (1-3 mo) but later recovered with time (6-12 mo) irrespective of surgical modality. One study^[9] found that IPSS score change from baseline was less in the robotic group at 12 mo after surgery, but failed to reach statistical significance ($P = 0.051$).

Kim *et al*^[31] reported IPSS scores in favour of the robotic group. They found that IPSS scores significantly increased 1 mo after surgery; but then recovered in 3 mo in the robotic group and 6 mo in the laparoscopic group with a statistically significant lesser deterioration of scores from baseline in the 3 mo follow up period in the robotic group ($P = 0.036$). It is worth noting that Kim *et al*^[31]'s study was the only one to assess urinary function by means of urodynamic studies in conjunction with a functional score. He reported that the deterioration in mean voiding volume from baseline was statistically less in 3 and 6 mo post-op in favour of the robotic group ($P = 0.007$, $P = 0.049$). The only other study to report urological outcomes in favour of the robotic group was Cho *et al*^[35]'s study; reporting a higher voiding dysfunction rate in the laparoscopic group (4.3% *vs* 0.7%; $P = 0.012$). However, this study did not use any functional scores to assess urological function.

Female urological function

Seven studies reported female urological functional

Table 2 Further characteristics of original studies

Park <i>et al</i> ^[9]	No	No	No control group	30	Not stated	As in Table 3
Cho <i>et al</i> ^[35]	No	No	Robot vs lap	278 vs 278	1	As in Table 3

This table describes the same study characteristics included in Table 3 but for female instead of male patients. Robot: Robotic; lap: Laparoscopic; f/u: Follow up.

outcomes (Table 4). However, there are only two studies that report female urological dysfunction independently to that of males.

Both studies used approved functional scores to assess urinary function and both studies compared robotic surgery patients with laparoscopic surgery patients. Morelli *et al*^[30] found no difference between the pre-operative and post-operative scores concerning voiding and filling symptoms in both groups. Conversely, Luca *et al*^[6] reported worsening of symptoms one month post operatively with full recovery by 12 mo in both robotic and laparoscopic groups.

Male sexual function

Fourteen original studies reported male sexual functional outcomes (Table 5). Ten of those assessed male sexual function *via* the IIEF^[42] questionnaire.

Six of the ten studies using the IIEF scores compared the scores of patients receiving robotic rectal cancer surgery with that of a control. Park *et al*^[9]'s study showed that sexual function recovers faster in the robotic group. At 6 mo the IIEF scores in the robotic group were higher than in the laparoscopic group and showed a significantly smaller decrease from baseline ($P = 0.03$). Kim *et al*^[31] also found that sexual function recovered quicker in the robotic group (6 mo vs 12 mo), but unlike Park *et al*^[9]'s study, when comparing the change of total IIEF scores from baseline no significant difference was detected. However, erectile function and libido had deteriorated significantly more in the laparoscopic group 3 mo post op. Park *et al*^[32] showed similar results, with significantly higher mean IIEF scores at 3 and 6 mo post op in favour of the robotic group. Like Kim *et al*^[31]'s study, the change of scores from baseline did not statistically favour either intervention. In Morelli *et al*^[30]'s study erectile and orgasmic function was significantly worse 1 mo after RobTME while it was significantly worse after 1 and 6 mo after LapTME, with erectile and orgasmic function normal at 12 mo in both groups. The other components of the IIEF score deteriorated 1 and 6 mo

following surgery in both groups, with normalisation of the scores at 12 mo. D'Annibale *et al*^[33] reported better restoration of erectile function 1 year after surgery in the robotic group; however, there is no mention of the actual IIEF scores or their change from baseline in the study so any results need to be interpreted with caution. Overall, the above comparative studies seem to report a trend towards quicker recovery of sexual function in the robotic group. However, Park *et al*^[9]'s study was the only one to reveal an interval change in IIEF scores in favour of the robotic group that was statistically significant.

Female sexual function

In contrast to male sexual function, only a few studies have investigated sexual function in females (Table 6). Only three studies have examined female sexual dysfunction independently with that of males^[6,30,37] and only one of those compared robotic outcomes to those of a control group^[30]. All three studies assessed female sexual function *via* the FSFI.

Morelli *et al*^[30] reported worsening of sexual outcomes in both groups 1 and 6 mo following surgery, but sexual outcomes were restored by 12 mo. There were no differences between the robotic and laparoscopic groups. Luca *et al*^[6] demonstrated similar results in their robotic group as in Morelli *et al*^[30]'s study, whereas Stănciulea *et al*^[37] reported no difference between pre- and post-operative FSFI scores.

DISCUSSION

This literature review highlights the fact that the impact of robotic rectal surgery on urogenital functional outcomes is yet to be established. There are number of limitations in the current studies. These include poor study design, small number of participants, lack of stringent follow up and limitations to the methods and types of data collected.

The main limitations of the primary studies were the lack of randomisation, retrospective design and small

Table 5 Original studies reporting male sexual function

Ref.	Males assessed independently of females	Functional scores applied	Control group	No. of cases examining male sexual function	Follow up in months	Outcome summary
Kim <i>et al</i> ^[31]	Yes	Yes	Robot <i>vs</i> lap	18 rob <i>vs</i> 20 lap	1, 3, 6, 12	Quicker recovery of male sexual function in robotic group (6 mo <i>vs</i> 12 mo) No difference in IIEF change from baseline between two groups at any stage Erectile function and libido deteriorated significantly more in lap group at 3 mo
Park <i>et al</i> ^[9]	Yes	Yes	Robot <i>vs</i> lap	20 <i>vs</i> 20	3, 6, 12	Quicker recovery of male sexual function in robotic group (6 mo <i>vs</i> 12 mo) IIEF deterioration significantly higher in lap group at 6 mo ($P = 0.03$)
Park <i>et al</i> ^[32]	Yes	Yes	Robot <i>vs</i> lap	14 rob <i>vs</i> 15 lap	3, 6, 12	Better male sexual function scores at 3 and 6 mo in robotic group No difference in IIEF change from baseline between two groups at any stage
D'Annibale <i>et al</i> ^[33]	Yes	Yes	Robot <i>vs</i> lap	18 rob <i>vs</i> 23 lap	1, 12	Erectile function restored 1 yr post-operatively in robotic group ($P = 0.066$) and partially in lap group ($P = 0.048$) No statistical comparison of IIEF change from baseline b/n 2 groups at any stage
Ozeki <i>et al</i> ^[18]	Yes	Yes	Robot <i>vs</i> open	15 rob <i>vs</i> 22 open	3, 6, 12	IIEF scores unchanged at 3, 6 and 12 mo in both groups
Morelli <i>et al</i> ^[30]	Yes	Yes	Robot <i>vs</i> lap	Not available	1, 6, 12	Quicker recovery of erectile and orgasmic function in robotic group (6 mo <i>vs</i> 12 mo) No difference in IIEF change from baseline between two groups at any stage
Leung <i>et al</i> ^[5]	Yes	Yes	No control group	15	3	No significant difference between post- and pre-operative IIEF scores
Luca <i>et al</i> ^[6]	Yes	Yes	No control group	38	1, 6, 12	Male sexual function scores decreased at 1 and 6 mo, recovered at 12 mo
Stănciulea <i>et al</i> ^[37]	Yes	Yes	No control group	31	Once b/n 6 and 12	No difference of pre- and post-op IIEF scores with exception of 3 patients (9.68%) with severe erectile dysfunction
Alecu <i>et al</i> ^[36]	No	Yes	No control group	79	Not stated	3 patients (3.79%) developed important sexual dysfunction. No mention of IIEF scores in results
Patriiti <i>et al</i> ^[40]	Yes	No	Robot <i>vs</i> lap	11 rob <i>vs</i> 12 lap	Mean f/u 12 mo	No difference in the incidence of sexual dysfunction between the 2 groups
Erguner <i>et al</i> ^[38]	No	No	Robot <i>vs</i> lap	27 rob <i>vs</i> 37 lap	Not stated	No difference in the incidence of sexual dysfunction between the 2 groups
Cho <i>et al</i> ^[35]	No	No	Robot <i>vs</i> lap	278 <i>vs</i> 278	1	No difference in the incidence of sexual dysfunction between the 2 groups
Park <i>et al</i> ^[39]	Yes	No	No control group	16	Not stated	1 patient (6.25%) developed ejaculatory dysfunction, no patients developed erectile dysfunction

This table describes the same study characteristics included in Tables 3 and 4 but for studies assessing male sexual function. Robot: Robotic; lap: Laparoscopic; f/u: Follow up; IIEF: International Index of Erectile Function score.

number of cases in the majority of studies (Tables 1 and 2). As for the prospective studies, most of them failed to mention the number of patients excluded during recruitment, the number of patients refusing to participate and the number of drop outs. There was one RCT but randomisation was abandoned early on as the operating surgeon quickly favoured the robotic approach for low rectal tumours. In terms of participant selection only nine studies reported their outcomes against those of a control, with the other studies essentially only describing their case series rather than comparing them to alternative treatment methods.

Case matching was performed in 2 of the comparative studies^[9,35], but in the remaining studies patient

selection was susceptible to selection bias due to the method of patient selection and allocation. In a number of studies patients were only able to receive robotic surgery if they covered the extra costs themselves, leaving the patients that couldn't afford it opting for laparoscopic or open surgery instead. Therefore the validity of the data may be skewed since patients that opted for robotic surgery were more likely to be from a higher socio-economic background, which is a potential confounding factor. Moreover, two studies compared their robotic cases with an equivalent number of their first laparoscopic cases^[30,33]. This selection method was done to eliminate the confounding factor of a learning curve from either method. However, the learning curve for

Table 6 Original studies reporting female sexual function

Ref.	Females assessed independently of males	Functional scores applied	Control group	No. of cases examining female sexual function	Follow up in months	Outcome summary
Morelli <i>et al</i> ^[30]	Yes	Yes	Robot <i>vs</i> lap	not available	1, 6, 12	Female sexual function worse at 1 and 6 mo and restored by 12 mo, in both groups
Luca <i>et al</i> ^[6]	Yes	Yes	No control group	36	1, 6, 12	Female sexual function worse at 1 and 6 mo and restored by 12 mo
Stănciulea <i>et al</i> ^[37]	Yes	Yes	No control group	13	Once b/n 6 and 12	No difference between pre- and post-operative FSFI scores (but data not provided in results section)
Alecu <i>et al</i> ^[36]	No	Yes	No control group	79 pts	Not stated	As in Table 5
Erguner <i>et al</i> ^[38]	No	No	Robot <i>vs</i> lap	27 rob <i>vs</i> 37 lap	Not stated	As in Table 5
Cho <i>et al</i> ^[35]	No	No	Robot <i>vs</i> lap	278 <i>vs</i> 278	1	As in Table 5

This table describes the same study characteristics included in Tables 3-5 but for studies assessing female sexual function. Robot: Robotic; lap: Laparoscopic; FSFI: Female Sexual Function Index.

each method is not equal^[48] and since in both studies all cases were performed by one surgeon only, it is possible that many of the skills acquired from the laparoscopic method were transferable to the robotic one. This way, results in favour of the robotic group could simply represent advancement in the surgeon's operative technique rather than superiority for the robot.

Patients in the robotic cohort either had a fully robotic procedure or a hybrid procedure (Table 2). The main difference between the two approaches is that in the hybrid approach robotic rectal dissection is preceded by laparoscopic mobilisation of the left colon and ligation of the inferior mesenteric vessels. It is possible that the difference in approach could influence urogenital outcomes. Supporters of the fully robotic approach would advocate that robotic dissection around the inferior mesenteric artery pedicle is an essential step of the procedure for identification and preservation of the periaortic nerves^[49], which is where the superior hypogastric plexus lies. Moreover, the paired hypogastric nerves are susceptible to injury during mobilisation of the rectosigmoid colon from the gonadals and the ureter^[13]; a step performed laparoscopically during the hybrid approach. Since injury to those nerves can lead to urogenital dysfunction, the hybrid approach might not exploit the full potential of the robotic system.

Five studies did not use functional scores to assess urogenital outcomes. The challenge with only reporting the incidence of urological or sexual dysfunction is not only the inability to quantify the level of dysfunction but also to define what makes a case. Furthermore, where studies fail to report how many of the patients were sexually active pre-operatively, observational bias may be present.

It is important to mention that even though iatrogenic nerve injury is the primary cause of urogenital dysfunction^[14-16], this group of symptoms is probably multifactorial in origin. Ozeki *et al*^[18] utilised univariate analysis and found that age and post-operative complications significantly affected urinary function and

sexual function respectively at 12 mo follow up. Sexual function in comparison to urological function is reported as being influenced by psychological factors and this is the case more so in women^[4,6]. Luca *et al*^[6] showed that whereas the presence of an ileostomy in men did not influence sexual function, it deeply affected it in women. Furthermore, poor body image, fatigue, depression, loss of independence and changes in relationships have all been identified as important factors in women's sexual dysfunction^[4]. In addition, radiation induced ovarian failure in premenopausal women can further worsen sexual symptoms^[4]. Since the above are potentially important confounding factors, it is important for the control group to be as similar to the experimental group as possible or control for these confounders in the analysis, something absent in the studies examined in this review.

In this review we did not perform a meta-analysis due to the heterogeneity of the included studies. Nevertheless, it should be mentioned that two review articles have performed meta-analyses on male urological and sexual function scores of patients receiving robotic *vs* laparoscopic rectal surgery^[46,47]. For male urological function, the reviews pooled the data from three studies and found that at 3 mo there was a significant difference of IPSS scores in favour of the robotic group. However, this was not the case at 6 mo following surgery and at 12 mo the two meta-analyses reported contradictory results, one showing favourable IPSS scores for the robotic group^[46] whilst the other demonstrated no difference between the two groups^[47]. Regarding male sexual function, the meta-analyses pooled the data for erectile function only. By including three and two studies respectively^[46,47], both reviews demonstrated favourable erectile function scores for the robotic group at 3 and 6 mo following surgery. Weighing these results one should note that as a rule, the overall quality of a meta-analysis is limited to the quality of its primary studies, and since the quality of the evidence available is low, the results of the available meta-analysis are of equally low quality.

There is a degree of inconsistency of results across the research examined in this review and the potential for bias amongst the various studies on the subject. There is a lack of high level evidence supporting any particular approach for preservation of urogenital function following rectal surgery. Nevertheless, the current evidence suggests that robotic surgery might lead to a quicker recovery of male urological and sexual function when compared to alternative methods. It is less clear whether robotic surgery makes any difference in male urogenital outcomes 1 year following surgery. In females the evidence on urogenital function following robotic rectal surgery is further limited. Again functional outcomes seem to improve with time but this is regardless of operative approach.

Larger randomised controlled trials such as the ROLARR trial^[50] might provide more insight into this matter. However, even though the ROLARR trial is underway, urogenital outcomes are not one of its primary end points and urogenital outcomes are only assessed once following surgery, at six months. Therefore, to answer whether robotic rectal cancer surgery truly offers superior urogenital outcomes further randomised control trials specifically designed to evaluate urogenital function with appropriate short and long term follow up are recommended. In addition, urogenital dysfunction should be rigorously assessed through appropriate validated functional scores and males should be analysed separately to females.

COMMENTS

Background

Urological and sexual dysfunctions are unfortunate sequela of rectal cancer surgery. They occur due to iatrogenic injury to the pelvic autonomic nerves during the surgical process and cause significant quality of life limitations for patients. Better visualisation of the pelvis such as during laparoscopy has failed to address this issue due to the stiff, fixed tip instruments used for laparoscopy being hard to use in narrow spaces such as the pelvis. Robotic surgical systems overcome many of the limitations of laparoscopic surgery but whether robotic rectal surgery can lead to superior urological and sexual functional outcomes remains to be determined.

Research frontiers

Robotic surgical systems possess several advantages over conventional laparoscopy such as flexible wristed instruments that mimic the surgeon's hands. They eliminate the surgeon's tremor and offer far superior ergonomics and dexterity. In addition, the surgeon, rather than the assistant, controls a 3-D, high definition stable camera, an important aspect for co-ordinated surgery. These advantages allow for precision surgery in narrow spaces such as the pelvis, where other methods have failed and in rectal surgery could enable preservation of the pelvic autonomic nerves and therefore increase the quality of life for these patients.

Innovations and breakthroughs

There are only a few studies that have investigated the urological and sexual outcomes of robotic rectal surgery and these tend to be predominantly about male patients. This study differs by critically reviewing the available literature on the postoperative urological and sexual outcomes of robotic rectal surgery on both male and female patients. As such, this review is unique in that it examines the largest number of relevant studies to date; it focuses solely on the urogenital outcomes of robotic rectal surgery and examines the evidence on both males and females.

Applications

This review critically analyses the literature examining the urogenital outcomes of robotic rectal cancer surgery. Readers will be able to have a concise understanding of the available literature on this subject. Furthermore, this review leads to clear conclusions indicating a paucity of evidence of whether robotic rectal surgery offers favourable urogenital functional outcomes and establishes quality of life differences. Nevertheless, the authors identify that robotic surgery might lead to a quicker recovery of male urological and sexual function when compared to alternative methods of surgery and recommend the direction of further research.

Terminology

Urogenital function is a term referring to the combination of urological and sexual function. Laparoscopic and robotic surgeries are forms of minimally invasive surgery which offer several advantages over open surgery, such as smaller wounds and quicker postoperative recovery.

Peer-review

The manuscript is a comprehensive review addressing pelvic functions (rectal and sexual) after robotic surgery. Content coverage is adequate and focus. Language quality and flow of idea are excellent.

Abstract

Gallstone ileus due to erosion of one or more gallstones into the gastrointestinal tract is an uncommon cause of small bowel obstruction. The site of impaction is usually distal ileum, and less commonly the jejunum, colon, duodenum, or stomach. We report a rare case of gallstone ileus with impaction at the proximal small bowel and at a Meckel's diverticulum (MD) in a 64-year-old woman managed with laparoscopic converted to open small bowel resections. Patient was discharged home in stable condition and remained asymptomatic at 6-mo follow up. We review the current literature on surgical approaches to MD and gallstone ileus. Diverticulectomy or segmental resection is preferred for complicated MD. For gallstone ileus, simple enterolithotomy or segmental resection are the most the most favored especially in older co-morbid patients due to lower mortality rates and the rarity of recurrent gallstone ileus. In addition, laparoscopy has been increasingly reported as a safe approach to manage gallstone ileus.

Core tip: Gallstone ileus is an uncommon cause of small bowel obstruction in the population at large but is responsible for up to a quarter of mechanical bowel obstructions in the elderly in the United States. We report a rare case of gallstone ileus with impaction at the jejunum and at a Meckel's diverticulum in a 64-year-old female managed by laparoscopic converted to

open segmental bowel resections. We review current literature comparing surgical procedures for Meckel's diverticulum and gallstone ileus.

INTRODUCTION

We are reporting a case of gallstone ileus involving multiple gallstones managed by laparoscopic converted to open small bowel resections of impacted stones at the jejunum and at a Meckel's diverticulum (MD). MD is the most common congenital anomaly of the gastrointestinal tract and is caused by the incomplete obliteration of the omphalomesenteric duct^[1]. It can be found in nearly 2 percent of the population but in most cases it remains asymptomatic^[2]. Most reported complications include bleeding, infection and obstruction^[3]. Gallstone ileus is an uncommon cause of obstructions in the general population but is responsible for 25% of mechanical bowel obstructions in the elderly^[4-6]. We found only 3 other case reports with mention of gallstone impaction at MD^[7-9].

CASE REPORT

A 64-year-old morbidly obese woman with a history of diabetes, hypertension, and atrial fibrillation presented to an outside hospital (OSH) for PO intolerance with nausea, bilious emesis, and post-prandial abdominal pain. Computerized tomography (CT) of abdomen and pelvis demonstrated small bowel obstruction. Hepatobiliary iminodiacetic acid scan was performed and demonstrated probable mass in the second portion of the duodenum. She was transferred to our institution for escalation of care where she was found to be tachypneic, tachycardic and in atrial fibrillation. On abdominal exam she was distended and mildly tender without rebound or guarding. Her white blood cell count was 14.9 without left shift. She was admitted to the medical intensive care unit for respiratory failure and metabolic acidosis in the setting of frequent bilious emesis.

Repeat CT of the abdomen and pelvis at our institution demonstrated pneumobilia, small bowel dilation and intraluminal small bowel filling defects consistent with cholecystoduodenal fistula with gallstone ileus. Three gallstones were identified, one in the jejunum and two in the ileum along with a mechanical small bowel obstruction with a transition point near the distal calculi in the distal jejunum/proximal ileum (Figure 1). She was taken to the operating room for laparoscopic small bowel resection.

During laparoscopy, bleeding from the deep inferior epigastric vessels necessitated conversion to laparotomy. The small bowel was then run and a large gallstone was found to be obstructing the distal jejunum. We also identified a MD impacted with two smaller stones. A longitudinal incision was made in the jejunum to remove the stone and perform an enterolithotomy. However due to significant edema and inability to milk the stone distally, a small bowel resection was performed.

Once this was complete, we turned our attention to the MD and performed a small bowel resection to include the MD with approximately 5 cm of adjacent small bowel. This resection was performed in lieu of a diverticulectomy due to concern about narrowing of the small bowel lumen. At the end of the surgery the patient required pressor support. She was kept intubated and transferred to the surgical intensive care unit.

Patient recovered bowel function on postoperative day 4 but her postoperative course was remarkable for a midline incision hematoma secondary to treatment with therapeutic Lovenox for previous history of atrial fibrillation. She required wound opening, evacuation, and packing. Patient subsequently remained stable on Lovenox without further bleeding episodes and was eventually discharged in stable condition to a skilled nursing facility. Upon follow up, 6 mo later, patient was asymptomatic.

Pathological examination of the surgical specimen demonstrated mucosal ulceration and transmural inflammation of both of the resected bowel segments. The stone found in the jejunum was identified as a mixed type gallstone measuring 4.7 cm × 3.2 cm × 3.2 cm and the stones found at the MD were identified as mixed type gallstones measuring 4.0 cm × 2.7 cm × 2.7 cm and 2.5 cm × 2.0 cm × 1.4 cm (Figure 2).

DISCUSSION

Gallstone ileus is an uncommon complication, occurring in 0.3% to 0.5% of all cases of cholelithiasis, and accounting for 1% to 4% of mechanical small bowel obstructions. However, while gallstone ileus is rare in the general population, it accounts for 25% of mechanical bowel obstructions in patients over 65 years of age in the United States^[4-6]. Because of the advanced age at presentation, patients often have multiple comorbidities, which contribute to the high morbidity and mortality associated with gallstone ileus. The pathophysiology of gallstone ileus involves the erosion of one or more gallstones from a chronically inflamed gallbladder into the gastrointestinal tract, creating a cholecystenteric fistula. Gallstones less than 2 to 2.5 cm generally pass into the intestine without causing obstruction while stones 5 cm or larger are more likely to impact usually at the distal ileum, the narrowest part of the small bowel^[10]. Other reported sites of impaction include proximal ileum, jejunum, colon, and rarely the duodenum or stomach (Bouveret's syndrome)^[11]. In our case, a large,

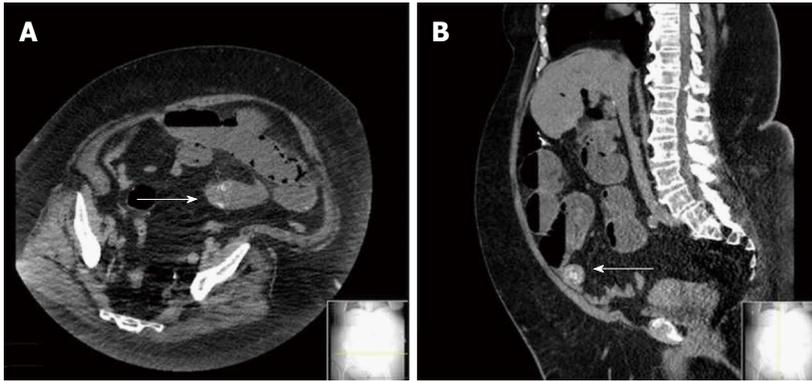

Figure 1 Computed tomography of abdomen pelvis without contrast. A: Axial section demonstrating 31.8 mm gallstone (arrow) in jejunum; B: Sagittal section demonstrating transition point and smaller gallstone (arrow) at proximal ileum.

Figure 2 Gross specimen of Meckel's diverticulum impacted with two gallstones.

approximately 5 cm, gallstone was found impacted at the jejunum while two smaller stones were found impacted at a MD. Clinical presentation of gallstone ileus is variable and often insidious. Patients can have painless intervals due to “tumbling” or incomplete small bowel obstruction in which the impacted stone intermittently passes and lodges in the intestinal lumen, until the stone either passes through the gastrointestinal tract or is impacted. It is possible this pattern of remitting symptoms may have contributed to the delay in diagnosis for our patient after her initial presentation to the OSH.

MD is a common congenital anomaly of the small intestine occurring in up to 3% of the population, typically 55 cm from the ileocecal valve^[8]. It is usually asymptomatic, with a low lifetime risk of developing complications, with most occurring later in adulthood. Most reported complications include obstruction, hemorrhage, perforation, and neoplasia^[8]. Small bowel obstruction can be caused by intussusception or volvulus of MD. In rare cases enteroliths, can form within a MD and cause an obstruction from impaction within the small bowel. Stasis in the diverticulum in combination with the alkalotic environment of the small bowel can promote precipitation of calcium and is

thought to contribute to formation of an MD enterolith^[7]. In our case the patient had an impaction of a gallstone in the MD. This is exceptionally rare with only 3 cases having been reported in the literature.

Impaction of a gallstone at MD can cause intermittent abdominal pain, bleeding, diverticulitis, perforation or small bowel obstruction (SBO). The presence of stones in a MD predispose to SBO by promoting local inflammation of the diverticulum and intussusception or by impaction of the stone in the bowel following its extrusion from the diverticulum. Clinical differentiation of MD enterolith from gallstone ileus can be difficult as both present similarly with bowel obstruction with prolonged indolent course. Pneumobilia on abdominal plain film suggests gallstone ileus but abdominal film has very low sensitivity for detecting gallstone ileus or MD enterolith^[12]. CT is the ideal diagnostic modality with sensitivity, specificity and diagnostic accuracy of over 93%^[13]. However, gallstone ileus is often diagnosed only at the time of laparotomy in up to 25% to 50% of cases^[5,14,15].

The surgical management of an incidentally found MD in the adult population remains controversial. Most surgeons would advise removing an asymptomatic diverticulum when found incidentally at laparotomy in pediatric patients and young adults secondary to the seemingly significant risk of developing complications. However, the literature is less decisive regarding prophylactic resection in adults. For example, Peoples *et al*^[16] found a high morbidity and mortality rate associated with resection but low lifetime risk (6.2%) of developing symptoms from a MD, with the majority of complications occurring during the first 2 decades of life. Cullen *et al*^[17] demonstrated operative morbidity and mortality for elective MD resection (2% and 1%) was significantly lower as compared to non-elective resection (12% and 2%)^[17]. However, Zani *et al*^[18] pointed out 758 resections would have to be performed to prevent one death when consideration is given to the overall low number of patients affected by MD. Therefore, incidental diverticulectomy is generally discouraged, with exception in cases of narrow base,

long length, and palpable heterotopic tissue, where operative management is given special consideration.

On the other hand, it is more uniformly accepted that complicated and symptomatic MD requires operative management. The operative management options for MD with gallstone impaction include gallstone fragmentation and milking into the proximal colon, or gallstone removal through an enterotomy. The diverticulum itself should also be resected to prevent recurrent stone formation and further complications. The decision to perform a diverticulectomy or segmental resection remains contested. The diverticulum can be easily resected with a stapler without entering the bowel's lumen^[19]. However, bowel resection with primary anastomosis is indicated in cases of inflammation, perforation, and necrotic bowel. As in our case, if the small bowel lumen is in danger of being narrowed or the neck of the diverticulum is wide, a segmental resection is favored over a simple diverticulectomy^[8]. As far as we know, there are no studies directly comparing diverticulectomy with segmental resection.

The operative management of gallstone impaction of the small bowel are: (1) enterolithotomy, cholecystectomy and fistula repair (single-stage surgery); (2) enterolithotomy with delayed cholecystectomy and fistula closure (two-stage surgery) and (3) simple enterolithotomy (most reported surgical procedure). Proponents of the single-stage procedure cite recurrence and increased risk of developing cholangitis or gallbladder carcinoma as reasons for performing concurrent cholecystectomy and fistula closure^[20]. Those who support the two-stage procedure or simple enterolithotomy point to high mortality rates of single-stage procedures and low rates of recurrence and gallbladder carcinoma as reasons for deferring cholecystectomy or avoiding it altogether. Furthermore, fistulas have been shown to close spontaneously once the distal obstruction is removed^[20].

No randomized trial has been performed to address the question of appropriate treatment due to the ethical implausibility of randomizing patients to one group over the other. The literature on gallstone ileus is largely limited to retrospective studies or case series (Table 1). In one of the largest studies comparing outcomes between single stage and simple enterolithotomy, Reisner *et al*^[5] reviewed 1001 cases and found that a single-stage procedure had a higher mortality rate at 16.9% compared to 11.7% with simple enterolithotomy ($P < 0.17$). Moreover, recurrence rates, from retained stones missed during initial surgery or formation of new gallstones, were the same in both groups.

Thus, the one-stage procedure, while associated with higher mortality rates, did not reduce recurrence rates as its proponents have predicted. Confirming these findings is a review by Halabi *et al*^[21] which now exceeds Reisner and Cohen as the largest review of gallstone ileus. They used the Nationwide Inpatient Sample from 2004 to 2009 to compare data for 3268

Table 1 Mortality rates of two main surgical approaches in treating gallstone ileus, one-stage and two-stage procedure

Ref.	With cholecystectomy (single-stage)		Without cholecystectomy (two-stage)		Total
	Total	Mortality	Total	Mortality	
	Kasahara <i>et al</i> ^[15]	105	19%	7	
Reisner <i>et al</i> ^[5]	113	16.8%	801	11.7%	1001
Doko <i>et al</i> ^[26]	19	10.5%	11	9.1%	30
Tan <i>et al</i> ^[27]	12	0%	7	0%	19
Mallipeddi <i>et al</i> ^[23]	14	7.1%	113	5.3%	127
Halabi <i>et al</i> ^[21]	741	7.3%	2527	6.5%	3268

patients. They found fistula repair and bowel resection to be independently associated with higher mortality rates and longer hospital stays when compared to simple enterolithotomy repair with an odds ratio of 2.86 (95%CI: 1.16-7.07) and 3.68 (95%CI: 1.59-5.76), respectively. In support of these studies are reviews by several other authors showing a preference for reserving the higher risk single-stage procedure for patients with lower ASA classifications^[14,22,23].

Just as with initial presentation, management options for recurrent gallstone ileus include simple enterolithotomy, single-stage, and two-stage surgery. In a systematic literature review, Mir *et al*^[24] compared treatment options in patients with recurrent gallstone ileus over the last 25 years and found a significantly lower mortality rate of simple enterolithotomy when compared to single-stage surgery (4.8% vs 22.2%). Several case reports of recurrent gallstone ileus successfully managed by repeat enterolithotomies lend support to this approach^[25-27].

A new development in the surgical management of gallstone ileus is the use of laparoscopy. There is to date one retrospective review of laparoscopic assisted vs open enterolithotomy of gallstone ileus by Moberg *et al*^[28]. Both groups had a similar duration of operation (60 min vs 58 min), similar median hospital stay (10 d vs 7 d), and similar complication rates (6 vs 5), and no deaths. In support of this is the publication of several recent case reports demonstrating the successful use of laparoscopic assisted surgery for gallstone management^[29-31]. Moreover, many case reports have been published on the efficacy of a totally laparoscopic approach in the management of gallstone ileus^[32-37]. However, in these reports only a single stone was involved. Our attempt at laparoscopic enterolithotomy was limited by bleeding from injury to the epigastric artery during port insertion and was complicated by involvement of multiple stones.

While mortality rates remain high for patients with gallstone ileus they are overall lower in more recent literature, which is likely a reflection of improved modern surgical and peri-operative care. A laparoscopic approach may be suited for the uncomplicated patient with a single stone who can tolerate the longer operative time required to close the enterolithotomy. However, com-

plicated cases such as impaction at a Meckel's diverticulum in a morbidly obese high-risk patient will benefit from an open approach. In such patients, diverticulectomy or segmental bowel resection of the should be strongly considered. These patients then have the option of undergoing an elective cholecystectomy at a later time. Patients who develop recurrence can be managed similarly. A single-stage procedure is rarely performed, typically in lower risk patients, or those with conditions requiring urgent attention to the gallbladder. It is associated with high mortality and morbidity and the decision to perform a single-stage procedure should be weighed carefully against the perceived benefits.

COMMENTS

Case characteristics

A 64-year-old female morbidly obese female with a history of diabetes, hypertension, an atrial fibrillation presented with post-parandial abdominal pain and bilious emesis.

Clinical diagnosis

Gallstone ileus with impaction in small bowel and at Meckel's diverticulum (MD).

Differential diagnosis

The differential diagnosis in this patient involves other causes of small bowel obstruction and mesenteric ischemia, which includes.

Laboratory diagnosis

Leukocytosis with left shift and metabolic acidosis were found in setting of frequent bilious emesis.

Imaging diagnosis

Hepatobiliary iminodiacetic acid scan demonstrating probable mass in small bowel and CT of abdomen and pelvis demonstrating pneumobilia, small bowel dilation and intraluminal small bowel filling defects were consistent with gallstone ileus.

Pathological diagnosis

Surgical small bowel specimen demonstrated distal jejunum with 4.7 cm stone and MD with two gallstones measuring 4 and 2.7 cm.

Treatment

Operative management with laparotomy, enter lithotomy of impacted jejunum, and small bowel resection of impacted MD.

Related reports

Other case reports of gallstone ileus associated with impacted MD have been very rarely presented in the literature. To our knowledge only three cases (two in English and one in Danish) have been published with varying presentations and varying treatment modalities.

Experiences and lessons

Gallstone ileus, while a rare occurrence over all is a more common cause of small bowel obstruction in the elderly and carries a high rate of morbidity and mortality making early clinical suspicion and intervention very important.

Peer-review

This is an important presentation of a rare finding that explores the appropriate management of gallstone ileus in an elderly co-morbid patient with an incidental finding of MD. It is accompanied by a very thorough and well written literature review of management of both symptomatic Meckel's diverticulum and gallstone.

Abstract

Sclerosing mesenteritis is a rare pathology with only a few described cases in the literature. The etiology is unclear; however, several potential triggers, including abdominal surgery and abdominal trauma, have been discussed. The pathology includes a benign acute or chronic inflammatory process affecting the adipose tissue of the mesenterium. Despite it being a rare disease, sclerosing mesenteritis is an important differential diagnosis in patients after abdominal surgery or patients presenting spontaneously with signs of acute inflammation and abdominal pain. We present here three cases with sclerosing mesenteritis. In two cases, sclerosing mesenteritis occurred postoperatively after abdominal surgery. One patient was treated because of abdominal pain and specific radiological signs revealing spontaneous manifestation of sclerosing mesenteritis. So far there are no distinct treatment algorithms, so the patients were treated differently, including steroids, antibiotics and watchful waiting. In addition, we reviewed the current literature on treatment options for this rare disease.

Core tip: Sclerosing mesenteritis is a rare pathology including a benign acute or chronic inflammatory process affecting the adipose tissue of the mesentrium. The etiology is unclear; however, several potential triggers, including abdominal surgery and abdominal trauma, have been discussed. So far there is no evidence in the treatment of these patients. But, in the case of a non-resolving bowel obstruction, surgery is needed.

Klasen J, Güller U, Muff B, Candinas D, Seiler CA, Fahrner R. Treatment options for spontaneous and postoperative sclerosing mesenteritis. *World J Gastrointest Surg* 2016; 8(11): 761-765 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i11/761.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i11.761>

INTRODUCTION

Sclerosing mesenteritis is a rare, benign pathology of the abdominal adipose tissue^[1]. It was first described by Jura^[2] in 1924. Sclerosing mesenteritis, mesenteric or omental panniculitis, mesenteric lipodystrophy, or mesenteric manifestation of Weber-Christian disease are often used as synonymous terms^[1,3]. The etiology is unclear and often remains idiopathic, but abdominal surgical procedures, abdominal trauma, infections, autoimmune processes, drugs, vasculitis, avitaminosis and hypersensitivity have been discussed as potential triggers^[1,3,4]. The symptoms of sclerosing mesenteritis are mostly unspecific. Hence, it is crucial to rule out other pathologies such as lymphoma, sarcoma, peritoneal mesothelioma, infectious diseases (tuberculosis or histoplasmosis) or amyloidosis^[3].

The objective of these case presentations and the summary of the literature is to raise awareness regarding this rare, yet important, differential diagnosis in a patient presenting with signs of acute inflammation and abdominal pain. Furthermore, the current literature regarding possible treatment regimens will be discussed.

CASE REPORT

Case 1

A 64 years old male patient with attenuated familial polyposis coli was electively admitted for laparoscopic subtotal colectomy. His previous surgical history consisted of inguinal hernia repair. Comorbidities included coronary artery disease, status post percutaneous transluminal coronary angiography and stenting two years earlier. Laparoscopic subtotal colectomy, including an ileo-rectal anastomosis and preservation of the greater omentum, was performed without any intraoperative complications. After an uneventful initial

Figure 1 Transverse abdominal computed tomography scan with a tumor mass (15 cm × 8.8 cm × 7.8 cm, white arrow) in the upper left hemiabdomen. The mass shows increased density in comparison to normal fat and a tumoral pseudocapsule.

Figure 2 Sagittal abdominal computed tomography scan with an unclear mass in the omental fat with obstruction of the small intestine (white arrow).

course, the patient developed symptoms of incomplete intestinal obstruction with vomiting and diarrhea on the third postoperative day. Moreover, the temperature rose to 101.3 degrees Fahrenheit. On clinical examination, the patient was very tender over his left hemiabdomen. The blood work revealed a dramatic elevation of the C-reactive protein (CRP) to 478 mg/L (normal: Less than 3 mg/L) and a white blood cell count of 16.1 G/L (normal: Less than 10.0 G/L). An abdominal computed tomography (CT) showed an unclear mass of 15 cm × 8.8 cm × 7.8 cm in the left hemiabdomen (Figures 1 and 2), consisting of omental fat and causing a partial intestinal obstruction. After administration of intravenous antibiotics (tazobactam/piperacillinum) and conservative treatment of the bowel obstruction with insertion of a naso-gastric tube and rectal catheter, the patient's general condition improved and the bowel function normalized over the following days. The abdominal tenderness disappeared and the blood values returned to within normal limits. The patient was discharged with oral antibiotics (amoxicillinum/acidum clavulanicum) on postoperative day 20 in good general condition. The patient, who was seen in the outpatient

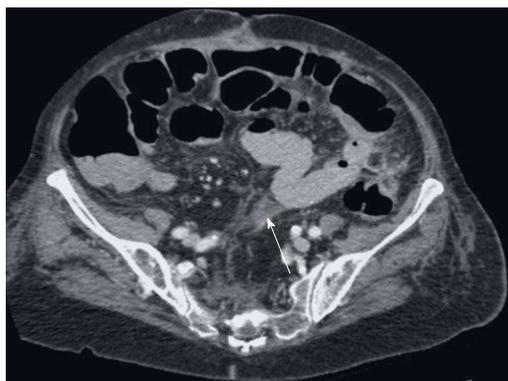

Figure 3 Transverse abdominal computed tomography scan as the gold standard with an inflammation of the mesentery at the height of the navel.

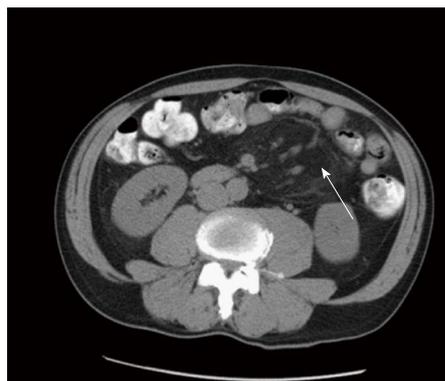

Figure 5 Inflammation of the small bowel adipose tissue formed as a pseudotumor in the left abdomen in the transverse abdominal computed tomography (white arrow).

Figure 4 Transverse abdominal computed tomography scan shows a nonspecific inflammatory process involving the adipose tissue of the small bowel mesentery.

Figure 6 Signs of sclerosing mesenteritis with lymphadenopathy in the lower left abdomen in the transverse abdominal computed tomography (white arrow).

clinic 4 wk later, remained asymptomatic.

Case 2

An 84 years old female patient was referred to the hospital with upper abdominal pain associated with diarrhea and vomiting for one week. The CT scan confirmed the diagnosis of an intestinal obstruction. An explorative laparotomy with adhesiolysis and a partial resection of the small bowel with an end-end-anastomosis of the small bowel was performed because of an ischemic perforation. During the postoperative course, the patient complained of progressive and vague abdominal pain. In addition to elevated inflammatory parameters (CRP, white blood cell count), no surgical complication or infection was detected. The repeated CT scans showed signs of mesenteritis without signs of leakage or abscess (Figures 3 and 4). There was no improvement with antibiotic treatment, but empirical therapy with prednisolone reduced the pain and the inflammatory parameters decreased. In the follow-up 40 d after surgery, the patient was asymptomatic.

Case 3

A healthy 56-year old male patient presented with history of pain in the lower abdominal quadrant for 3 to

4 mo, provoked by exercise. The patient's past medical history was uneventful, with no weight loss, no episodes of fever or shivering, no evidence for dysfunction of the gastrointestinal tract, and no previous abdominal surgeries. The patient underwent a screening colonoscopy without any pathologic findings. A clinical examination revealed abdominal distention in the left lower quadrant without peritonitis or resistance. An abdominal CT scan showed an inflammatory infiltration of the mesenteric adipose tissue with lymphadenopathy, interpreted as sclerosing mesenteritis without evidence of malignancy or other pathology (Figures 5 and 6). The pain declined further in the course spontaneously without any treatment.

DISCUSSION

There are only a few described cases of sclerosing mesenteritis in the literature. The pathogenesis of sclerosing mesenteritis remains to be elucidated; however, it seems to be an inflammatory and immune response to local stimuli, such as abdominal surgery or trauma. Moreover, infections, autoimmune processes, malignancy, drugs, vasculitis, avitaminosis and hypersensitivity have been described as potential

causes for sclerosing mesenteritis^[5-7]. Furthermore, immunological disorders, such as elevated IgG4 levels, have been discussed as related to the occurrence of sclerosing mesenteritis^[8,9]. However, the causes for sclerosing mesenteritis often remain idiopathic^[1,3,4]. Histological exams reveal a benign fibro-inflammatory process of the intra-abdominal fat, including fat necrosis, signs of chronic inflammation with lymphocytes, plasma cells, lipid-laden macrophages and fibrosis. However, no malignant cells are identified^[1,4,10]. The symptoms of sclerosing mesenteritis are nonspecific and may include fever, vomiting, abdominal pain with distension, abdominal tenderness as well as intestinal obstruction^[3,11,12]. Because of its nonspecific presentation, it is crucial to rule out other pathologies, such as lymphoma, sarcoma, peritoneal mesothelioma, infectious diseases (tuberculosis or histoplasmosis) or amyloidosis and post-interventional abscesses and other complications^[3]. Differentiating between a “real” postoperative/post-interventional complication and a sclerosing mesenteritis may be extremely challenging. As sclerosing mesenteritis is extremely rare, it is often difficult to establish a definitive diagnosis^[13]. Due to the nonspecific clinical presentation, a surgical biopsy is often performed^[12]; however, it is rarely actually necessary^[3]. It used to be the only method to confirm the diagnosis. Today, based on the increasing use of ultrasonography and CT scan with improved quality, the diagnosis can be established based on imaging and clinical presentation^[10]. In ultrasonography the features are nonspecific, including a poorly defined hyperechoic mesenteric fat with a decreased compressibility^[10]. CT scans reveal a well-defined mass of fatty tissue with increased density in comparison to normal fat or a nonspecific inflammatory process involving the adipose tissue of the mesenterium of the small bowel^[10,14]. In addition, a fat-ring sign, a tumoral pseudocapsule or soft-tissue nodules may be observed^[10]. Clinical manifestations are nonspecific and can consist of abdominal pain (70%), diarrhea (25%), weight loss (23%), abdominal muscle defense (50%), rebound tenderness (10%-15%), ascites/chylous (14%)^[3,7] and, in rare cases, fever^[15]. Most patients with sclerosing mesenteritis have an uneventful course and the symptoms resolve spontaneously^[3]. Several therapeutic approaches with agents such as steroids, colchicine and azathioprine have been described with various therapeutic effects^[16-18]. In cases of non-resolving bowel obstruction or an advanced inflammatory reaction, surgical resection of the inflamed fat may be necessary^[1,12]. Asymptomatic sclerosing mesenteritis requires no therapy^[7]. However, the symptomatic sclerosing mesenteritis must be treated surgically or with a trial of immunosuppressive medication^[7].

These case presentations reflect that currently the etiology and the treatment of sclerosing mesenteritis are still not fully understood and further investigations are needed. The only evidence in the treatment of these patients is that, in the case of non-resolving bowel

obstruction, surgery is needed. Because of the small number of patients suffering from sclerosing mesenteritis, prospective and randomized trials are difficult to perform. Therefore, it is still under investigation if patients need immunosuppressive agents.

COMMENTS

Case characteristics

Abdominal pain and signs of acute inflammation after abdominal surgery, with specific radiological signs in two patients and in one patient without prior surgical intervention.

Clinical diagnosis

Nonspecific with signs of acute inflammation and abdominal pain.

Differential diagnosis

Lymphoma, sarcoma, peritoneal mesothelioma, infectious diseases (tuberculosis or histoplasmosis) or amyloidosis and post-interventional abscesses.

Laboratory diagnosis

Elevated C-reactive protein levels and increased white blood count.

Treatment

Steroids, antibiotics and watchful waiting. In the case of non-resolving bowel obstruction or an advanced inflammatory reaction, surgical resection is needed.

Related reports

In the current literature, there are several case reports of mostly single cases. Data from prospective and randomized studies are lacking.

Term explanation

Sclerosing mesenteritis is a rare pathology and the etiology is unclear. Several potential triggers, including abdominal surgery and abdominal trauma, have been discussed. The pathology includes a benign acute or chronic inflammatory process affecting the adipose tissue of the mesenterium.

Experiences and lessons

This disease is rare and often misdiagnosed. Especially in the postoperative course, the occurrence of sclerosing mesenteritis is often difficult to identify. The etiology is unclear and there are currently no specific treatment algorithms. The only evidence is that in the case of non-resolving bowel obstruction or an advanced inflammatory reaction, surgical resection is needed.

Peer-review

It is a well written clinical report about the rarely occurring sclerosing mesenteritis including three cases with pictorial presentation. The information conveyed should be of help to the peers in the same field for improving their clinical practice.

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Xiu-Yan Huang, MD, PhD, Associate Professor, Surgeon, Department of General Surgery, the Sixth People's Hospital of Shanghai, Shanghai Jiao Tong University, Shanghai 200233, China

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Select group of patients with concurrent esophageal

and gastric stricturing secondary to corrosive intake requires colonic or free jejunal transfer. These technically demanding reconstructions are associated with significant complications and have up to 18% ischemic conduit necrosis. Following corrosive intake, up to 30% of such patients have stricturing at the pyloro-duodenal canal area only and rest of the stomach is available for rather less complex and better perfused gastrointestinal reconstruction. Here we describe an alternative technique where we utilize stomach following distal gastric resection along with Roux-en-Y reconstruction instead of colonic or jejunal interposition. This neo-conduit is potentially superior in terms of perfusion, lower risk of gastro-esophageal anastomotic leakage and technical ease as opposed to colonic and jejunal counterparts. We have utilized the said technique in three patients with acceptable postoperative outcome. In addition this technique offers a feasible reconstruction plan in patients where colon is not available for reconstruction due to concomitant pathology. Utility of this technique may also merit consideration for gastroesophageal junction tumors.

Key words: Corrosive strictures; Roux-en-Y augmented gastric advancement; Colonic interposition

INTRODUCTION

Corrosive upper gastrointestinal (GI) strictures still remain challenging in surgical practice^[1]. Fortunately in majority of cases these either preferentially involve esophagus or stomach making surgical decision easier in favor of either esophagectomy or a form of gastric bypass^[1,2]. However in approximately 6%-50% of the cases it involves both esophagus and stomach making reconstruction a technically demanding task with inherent potential of multiple complications^[1-3].

Various surgical techniques with pros and cons have been advocated previously^[4-6]. Colonic and free jejunal conduits remain a standard for such difficult cases with favorable outcomes however with significant graft necrosis rates of 2.4%-18% and 14.1% respectively^[6-8]. Although proponents of colonic conduit have significant reasons in favor of its use however majority of the surgeons doing transhiatal resections of esophagus would agree that stomach is the most favorable conduit in terms of quality of blood supply and hence anastomotic leak rate^[9]. In a study by Mansour *et al*^[10], bowel interposition was associated with significant complications including 14.8% anastomosis leakage rate and 3% ischemic colitis rate. Similarly, Davis *et al*^[6] and Moorehead *et al*^[11] have previously shown that stomach is better in terms of postoperative ischemia than the colon. Stomach had lowest conduit ischemia rate of 0.5%-1% while jejunum had colon had ischemia up to 11.3% and 13.3% respectively^[6-11]. Patients having colonic interposition however, have low rates of GERD postoperatively^[12,13].

In a group of selected patients where the stomach has mere concentric pyloric stenosis along with esophageal involvement, many practicing surgeons would have questioned themselves per-operatively: "Can we employ this dilated well vascularized stomach instead of less vascular and technically more demanding colon or free jejunal transfer?" Here we describe alternative reconstruction plan which we have successfully employed in three of our patients with reasonable outcome.

OPERATIVE TECHNIQUE

A 33-year-old male patient presented with development of progressive dysphagia following history of caustic intake 3 years back. Endoscopy showed two significant strictures in upper GI tract, one 30 cm distal to cricopharynx and the second one in pyloric sphincter region. During last three years patient was managed by repeated dilatations of esophageal and pyloric strictures. Now he presented with strictures which were not dilatable due to extensive fibrosis in the said areas of the upper GI tract. A barium study showed esophageal stricture in the region of upper esophagus and the stomach was full

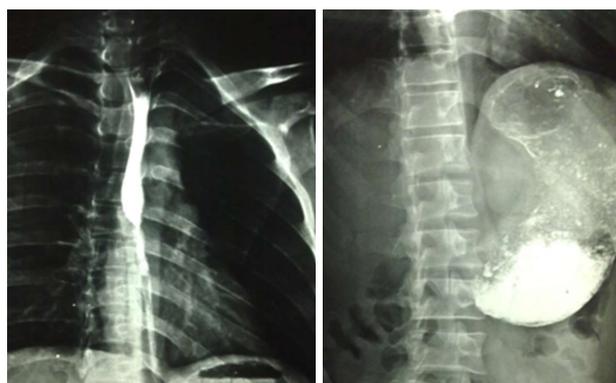

Figure 1 Barium study showing concurrent esophageal and gastric stenosis at pyloric canal level. Please note the distended stomach.

of the contrast material without any distal evacuation (Figure 1). Another dilatation of the upper esophageal stricture was possible in up to 5 mm at best. Considering the above surgical reconstruction was planned. Peroperatively the stomach was massively dilated with only distal stricturing at the pyloric region. Stomach was mobilized with preservation of right gastroepiploic vessels. Distal gastrectomy was done and distal end of stomach was closed along with closure of the duodenal stump. Transhiatal esophagectomy was done and jejunum was fashioned as a Roux-en-Y loop which was anastomosed to the distal end of the mobilized stomach. The stomach was delivered into the chest the way that the gastro-jejunal anastomosis of Roux-en-Y loop lays in hiatus. Neck dissection was done with predictable safety of recurrent laryngeal nerve. End to side triangulated gastroesophageal anastomosis was done with interrupted Prolene stitches (Figure 2). Postoperatively patient did well and was discharged on 18th postoperative day. We have employed the same technique in three of our patients, two males and one female. All three patients had technically viable reconstruction. We lost one of the three patients on 12nd postoperative day due to Acinobacter positive hospital acquired pneumonia. We did not find any evidence to suggest a procedural failure or anastomotic leakage in this particular case. We have followed up the cases over a period of 19 mo in one case and 5 mo in other case with only one with mild dumping symptoms.

CONCLUSION

Corrosive intake depending upon the chemical composition of ingested liquid, area and time of contact can cause mild to severe stricturing of the upper GI tract^[1-3]. Caustic soda preferentially affects the esophagus and the toilet cleaners in majority of cases affect the pyloric canal area^[3]. Endoscopic dilatation or surgical replacement is quite effective treatment in majority of the cases^[3]. In up to 50% percent of the cases there is concurrent involvement of esophagus and stomach leading to difficulty in reconstruction. In such cases, colonic interposition and free jejunal transfer still remain the gold standard conduits. Clearly such reconstructions are complex and

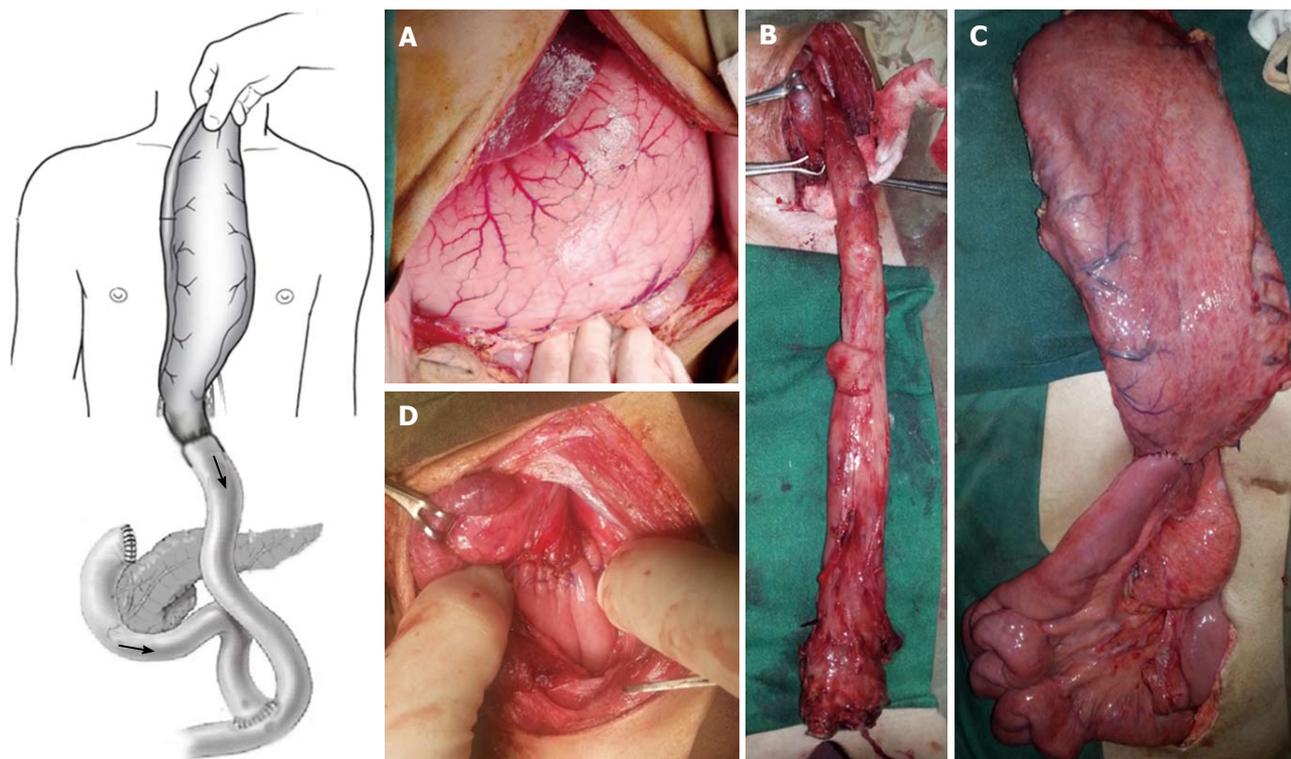

Figure 2 Roux-en-Y augmented gastric advancement with schematic reconstruction plan. A: Distended stomach; B: Esophageal specimen following standard transhiatal esophagectomy; C: Standard augmented gastric advancement reconstruction before esophageal anastomosis lying on the chest; D: Gastro-esophageal anastomosis in the neck.

are associated with higher morbidity and mortality^[4]. In words of T. DeMeester, these reconstructions should be flawless because the impact of complications is not additive but logarithmic^[14]. In experienced hands these reconstructions have favorable results however one of the frequently encountered problem is higher conduit necrosis rate in case of colon (2.8%-18%) and jejunum (14.1%) as opposed to stomach which has lower conduit necrosis rate (2.6%) and hence potentially lower leak rate^[6-8].

In select group of the patients with concurrent involvement of esophagus and stomach where stomach is merely affected at the pyloric sphincter area, surgeons have previously avoided using stomach in favor of colonic replacement. Here we have demonstrated that stomach tube along with Roux-en-Y reconstruction can be a feasible alternative to the colonic or jejunal interposition in this select group of patients.

The interposition of stomach tube potentially adds specific superiority of excellent vascular supply and potentially reduced conduit necrosis rate and low anastomotic leakage rate, which are subject of our upcoming randomized trial. The Roux-en-Y reconstruction adds to the complexity of the reconstruction however it has three distinct advantages: Firstly, it gives significant length to the conduit (about 30-40 cm), which normally would be attained by liberal kockerization of the duodenum in a standard case of the transhiatal esophagectomy; secondly, it would function as a pyloromyotomy which is frequently done by the surgeons during transhiatal

esophagectomy to prevent postoperative gastric stasis and thirdly, it potentially would reduce postoperative biliary reflux; and finally, this reconstruction plan can be of enormous value if the colon is not available for interposition due to some other concomitant reason like ulcerative colitis or Crohn's disease. Theoretically such reconstruction can also be beneficial in GE junction tumors, where we can achieve negative resection margins with limited resection of stomach.

RAGA like other constructions plans can be associated with potential complications. The preparation of the conduit requires special attention and preservation of blood supply as the conduit would be solely based on right gastroepiploic artery and its corresponding venous system as opposed to right gastroepiploic and right gastric arteries which are usually preserved during a standard transhiatal esophagectomy. This can potentially add to the probability of gastric erosions due to mucosal ischemia. Secondly the retention gastritis leading to postoperative gastric erosions are likely to be higher and hence patients may require use of proton pump inhibitors to prevent gastric erosions due to gastritis. One of our patient developed postoperative gastric erosions on 6th postoperative day owing to retention gastritis which was successfully treated with proton pump inhibitor infusion. A predicted comparison of the two said techniques has been tabulated in Table 1.

In select group of the patients of corrosive intake with concomitant involvement of esophagus and stomach where stomach is partially available for reconstruction, it

Table 1 Predicted potential comparison of the two techniques for esophageal replacement

	Colonic interposition	Roux-en-Y augmented gastric advancement
Vascular supply and conduit necrosis rates	Good; conduit necrosis rate 2.4%-18%	Potentially excellent; conduit necrosis rate 2%-5%
Mild mucosal ischemia	Ischemic colitis (3%)	Gastric erosions
Gastroesophageal and colo-esophageal reflux rates	Low (4%-5%)	Low
Conduit reservoir capacity	Acceptable	Better
Postprandial conduit fullness	Less	More
Probability of cervical esophageal anastomotic leakage rate	Low	Low
Probability of postoperative esophageal anastomotic stricture formation	Low	Higher
Potential complications	Higher probability of anastomotic leakage in colonic anastomosis	Higher probability of gastric erosions postoperatively due to retention gastritis

is feasible to utilize stomach for reconstruction in place of more complex colonic or jejunal transfer with favorable results. A randomized trial is warranted to compare this alternative reconstruction plan with gold standard colonic and jejunal transfer.

Abstract**AIM**

To investigate feasibility and outcome of abdominal-sacral resection for treatment of locally recurrent rectal adenocarcinoma.

METHODS

A population of patients who underwent an abdominal-sacral resection for posterior recurrent adenocarcinoma of the rectum at the National Cancer Institute of Milan, between 2005 and 2013, is considered. Retrospectively collected data includes patient characteristics, treatment and pathology details regarding the primary and the recurrent rectal tumor surgical resection. A clinical and instrumental follow-up was performed. Surgical and oncological outcome were investigated. Furthermore an analytical review of literature was conducted in order to compare our case series with other reported experiences.

RESULTS

At the time of abdomino-sacral resection, the mean age of patients was 55 (range, 38-64). The median operating time was 380 min (range, 270-480). Sacral resection was performed at S2/S3 level in 3 patients, S3/S4 in 3 patients and S4/S5 in 4 patients. The median operating time was 380 ± 58 min. Mean intraoperative blood loss was 1750 mL (range, 200-680). The median hospital stay was 22 d. Overall morbidity was 80%, mainly type II complication according to the Clavien-Dindo classification. Microscopically negative margins (R0) is obtained in all patients. Overall 5-year survival after first surgical procedure is 60%, with a median

survival from the first surgery of 88 ± 56 mo. The most common site of re-recurrence was intrapelvic.

CONCLUSION

Sacral resection represents a feasible approach to posterior rectal cancer recurrence without evidence of distant spreading. An accurate staging is essential for planning the best therapy.

Core tip: During the last years, great efforts have been invested by many authors to contribute in treatment of rectal cancer recurrence without evidence of distant spreading. The most difficult surgical problem is to perform an affective radical R0 salvage resection. However, with the introduction of sacral resection, consistent improvements have been achieved in recent years, particularly when local tumor relapse occurs in the posterior part of the pelvis, from the presacral to the retrovesical spaces. However, abdominosacral resection is a complex surgical procedure affected by several postoperative complications. For this reason, these patients should be treated into dedicated and specialized institutions.

Belli F, Gronchi A, Corbellini C, Milione M, Leo E. Abdominosacral resection for locally recurring rectal cancer. *World J Gastrointest Surg* 2016; 8(12): 770-778 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i12/770.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i12.770>

INTRODUCTION

Local relapse of rectal cancer is still one of the most complex and challenging issue concerning surgical oncology of the last years. Indeed, nowadays, rectal cancer relapses during the first two years in the 7%-30% of patients after receiving surgical resection^[1-3]. In about half of these cases of relapse, the cancer remains confined in the pelvis without extraregional diffusion and most of the deceases associated to the disease are only due to local progression of it in the following periods.

The infiltration of the pelvic walls had represented up to recent years the main limitation to achieve a radical resection in the majority of relapsed rectal cancer cases. Nevertheless, the recent advancements in surgical techniques especially regarding posterior and anterior relapse resection, have widen up the spectrum of possibilities for effective curative treatment^[4-6].

With the aim of contribute in the field, we present the review of the literature and report the implications from the experience obtained at our hospital, the National

Cancer Institute of Milan, on abdomino-sacral resection (ASR) for pelvic posterior recurrences of rectal cancers expanding toward the sacral plane.

MATERIALS AND METHODS

Between 2005 and 2013 in our Unit 1324 patients affected with rectal cancer were treated with different surgical procedures. One hundred and sixty-two (12.2%) recurred in the pelvis in a period ranging from 10 to 38 mo after surgery. One hundred and fifty-four of these were considered candidates to a second surgical salvage approach. Different surgical procedures were applied accordingly with the extension, the site and the characteristic of the relapsing lesion.

In the same period, a population of ten patients underwent an ASR for recurrent adenocarcinoma of the rectum at the National Cancer Institute of Milano. These patients are included in the present study.

All the patients underwent, in the first place, a radical resection for the rectal cancer followed by at our Institution in combination with a total mesorectal excision (TME) and a local, nerve sparing, node dissection extended to the origin of low mesenteric vessels. Local recurrence is defined as the relapse of the tumour at the primary site confirmed by radiologically and/or histologically. In all cases the recurrence was mainly posterior and invading the presacral space or directly the sacral plane.

Indications for ASR exist when there is evidence of involvement of the sacrum detected by preoperative exams (Figure 1) or when there is a highly probability of it according with the pelvic local extension of local relapse.

Patients were staged preoperatively by a thoraco-abdominal computed tomography (CT)-scan, a pelvic magnetic resonance imaging (MRI), a positron emission tomography and, when possible, a colonoscopy. The study excluded patients whose recurrent rectal cancer was developed after a simple local excision or patients receiving a simple and limited coccyx resection.

Patients who had undergone resection of liver metastasis at initial surgery or before the diagnosis of local relapse were also considered suitable for ASR, given an adequately long distant metastasis-free survival period. All data are retrospectively collected and registered prospectively into an electronic database. Collected data includes patient characteristics, treatment and pathology of the primary rectal cancer, neoadjuvant therapy and operative details for recurrent tumor, pathology of recurrent tumor, length of hospital stay, peri-operative complications, blood transfusion needed and oncological outcome.

The macroscopic and microscopic assessments of the pathology specimens were done by a single pathologist at our Hospital. Pathological examination included histological type, number of lymph nodes harvested, number of metastatic lymph nodes, analysis of specimen resection margins and evaluation of sacral involvement. An R0

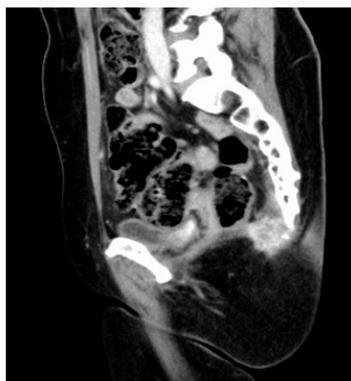

Figure 1 Radiological aspect of a local relapse infiltrating the coccyx and lower sacral bone.

Figure 2 Preparation of skin flaps allows a complete exposure of maximus gluteus muscles.

resection is defined when no tumour cells are shown in the surgical resection margin. Pathologic stage information was assessed using the 7th edition of the American Joint Committee on Cancer TNM system.

Surgical complications and overall morbidity complications are defined as adverse events that occurred within a 30 d period after surgery. Surgical complications are staged according to the Clavien Dindo Classification.

After ASR, clinical and instrumental evaluations were performed every 6 mo for the first three years and one a year for the following years. Computed axial CT-scan and MRI surveillance, as well as carcinoembryonic antigen levels, were the exams performed to assess patient outcome.

Surgical procedure

The surgical procedure is divided in three following steps: Abdominal, perineal and sacral.

Under general anesthesia the patient was placed in Lloyd-Davies position (lithotomic position with flexed and abducted thighs). After placement of ureteral stents (4 cases) in order to identify the ureters, a midline laparotomy was performed. The dissection of common and external iliac vessels is started from the promontorium. The anterior area from the aortic bifurcation to the sacral promontory is exposed to have access to the anterior surface of the sacrum. The dissection is made down to the distal sacrum paying the upmost attention to avoid bleeding from the presacral space that in some case could be really important. The area from the common iliac artery to the bifurcation between the internal and external iliac arteries is exposed. The dissection is then made toward the presacral space along the parietal pelvic fascia, outside the original plane of dissection. During this phase the endopelvic fascia and pubo-prostatic ligaments can be identified bilaterally and divided using electric cautery to expose the levator ani muscle. Some Authors propose preventive ligation of internal iliac vessels along the sacral plane, in order to control the risk of bleeding during surgical dissection. However, this procedure was not routinely performed in our series because we believe that this approach is needed only in upper sacral

resection due to a higher risk of local bleeding. The perineal phase corresponds to the typical procedure adopted in an abdomino-perineal resection performed for a primary rectal or anal carcinoma but avoiding to remove the surgical specimen through the perineal wound because the rectum and the other tissues will be removed "en bloc" with the sacrum during the following surgical steps. After formation of a terminal colostomy and closure of abdominal wound, the patient is placed in a prone position, with flexed and abducted thighs. Then, a posterior midline incision including the perineal lesion is made. The gluteus maximus muscles are dissected and detached from the sacrum in order to obtain a full exposure (Figure 2). The next step of this phase involves detaching the gluteal muscles, the sacrotuberous and sacrospinous ligaments and the piriform muscle from the sacrum to, subsequently, access the pelvic cavity. The surgeon inserts an index finger into the pelvic cavity from the lower edge of the sacroiliac joint and checks the dissected level of the anterior surface of the sacrum to determine the level of sacral amputation. The posterior wall of the sacrum is then osteotomized using a proper chisel and hammer at a stretch (Figure 3) scalpel and en-bloc resection of the tumor with the sacrum and the surrounding organs is accomplished (Figure 4). The canal is sealed with bone wax and fibrin sealant. A prolene mesh is placed anterior to the sacrum in order to close the perineal defect. A primary wound closure is usually performed. In some cases (two patients of the present series), perineal reconstruction is achieved with a pedicled musculocutaneous flap (Figure 5).

RESULTS

All ten patients included in this study (4 males and 6 females) underwent an anterior rectal resection as first operation at our hospital. Patients characteristics are reported in Table 1.

All the tumors were adenocarcinomas. Median distance from anal verge was 6 cm (range, 3-11). No patient received a pre-surgical neo-adjuvant therapy. In the pT3 cases this was mainly due to the bad clinical

Figure 3 After the level of sacral transection is identified the sacrum is osteotomized using normally a proper hammer and scalpel.

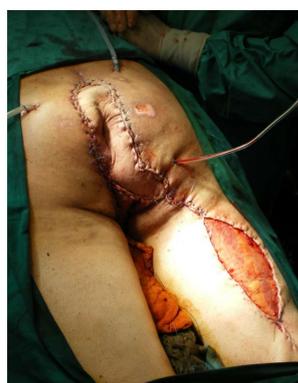

Figure 5 Example of a complex plastic reconstruction of the sacral area by a pedicled musculocutaneous flap and a thigh thin graft.

Figure 4 The figure shows a section of sacral specimen after S2 osteotomy.

status of the patients at the moment of diagnosis (occluding or bleeding lesions). All patients with histological nodal involvement or diffusion of disease into the perirectal fat received a post-operative CT-RT treatment in accordance to standardized schedules. The results of the pathological staging according to TNM are as follows: Stage I (5 cases), stage IIa (1 case), stage IIIa (1 case), stage IIIb (2 case) and stage IVa (1 case). In our case series, all stage I reported were high grade tumors with associated vascular and perineural invasion. Radicality was achieved during first surgery in all cases excepting one (R1, case 5).

At the time of ASR, the mean age of patients was 55 ± 9 years old, ranging from 38 to 64 years old. One out of ten patients was asymptomatic at presentation while 9 patients had increasing lower sacrococcygeal region pain. All patients were free of distant metastases at ASR and were considered eligible for a radical resection. In 6 patients surgery was performed 4 to 6 wk after the completion of a new chemo-radiation therapy. All patients underwent ASR according to the technique reported in the previous section. The median operating time was 380 ± 58 min (range, 270-480 min). In one case, a posterior colpectomy was needed due to a direct infiltration of posterior vaginal wall (Table 2). Sacral resection was performed at S2/S3 level in 3 patients, S3/S4 in 3 patients and S4/S5 in 4 patients.

In our case series, overall morbidity was 80%, *i.e.*, 5 presented postoperative type II complications, 2 had type IIIb and one 1 a type IIIa complication according to the Clavien-Dindo classification, whereas the most frequent complication (7 patients) was sacral wound skin infection and dehiscence. List of main complications are reported in Table 2. No differences in complication rates between higher and lower sacral resection are detected. Mean intraoperative blood loss was 1750 mL (range, 200-6800 mL). Blood transfusion was administered to 5 patients (median 1 unit; range, 0-8 units) during the surgical procedure and to 5 patients (median 2 units,

Table 2 Treatments for recurrence and complications

	Pre-ASR CT-RT	Surgical procedure	Level of sacrectomy	Procedure length (min)	In-hospital stay (d)	Sacral involvement	Early complications (within 30 d)	Late complications (after 30 d)
1	Yes	ASR	S2-S3	380	11	Yes	Neurologic bladder dysfunction	Perineal wound infection and leakage
2	Yes	ASR	S4-S5	400	10	Yes	Pelvic abscess	Uterus/bladder prolapsus
3	Yes	ASR	S2-S3	420	24	Yes	Perineal wound leakage and Neurologic bladder	No
4	No	ASR	S4-S5	370	10	Yes	Perineal wound leakage	No
5	No	ASR	S3-S4	430	93	No	Uretral fistula, perineal flap necrosis and wound leakage	No
6	Yes	ASR	S3-S4	360	25	No	Perineal wound leakage	No
7	CT only	ASR and posterior colectomy	S3-S4	360	8	No	Perineal wound leakage	Pelvic abscess and ileal fistula
8	No	ASR	S4-S5	480	11	Yes	No	No

10	Yes	ASR	S4-S5	330	15	No	Perineal wound infection	No

ASR: Abdomino-sacral resection; CT: Computed tomography.

range, 0-8 units) during the postoperative period. No in-hospital mortality was observed. The median hospital stay was 22 d (range, 8-93 d). Adjuvant chemotherapy was performed in 2 patients under suggestion of medical oncologists due to local extension of disease. Microscopically negative margins (R0) is obtained in all patients. Previous diagnosis was confirmed by histopathological examination. Sacral bone invasion was detected in 50% of the cases. Postoperative lymph node harvested are 4 ± 3 (range, 0-10). No node localizations are identified.

Survival

Five of 10 patient (50%) died at a median time from ASR of 38 ± 29 mo.

Overall 5-year survival after first surgical procedure is 60%, with a median survival from the first surgery of 88 ± 56 mo. Median disease free interval from first surgery to local recurrence is 39 ± 39 mo (range 12-114 mo). The most common site of re-recurrence was intrapelvic in 4 patients and two of these presented also lung metastases. One patient had liver metastasis alone.

DISCUSSION

The adoption of TME, described by MacFarlane *et al*^[7] associated with preoperative radiation has improved surgical management of primary rectal cancer leading to a significant decrease of locoregional recurrence from 33% to less than 10%^[8,9].

Despite these recent advancements, the occurrence of local relapse of rectal cancer is still quite frequent and produces a particular cancer situation characterized by the persistence of the disease in the pelvis without extraregional diffusion to distant sites. The specific behavior of this recurring tumor calls for the need of an advanced surgical or combined therapy in order to obtain a R0 resection in the pelvis.

Regretfully, these locoregional recurrences are often

spread through the whole pelvis and a salvage surgery cannot be attempted. As a result many of them die in very bad conditions only for progression of the local relapse.

Several risk factors for the recurrence of rectal tumors have been studied. Some of them are related to tumor features, including tumor localization and pathological stage^[10]. However, the main risk factors are linked to which and how surgical technique is performed, *e.g.*, incomplete resection of mesorectal fatty tissue and R1/R2 resection^[11]. This explains why up to 90% of these relapses occur in an extra-bowel site and justify the difficulties of diagnosis and complexity of surgical resection for the adhesion-infiltration of these recurrences to the pelvic structures.

An accurate locoregional staging of a rectal relapsing tumor is essential for planning the best therapy^[12-14]. A careful radiological examination provides information about the local extension of the disease, which is critical for the treatment decision-making process. A attentive evaluation of both tumor extent and anatomic planes is needed to determine a correct line during resection that is usually altered by the previous surgery and radiotherapy. Pelvic MRI and CT-scanning of the thorax and abdomen are the most used imaging modalities technique in pre-operative staging to evaluate whether or not curative surgery is feasible, although some authors underline a low sensitivity in accurate assessment of side wall involvement^[15,16].

The definition of the site distribution of the relapse is crucial because, from a practical point of view, the factor that seems to play the upmost relevant role in evaluating the surgical resectability of these peculiar lesions is the anatomical sites of recurrences in the pelvis, irrespective in many cases, of the dimension and time of occurrence.

The relevance of the sites of recurrences is confirmed by the effort that has been dedicated to this issue in all the schemes of classifications proposed in the past recent

years^[17-21]. Guillem *et al.*^[19] in 1998 classified relapses into four groups: Axial, anterior, posterior and lateral. Furthermore, Guillem's classification was adopted by Moore *et al.*^[21] to show that the likelihood of achieving a R0 resection is strongly correlated to the type of recurrence, reporting an higher R0 resection rate in axial and anterior lesions than in lateral and posterior ones. Others studies confirm that central or anterior localization of a relapse produced less complex difficulties due to the possibility of removing pelvic organs such as uterus, vagina or bladder by means of well defined procedures^[22-24]. With respect to lateral and posterior relapses, a crucial role is played by the presence/absence of infiltration of structures such as iliac vessels, ureters, bony pelvis and great sciatic notch. Extensive infiltration of the pelvic sidewall is also a poor prognostic factor for the oncological outcome^[25,26].

There are, anyway, bone sections that can be removed through complex surgical procedures with relatively limited functional consequences. This concerns, specifically, the middle and distal portion of the sacrum. Facing this technical problem there are many points that should be considered.

The first one is defining the level of bone transection to be done that must be at least 1-2 cm above the upper edge of the visible tumor, when possible. As a matter of fact, the level of resection in almost all published series remains as the key factor, influencing the neurological and intraoperative complications rate^[27-29]. In all generality, there are not absolute limitation even to the resection of the whole sacrum from S1 to the coccyx, but this massive resection has been considered an alternative in rare situations, mainly due to the complexity of the procedure and to the functional consequences that may affect the patient against the expected limited benefit for the extension of the disease^[30,31]. Regularly, the section of neural roots at S3 level has no main sequelae and it is well accepted. Moving to S2 the cutting of the second root could produce important modification of bladder function up to a complete loss of bladder motility. Upper sections produce remarkable lower limb motor disability and plantar flexion weakness and the need of a walking aid. Commonly, the level considered as acceptable limit for this type of surgery is the space between S2 and S3; this allows classifying as "high sacrectomy" all resections extended from the space between S2 and S3 and, as "low sacrectomy", the procedures performed below this level^[18,26,32]. Other authors suggest a different classification indicating as "high sacrectomy" resection from the intervertebral disk between S1 and S2, "middle sacrectomy" resections between S2 and S3, and "low sacrectomy" all the others below^[33]. High sacrectomy are indeed followed by significant complications and morbidity. Bhangu *et al.*^[23] reports a 60% incidence of major complications for S1-S2 resection in comparison to a 27%-29% rate for S3 and S4-S5 sacrectomy. These data have been strongly confirmed in the recent years by many others studies^[1,6,34-38].

A other relevant technical aspect concerns the intraoperative complications related to this difficult surgical

procedure with special regards to the occurrence of sacral bleeding. Furthermore, in this case, the level of transaction is directly correlated to the incidence and severity of venous blood loss that, in some cases, could be not easily controlled, even become life threatening. Intraoperative bleeding during this surgery can be sudden and severe, and more often in patients who underwent preoperative radiotherapy, as frequently observed in these cases^[39-42].

The postoperative period could also be compromised by different and complex problems. As indicated in several studies, perioperative complication rate is high, especially in upper sacral resections. Morbidity and mortality rate at three months after radical ASR for recurrence are reported to be 30% and 8%, respectively^[1,6,34-36]. The most common complications occurring after sacropelvic resection are wound infections and dehiscences, pelvic abscesses and clinical complication, like as pneumonia, urinary tract infections and sepsis^[6]. Between the 15%-58% local complication rate (wound dehiscence, pelvic sepsis, flap necrosis, etc.) are justified by a modified and affected wound healing processes of the perineal and sacral zone. This event is often due to a heavy and prolonged radiotherapy treatment applied to the perineum and to the sacral area following rectal resection^[6,23,29,36]. All these occurrences explain as well the need to perform, in many of these cases, different and elaborated plastic reconstructions (mio-cutaneous or fascial-cutaneous flaps, rotation flaps or others) or more specific procedures when the site of the disease request further and more extended demolitions, *e.g.*, the vaginal or bladder areas^[37].

Up to few years ago, the diagnosis of a local recurrence was strongly correlated to a poor prognosis with a mean 5 years overall survival not greater than 10%^[26]. However, despite all these technical difficulties, the application of correct, enlarged and radical procedures have achieved positive and consistent clinical results in terms of local control of disease and improvements in the final outcome of these patients.

Recently, many authors have contributed to this topic, most of them confirming the safety of these surgical approaches when performed by dedicate and experienced groups of physicians. Several studies have demonstrated a 5-year global survival rates in local relapses surgery ranging between 25% and 60%^[1,6,30-36], rate confirmed by our study in which out of 10 operated patients, all submitted a middle-distal resection of sacral body, 50% are currently alive with a 38 mo mean follow-up from ASR.

In order to increase radicality rate and have a better local control, neoadjuvant treatment may be useful, excepting patients who had previously received high dose radiotherapy for primary cancer or other diseases^[43-45]. The role of intraoperative radiotherapy in the treatment of patients with pelvic relapses is still under discussion, notwithstanding several studies have shown the benefits in survival, especially in recurrent unresectable rectal tumors due to bone involvement. Some authors have

reported an increase survival rate of 15% when this modality of radiotherapy is performed^[43].

Despite all these particular aspects, the key issue to be addressed when managing this kind of disease is the appropriate selection of treatment by the patient in order to achieve symptom control and even a curative treatment with acceptable morbidity. When presenting a surgical alternative to the patient, the specialist should take into account several prognostic factors including: The age and comorbidities of the patient, disease free interval and features of the recurrence of tumor presented earlier.

The most recent studies, as well as the one presented here, are highlighting that partial sacrectomy can be considered a safe and feasible approach for recurrent rectal cancer but also that such a complex surgical resection must only be considered if a radical resection is technically possible^[37,46-53] on the basis of a multidisciplinary team evaluation only into dedicated and specialized institutions.

The results obtained in our series are consistent with what reported in other studies and suggest that, currently, a 5 years survival up to 60% is achieved with an acceptable morbidity and minor functional failure, when partial sacrectomy, below S2 level, is performed.

COMMENTS

Background

Local relapses of rectal cancer remain one of the most complex and challenging aspects of surgical oncology of the last years.

Research frontiers

Recently, a consistent improvement has been achieved with the introduction of sacral resection for the patients with posterior pelvic extension of the recurrent tumor. Although abdominosacral resection could improve outcome in patients affected by rectal cancer recurrence, it is been reported to be a complex surgical procedure affected by several postoperative complications.

Innovations and breakthroughs

Reporting their experience, the authors would like to give a better comprehension of a challenging disease with some suggestions about its surgical management.

Applications

The results of this study support the previously published evidences, underling the indication to performed a carefully selection of patient to treat. Further researches are needed to improve surgical technique and patient selection.

Peer-review

This is an interesting article on a limited series of a surgical procedure which is not often performed for treatment of local recurrent rectal cancer. Authors report data from their own experience and also make a review of the literature on this subject.

Abstract**AIM**

To investigate the assumption that schistosomiasis is the main cause of rectal prolapse in young Egyptian males.

METHODS

Twenty-one male patients between ages of 18 and 50 years with complete rectal prolapse were included in the study out of a total 29 patients with rectal prolapse admitted for surgery at Colorectal Surgery Unit, Ain Shams University hospitals between the period of January 2011 and April 2014. Patients were asked to fill out a specifically designed questionnaire about duration of the prolapse, different bowel symptoms and any past or present history of schistosomiasis. Patients also underwent flexible sigmoidoscopy and four quadrant mid-rectal biopsies documenting any gross or microscopic rectal pathology. Data from questionnaire and pathology results were analyzed and patients were categorized according to their socioeconomic class.

RESULTS

Twelve patients (57%) never contracted schistosomiasis and were never susceptible to the disease, nine patients (43%) had history of the disease but were properly treated. None of the patients had gross rectal polyps

and none of the patients had active schistosomiasis on histopathological examination. Fifteen patients (71%) had early onset prolapse that started in childhood, majority before the age of 5 years. Thirteen patients (62%) were habitual strainers, and four of them (19%) had straining dating since early childhood. Four patients (19%) stated that prolapse followed a period of straining that ranged between 8 mo and 2 years. Nine patients (43%) in the present study came from the low social class, 10 patients (48%) came from the working class and 2 patients (9%) came from the low middle social class.

CONCLUSION

Schistosomiasis should not be considered the main cause of rectal prolapse among young Egyptian males. Childhood prolapse that continues through adult life is likely involved. Childhood prolapse probably results from malnutrition, recurrent parasitic infections and diarrhea that induce straining and prolapse, all are common in lower socioeconomic classes.

Key words: Rectal prolapse; Schistosomiasis; Young Egyptian males; Low socioeconomic status; Chronic straining

Core tip: Rectal prolapse in Western countries is mainly a disease of old women but in Egypt, the incidence of complete rectal prolapse was found to be highest among young males. Previous studies have attributed this to proctosigmoiditis caused by schistosomiasis, which is endemic in many rural areas of Egypt, and to which young males are more susceptible. In this study we disprove this assumption and shed light on other factors related to socioeconomic status that are more likely to be the cause of this disease distribution in the population.

Complete rectal prolapse in young Egyptian males: Is schistosomiasis really condemned? *World J Gastrointest Surg* 2016; 8(12): 779-783 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i12/779.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i12.779>

INTRODUCTION

Complete rectal prolapse is not uncommon. Unlike Western countries, the disease in Egypt predominantly affects young males. This has been attributed to intestinal schistosomiasis^[1-3], a parasitic endemic disease in Egypt that predominantly affects young males causing periportal hepatic fibrosis, portal hypertension, and proctosigmoiditis. The latter is associated with thickening, edema and inflammation of the bowel wall as well as rectal inflammatory polyps, fibrosis and strictures. It has been postulated that the heavy weight of the rectum caused by rectal wall edema and polyps, the chronic

dysentery and straining during defecation caused by rectal wall inflammation, and the pelvic floor myopathy caused by the general malnutrition that is frequently seen in schistosomiasis patients are the cause of complete rectal prolapse in this young Egyptian age group^[1-3]. Despite those plausible explanations, it is not clear why complete rectal prolapse in Egypt is so infrequent when compared to other diseases associated with schistosomiasis such as liver cell failure, ascites, splenomegaly and hematemesis^[4]. It is also not clear why other inflammatory and polypoidal diseases such as ulcerative colitis, Crohn's colitis and familial adenomatous polyposis are not known to be associated with complete rectal prolapse. Finally, it is not clear why the significant reduction in the incidence of schistosomiasis in Egypt that resulted from the aggressive national program for eradication of the disease was not reflected in a similar decrease in the incidence or change in the pattern of rectal prolapse in this country^[5,6]. The present study is trying to answer the question: Is schistosomiasis really condemned as a cause of complete rectal prolapse in young Egyptian males.

MATERIALS AND METHODS

Patient recruitment

This prospective study included all male patients with complete rectal prolapse in the age group 18-50 years ($n = 21$, median age 23 years, range 18-45 years) who were admitted for surgery for their disease to the Unit of Colorectal Surgery, Ain Shams University Hospitals, Cairo, Egypt in the period between January 2011 and April 2014. Female patients in the same age group ($n = 3$), patients younger than 18 years ($n = 2$) or older than 50 years ($n = 4$) were excluded from the study.

Assessment methods

All patients were requested to fill out a questionnaire about duration of the prolapse, different bowel symptoms and any past or present history of schistosomiasis. All patients had flexible sigmoidoscopy and four quadrant mid-rectal biopsies documenting any gross or microscopic rectal pathology. Patients were categorized according to their socioeconomic class (Table 1)^[7].

Ethical considerations

The nature and importance of the study were explained to all patients who were consented to participate in the study. The study was reviewed and approved by the IRB.

RESULTS

Twelve patients (57%) never contracted schistosomiasis and neither lived in a rural area nor worked in a job where they can come in contact with infested Nile water to contract the disease. Nine patients (43%) contracted the disease in the past and received timely proper treatment. None of the patients had gross polyps on sigmoidoscopy and none of the patients had evidence of

Table 1 Description of different socioeconomic classes

Class	Description
The lower class	Typified by poverty, homelessness, and unemployment Few individuals in this class finish their high school education
The working class	They suffer from lack of medical care, adequate housing and food, decent clothing, safety, and vocational training Minimally educated people who engage in "manual labor" with little or no prestige Unskilled workers in the class-dishwashers, cashiers, maids, and waitresses-usually are underpaid and have no opportunity for career advancement Skilled workers in this class-carpenters, plumbers, and electricians-may make more money than workers in the middle class, however, their jobs are usually more physically taxing, and in some cases quite dangerous
The middle class	Have more money than those below them on the "social ladder," but less than those above them The lower middle class is often made up of less educated people with lower incomes, such as managers, small business owners, teachers, and secretaries The upper middle class is often made up of highly educated business and professional people with high incomes, such as doctors, lawyers, stockbrokers, and CEOs
The upper class	The lower-upper class includes those with "new money," or money made from investments, business ventures, and so forth The upper-upper class includes those aristocratic and "high-society" families with "old money" who have been rich for generations. The upper-upper class is more prestigious than the lower-upper class Both segments of the upper class are exceptionally rich. They live in exclusive neighborhoods, gather at expensive social clubs, and send their children to the finest schools. As might be expected, they also exercise a great deal of influence and power both nationally and globally

CEOs: Chief executives.

Table 2 Distribution of gross appearance by sigmoidoscopy

Gross pathology	n (%)
Normal mucosa	10 (48)
Mucosal edema	8 (38)
Fine mucosal granularity + small superficial ulcers	3 (14)

Data are number of patients (and percentage of total).

Table 3 Distribution of histopathology of sigmoidoscopic biopsies

Histopathology	n (%)
Normal mucosa	8 (38)
Submucosal infiltration with chronic non-specific inflammatory cells	8 (38)
Features of solitary rectal ulcer	5 (24)

Data are number of patients (and percentage of total).

active schistosomiasis on histopathology. The detailed gross and histopathology results are shown in Tables 2 and 3.

Fifteen patients (71%) had early onset prolapse that started in early childhood (age < 5 years) in 11, or in late childhood or early teen ages (age between 5 and 15 years) in 4. The duration of prolapse in those patients ranged between 3 and 40 years (median duration 15 years). The median age of presentation in this group was 21 years (range 18-42 years). Six patients had late onset prolapse that started to appear in late teen ages or adulthood. The duration of prolapse in those patients ranged between 6 mo and 10 years (median duration 2 years). The median age of presentation was 34 years (range 21-41 years) (Figure 1).

Thirteen patients (62%) were habitual strainers (9 patients with long duration prolapse and 4 patients with short duration prolapse). Four patients (19%) reported straining since early childhood and four (19%) stated that prolapse followed a period of straining that ranged between 8 mo and 2 years. Two chronic strainers had stool incontinence after long period of straining; one of them was a habitual strainer since early childhood. Seven patients had recurrent prolapse when they first presented to our institution. Five of those patients were habitual strainers and all did not stop straining after their previous non-resection surgery. Three patients stated that the prolapse followed an anal operation (haemorrhoidectomy

in 2 patients and lateral sphincterotomy in one patient). Two of those patients were habitual strainers.

Nine patients (43%) in the present study came from the low social class, 10 patients (48%) came from the working class and 2 patients (9%) came from the low middle social class.

DISCUSSION

Complete rectal prolapse in Western countries occurs most commonly in elderly females, the disease being attributed to damage to the pudendal nerves during childbirth, prolonged straining at stool, and/or anatomical considerations such as a wider pelvis^[8]. The majority of complete rectal prolapse in Egypt occurs in young males. Previous studies from this country attributed this young male preponderance to intestinal schistosomiasis with its associated proctosigmoiditis, the disease being prevalent in 30% to 81% of prolapse patients in those studies^[1-3]. Unlike previous results, none of the patients in the present study had symptoms of active schistosomiasis at the time of presentation, none had gross polyps or dysentery and none had histologic evidence of schistosomiasis on rectal biopsies. Despite this, the majority of patients with rectal prolapse that we see in our institution are young males, implying that predisposing factors other than schistosomiasis must be

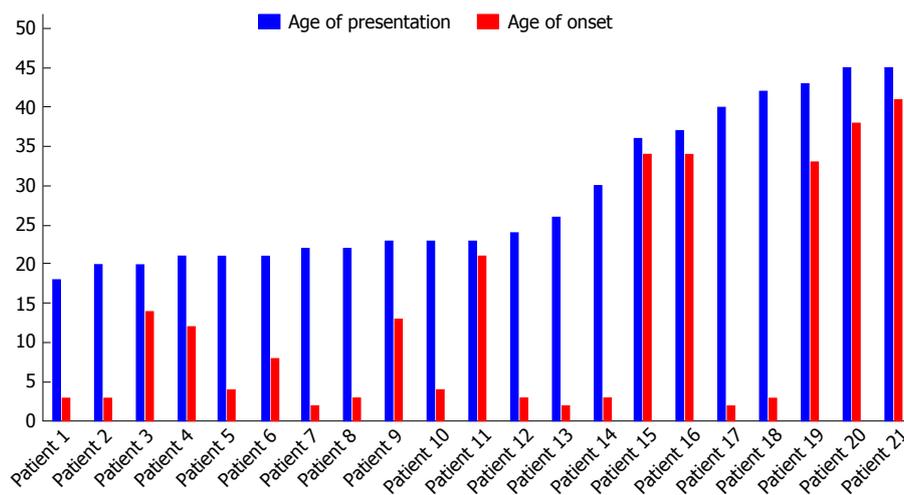

Figure 1 Age of presentation and age of onset of rectal prolapse in study subjects.

involved.

In the present study, 71% of patients had childhood or early teen age prolapse that continued through adulthood, 81% were chronic strainers at stools, and 19% started straining in their early childhood. It is therefore likely that early childhood prolapse that continues through adulthood together with chronic straining during defecation are important factors that predispose to occurrence of rectal prolapse in young Egyptian males.

Childhood rectal prolapse is uncommon in Western countries. The disease is seen more frequently in poor and developing countries where it is predisposed to by malnutrition and inadequate food hygiene^[9]. Malnutrition aggravates the natural laxity of the rectal pelvic supports that is present in infants and children, and inadequate food hygiene is associated with parasitic infections of the gastrointestinal tract and chronic diarrhea that induces excessive straining during defecation and rectal prolapse^[10]. Enterobiasis, Amoebiasis, Shigellosis, Giardiasis and infection with *Hymenolepis nana* are all common parasitic diseases that have been reported to cause diarrhea and complete rectal prolapse in children in developing countries^[11-13].

Even in developing countries, a group of countries in which Egypt is categorized, malnutrition and parasitic infections are diseases that mainly affect the lower socioeconomic classes^[14,15]. Population coming from lower socioeconomic classes suffer from poverty, unemployment, lack of high school education, lack of medical care and lack of adequate housing and food (Table 1). Ninety one percent of patients in the present study came from the low and working socioeconomic classes. Those patients are thus likely brought up in an environment in which they were malnourished and had recurrent infectious diarrhea that caused straining and complete rectal prolapse which continued to their adult life. Indeed, complete rectal prolapse is almost never seen in this age group in upper middle and high social classes in Egypt. The importance of malnutrition, diarrhea and straining in causing complete rectal prolapse in children was clearly demonstrated during the 1994 crisis in Rwanda when

a high incidence of full-thickness rectal prolapse was noted among the refugee children in the south-west of the country, the prolapses arose as a result of acute diarrheal illness superimposed on malnutrition and worm infestation^[16].

Other factors that might contribute to occurrence of complete rectal prolapse in the lower social classes are the lack of medical care for the children and the lack of high school education of the parents, the former indicates that infectious diarrhea that affects the children is unlikely to be properly treated and the latter can be reflected in bad potty training that has been shown in many studies to predispose to straining during defecation and complete rectal prolapse^[11,17].

Three patients in the present study had their prolapse after different anal operations. Probably the anal complaint in those patients was a result of straining and that they also had occult prolapse when they had their surgeries, the anal procedure just unveiled the occult prolapse. Indeed, two of those patients were chronic strainers.

Finally, we believe the high incidence of schistosomiasis in prolapse patients in previous studies from Egypt was a mere coincidence because those studies came from centers which drain rural northern delta regions where schistosomiasis is prevalent. Human infection with *Schistosoma* requires continuous contact with fresh Nile water where cercaria, a stage of *Schistosoma* life cycle, live and can infect man by penetrating his skin. This scenario essentially occurs in farmers living in rural Nile delta regions where they contact Nile water all the time during irrigation of their fields. The center in which the present study was performed is located in Cairo and it drains urban regions where schistosomiasis is non-existent. This can explain the low incidence of schistosomiasis in the present study.

Schistosomiasis should no longer be considered the main culprit for the unconventional distribution of rectal prolapse among young Egyptian males. Other factors related to socioeconomic status such as malnutrition, recurrent infectious diarrhea and bad toilet training result

in habitual straining and hence increase incidence of childhood prolapse, which when combined with neglect of treatment result in continuance of the problem through adult life. We believe this to be the cause of the currently observed distribution of complete rectal prolapse in the population.

COMMENTS

Background

In Egypt, there is an abnormal distribution of rectal prolapse among young men although in Western countries the disease is usually more common in old women. Previous literature from the area has attributed this to the spread of schistosomiasis in rural areas of Egypt which causes proctosigmoiditis and hence according to the literature - rectal prolapse.

Research frontiers

There were several findings that brought doubt to this assumption; eradication programs that caused great reduction in schistosomiasis infection, didn't similarly reduce the incidence of rectal prolapse and many of the patients with prolapse had no history of contracting schistosomiasis or even living in rural areas. This raised questions about the actual etiology for this distribution in Egypt.

Innovations and breakthroughs

Through analysis of history given by patients with rectal prolapse and assessment of possible risk factors, the authors found that socioeconomic status plays a great role in the epidemiological distribution of rectal prolapse among young males. Low socioeconomic status was associated with malnutrition, infectious diarrhea, bad toilet habits and neglect of proper treatment all of which contribute to the preponderance of rectal prolapse in this unusual subset of the population.

Applications

Identification of the actual factors causing rectal prolapse in young males is the first step in addressing the problem and directing efforts to improve conditions of lower social classes regarding sanitation, nutrition and proper treatment of various diarrheal illnesses. The authors have tried to shed some light on what the authors believe are the main causes of prolapse in young population and further studies are required in this area as proper management of etiological factors will reduce the incidence of the disease and its economic burden since young males are the main earners and source of income in many areas of Egypt.

Terminology

Authors believe there is no unusual terminology that requires further description.

Peer-review

Nice paper, well written. Very "small subject" but relevant and well analysed and discussed.

Abstract

AIM

To assess the current literature describing various minimally invasive techniques for and to review short-term outcomes after minimally invasive pancreaticoduodenectomy (PD).

METHODS

PD remains the only potentially curative treatment for periampullary malignancies, including, most commonly, pancreatic adenocarcinoma. Minimally invasive approaches to this complex operation have begun to be increasingly reported in the literature and are purported by some to reduce the historically high morbidity of PD associated with the open technique. In this systematic review, we have searched the literature for high-quality publications describing minimally invasive techniques for PD-including laparoscopic, robotic, and laparoscopic-assisted robotic approaches (hybrid approach). We have identified publications with the largest operative experiences from well-known centers of excellence for this complex procedure. We report primarily short term operative and perioperative results and some short term oncologic endpoints.

RESULTS

Minimally invasive techniques include laparoscopic, robotic and hybrid approaches and each of these techniques has strong advocates. Consistently, across all minimally invasive modalities, these techniques are associated less intraoperative blood loss than traditional open PD (OPD), but in exchange for longer operating times. These techniques are relatively equivalent in terms of perioperative morbidity and short term oncologic outcomes. Importantly, pancreatic fistula rate appears to be comparable in most minimally invasive series compared to open technique. Impact of minimally invasive technique on length of stay is mixed compared to some traditional open series. A few series have suggested

that initiation of and time to adjuvant therapy may be improved with minimally invasive techniques, however this assertion remains controversial. In terms of short-term costs, minimally invasive PD is significantly higher than that of OPD.

CONCLUSION

Minimally invasive approaches to PD show great promise as a strategy to improve short-term outcomes in patients undergoing PD, but the best results remain isolated to high-volume centers of excellence.

Key words: Pancreatic adenocarcinoma; Periampullary malignancy; Pancreaticoduodenectomy; Minimally invasive surgery; Whipple

Core tip: In this contemporary review, we systematically review current literature regarding minimally invasive techniques and outcomes for pancreaticoduodenectomy. This review will be highly educational to providers-surgical and nonsurgical alike-who care for patients with resectable periampullary malignancies.

INTRODUCTION

Pancreaticoduodenectomy (PD) remains the only potentially curative therapy for periampullary malignancies, including, most commonly, pancreatic adenocarcinoma. Despite advances in minimally invasive techniques over the last 2 decades, the vast majority of PDs are still performed with the standard open technique that has evolved from the original Whipple procedure described in 1935^[1]. Even with modern improvements in perioperative care, contemporary complication rates after open PD (OPD) range from 25% to 65%, and thus highlight the need for surgical innovation aimed at reducing perioperative morbidity^[2-9].

In general, minimally invasive techniques have been shown to provide shorter postoperative length of stay, decreased postoperative pain, fewer wound complications, and quicker return to daily activities. Despite this evidence for the benefit of minimally invasive surgery across a broad array of surgical procedures, minimally invasive approaches to PD have not been widely adopted and remain confined to large tertiary referral centers with highly experienced surgeons^[10,11]. PD is a highly complex operation with a steep learning curve. This complexity has led some to question whether the advantages of minimally invasive approaches, seen in other general surgical procedures, translate to PD. In this review, we evaluate

the published literature to date on contemporary approaches to minimally invasive PD-including laparoscopic, robotic, and hybrid approaches-in regards to perioperative morbidity and short-term outcomes.

MATERIALS AND METHODS

Appropriate articles were identified by manually searching through PubMed and Google Scholar databases between January 1st, 2005 to January 1st, 2015, using "laparoscopic" or "robotic" or "minimally invasive" AND "pancreaticoduodenectomy" or "Whipple". Subsequent full-text papers were screened, and only the most recent publications from individual groups were used. We only included manuscripts that distinguished among or singularly published data from laparoscopic, robotic or hybrid PDs. Similarly, we only focused on studies which included greater than 5 patients, in order to assure the surgeon's experience with the technique. We only included studies which distinguished among laparoscopic, robotic or robotic assisted laparoscopic PDs (RALPDs).

Study variables included: (1) minimally invasive technique (laparoscopic, robotic, or hybrid approach); (2) number of patients; (3) age range; (4) body mass index (BMI) range; (5) American Society of Anesthesiologist physical status classification^[12]; (6) estimated blood loss; (7) operative time; (8) length of stay; (9) pancreatic fistula rate; and (10) postoperative mortality. The data are represented as average \pm SD, unless otherwise indicated in the text or table.

Average American Society of Anesthesiologist physical status classification (ASA) is used as a surrogate for an independent evaluation of how well the patient presents prior to the procedure^[13]. The higher the score, the more complicated the patient, where ASA I is defined as a normal healthy patient, and ASA III is someone with severe systemic disease. Overall complication is defined, if available, as the number of patients with post-operative complications with a graded Clavien-Dindo classification (\geq grade I)^[14]. Postoperative mortality is defined as surgical-related deaths within 30 d of procedure.

Surgical techniques

This manuscript focuses on primarily three minimally invasive surgical techniques for PD. The first is laparoscopic PD (LPD), which uses laparoscopic instrumentation to dissect, extract, and reconstruct intestinal continuity^[15]. Robotic PD (RPD) uses a robotic system (da Vinci Surgical System) in lieu of handheld laparoscopic instruments (Intuitive Surgical, Inc., Sunnyvale, CA)^[16]. Finally, hybrid RALPDs uses both laparoscopic and robotic techniques for various steps in the PD, most commonly laparoscopic dissection and specimen extraction followed by robotic reconstruction^[17].

RESULTS

LPD

Since its introduction by Gagner *et al*^[18] in 1994, widespread adoption of LPD has been limited by a steep

learning curve confounded by modest case volumes seen in most centers. Despite these challenges, LPD has clearly been shown to be technically feasible and is purported to have tremendous potential in improving patient outcomes. Six LPD studies without robotic components were analyzed, two of which directly compare laparoscopic with open techniques^[16,19-23]. There were no distinct differences in the patient populations (Table 1).

In the two studies which compared LPD outcomes to matched open cases at the same institution, the authors reported advantages of LPD over OPD^[16,19]. Asbun *et al*^[19] noted that LPD had significantly less intraoperative blood loss ($P < 0.001$), reduced rate of transfusion ($P < 0.001$), length of hospital stay ($P < 0.001$), and length of intensive care unit stay ($P < 0.001$). Both Asbun *et al*^[19] and Zureikat *et al*^[16] noted that operative time was significantly higher for LPD, but there were no differences in overall complications, pancreatic fistula rate, or delayed gastric emptying.

There were no significant differences in oncologic outcomes in these two studies. Asbun *et al*^[19] found that LPD had higher number of lymph nodes retrieved ($P = 0.007$), more favorable lymph node ratio ($P < 0.001$), less estimated blood loss, transfusions, and length of stay for laparoscopic procedures, while Zureikat *et al*^[24] found no significant difference in R0 resection rate, lymph node harvest, and estimated blood loss, transfusions, and length of stay.

Of the four studies that examined only LPD, all found that LPD was safe and feasible^[18,21-23]. Kendrick *et al*^[22] reported that only 3 of the 65 patients enrolled in the study converted to OPD, and of the 62 patients who underwent LPD, 26 experienced post-operative morbidity, including pancreatic fistula ($n = 11$), delayed gastric emptying ($n = 9$), bleeding ($n = 5$), and deep vein thrombosis ($n = 2$). There was one postoperative mortality within 30-d of operation. Median operating time reported was 368 min (range 258-608) and median length of hospital stay was 7 d (range 4-69 d)^[22].

Dulucq *et al*^[21] reported three of the 25 patients enrolled in the study converted to OPD, and of the 22 patients who underwent unconverted LPD, seven patients experienced postoperative complications and one patient died of a cardiac event three days after an uncomplicated surgery. A mean of 18 ± 5 lymph nodes were retrieved for malignant lesions, and all resected margins were free. Only two patients with metastatic disease received adjuvant therapy. The mean hospital stay was 16.2 ± 2.7 d. Mean operating time was 287 ± 39 min^[21].

Palanivelu *et al*^[23] also reported 5-year survival rates for the 42 patients enrolled in the study. They found that after 5-years, 32% survival over all malignancies, 30.7% with ampullary adenocarcinoma, 33.3% for pancreatic cystadenocarcinoma, 19.1% for pancreatic head adenocarcinoma, and 50% for common bile duct adenocarcinoma. The study presented with similar perioperative statistics with 8 patients with comorbidities, including gastrojejunostomy obstruction, postoperative pancreatic fistula, postoperative bile leak, pulmonary complications, intraabdominal abscess, and deep vein thrombosis. Mean operating time was 370 min, with 13 mean lymph nodes harvested, and 65 mL mean of estimated blood loss^[23].

Pugliese *et al*^[20] found that of the 19 patients undergoing LPD, 6 patients required conversion to laparotomy, 3 for bleeding and 3 for difficulties in dissection. The study recorded no mortality, but noted that 3 of the converted PDs resulted in complications including bile leakage, hemorrhage, and pulmonary embolism. The mean operating time was 461 ± 90 min, and hospital stay of 18 ± 7 d. An average of 13 ± 4 (range 4-22) lymph nodes were harvested^[18].

RPD

Robotic technology has many of the advantages ascribed to laparoscopic surgery by virtue of using laparoscopic ports and minimal incision size and was first reported by Giulianotti *et al*^[25] in 2003. Robotic instrumentation

provides 3-dimensional visibility, increased degrees of freedom, and improved ergonomics though possibly less haptic advantage^[26,27]. Advocates of robotic surgery suggest that the advantages in robotics provide obvious benefits for complex procedures such as PD surgeries^[28]. However there is little comparative data available to support the routine use of robotics over laparoscopy for pancreatic resections (Table 2).

This review describes four robotics experiences, of which two incorporated comparison studies with OPD^[29-31]. Buchs *et al*^[29] found that despite the RPD group having statistically significant older (63 years old RPD vs 56 years old OPD; $P = 0.04$) and heavier patients (BMI 27.7 RPD vs 24.8 OPD; $P = 0.01$), with a higher American Society of Anesthesiologist score (RPD 2.5 vs OPD 2.15; $P = 0.01$), when compared to OPD group, there were no significant differences in complications, mortality rates, and length of hospital stays between the two groups^[29]. The study found that RPD surprisingly had shorter operative time (444 min vs 559 min; $P = 0.0001$), reduced blood loss (387 mL vs 827 mL; $P = 0.0001$), and higher number of lymph nodes harvested (16.8 vs 11; $P = 0.02$).

Similarly, Zhou *et al*^[30] found that RPD group had longer operative times than OPD (718 min RPD vs 420 min OPD; $P = 0.011$), but less intraoperative blood loss (153 mL RPD vs 210 mL OPD; $P = 0.04$), fewer complications (25% RPD vs 75% OPD, $P = 0.05$), and decreased hospital stay (27.5 h RPD vs 96 h, $P = 0.000$). There was no significant difference in R0 resection rate between the two groups.

Boggi *et al*^[28] reported for 34 patients undergoing RPD, the mean operating time was 597 min (range 420-960 min) and mean intraoperative blood loss was 220 mL (range 150-400 mL), with 4 patients requiring blood transfusions. Nineteen of the 34 patients in the study developed postoperative complications (utilizing the Clavien-Dindo classification), five of which had a classification of III or higher. The mean number of lymph nodes retrieved in the study was 32 (range 15-76). Thirty-day mortality was 0%^[28].

Chan *et al*^[31] reported 55 patients undergoing robotic hepatobiliary and pancreatic surgeries, of which eight were pancreaticoduodenectomies. Of the patients under-

going pancreatic resections, Chan *et al*^[31] found that the operating time had a median of 478 min, ranging from 270-692 min, with blood loss of 200 mL (range 30-300 mL). There were 4 complications resulting in pancreatic fistula and biliary fistula, but all were treated conservatively and healed without any significant sequelae. There was no mortality in the postoperative hospital stay of a median 12 d (range 6-21 d).

RALPD: Hybrid techniques (RALPD) include a combination of laparoscopic and robotic utilization for PD. We report five hybrid studies here, three of which are comparison studies to OPD^[32-36]. In all 3 comparison studies, RALPD demonstrated significantly lower intraoperative blood loss. In the first reported RALPD study, Chalikonda *et al*^[32] found that there was a significant increase in operative time (476.2 min RALPD vs 366.4 min OPD; $P = 0.005$), but decreased length of stay for RALPD (9.79 d RALPD vs 13.26 d OPD; $P = 0.043$)^[24]. The study found that there was no significant difference between the two techniques in postoperative morbidity (30% RALPD vs 44% OPD; $P = 0.14$), or reoperation (6% RALPD vs 24% OPD; $P = 0.17$). The study noted that there were 3 patients (12%) undergoing RALPD that were converted to OPD due to excessive bleeding (Table 3).

Similarly, Kuroki *et al*^[34] found decreased intraoperative blood loss with RALPD (376 mL RALPD vs 1509.5 mL OPD; $P < 0.01$), but there was also a significantly higher number of blood transfusions compared with OPD (0 blood transfusions in RALPD vs 13 in OPD; $P < 0.01$). The study found that there was no significant difference between the two techniques in operative time or postoperative complications.

Lai *et al*^[35] reported that RALPD had a significantly longer operative time (491.5 min RALPD vs 264.9 min; $P = 0.01$), decreased blood loss (247 mL RALPD vs 774.8 mL OPD; $P = 0.03$), and shorter hospital stay (13.7 d RALPD vs 25.8 d OPD; $P = 0.02$). Conversion rate from RALPD to OPD was 5%, and the study did not find a significant difference between the two groups in overall complication rates (50% RALPD vs 49.3%; $P = 0.95$), mortality rates (0% RALPD vs 3% OPD; $P = 0.43$), rate

of reoperation (2% or 10% RALPD vs 3% or 4.5% OPD; $P = 0.04$), R0 resection rate (11% or 73.3% RALPD vs 34% or 64.1% OPD; $P = 0.92$), and harvested lymph node numbers (10 ± 6 RALPD vs 10 ± 8 OPD; $P = 0.99$).

Of the 2 noncomparison studies, Giulianotti *et al*^[33] published the largest series of robotic pancreatic surgery to date with 134 patients, 60 of which were PD. This study reported similar outcomes to previous studies, including mean operative time with 331 min (range 75-660 min), mean length of hospital stay at 9.3 d (range 3-85 d), postoperative complication rate at 26%, and mortality rate of 2.23% (3 patients).

Zeh *et al*^[36] examined 50 patients undergoing RALPD, 8 of which required conversion to open procedure (16%). Overall, 28 patients (56%) experienced postoperative complications, 13 of which were Clavien I / II. Intraoperative blood loss had a median of 350 mL (interquartile range: 150-625), with 11 patients (22%) requiring transfusions. The median length of stay reported by the study was 10 d (IQR 8-13). The median number of lymph nodes collected was 18 (IQR 5) and Zeh *et al*^[36] report that 89% of the resections had negative margins.

Pancreatic fistula

Pancreatic leak at the pancreaticojejunostomy anastomosis is one of the most serious and common postoperative complications after PD, and can lead to erosion of adjacent tissues, bleeding from large vessels, severe pancreatitis, peritonitis, and sepsis. The complexity of this anastomosis has often been cited as the primary obstacle to widespread adoption of minimally invasive techniques for PD. Broadly, there did not appear to be significant differences in pancreatic fistula rates between minimally invasive and open techniques. Pancreatic leaks can be classified according to the International Study Group on Pancreatic Fistula criteria^[37]. In Asbun *et al*^[19], there were 29 (13.5%) pancreatic fistulas in the open group (Grade A = 14, B = 5, C = 10), and 7 (13.2%) in the laparoscopic group (Grade A = 3, B = 1, C = 3), with a nonsignificant P -value^[19]. Similarly, there is no significant difference in the pancreatic fistula rate between robotic

and open groups as demonstrated in Buchs *et al*^[29], where both open and robotic had 8 pancreatic fistulas at a rate 21% (Grade A = 5, B = 1, C = 2) and 18% (Grade A = 4, B = 3, C = 1) respectively, with a $P = 1$. The same could be seen between open and RAL groups, such as in Chalikonda *et al*^[32], where there were 5 (16.7%) in the open group (Grade B = 2, C = 5), and 2 (6.7%) in the RAL group (Grade B = 1, C = 1)^[32].

Cost analysis

In 2013, Mesleh *et al*^[38] published an analysis of a single institution analysis of the cost of LPD vs OPD. Using a similar dataset as Asbun *et al*^[19], Mesleh *et al*^[38] found that of 123 patients who underwent PD, with 48 OPD (39%) and 75 LPD (61%), there was no significant difference in overall cost of LPD compared to OPD, because of increased postoperative cost of OPD.

Consistent with other studies, Mesleh *et al*^[38] found that the intraoperative cost of LPD was significantly higher than that of OPD, due to increased equipment expense and mean operative time ($P < 0.0001$, OPD 355 min, range 199-681; LPD 551 min, range 390-819). Similarly, they determined that both OPD and LPD had similar rates of morbidity of 31% for both groups, with median hospital stay for OPD at 8 d (range 5-63), and 7 d (range 4-68) for LPD ($P = 0.5$). However in postoperative categories, OPD represented slightly higher cost per unit in anesthesia, critical care, pathology, pharmacy, nursing, and radiology. Because admission accounted for 65%-70% of the total cost, the increased postoperative cost of OPD balanced the excess intraoperative cost of LPD.

Similarly, Boggi *et al*^[28] reported a cost analysis of RPD compared to OPD, and found that RPD's intraoperative cost significant exceeds that of OPD by approximately 6193 euros, or \$5034.90 based on the currency exchange rate used in the study on 15 August 2012 (<http://www.x-rates.com/calculator.html>). In the United States, according to Chalikonda *et al*^[32], the cost of disposables of robotic and laparoscopic equipment can be as high as \$4000-5000 per case, plus the associated significant higher operative time.

Thus, in an era of limited health care dollars, cost

issues associated with minimally invasive techniques, especially robotic platforms, are important considerations as these techniques are adopted more broadly into less experienced centers.

With the emergence of newer technologies and improving minimally invasive techniques, it is important to understand the potential benefits of laparoscopic, robotic, and robotic assisted techniques. From this systematic review of the data presented, LPD, RPD, and RALPD in general appear to have less intraoperative blood loss than OPD, but in exchange for longer operating times. However, it is important to realize that all of these studies are subject to heavy selection bias, with the most difficult cases still typically being performed with open technique.

Most studies have failed to show any significant difference between the open and minimally invasive techniques in terms postoperative mortality and overall complications, though mortality may be higher with minimally invasive PD at less experienced centers^[39,40]. This issue is an extraordinarily important consideration for centers with lower surgeon volume and potentially less expertise with minimally invasive techniques. Regarding pancreatic fistula, there does not appear to be a significant difference between minimally invasive and open techniques. As the learning curve improves and technology improves, differences between techniques may begin to emerge. This issue has been most consistently touted by robotics advocates. Finally, minimally invasive techniques also appear to be equivalent in terms of short-term oncologic endpoints.

In the context of broader oncologic issues, Some studies suggest that more favorable short-term outcomes including decreased pain, quicker return to daily activities, and potentially fewer wound issues may favor increased utilization of and shorter time to adjuvant therapy^[41-44]. This issue too remains somewhat unproven but is an important consideration given the dismal outcomes with surgery alone for this disease^[23,45-47].

In summary, there remain many hurdles before the widespread use of laparoscopic and RPD take hold, the most significant of which is the steep learning curve associated with minimally invasive PD^[48,49]. Currently, minimally invasive PDs require extensive training and advanced equipment, and so are only performed by select surgeons for select patients at select tertiary centers^[50]. Robotic approaches may shorten the learning curve for minimally invasive PD but this has yet to be definitely proven^[51]. Even for OPD, the learning curve is steep, and a robust literature has shown tremendous variations in outcome for patients, depending on surgeon volume, hospital volume, and multidisciplinary collaboration. Thus, minimally invasive approaches to PD appear to be feasible and safe in the hands of highly experienced surgeons at centers of expertise, but widespread adoption remains a challenge given the steep learning curve, limitations of technology, and important cost considerations in an era of limited health care resources.

COMMENTS

Background

Pancreaticoduodenectomy (PD) remains the only potential curative therapy for periampullary malignancies, including, most commonly, pancreatic adenocarcinoma. Despite advances in minimally invasive techniques over the last 2 decades, the vast majority of PDs are still performed with a standard open technique (OPD) that has evolved from the original Whipple procedure described in 1935.

Research frontiers

Even with modern improvements in perioperative care, contemporary complication rates after OPD range from 25% to 65%, and thus highlight the need for surgical innovation aimed at reducing perioperative morbidity.

Innovations and breakthroughs

Despite a growing body of evidence supporting minimally invasive techniques to expedite post-operative recovery, decrease postoperative pain and reduce wound complications, minimally invasive approaches to PD have not been widely adopted and remain confined to large tertiary referral centers with highly experienced surgeons.

Applications

In general, minimally invasive techniques have been noted to provide shorter hospitalizations, fewer post-operative complications, and less time to adjuvant therapy. However, whether the advantages of minimally invasive approaches, seen in other general surgical oncologic procedures, translate to PD remains unclear. Here, the authors review current data regarding the applicability of minimally invasive approaches to PD.

Peer-review

This is an interesting and timely study.

Abstract

We report a case of severe, refractory gastrointestinal (GI) bleeding in a patient with hereditary hemorrhagic telangiectasia (HHT) whose massive transfusion dependence was lifted shortly after treatment with bevacizumab, an anti-vascular endothelial growth factor. The patient's bleeding had been refractory to repeated endoscopic interventions, tranexamic acid, and tamoxifen. However, following treatment with bevacizumab at 5 mg/kg every other week, nearly 300 units of packed red blood cell transfusions were avoided in one year's time. Despite its relatively high cost, bevacizumab may have a more active role in the management of severe GI bleeding in HHT if such remarkable response can be consistently demonstrated.

Core tip: Management of gastrointestinal (GI) bleeding in patients with hereditary hemorrhagic telangiectasia (HHT) can be challenging when the vascular lesions recur despite repeated endoscopic treatments. There is increasing evidence supporting the use of anti-angiogenesis agents in the management of bleeding in HHT patients. Bevacizumab, a monoclonal antibody against vascular endothelial growth factor, has been shown to reduce recurrent epistaxis. This case demonstrates the therapeutic potential of bevacizumab in patients with severe GI bleeding requiring massive transfusions.

bleeding in hereditary hemorrhagic telangiectasia. *World J Gastrointest Surg* 2016; 8(12): 792-795 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i12/792.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i12.792>

INTRODUCTION

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant condition characterized by vascular malformations that occur systemically, leading to manifestations such as recurrent epistaxis, gastrointestinal (GI) bleeding, and arteriovenous malformations (AVM) of the lung, liver, and brain. Since the discovery of elevated vascular endothelial growth factor (VEGF) expression in patients with HHT^[1], reports of bevacizumab, a monoclonal antibody against VEGF, in managing complications of HHT have emerged^[2-16], with most of the reported experience in recurrent epistaxis. We present a case of HHT with massive, refractory transfusion requirements secondary to severe GI bleeding that did not respond to conventional therapy, but subsequently achieved transfusion-independence with anti-VEGF mono-therapy.

CASE REPORT

A 58-year-old female with HHT and positive family history, involving her mother, sister, and daughter, presents with a 30-plus-year history of increasing transfusion dependency due to a combination of daily epistaxis, gastrointestinal bleeding, and intermittent gross hematuria. She did not have hemoptysis. Relevant medical history included hepatitis C infection secondary to transfusions, pulmonary hypertension from high-output cardiac failure secondary to chronic severe anemia, pulmonary AVMs with previous embolizations, and hysterectomy at the age of 26 for menorrhagia.

Her initial transfusion requirement was approximately one unit of packed red blood cells (pRBC) per month, but as of 2003 required > 40 units per year due to persistent epistaxis and increasing upper GI bleeding in the form of melena. Capsule endoscopies and upper endoscopies demonstrated innumerable AVMs in the esophagus, stomach, duodenum, and jejunum, with the bulk of the lesions located in the proximal small bowel where active bleeding was most frequently seen. Mesenteric angiography also demonstrated diffuse vascular abnormality/telangiectasia involving proximal small bowel but no focal AVM amenable to embolization. Biochemical investigations excluding other etiologies included normal renal function, thyroid stimulating hormone, haptoglobin, bilirubin, lactate dehydrogenase, direct agglutination testing, serum protein electrophoresis, serum free light chain, urine protein electrophoresis, and von Willebrand factor studies. Her hepatitis C viral load was low and abdominal ultrasound did not demonstrate cirrhosis.

Her transfusion requirement further escalated despite successful interventions including multiple septal

dermatoplasties and facial/nasal vessel angiography with embolization. At least seven upper endoscopies with argon plasma coagulation, two-month tamoxifen therapy, and tranexamic acid which led to upper extremity deep vein thrombosis, were used for ongoing bleeding from the duodenum/proximal jejunum. She received neither estrogen therapy nor thalidomide due to risk of hormone-sensitive malignancy and limited access/financial constraint, respectively. Additionally, her advanced cardiopulmonary comorbidities, which were complications of HHT, precluded surgical resection of the proximal small bowel (*i.e.*, Whipple procedure) containing the majority of the vascular lesions in order to reduce GI bleeding. Between 2008 and 2015, she received on average six units of pRBC weekly (*i.e.*, 312 unit per year) as well as monthly intravenous iron infusion.

In April 2015, she was started on bevacizumab, an anti-VEGF antibody, at 5 mg/kg every two weeks as a last resort. The patient's response to bevacizumab in terms of GI bleeding was immediate and dramatic: Her stools returned to normal color and consistency, and her transfusion requirement dropped to four units per month between May and September, and further down to only two units over the course of the following seven months with intravenous iron supplementation (Figure 1). She continued to experience minor epistaxis that was much less severe than previous, and ongoing microscopic hematuria without proteinuria or renal function impairment.

Over the past 12 mo, the administration of bevacizumab has resulted in a decrease of approximately 290 units of pRBC's and improved the patient's quality of life immensely. The patient has tolerated the infusions without any reported side-effects.

DISCUSSION

This case highlights the potential challenges in managing HHT with complicated, refractory GI bleeding. In our patient's case, she acquired hepatitis C infection due to repeated transfusions, and developed high-output cardiac failure and pulmonary hypertension due to severe chronic anemia. Her functional capacity was poor due to anemia and pulmonary hypertension, but the need for frequent transfusions three times a week (> 1400 units of pRBC in the five years prior to treatment) also posed a tremendous negative impact on her quality of life in addition to causing a significant burden on the health care system. Fortunately, the patient's response to bevacizumab exceeded our expectations. The greatest hurdle of obtaining the drug was in fact, obtaining approval from regulatory bodies for financial coverage of it. However, after one year, the overall cost to the health care system of avoiding most transfusions is staggering. Given the severity of her blood loss, which to our knowledge is one of the most severe cases reported, our initial goal had been to reduce her transfusion requirement by 40%-50%, but she essentially became transfusion-independent.

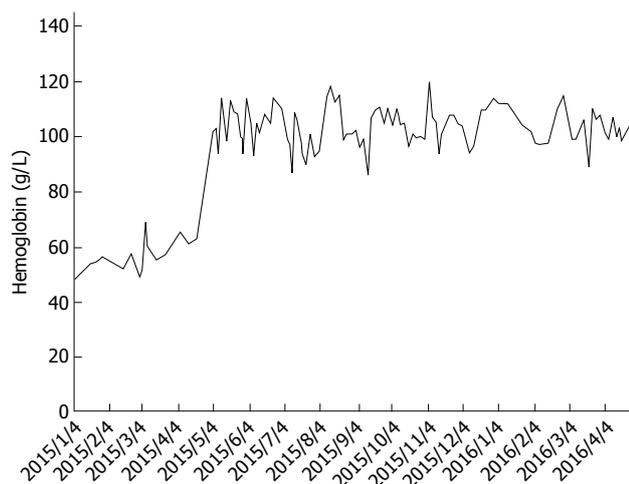

Figure 1 Hemoglobin trend. Hemoglobin trend before and after initiation of bevacizumab 5 mg/kg every other week starting in April 2015.

We opted to prescribe 5 mg/kg every other week, which is the typical dose for solid organ malignancies, since this is the regimen with the most clinical evidence to date for HHT^[17]. The optimal dosage and duration of bevacizumab for GI bleeding in HHT remains to be determined, and requires balancing the clinical benefits against potential adverse events of systemic treatment such as hypertension, nephrotic syndrome, poor wound healing, bowel perforation, and thromboembolic events^[18]. There have been reports successfully utilizing lower doses for GI bleeding, based on the drug's pharmacokinetics^[4,5,7,15], but some patients may require higher doses to maintain optimal response^[10]. Although the specific optimal dosage is not entirely clear at this time, the duration of treatment is likely indefinite as relapses upon discontinuation of therapy have been noted in previous reports, with the interval ranging from one to three months after the last dose^[4,7,8,15].

This case demonstrates a remarkable response in regards to GI bleeding to bevacizumab in the setting of HHT. Although not specifically examined yet in our patient, additional benefits such as partial reversal of liver failure and high-output cardiac failure have also been reported^[19-21]. Despite its high cost, earlier administration should be considered if benefit of this extent is regularly demonstrated in this group of patients as prevention of end organ complications (*i.e.*, cardiac/hepatic) theoretically might have been prevented with early administration. The issue of cost in many situations perhaps should not be paramount when aiming for ideal care in these patients with limited options.

Bevacizumab effectively controlled severe GI bleeding in this patient with complicated HHT.

COMMENTS

Case characteristics

A 58-year-old woman with hereditary hemorrhagic telangiectasia (HHT) presented with severe, chronic gastrointestinal (GI) bleeding refractory to multiple treatment modalities.

Clinical diagnosis

Endoscopies demonstrated numerous arteriovenous malformations in the esophagus, stomach, duodenum, and jejunum. The majority of the lesions were located in the proximal small bowel where active bleeding was frequently seen.

Differential diagnosis

Vascular lesions of GI tract: Angiodysplasia (sporadic, end-stage renal disease, aortic stenosis, von Willebrand disease, left ventricular assist device), systemic disease (CREST, HHT).

Laboratory diagnosis

Biochemical investigations included normal renal function, thyroid stimulating hormone, haptoglobin, bilirubin, lactate dehydrogenase, direct agglutination testing, serum protein electrophoresis, serum free light chain, urine protein electrophoresis, and von Willebrand factor studies. Pre-bevacizumab mean hemoglobin was 57.2 ± 5.8 g/dL. Post-bevacizumab hemoglobin was 103.4 ± 8.3 g/dL.

Imaging diagnosis

Mesenteric angiography did not identify suitable arteriovenous malformation that was amenable to treatment via embolization of the gastroduodenal artery.

Treatment

Bevacizumab 5 mg/kg infusion every other week.

Related reports

There is growing evidence in the literature on bevacizumab's efficacy in treating recurrent epistaxis due to HHT, but relatively few reports exist for the management of severe, chronic, refractory GI bleeding. This case highlights the potential utility of bevacizumab for such management.

Term explanation

HHT is an autosomal dominant condition characterized by vascular malformations that can occur anywhere in the body, leading to various presentations including epistaxis, GI bleeding, high-output cardiac failure, and hypoxemia.

Experiences and lessons

Earlier administration of bevacizumab should be considered in patients with severe, refractory GI bleeding despite its relatively high cost given the potential benefit.

Peer-review

This is a pretty straightforward case report.
