ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Dr. Simon Bramhall, FRCS (Gen Surg), MD, Consultant Upper GI/HPB Surgeon, the County Hospital, Hereford, Union Walk, Hereford HR1 2ER, United Kingdom

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

In the last two decades, hemorrhoidal dearterialization has become universally accepted as a treatment option for symptomatic hemorrhoids. The rationale for this procedure is based on the assumption that arterial blood overflow is mainly responsible for dilatation of the hemorrhoidal plexus due to the absence of capillary

interposition between the arterial and venous systems within the anal canal. Dearterialization, with either suture ligation (Doppler-guided hemorrhoid artery ligation/transanal hemorrhoidal dearterialization) or laser (hemorrhoidal laser procedure), may be successfully performed alone or with mucopexy. Although the added value of Doppler-guidance in association with dearterialization has recently been challenged, this imaging method still plays an important role in localizing hemorrhoidal arteries and, therefore, minimizing the effect of anatomic variation among patients. However, it is important to employ the correct Doppler transducer. Some Doppler transducers may not easily detect superficial arteries due to inadequate frequency settings. All techniques of dearterialization have the advantage of preserving the anatomy and physiology of the anal canal, when compared to other surgical treatments for hemorrhoids. This advantage cannot be underestimated as impaired anal function, including fecal incontinence and other defecation disorders, may occur following surgical treatment for hemorrhoids. Furthermore, this potentially devastating problem can occur in patients of all ages, including younger patients.

Key words: Dearterialization; Laser dearterialization; Hemorrhoids; Mucopexy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This editorial analyzes the techniques of dearterialization for hemorrhoids. The advantages and pitfalls of the various techniques of dearterialization are reported, with specific attention given to the role of Doppler ultrasound and technical tips on the various procedures. Finally, the author reports the efficacy of dearterialization based on data in the literature as well as personal experience in this field.

Giamundo P. Advantages and limits of hemorrhoidal dearterialization in the treatment of symptomatic hemorrhoids. *World J*

INTRODUCTION

The surgical treatment of hemorrhoids has evolved over the last three decades. Significant postoperative pain as well as changes to the anatomy of the anal canal leading to impaired defecation has led surgeons to adopt new procedures that are less invasive than traditional surgical hemorrhoidal excision.

A variety of surgical procedures are currently available for the treatment of hemorrhoids, however no single technique has been universally accepted as superior. Theoretically, surgical procedures should be tailored to individual patients. In reality, the choice of the surgical technique is often based upon the surgeon's preference or the availability of specialized equipment.

Hemorrhoidal disease has a multifactorial etiology and theories on its actual pathogenesis are still being debated. Symptoms related to hemorrhoidal disease may vary substantially among patients. An accurate preoperative evaluation is therefore mandatory and extremely useful in selecting the most appropriate surgical approach. Rectal mucosal prolapse is one among many potential anatomical alterations related to hemorrhoidal disease that impairs a patient's quality of life. In addition, bleeding, pruritus, pain, soiling, and recurrent thrombosis of piles cannot be underestimated.

The Goligher classification^[1] is commonly used to grade the severity of hemorrhoids and, consequently, indicates the modality of surgical treatment. However, the grade of prolapse and hemorrhoidal symptoms are often poorly correlated^[2]. Tolerance to hemorrhoidal symptoms varies among patients. Therefore the surgeon should be prepared to consider not only the anatomical aspects of the anal canal but also the patient's characteristics and symptoms. In particular, successful treatment should focus on the cure of symptoms affecting the patient's quality of life. In this regard, studies related to surgical treatment of hemorrhoids should include a thorough evaluation of the patient's quality of life as it represents one crucial aspect of successful therapy.

With this in mind, the current trend is to give preference to less invasive procedures with the aim of minimizing postoperative pain, providing relief of symptoms, and reducing the risk of anatomical alterations and dysfunction of the anal canal.

In the last two decades, hemorrhoidal artery ligation (HAL) has become universally accepted for the treatment of hemorrhoids. The rationale for this procedure is based on the assumption that arterial blood overflow is mainly responsible for dilatation of the hemorrhoidal plexus due to the absence of capillary interposition between the arterial and venous systems within the anal canal. This has been clearly demonstrated in anatomical studies^[3,4].

Both the mean caliber and blood flow of the arterial branches of the superior rectal artery (SRA) were found to be significantly higher in patients with hemorrhoids than in a control group^[5]. Closure of the terminal branches of the SRA is therefore expected to shrink the hemorrhoidal piles and alleviate symptoms, and even possibly reduce hemorrhoidal prolapse. Closure of the terminal branches of the SRA can also be performed in combination with plication of the prolapsing mucosa in cases of large and symptomatic prolapse [transanal hemorrhoidal dearterialization (THD) + mucopexy].

A systematic review of 17 case series that included 1996 patients reported satisfactory overall results in grade II and III hemorrhoids with mean recurrence rates of 11% for prolapse, 9% for pain at defecation, and 10% for bleeding at an average of 1-year follow-up after Doppler-guided hemorrhoidal dearterialization^[6]. In another recent review^[7], 2904 patients from 28 studies were included in the final analyses. Overall recurrence rates varied among studies with a pooled rate of 17.5% and an overall reintervention rate of 6.4%. In both of these systematic reviews, it was concluded that Doppler-guided hemorrhoidal dearterialization can be safely considered for primary treatment of grade II and III hemorrhoids. Grade IV hemorrhoids, however, had the highest recurrence rate at long-term follow-up. It is interesting to note that not all patients included in these reviews underwent a mucopexy in addition to dearterialization.

A recent multicenter trial including 803 patients who underwent Doppler-guided THD reported an overall success rate of 90.7% after a mean follow-up of 11.1 + 9.2 mo. These authors also reported a recurrence of hemorrhoidal prolapse, bleeding, or both in 6.3%, 2.4% and 0.6% of patients, respectively^[8].

The advantage of HAL/THD when compared to excisional methods is the absence of anal wounds, which significantly reduces the patient's postoperative pain and discomfort. In addition, preservation of the anal anatomy and physiology cannot be underestimated^[9]. In this regard, it must be stressed that one of the primary causes of fecal incontinence is anorectal surgery^[10].

The anticipated reduction of postoperative pain and alleviation of symptoms makes these procedures the most favored by patients. Early and mid-term results have shown high success and patient satisfaction rates^[11]. When compared to other non-excisional procedures for hemorrhoids such as stapled hemorrhoidopexy (PPH), dearterialization may have the added advantage of reducing the incidence of serious or life-threatening complications^[12]. Despite these advantages, long-term results may be associated with higher recurrence rates compared to conventional hemorrhoidectomy^[13]. In addition to the advantages of shorter-term decreased pain and quicker return to daily activities, patients should be informed of this potential eventuality, especially in case of 4th degree hemorrhoids.

Recent studies have called into question the true value of Doppler-assisted localization of the terminal

branches of the SRA in the HAL/THD procedures^[14]. According to this theory, the efficacy of artery ligation in all six of the odd-numbered clock positions around the anus (1, 3, 5, 7, 9 and 11 o'clock in the lithotomy position) followed by mucopexy would be equal to the same operation performed with Doppler-assistance. This would then suggest that there is no real need for the costly Doppler instruments. Conversely, it has been demonstrated that one-third of the population has at least one artery in an even-numbered clock position, and for this reason Doppler-assisted localization is important in correctly locating the arteries^[15].

Some studies have shown good overall success rates when hemorrhoidopexy is performed without dearterialization^[16]. Skepticism over the true value of dearterialization might therefore be justified. However, hemorrhoidopexy, beyond the treatment of mucosal prolapse, can most likely be considered an empiric form of de-arterialization, although the closure of underlying arteries cannot be proven by Doppler ultrasound. In fact, the running sutures placed on the redundant mucosa may include the underlying arteries. In this regard, there are some important issues regarding the anatomy of the anal canal and the type of Doppler device used for HAL/THD that need to be addressed.

Aigner *et al*^[3] and Schuurman *et al*^[4] have described in detail the vascular pattern of the anal canal. At approximately 2-3 cm above the dentate line, the terminal branches of the superior rectal arteries become superficial (2 mm deep) and thin (0.6-2 mm). These terminal branches may be directly responsible for blood overflow into the hemorrhoidal piles due to the lack of capillary interposition between the arterial system and the hemorrhoidal plexus. However, the Doppler transducers used by the majority of DGHAL and THD equipment operate at 7-8 MHz. At these frequency settings, Doppler probes can only detect deep arteries that may not directly contribute to the hemorrhoidal pile overflow.

In addition, in commonly used equipment, suture ligation is placed approximately 1 cm above the point where the arterial pulse is located by Doppler ultrasound, which may not succeed in closing the artery.

In this regard, dearterialization with laser [hemorrhoidal laser procedure (HeLP)] seems to be more precise and effective^[17]. This procedure uses a 20 MHz Doppler-transducer, which is more accurate in detecting superficial arteries at approximately 2 cm above the dentate line. In addition, diode laser energy delivered at 980 nm of wavelength causes shrinkage of the mucosa and submucosa to a depth of 4 mm, which can easily include the underlying superficial arteries. The efficacy of arterial shrinkage is in fact improved by the selective action of laser energy on hemoglobin at that specific wavelength. Furthermore, in the HeLP procedure, the laser fiber is placed in contact with the mucosa exactly at the same point where the Doppler signal locates the artery. By doing so, the risk of missing the artery is minimized.

Laser treatment may also have the added advantage of closing a larger number of arteries (12 instead of 6) and being less invasive than artery ligation, therefore requiring neither anesthesia nor sedation^[18]. However, one pitfall associated with this procedure is the low success rate of curing severe mucosal prolapse. In fact, the standard HeLP procedure does not address the issue of prolapsed mucosa. Nevertheless, in cases of concomitant severe and symptomatic prolapse, a mucopexy can easily be incorporated into the same procedure, following the laser treatment (HeLP + rectoanal repair)^[19].

The number of arteries closed as well as the level at which the arteries are located might also play a significant role in the clinical success of techniques that employ dearterialization. In order to optimize the results of THD, Ratto *et al*^[20] modified their technique of dearterialization by performing a "distal" ligation, rather than the original technique of closing the arteries approximately 4-5 cm above the dentate line, located by Doppler signal.

The terminal branches of the SRA multiply and become more superficial as they get closer to the dentate line. This explains the fact that 20 MHz Doppler probes, as seen in the HeLP procedure^[16], can easily identify and locate at least 12 arteries, compared to only 6 as has been previously described in other procedures employing different Doppler probes.

IN SUMMARY

The techniques of dearterialization for symptomatic hemorrhoids seem to have maintained the encouraging early results, despite a progressive increase in long-term recurrence rates that have been reported in some studies, especially for grade III and IV hemorrhoids. The rationale for this procedure seems to be valid, as demonstrated not only by anatomical studies but also by clinically successful results reported in numerous series in the literature, even when no additional mucopexy is performed.

Dearterialization, either with suture ligation (DGHAL/THD) or laser (HeLP), may be successfully performed alone or in association with mucopexy, when necessary.

Mucopexy improves resolution of short- and long-term symptoms when significant prolapse altering the patient's quality of life is present in grade III hemorrhoids. Dearterialization plus mucopexy should be indicated only in very selected cases of grade IV hemorrhoids. Mucopexy alone can be performed when prolapse is the only symptom, but this procedure may fail to control bleeding and recurrent acute symptoms in the long-term.

Although the added value of Doppler-guidance in association with dearterialization has recently been challenged, this imaging method still plays an important role in localizing hemorrhoidal arteries, and minimizing the effect of anatomic variation among patients.

Some Doppler transducers may not easily detect

superficial arteries due to inadequate frequency settings (7-8 MHz). In HAL/THD procedures, dearterialization may be empirically effective in that the arteries may be successfully closed because the width of the suture ligation would close a larger quantity of tissue, thus incorporating the underlying arteries regardless of Doppler-guidance. Unfortunately, these results may not be easily reproducible.

Finally, all techniques of dearterialization have the advantage of preserving the anatomy and physiology of the anal canal, when compared to other surgical treatments for hemorrhoids. This advantage cannot be underestimated as impaired anal function, including fecal incontinence and other defecation disorders, may occur following surgical treatment for hemorrhoids. Furthermore, this potentially devastating problem can occur in patients of all ages, including younger patients.

Abstract

Laparoscopic liver resection (LLR) has been progressively developed along the past two decades. Despite initial skepticism, improved operative results made laparoscopic approach incorporated to surgical practice and operations increased in frequency and complexity. Evidence supporting LLR comes from case-series, comparative studies and meta-analysis. Despite lack of level 1 evidence, the body of literature is stronger and existing data confirms the safety, feasibility and benefits of laparoscopic approach when compared to open resection. Indications for LLR do not differ from those for open surgery. They include benign and malignant (both primary and metastatic) tumors and living donor liver harvesting. Currently, resection of lesions located on anterolateral segments and left lateral sectionectomy are performed systematically by laparoscopy in hepatobiliary specialized centers. Resection of lesions located on posterosuperior segments (1, 4a, 7, 8) and major liver resections were shown to be feasible but remain technically demanding procedures, which should be reserved to experienced surgeons. Hand-assisted and laparoscopy-assisted procedures appeared to increase the indications of minimally invasive liver surgery and are useful strategies applied to difficult and major resections. LLR proved to be safe for malignant lesions and offers some short-term advantages over open resection. Oncological results including resection margin status and long-term survival were not inferior to open resection. At present, surgical community expects high quality studies to base the already perceived better outcomes achieved by laparoscopy in major centers' practice. Continuous surgical training, as well as new technologies should augment the application of lap-

aroscopic liver surgery. Future applicability of new technologies such as robot assistance and image-guided surgery is still under investigation.

Core tip: Liver surgery was one of the last frontiers reached by minimally invasive surgery. Surgical technique and specialized equipment evolved to overcome technical limitations, making laparoscopic liver resections (LLR) safe and feasible. Surgeons developed skills in a stepwise approach, beginning with low complexity operations for benign diseases and reaching high-complexity surgeries for malignant cases and living donor organ harvesting. Despite a cautious slow start laparoscopic liver surgery has been incorporated to practice. On the following pages the successful history of LLR is depicted, along with an updated panel of its current role and expected achievements.

INTRODUCTION

In the last two decades, minimally invasive liver surgery (MILS) underwent a major evolution. Willing to explore the possibility of laparoscopic liver resection (LLR), specialized centers with solid background on hepatic and laparoscopic surgery took the first steps^[1,2].

Initial development of MILS was slow, withheld by three main barriers. The first limit to overcome was technical, hence the translation of conventional techniques to the laparoscopic approach was needed. For instance, organ mobilization, manual palpation, vascular dissection, vascular control and parenchymal transection were steps universally applied to open liver resection (OLR) that had to be adapted to laparoscopy. The second barrier consisted of anticipated intraoperative hazards, such as massive bleeding and the theoretical increased risk of gas embolism secondary to pneumoperitoneum. The third step toward acceptance of LLR concerned about oncological outcomes such as adequate margins, port site seeding and long-term survival^[1,3-5].

The first wedge resection was reported by Reich *et al*^[6] (1991). Since then, improvements in surgical techniques associated with technological advances significantly expanded the complexity and safety of

MILS. The first laparoscopic anatomic hepatectomy was reported in 1996 simultaneously by Azagra *et al*^[7] and Kaneko *et al*^[8]. The first laparoscopic major hepatectomy in 1997 by Hüscher *et al*^[9]. In 2000, Cherqui *et al*^[11] and Descottes *et al*^[12] published the first structured case-series with results favoring laparoscopic liver operations. Many other small single center or multicenter case series emerged on the following years, with promising good results^[10-12].

By the year 2007 Koffron *et al*^[13] published the first major series showing operative results on 300 consecutive patients. On the following year a landmark meeting produced the Louisville Statement^[14], the first expert consensus conference on laparoscopic liver surgery. In 2009 a comprehensive review on published series accounted that 2804 LLR had been performed worldwide^[15]. Of note, previous publications reported mainly on resected benign lesions and this review showed, for the first time, a predominance of malignant cases.

The years 2010 witnessed many reports on safety and feasibility of laparoscopic operations^[16-18] including complex procedures such as major hepatectomies and graft harvesting for living donor liver transplantation (LDLT)^[19,20]. Clinically significant events of carbon dioxide (CO₂) embolism were extremely rare^[21,22] and no port seeding or peritoneal implant could be attributed to laparoscopy, dismissing many of the initial worries on LLR^[23,24].

Evidence supporting MILS comes from case-series, comparative studies and meta-analyses. Only recently, a prospective randomized study was published comparing the results of LLR with the OLR^[25]. There are prospective studies in course and their results are expected to provide the best scientific evidence to the already perceived superiority of MILS^[26,27]. Despite the lack of evidence level 1, existing data confirms the safety, feasibility and benefits of MILS. Also, many comparative series indicated the role of laparoscopy in disease specific settings, such as benign diseases^[12,17,25,28-33], hepatocellular carcinoma (HCC)^[34-49] and colorectal liver metastases (CRLM)^[50-58]. Recently, the 2nd International Consensus Conference (2nd ICC) on LLR in Japan demonstrated the progress and dissemination of the method worldwide^[59].

TERMINOLOGY AND DEFINITIONS

Extent and complexity of resection

LLR should be classified according to the complexity of the operation and the technique of minimally invasive access^[14]. Referring to complexity categories, laparoscopic operations might consist of: (1) small wedge resections; (2) resections of the left lateral section (segments 2 and 3) or anterior segments (segments 4b, 5 and 6); and (3) hemihepatectomies, trisectionectomies and resections of the difficult postero-superior segments (segments 1, 4a, 7 and 8). The first two categories are classified as "minor resections". The Louisville

Table 1 Laparoscopic liver resection learning curve key points

Knowledge of caudal view anatomy
Training in cadaveric and/or animal model
Clinical training should follow an increasing order of procedure difficulty (Difficult Scoring System for LLR ^[78] can be used to point difficulty levels)
Minor anterolateral resections
Minor anatomical resections (start with LLS)
Difficult resections
Major resections
Graft harvesting for LDLT
HALS and hybrid resections can be used in the early experience to overcome the learning curve

LLR: Laparoscopic liver resection; LLS: Left lateral sectionectomy; LDLT: Living donor liver transplantation; HALS: Hand-assisted liver surgery.

Statement^[14] defined the third group of operations as “major hepatectomies”, unlike the classical concept of open surgery, in which major resections are defined as operations resecting 3 or more contiguous liver segments^[60]. Subsequently, other authors have shown that resection of lesions located in the posterior and superior segments require greater technical proficiency and have higher complication rates than anterolateral resections. These operative results justify the “upgrade” of difficult resections to major resections due to their technical complexity^[61,62]. In a recent study, Di Fabio *et al.*^[62] evaluated the outcomes of the “traditional” major hepatectomies (hemi-hepatectomy, trisectionectomies) compared to laparoscopic “postero-superior” resections and concluded that the creation of two subcategories of laparoscopic major hepatectomy seems appropriate to reflect differences in intraoperative and postoperative outcomes between those two sets of patients. In the 2nd ICC the classical definition was used (minor resection: ≤ 2 segments, major resections > 2 segments)^[59]. In this review, we employ the term “major resection” for hemi-hepatectomies and trisectionectomies and the term “difficult resections” for resections of the postero-superior segments (segments 1, 4a, 7 and 8).

Types and techniques of LLR

LLR can be categorized in three different approaches^[14]: (1) Pure LLR (PLLR): the entire resection is performed through laparoscopic ports and an auxiliary incision is used only for specimen extraction; (2) Hand-assisted laparoscopy surgery (HALS): The operation is carried out with elective placement of an auxiliary hand-port, which also aids specimen extraction. If a pure laparoscopic procedure demands the insertion of a hand-port in order to overcome difficulties and to complete the procedure, this should be considered a “conversion from pure laparoscopy to hand-assisted hepatectomy”. The third type of minimally invasive liver resection is (3) Hybrid hepatectomy (also termed laparoscopy-assisted hepatectomy): The operation begins with laparoscopic liver mobilization (with or without hand-assistance), followed by an elective mini-laparotomy for a conventional approach to vascular pedicles (if

necessary) and parenchymal transection.

Along the development of MILS the pure laparoscopic approach was the overall preferred method, especially in European centers^[63-66]. The hybrid and hand-assisted methods are adopted more liberally to perform complex resections in United States and Japan, although there is a trending shift towards PLLR in Japan^[67-70].

LEARNING CURVE

To overcome the difficulties associated with minimally invasive hepatic resections the training of surgeons is essential in order to safely spread the benefits of laparoscopic liver surgery^[71-73].

A consensual observation in many papers on LLR is that laparoscopic hepatectomies should be performed by surgeons with extensive training in hepatobiliary and advanced laparoscopic surgery^[14,74]. Thence, fellowships in specialized centers should offer high-level training in order to accomplish competence in both domains. The key points related to the training with LLR are summarized in Table 1.

A major change in MILS is the way surgeons approach the liver, as the classic open frontal view is modified. In laparoscopy, due to the insertion of the optical equipment in or near the umbilicus, a caudal approach is forcefully undertaken. In the caudal view the surgeon sees the well-known anatomy from a different perspective^[64]. Basic technical skills acquisition can occur through practicing in cadaveric or animal model^[75] and further clinical training should follow an increasing order of procedure difficulty^[14,73,76]. Case selection is essential in early clinical experience; first cases should involve lesions prone to small wedge resections located on the anterolateral segments (segments 2, 3, 4b, 5 and 6). Anatomic resections can be started with left lateral sectionectomy (LLS), which is a patterned straightforward segmental resection that requires liver mobilization, pedicle treatment and parenchymal transection^[33,71,76,77]. It is safer to move on to complex resections after the surgeon has acquired proficiency in minor resections (Table 1)^[73].

In order to better understand the difficulty associated with each kind of operation, a recent paper proposed a scoring index for LLR^[78]. This scoring system incorporates factors such as tumor size and location; proximity to major vessels; liver function and extent of liver resection. Resections are graded from 1 to 10, being score 1 for peripheral wedge resection; 4 for LLS; 7 for hemihepatectomy and 10 stands for extremely difficult resections. This interesting index offers a numeric score of progressive difficulty that can help learners to evaluate their progress. This scoring system can be used as a guide in training and progressive skill acquisition.

Learning curve analysis is somewhat a preoccupation linked to laparoscopic operations. When a laparoscopic operation is proposed, it is usually compared with its conventional counterpart in order to assess results

and to establish the number of operations required for technical competence. To our knowledge there is no data on open hepatectomy learning curve, and Rau *et al.*^[79] published the first mention of a LLR learning curve in 1998. Cherqui's group published a seminal paper on the subject and their analysis revealed that 60 cases were needed in order to achieve optimal results^[72]. Of notice, the use and duration of Pringle maneuver, and use of HALS decreased over time. This indicates that pedicle clamping and HALS play an important role during the learning curve. Likewise, hybrid resections can also be used in the early experience to overcome the learning curve^[13,70,80].

Other series have indicated a smaller number in order to obtain expertise. A recent Chinese paper observed a variable number on cases needed to achieve competence, according to the complexity of the operation. Their caseload ranged between 15 to 43 operations^[81].

Other authors have made some interesting conjoined analysis, looking beyond the numbers, also considering the effect of expert training. Hasegawa *et al.*^[58] made an analysis on their experience with 24 cases of LLS divided in 3 eras; initially a senior surgeon performed the first 8 operations with no technical standardization. In the second era a senior surgeon operated on 8 cases with a standardized technique. The third group of 8 patients underwent operations performed by junior surgeons under senior guidance. Comparative analysis showed better results of the second and third eras in comparison to the first period and, most important, results did not differ between the second and third periods.

Other authors studied the learning curve for complex and major hepatic resections^[73,82]. Nomi *et al.*^[83] studied 173 patients that underwent major LLR in a high-volume center using the cumulative sum method. The learning curve identified three phases: Phase 1 (45 initial patients), phase 2 (30 intermediate patients) and phase 3 (the subsequent 98 patients). These data suggests that the learning phase of major LLR included 45 to 75 patients^[83].

INDICATIONS AND LIMITATIONS OF LLR

Laparoscopic access offers some benefits over conventional operations^[66,84]. The magnified view of the operating field allows meticulous haemostasis. During parenchymal transection, most of the blood loss derives from the hepatic veins and laparoscopy offers the possibility of parenchymal transection under positive pressure, resulting in less bleeding. However, minimally invasive liver operations has some drawbacks, such as lack of tactile feedback, restricted manoeuvres and difficult visualization of the posterior and superior segments of the liver^[85].

Nowadays, LLR is utilized in a small percentage of liver resections (5%-30%) in most centers, although some very skillful surgeons have reported higher rates, reaching from 50% to 80%^[59,64,86]. The majority of data arise from minor resections but the proportion

of major resections is increasing^[64]. A recent analysis performed in a general medical population, including all liver resections in France along the year 2013, resulted that 15% of liver resections were performed through minimally invasive surgery^[87]. Another surgical population profile indicates that less than 10% of all liver resections done for benign conditions are carried out with laparoscopy in North American centers^[88]. In fact, there are few centers with extensive experience with LLR, Table 2 presents per operative results in high-volume centers with more than 150 cases.

Indications for LLR do not differ from those for open surgery^[3,89,90]. Indications are based on tumour characteristics, liver function and patient's general health status. In patients who cannot tolerate pneumoperitoneum due to their cardiopulmonary status LLR is contraindicated.

MILS may be used for benign and malignant (primary and metastatic) tumors and living donor liver harvesting. A high percentage of benign tumors was presented in early series of MILS, whereas the proportion of malignant has significantly increased in recent years^[15,79,91,92]. Between June 2007 and December 2014, 214 LLR were performed at the Liver Surgery Unit, University of Sao Paulo Medical School. In our experience, 65.9% of LLR patients were by malignant diseases and their proportion has significantly increased in recent years (Table 2).

Classic indications for LLR are tumours confined to the so-called "laparoscopic segments": The left lateral section (segments 2 and 3) and the anterior segments (segments 4b, 5, 6). It is also preferable to operate on tumours smaller than 5 cm, located away from major blood vessels and hilar structures. Those are the most frequently adopted indications, but are not restrictive, once indications can be shifted and extent of resection can be expanded according to the expertise of a particular center^[85,93]. For instance, peripheral tumours are amenable to laparoscopic approach, even when greater than 5 cm. On the other hand, LLR is not advised for large intrahepatic lesions, because of difficult tumor mobilization and risk of rupture^[3]. Laparoscopic LLS is considered the gold standard treatment for lesions located on segments 2 and 3 and should be routinely applied^[33,71,94]. This successful policy has led some experts to expand the indication of routine laparoscopic approach to left hepatectomy^[95].

Major liver resections (*i.e.*, right hepatectomy) showed to be feasible but remain technically demanding procedures reserved to experienced surgeons. Patients with bilateral or central tumors, close to the liver hilum, major hepatic veins or inferior vena cava (IVC) are not standard candidates for a laparoscopic approach. However, in some expert centers, even these cases are addressed laparoscopically in selected patients^[96,97].

Posterior and superior segments of the liver have been traditionally considered as "non-laparoscopic segments" because laparoscopy offers a caudal vision of the liver and there is a great amount of parenchyma interposed between the surgeon's view and those

segments^[64,98]. The combination of oddly located lesions and extensive liver mobilization implies in worst operative outcomes, such as prolonged operative time, higher blood loss and narrower margins^[61,99,100]. Moreover, lesions located on the posterior and superior segments have been identified as an independent risk factor for bleeding and conversion^[99].

Fortunately, there are strategies to overcome limitations of laparoscopy, as some authors have pointed out, HALS and hybrid procedures are safe methods of performing "difficult" and major resections^[68,69]. Other alternative accesses include the superior and lateral approaches with or without use of intercostal or transthoracic trocars. These techniques offer direct access to superior segments, but they have been performed only in few expert centres with small case series reported^[101-104].

Disease specific indications

Benign diseases: There is general consensus that indications for benign lesions should not be expanded in face of lesser invasive technology^[14]. Symptomatic benign diseases (complex cystic diseases, haemangioma, focal nodular hyperplasia) or risk bearing tumours (hepatocellular adenomas) might be suitable for LLR. Cases of segmental hepatolithiasis associated with parenchymal atrophy are also good candidates for LLR^[105]. Some series have demonstrated the feasibility and safety of LLR for benign diseases with low morbidity (< 20%) and no mortality (Table 3)^[12,17,25,28-33]. There are few comparative studies between LLR and OLR for benign tumours^[30,33], showing significantly reduced blood loss, time to oral intake, hospital stay and total cost of hospitalization in patients that underwent LLR. Recently, Ding *et al.*^[25] published a randomized trial comparing patients with hepatolithiasis undergoing laparoscopic and OLR, showing benefits for the LLR group. In the authors' experience with 73 LLR for benign liver diseases, the main indication was hepatocellular adenoma (HA) (n = 50; 68.5%). There were 11 (15.1%) major resections: 9 right and 2 left hepatectomies. Blood transfusion was required in 4.1% of patients and there was no need for conversion. Postoperative complications occurred in 6.9% of the patients and operative mortality was nil (Table 3).

Despite rare benign tumours, HA are clinically relevant due to the risk of malignant degeneration and bleeding. HA have specific indications for surgery such as male sex and lesion larger than 5 cm or symptomatic in females^[17,106]. When operation is required, LLR has proved to be safe and feasible, even when major resections were required^[17,31]. In a recent series by our group, we found excellent results using PLLR, with low rate of operative complications, without mortality or long-term recurrence^[17].

This group of patients seems to be specially benefited by laparoscopic surgery, once this disease occurs in patients along their productive life where a less invasive approach offers faster recovery, shorter hospital stay, lower morbidity and better cosmetic result. LLR should be considered standard of care for patients with adenomas, when performed by experienced laparoscopic liver surgeons^[17].

HCC

HCC usually occurs in the setting of chronic liver disease and liver transplantation (LT) would offer adequate treatment for HCC as well as for the underlying disease. In

patients with preserved liver function or limited signs of portal hypertension, resection is the mainstay treatment and provides the same results in an intention-to-treat fashion that LT offers^[66,107].

In the early experience with LLR the chronically diseased liver was believed to increase the feared hazard of intraoperative bleeding^[108,109]. However, some initial series demonstrated the safety and feasibility of LLR in selected patients^[34-46,48,49,110]. Pioneer specialized centers performed minimally invasive resections on patients with preserved liver function (Child-Pugh class A), limited signs portal hypertension (platelet count over 80000-100000; oesophageal varices grade 1 or less; absence of ascites) and good general health (ASA III or less)^[65,66].

In addition to liver function, tumour characteristics also restrict the use of laparoscopy in the treatment of HCC. In Tranchart series, case selection resulted in 27% of HCC patients treated with minimally invasive approach^[35]. Usually, centrally located lesions are managed via ablative techniques and larger resections (> 2 segments) are rarely carried out. Laparoscopy is preferred for anterolateral segments, smaller tumours (less than 5 cm) and lesions far from vascular structures^[111]. Anatomical resection is preferred whenever possible for the treatment of HCC in order to achieve adequate margins and prevent local recurrence. However, in small peripheral and well-differentiated HCC there are studies showing similar results for anatomic and non-anatomic resections^[112-114].

Judicious patient selection improved surgical outcomes and the accumulated experience once again ruled out the initial fears of LLR for HCC^[34-46,48,49,110]. Since 2000, over 600 cases of LLR of HCC were reported^[23] and, interestingly, LLR results in less blood loss and less requirement for blood transfusion^[86,115]. The reduced blood loss must be considered an outstanding outcome, once operative blood loss has a strong association with prognosis in HCC patients^[116].

Laparoscopy also reduces operative morbidity, considering general and liver specific complications. Patients suffer fewer pulmonary complications and, importantly, there is an impressive reduction in postoperative ascites and liver insufficiency^[23,109,117,118]. Laparoscopy avoids abdominal wall disruption; consequently avoiding discontinuation of the compensatory collateral circulation secondary to portal hypertension. Laparoscopic surgery also implies in limited liver manipulation, restricted fluid management, decreased blood loss and consequently reduced third space accumulation and hyper aldosteronism^[111]. Table 4 summarizes operative results of MILS in comparatives series with more than 30 patients in each studied group (OLR × LLR).

Another beneficial implication of LLR in cirrhotic patients is better results of LT after laparoscopic resection when compared with OLRs^[119]. After laparoscopic procedures there are fewer adhesions, which ultimately translates as a shorter dissection time, with less bleeding from hypervascularized adhesions associated to portal hypertension. Therefore LLR resulted in shorter operative time, less blood loss and quicker hepatectomy phase during LT^[119,120]. Other studies also pointed out that reoperations for recurrent HCCs are feasible and facilitated by a previous LLR^[121-123]. This is a clear advantage in the setting of chronic liver disease, where patients are prone to develop new

tumours or hepatic insufficiency, requiring further resection or LT.

CRLM

Resection is considered the gold standard treatment for CRLM and offers the best chance of long-term survival^[124,125]. Many of the oncological fears were shared with HCC and included surgical margins, adequate intraoperative staging, peritoneal dissemination and port site seeding.

Laparoscopic treatment of CRLM was one of the most recent achievements of MILS. Until 2008, only 35% of LLR for malignancy were performed for CRLM^[14]. The first multi-institutional cohort with 109 patients was published only in 2009^[126], with a stringent selection criteria: tumours smaller than 5 cm, lesions located on the peripheral segments and multiple lesions were treated only if tumor clearance could be achieved with a single anatomic resection. The transfusion rate was 10%, the resection margin was negative in 94.4% of the patients and the conversion rate was 3.7%^[126].

Case series and comparative studies indicated that well selected patients presented reduced morbidity and blood loss^[50-58] (Table 5). Recent meta-analysis confirmed the benefits of laparoscopy approach when compared to OLR (Table 6)^[127-130].

A recent paper made an interesting matched pair analysis of open and laparoscopic approaches for CRLM^[56] and showed increased rate of third liver resections on the laparoscopy group. This confirms, once again, that laparoscopy eases further interventions, as mentioned for HCC.

Good outcomes have encouraged some specialized centres to widen the indications of MILS, for instance, in elderly patients^[131]. Another progress appears related to synchronous resections of the colorectal primary tumour and CRLM. The association of these two operations appears to be feasible and safe in specialized centers^[127,132,133].

Other malignant diseases

Other liver malignancies such as peripheral cholangiocarcinoma, hilar cholangiocarcinoma, as well as non-CRLM have had only anecdotal reports^[16,134,135]. Although

considered a contraindication for LLR by most specialized centers, successful minimally invasive approach to gallbladder cancer has been performed in few cases with no reports of port site metastasis^[1,36]. Despite being an interesting topic, to date the available data is very limited and no major conclusion can be disclosed.

Laparoscopic living donor graft harvesting

Laparoscopic graft harvesting has raised the same questions on technical issues and operative hazards as other LLR. One specific limitation associated with laparoscopic organ harvesting is the risk of prolonged warm ischemia time^[19], although this has not shown to be harmful and had no negative effect on graft function^[65]. Thenappan *et al*^[137] compared laparoscopic and open donor hepatectomies and found no significant differences except a minor increase in international normalised ratio on day 7 in the laparoscopic group. Perioperative allograft biliary and vascular complication rates were also comparable between groups. One-year graft and patient survival for laparoscopic group was 100% compared with 93% for the open group^[137].

Cherqui *et al*^[138] reported the first pure laparoscopic LLS for donor hepatectomy in 2002. Subsequently, studies have identified benefits for the donor as decreased blood loss, decreased postoperative complication rates and shorter postoperative recovery and hospital stay^[20,65,139]. Experienced centers point out that laparoscopic LLS should be shortly accepted as standard of care^[19,20].

Laparoscopic major hepatectomies are usually performed in the setting of adult-to-adult LDLT. Left liver harvesting offers a lower risk strategy for the donor while gives to the recipient a relative large amount of functioning liver parenchyma^[140]. Smaller grafts tend to shift the risks from the donor to the recipient, as they increase the risk of a small for size syndrome. Technical improvements have led to better results and small series have shown that this strategy can be undertaken with low morbidity^[141,142].

Right hemilivers offer great amount of functional liver parenchyma, but implies in a larger resection associated with higher risks to donors^[143]. Some centers advocated that laparoscopic harvesting could decrease postoperative complication rates; however there are concerns about the safety of the procedure. Some authors advocate HALS and hybrid procedures in order to reduce donor morbidity^[70,144-146]. Cauchy *et al*^[19] reported 167 right livers harvested through laparoscopy being 98.2% operated with HALS or hybrid techniques. Results showed no mortality, and low rate of severe complications (0% to 17%).

In a recent meta-analysis by Berardi *et al*^[147] 11 studies were included (608 adult patients) comparing minimally invasive and open living donor hepatectomy. Blood loss and operative time were comparable between groups, while hospital stay, analgesia use, donor morbidity rate and wound-related complications were significantly reduced in laparoscopic group^[147].

At present, laparoscopic major hepatectomy for LDLT graft harvesting is a debatable procedure, restricted to few centers and needs further scientific confirmation. According to the 2nd ICC laparoscopic donor harvesting requires both ongoing institutional ethical approval and a reporting registry of all cases to determine the short and long-term outcomes in donors and recipients. Considering the high level of surgical skills required, it is advised to perform this procedure only at centers with experience in MILS and LT^[59].

INTRAOPERATIVE CONSIDERATIONS

Operative time

Operative time varies significantly between studies, influenced by the type of resection and surgeon's experience. Viganò *et al.*^[72] studied three consecutive periods, each with 58 patients undergoing LLR, and observed a significant decrease in mean operative time. Other authors have confirmed the trend of significant reduction in operative time related to increasing experience, both in minor and major resections^[77,82].

When compared to open approach, results are conflicting. Some studies have shown longer operative time in LLR group, including 2 meta-analysis^[148,149]. Other authors, however, showed comparable operative times (Table 6)^[150-152]. In a recent meta-analysis, Jackson *et al.*^[153] analyzed 46 publications and found similar results (OLR 203.9 min vs LLR 203.6 min), although there was great heterogeneity among the studies.

Gas embolism

A serious concern in the early days of LLR was the use of pneumoperitoneum with positive pressure. There was a theoretical increased risk of CO₂ embolism due to the elevated gradient between the insufflation pressure and the central venous pressure (CVP).

Animal model studies using transesophageal echocardiography demonstrated that gas embolism occurs in more than 2/3 of the animals undergoing LLR. Despite radiologic demonstration of CO₂ embolism, this was not associated with any clinical deterioration^[21,22,154]. Indeed, the occurrence of gas embolism in clinical practice is anecdotal^[91]. CO₂ is a highly diffusible gas, which minimizes the risk of embolism as compared to air, and low pneumoperitoneum pressure further reduces its incidence^[22,155].

In 2002, Biertho *et al.*^[156] reviewed published series of LLR and reported only two cases (1.1%) of possible gas embolism in approximately 200 LLR. In a meta-analysis of comparative studies, Mirnezami *et al.*^[149] reported 0.1% incidence of gas embolism.

During major LLR the risk of gas embolism was believed to be higher than for minor hepatectomy due to the wide transection plane with dissection of major hepatic

veins and long operative time. However, the occurrence of gas embolism in this scenario is also extremely low. Dagher *et al*^[67] in a multicenter study with 210 cases of major LLR; reported 3 (1.43%) patients that developed gas embolism. However, there was no influence of gas embolism on postoperative morbidity and mortality^[67]. Otsuka *et al*^[157] reviewed 477 major hepatectomies from high-volume centers and observed only 3 (0.2%) cases of gas embolism. In recent series, as well as in our experience, no cases of air embolism were observed.

The occurrence of gas embolism has been also related to argon beam coagulation, which increases intra-abdominal pressure leading to an increased risk of gas embolism^[158-160]. As argon is not diffusible as CO₂, the use of argon beam coagulator during liver transection is not recommended by many experts^[59].

Intraoperative bleeding

The main technical challenge of LLR remains intraoperative hemorrhage during parenchymal transection. Even though intraoperative bleeding rarely occurs, it is difficult to manage in the absence of manual compression.

Some cases of hemorrhagic complications have been reported, mainly related to hepatic veins injuries^[161,162], and were managed either laparoscopically or by conversion to laparotomy. Intraoperative bleeding is the main cause of conversion to laparotomy in most series^[13,14,81,93,99,163-165].

Major blood loss during liver resection has a direct effect on postoperative course^[166] and negatively affects oncological outcomes^[116]. Perioperative blood transfusions are associated with a higher rate of recurrence and lower survival after surgical treatment of malignant diseases, especially HCC^[10].

Blood loss reported during laparoscopic surgery varies between series, and is directly related to the type and difficulty of LLR^[13,14,81,93,99,163-165]. In several meta-analysis of comparative studies intraoperative bleeding tends to be lower at laparoscopic approach than at open resection resulting in decreased requirement for blood transfusion (Table 6)^[149,151,153].

Studying patients with malignant diseases (HCC and CRLM), Parks *et al*^[167] showed significantly lower blood loss in the group undergoing LLR than in the group undergoing OLR. Analyzing only patients with HCC, other meta-analyses yielded similar results, with systematic advantage for the group undergoing LLR, with less intraoperative bleeding and lower rates of blood transfusion^[117,118,168,169].

The factors responsible for reduced blood loss during LLR are magnified view of the operating field, the positive pressure of the CO₂ pneumoperitoneum that avoids retrograde bleeding from hepatic veins, the emergence of new transection devices and adequate inflow and outflow control^[170]. In order to address essential steps in bleeding control during LLR, a recent experts' literature review made some recommendations: Maintenance of pneumoperitoneum between 10-14

mmHg; low CVP (< 5 mmHg); laparoscopy control of inflow and outflow; and surgeons should be experienced with the use of all surgical devices for liver transection and should master laparoscopic suture before starting LLR^[170].

Conversion

The reported conversion rate is in the range of 0%-20%^[171], varying mostly according to the indication for LLR. Series on benign disease show conversion rates from nil to 10%^[12,17,25,28-33]. Observational comparative studies focused on malignant diseases (Tables 4 and 5) showed conversion rates ranging from 0% to 23.3%^[34-58]. However, with surgical expertise the conversion rate can be reduced to < 5% in high-volume expert centers^[32,58]. In our experience the overall conversion rate was 6.5%; however, in the last 100 cases, the conversion rate was 3.0%.

The conversion rate is also related to the complexity of the surgical procedure and accumulated experience. In a multicentric review of 210 major hepatectomies conversion rate was 12.4%. To evaluate the effects of learning curve on outcomes, a comparison was made between the first 15 major LLR performed at each center and the subsequent 120 major hepatectomies. Conversion rate (18.8% vs 7.5%, $P = 0.0018$) was significantly lower in the late group^[67]. In patients with cirrhosis reported conversion rates are higher, ranging from 7% to 19.4%^[168].

EFFICACY OF LLR

Postoperative outcomes: Comparison with OLR

The literature data cited above indicate that LLR is feasible and safe when compared to OLR for both benign and malignant liver lesions. At present, there are 20 meta-analysis summarized on Table 6 comparing the results of LLR and OLR^[94,111,117,118,127-130,148-153,167-169,172-174]. Most studies have consistently demonstrated a significantly lower length of stay (LOS) as compared to the open approach. The overall shorter LOS in laparoscopic resection is not only associated with quicker hospital discharge, but an earlier return of bowel activity and lesser requirement of analgesics^[148-151]. Rao *et al*^[148] pooled analysis of 32 comparative studies showed significant reduction in LOS (2.96 d, 95%CI: -3.70 to -2.22) and in the time to oral intake (1.33 d, 95%CI: -1.86 to -0.80) in the laparoscopic group.

Morbidity and mortality

Nguyen *et al*^[15] found that the overall mortality rate was 0.3% (range 0% to 10%) in 2804 patients operated by LLR until 2008. There were no reported intraoperative deaths. Most common cause of postoperative death was liver failure^[15]. Modern series from large volume centers report mortality for LLR in the range of 0% to 2.4%^[17,25,32,33,35-49,52-58,81,93,99,164,165]. Jackson *et al*^[153] pooled results of 40 studies comparing mortality rates between LLR and OLR and there were no significant differences

between the groups for both in-hospital mortality and postoperative mortality within 30 d of discharge^[153].

The comprehensive review of LLR published series by Nguyen *et al*^[15] found an overall morbidity rate was 10.5% (range 0% to 50%). The most common liver-related complication was bile leakage (1.5%) followed by transient hepatic insufficiency (1.0%). The most common general and surgical-related complications were pleural effusions, incisional bleeding and wound infections each with less than 1%^[15].

In large series including benign and malignant disease, the overall morbidity rate ranges from 3.2%^[175] to 45%. In our series of 214 LLR, morbidity rate was 15% and mortality was 0.5% (one cirrhotic patient died of sepsis). The most common postoperative complications were: Ascitis (15.6%) followed by incisional hernias (9.4%), ileus (9.4%) and pneumonia (9.4%).

Comparative studies showed significant decrease in the complication rate in patients undergoing LLR^[149,150,152,153,172]. A meta-analysis published by Mirnezami *et al*^[149] showed a significant decrease in the incidence of liver-specific complications with LLR compared with OLR. Similarly, Jackson *et al*^[153] analyzed 47 studies and demonstrated that patients who underwent LLR had lower postoperative complications rates when compared with OLR. Specifically, minimally invasive approaches had lower rates of wound infections, incisional hernias, and cirrhotic decompensation events.

Regarding malignancies, patients with CRLM who underwent laparoscopic resections also have lower rates of postoperative complications than the open group^[127,128,130].

Recently, our group published a series including 30 patients with HCC that underwent LLR. Postoperative complications were observed in 40% of patients (75% grade I by Dindo-Clavien classification) and the mortality rate was 3.3%^[176]. A consistent finding among the meta-analysis of LLR for HCC includes reduced complication rates^[117,169,173,174]. Xiong *et al*^[117] examined ascites and postoperative liver failure and reported reduced incidences of both. Recently, Morise *et al*^[169] analyzing the subset of patients with known cirrhosis also noted a significant reduced incidence of postoperative ascites and liver failure.

Cost analysis

There are concerns that LLR may be associated with increased cost due to laparoscopic equipment^[13,74]. Koffron *et al*^[13] showed that the operating room costs for MILS were significantly higher than those of OLR; however, overall costs were reduced due to shorter LOS. Similarly, Polignano *et al*^[177] reported increased disposable instrument costs with LLR. However, these expenses were offset by reduced high dependency unit and ward stay costs, resulting in significantly lower total costs with LLR^[177].

In a recent meta-analysis published by Limongelli *et al*^[178], 9 studies were analyzed comparing the costs of patients undergoing LLR ($n = 344$) vs conventional

approach ($n = 338$). LLR was associated with lower ward stay cost than OLR (2972 USD vs 5291 USD) but costs related to operation (equipment and theatre) were higher in the group of patients undergoing LLR. The total cost was lower in patients managed by LLR (19269 USD) compared to OLR (23419 USD). The same trend of overall cost reduction was observed when the subset of patients undergoing minor LLR was analyzed (total cost: LLR 12720 USD vs OLR 17429 USD).

Regarding major hepatectomies results are contradictory. There is no proven economic benefit related to the laparoscopic procedure when compared to conventional counterparty^[13,179-181].

ONCOLOGICAL RESULTS

Initial limitations of laparoscopic liver surgery included the fear of unfavorable oncological outcomes^[3]. As a new technique, LLR should prove to be non-inferior when compared to the established methods. Pursued oncological results were two-fold: Intraoperative tumor clearance (complete resection with adequate margins) and long-term survival.

Surgical margins

As observed for any laparoscopic operation, LLR is performed without tactile feedback along with a limited bi-dimensional field of view. Moreover, as mentioned earlier, the insertion of the laparoscope through or near the umbilicus implicates in a caudal view of the liver^[84,98]. Complete resection is the goal for the treatment of hepatic malignancies and the limitations in tactile feedback associated with the modified field of view made surgeons concern about adequate intraoperative oncological results.

The encouraging results of LLR set surgeons to search alternatives to overcome those limitations. LLR performed either with laparoscopic or hand assistance offers the possibility of placing the surgeon's hand into to the operative field, ruling out the lack of tactile feedback^[14]. Moreover, during LLR intraoperative ultrasound should be extensively used, not only to identify occult previously unknown lesions, but most importantly to aid surgical planning in order to obtain clear surgical margins^[182].

The best evidence available to date indicates that surgical margins in LLR are as good as in conventional procedures. Comparative studies and meta-analysis have indicated that patients operated with LLR have no increased risk of positive surgical margins^[111,117,118,128-130,149,150,168,172-174]. LLR is carried out under a magnified field of view, which implies in augmented perception of operative blood loss and induces surgeons to be more meticulous, especially when employing a new technique^[86,115]. Another reason for adequate margins relies on patient selection and surgical planning for laparoscopic cases. Surgery should be extensively planned to include peripheral tumors located away from vascular structures and far from the transection plane^[3,14,63,85,93].

Long-term outcomes - CRLM

Inadequate intraoperative staging, insufficient surgical margins, port-site seeding and peritoneal dissemination were feared outcomes that limited the application of LLR to the treatment of CRLM. Those fears were not confirmed and LLR slowly gained acceptance for operations on CRLM.

The cautious progress demonstrated that results on selected patients proved to be equally good for LLR when compared to conventional operations (Tables 5 and 6)^[128,130]. Moreover, LLR increases the chance for future resections once laparoscopy reduces operative adhesions and eases future interventions^[56]. Other technical benefits include the expansion of liver resections to elderly patients and the possibility of synchronous colorectal resections made feasible by a less morbid approach^[131,132,183].

Long-term outcomes - HCC

HCC is the most common primary liver malignancy and figures as a leading cause of cancer related death^[184]. It has a frequent association with chronic liver disease, which implies that management of such tumors comes along with the management of cirrhosis and its complications.

Initial results of laparoscopic operations on cirrhotic patients have shown excellent short-term perioperative outcomes^[23,35,66]. One of the intraoperative benefits of LLR is reduced blood loss; perioperative blood transfusions have a negative impact in survival for HCC^[116], indicating that laparoscopic resection is a useful tool to improve long-term outcomes.

Comparative and meta-analytical studies took a look into survival rates of LLR and long-term outcomes were superimposed to conventional results (Tables 4 and 6)^[111,117,168,173,174]. Thus, LLR is an acceptable option for treating patients with HCC.

TECHNICAL CONSIDERATIONS

PLLR is the most frequent method of LLR and is mostly applied to less complex operations, such as wedge resections, non-anatomic and anatomic resections on the anterolateral segments^[14]. Some expert teams also perform PLLR for major resections and complex procedures such as living donor graft harvesting^[19]. HALS offers the advantage of regaining tactile feedback lost with PLLR. It is also helpful in instances where extensive liver mobilization is required, such as posterior sectionectomies and major resections^[68]. Hybrid resection associates laparoscopy for liver mobilization with an auxiliary incision for parenchymal transection and specimen removal^[14]. Hybrid resections have been reported as a useful tool to increase the frequency of major resections^[69]. Figure 1 demonstrates the rationale from the Liver Surgery Unit at University of Sao Paulo Medical School for selecting the best MILS approach for each scenario.

Minor resections

Minor resections were responsible for the successful start of LLR during the 1990's and still represent one of the major indications of LLR. Especially when located in easily accessible, minor resections should be routinely performed through laparoscopy^[14].

Another LLR minor resection that should be routinely performed is LLS^[14,33,95]. This resection was the first published successful anatomic LLR and has been extensively studied^[8]. Comparative studies have shown that LLS is technically feasible, with superior short-term outcomes and equal long-term oncological results^[71,185-187]. Moreover, it is a standardized procedure, allowing reproducibility and training for surgeons initiating their experience with LLR^[76,77].

Major resections

Laparoscopic major resections have been compared to conventional resections and operative results favor LLR on reduced blood loss, shorter length of stay and fewer complications^[188,189]. Major resections are feasible procedures but are clearly experts' job. Published series derive from multi-institutional studies that gather the experience of high-volume centers, where operations are carried out by experienced liver surgery teams^[62-64,67].

Difficult resections

Access to "non-laparoscopic" segments is difficult once they are located posterior and superior to the liver. Moreover, the postero-superior location demands extensive mobilization in order to bring these segments to the operative field^[190]. Mobilization can be toilsome once the right liver should be detached from its ligaments, the diaphragm, retroperitoneum and, sometimes, the IVC.

The perceived technical difficulty to operate on the non-laparoscopic segments has been confirmed in papers that indicate posterior sectionectomies as "major operations" (despite including only two segments), associated with higher conversion rates, higher blood loss, prolonged operative times and narrower surgical margins^[61,85,99,100].

Resections on these difficult segments can be performed, but usually demand special techniques to overcome above-mentioned limitations. HALS, laparoscopy-assisted and trans-thoracic port placement are useful strategies applied to difficult resections^[103,104,190,191].

NEW TECHNOLOGIES

MILS has evolved during the past two decades and still moves forward. Robot assisted resections are feasible as reported in case series. Robotic surgery might improve results of LLR once it offers a three-dimensional view and has a greater range of movements, which can be useful for complex resections^[24,192,193].

Another perspective for LLR is the association of three-dimensional (3D) image guidance to help surgeons

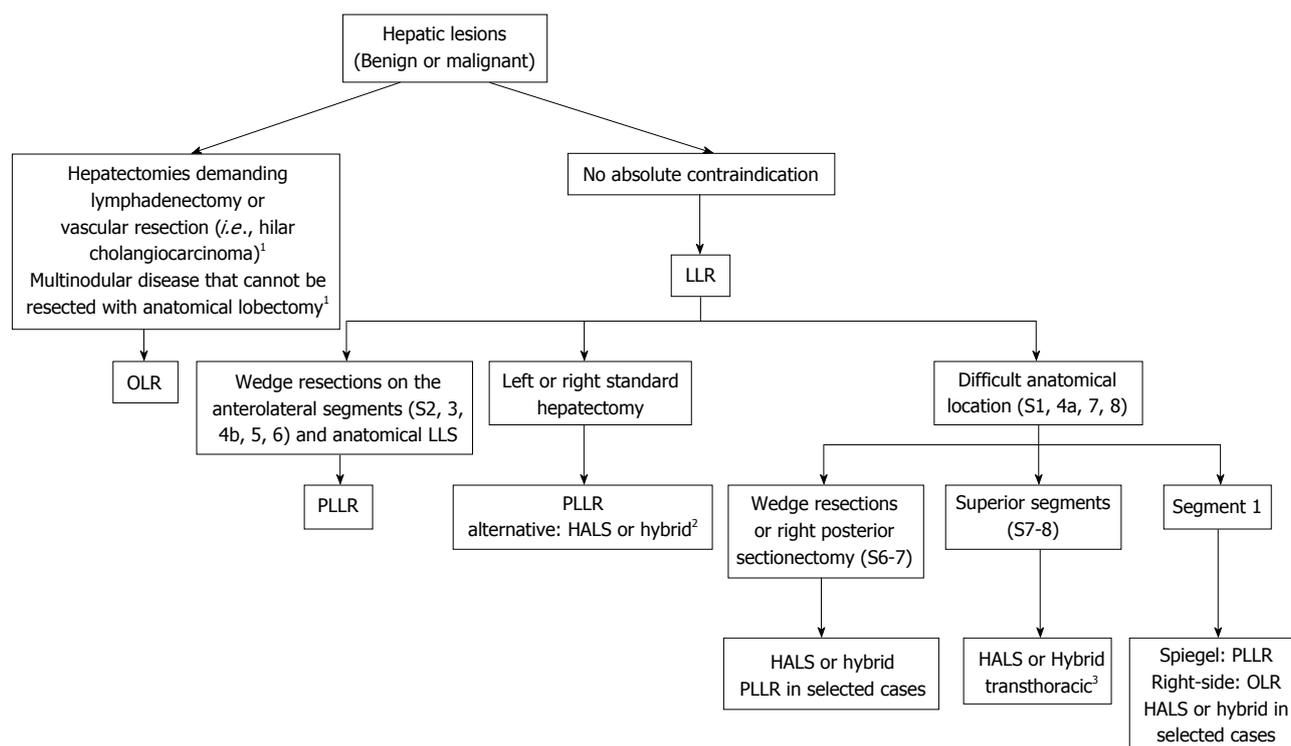

Figure 1 Flowchart demonstrating a suggested approach to the liver nodules using the minimally invasive approach (Liver Surgery Unit, University of São Paulo Medical School). ¹HALS or hybrid in selected cases; ²When technical difficulties are anticipated/intraoperative difficulties; ³When abdominal approach is not possible. HALS: Hand-assisted liver surgery; LLR: Laparoscopic liver resection; OLR: Open liver resection; LLS: Left lateral sectionectomy; PLLR: Pure laparoscopic liver resection.

to navigate along the liver anatomy while planning and executing de resection. 3D image simulation appears to be useful for surgical planning and has a high accuracy for predicting surgical margins and liver volumes. Further dynamic applicability of the 3D planning to navigation during operation is expected to improve operative results^[194].

Single port operations have been recently incorporated to LLR and anecdotally described. Recent reviews of the scarce available data identified around 30 reported cases. Most cases were highly selected and included small resections, even though major hepatectomy has also been performed. At this point no conclusion or recommendation can be made for single port LLR, further studies are needed to indicate it's role in LLR^[195,196].

CONCLUSION

LLR has been progressively developed along the past two decades. Despite initial skepticism, improved operative results made LLR incorporated to surgical practice and operations increased in frequency and complexity. However, the expansion of MILS becomes essential when we consider that countries with long-standing tradition in surgery apply laparoscopy to liver surgery in less than 15% of cases. High quality studies allied with high-level surgical training are required to base surgical practice and to disseminate the benefits of MILS to many centers as possible. LLR should be

standard practice for anterolateral resections and LLS, major resections are feasible procedures but restricted to experienced centers. Future applicability of new technologies such as robot assistance and image-guided surgery is still under investigation.

Abstract

According to the United States census bureau 20%

of Americans will be older than 65 years in 2030 and half of them will need an operation - equating to about 36 million older surgical patients. Older adults are prone to complications during gastrointestinal cancer treatment and therefore may need to undergo special pretreatment assessments that incorporate frailty and sarcopenia assessments. A focused, structured literature review on PubMed and Google Scholar was performed to identify primary research articles, review articles, as well as practice guidelines on frailty and sarcopenia among patients undergoing gastrointestinal surgery. The initial search identified 450 articles; after eliminating duplicates, reports that did not include surgical patients, case series, as well as case reports, 42 publications on the impact of frailty and/or sarcopenia on outcome of patients undergoing gastrointestinal surgery were included. Frailty is defined as a clinically recognizable state of increased vulnerability to physiologic stressors resulting from aging. Frailty is associated with a decline in physiologic reserve and function across multiple physiologic systems. Sarcopenia is a syndrome characterized by progressive and generalized loss of skeletal muscle mass and strength. Unlike cachexia, which is typically associated with weight loss due to chemotherapy or a general malignancy-related cachexia syndrome, sarcopenia relates to muscle mass rather than simply weight. As such, while weight reflects nutritional status, sarcopenia - the loss of muscle mass - is a more accurate and quantitative global marker of frailty. While chronologic age is an important element in assessing a patient's peri-operative risk, physiologic age is a more important determinant of outcomes. Geriatric assessment tools are important components of the pre-operative work-up and can help identify patients who suffer from frailty. Such data are important, as frailty and sarcopenia have repeatedly been demonstrated among the strongest predictors of both short- and long-term outcome following complicated surgical procedures such as esophageal, gastric, colorectal, and hepato-pancreatico-biliary resections.

Core tip: It is estimated that by the year 2030, 36 million Americans > 65 years will require surgery. Frailty as defined by a clinically recognizable state of increased vulnerability due to physiologic stressors resulting from aging has been associated with a decreased physiologic reserve and function across multiple physiological systems. Recently, a loss of muscle mass or sarcopenia has been proposed as an accurate and quantitative global marker of frailty. The current review demonstrates that frailty as defined by sarcopenia can be accurately used as a preoperative predictor of poor short- and long-term postoperative outcomes following complex gastrointestinal surgery.

Wagner D, DeMarco M, Amini N, Buttner S, Segev D, Gani F, Pawlik TM. Role of frailty and sarcopenia in predicting outcomes among patients undergoing gastrointestinal surgery. *World J Gastrointest Surg* 2016; 8(1): 27-40 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i1/27.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i1.27>

INTRODUCTION

The life expectancy of the average person doubled over the course of the last century. In addition, between 1982 and 2003 the American population aged over 65 years doubled and the population older than 85 years quadrupled^[1]. According to the United States census bureau 20% of Americans will be older than 65 years in 2030 and half of them will need an operation - equating to about 36 million older surgical patients^[2]. The process of aging is associated with an increasing prevalence of frailty, comorbidities, a decline of functional reserve and a progressive restriction in personal and social resources. All of these factors can contribute to less favorable postoperative outcomes among older patients^[3]. Older patients are at increased risk for complications which include delirium, urinary incontinence, pressure ulcers, depression, infection, functional decline and adverse drug affects^[4-8]. Despite the fact that surgery is the most effective cancer therapy, complication rates, mortality, length of hospital stay and intensive care unit admissions increase with patient age, which can offset oncologic advantages^[9-13].

Many cancer treatment guidelines have been formulated based on clinical data that may have under-represented older and more frail patients; therefore, more attention is needed to guide the management of this vulnerable population^[14,15]. Several studies have noted potential differences in gastrointestinal surgical care between older and younger patients^[16,17]. For example, commonly used predictor scores for postoperative complications like the American Society of Anesthesiology

score have substantial limitations in older patients, as most are based on a single organ system, are subjective and none measures the patients' physiologic reserve^[18]. In fact, a recent review by McCleary *et al*^[16] stressed that older adults are prone to complications during gastrointestinal cancer treatment and therefore need to undergo special pretreatment assessments incorporating frailty and sarcopenia assessments.

More recently, sarcopenia and frailty have increasingly been recognized as important factors that can be markers of decreased physiologic reserve. Several studies have highlighted the importance of frailty and sarcopenia to predict perioperative outcomes among patients undergoing surgery for gastrointestinal cancer^[19-22]. Recent guidelines from the American College of Surgeons have highlighted the importance of assessing both frailty and sarcopenia prior to oncologic surgery in the elderly^[23]. As such, there is increasing interest in screening patients for frailty and sarcopenia to better predict patients at highest risk of complications after surgery^[24]. Given this, we sought to review the available literature on the association of frailty and sarcopenia with patient outcome, as well as the risk of perioperative morbidity and mortality after gastrointestinal surgeries.

SYSTEMATIC LITERATURE REVIEW

A focused, structured literature review was performed using PubMed and Google Scholar to identify primary research articles, review articles, as well as practice guidelines on frailty and sarcopenia among patients undergoing gastrointestinal surgery. Articles published between January 2000 to March 2015 were identified using the search terms "sarcopenia and gastrointestinal surgery", "frailty and gastrointestinal surgery", "sarcopenia and outcome and surgery", as well as "frailty and outcome and surgery". In addition, references of relevant articles were also reviewed to identify potentially eligible studies. As per the methodology specified under the PRISMA guidelines, only studies published in English were included, while conference abstracts that did not proceed to publication in peer-reviewed journals were excluded^[25]. The initial search identified 343 articles; 53 duplicates were eliminated and 290 abstracts were reviewed for further assessment. Among these 25 editorials, 97 studies that did not include gastrointestinal patients, 99 articles that did not use standard frailty or sarcopenia assessments, 19 case series, as well as 5 case reports and 3 consensus statements were eliminated (Figure 1). In total 42 publications assessing the impact of frailty and/or sarcopenia on postoperative outcomes among patients undergoing gastrointestinal surgery were identified that met inclusion criteria. Among all studies that were included, 10 studies were performed prospectively (2 gastroesophageal surgery, 6 colorectal surgery, and 2 hepato-pancreaticobiliary surgery, Tables 1-3)^[26-33]. Sixteen studies were conducted retrospectively on an unmatched cohort (2 gastroesophageal, 4 colorectal, and 10 hepato-

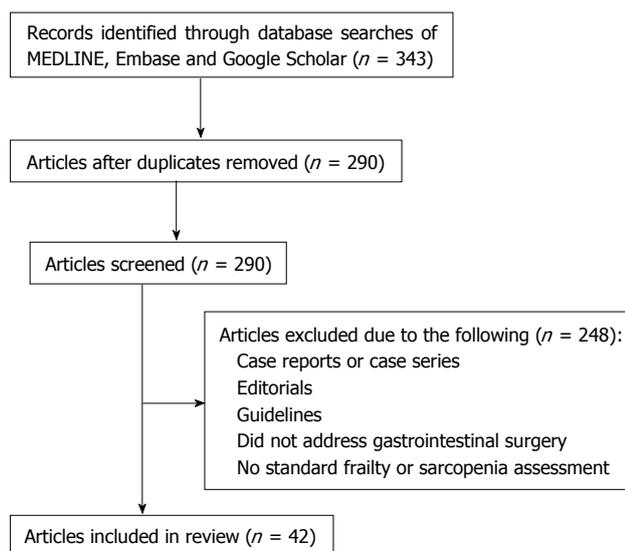

Figure 1 Flow chart depicting the review process for the inclusion of publications.

pancreatico-biliary), 2 studies retrospectively analyzed prospectively collected data while two articles analyzed data from multiple centers in the United States^[34-50]. Additionally, 15 narrative reviews were included in the study. The quality of each study was assessed using the Newcastle-Ottawa Scale based on case selection, comparability, and outcome reporting (Tables 1-3); the median quality score of the studies was 6.5 (range 4-9).

Data pertaining to patient demographics (age and sex), assessment used, type of surgery and the number of patients were collected for each article and are displayed in Table 4. Additionally, data relating to short-term clinical outcomes such as 30-d morbidity and mortality, as well as long-term outcomes including median, 5-year overall and 1-year overall survival were recorded from each study. Sarcopenia and frailty, as well as other end points used for analyses were not homogeneously defined throughout the studies. The different approaches to define sarcopenia and frailty along with relevant clinical and outcome parameters used along with the quality scale of the included studies (Tables 1-3). While a direct comparison between the studies was therefore not possible due to their heterogeneity, data were amassed from these studies to inform a comprehensive review.

FRAILTY AND SARCOPENIA IN OLDER ADULTS UNDERGOING SURGERY: GENERAL CONSIDERATIONS

Frailty is associated with a decline in physiologic reserve and function across multiple physiologic systems^[51]. In the absence of a gold standard, frailty has been operationally defined by Fried *et al.*^[20] as meeting 3 out of 5 phenotypic criteria indicating compromised energetics: Low grip strength, low energy, slowed waking speed, low physical activity, and/or unintentional weight loss.

While frailty has not been widely evaluated in surgical patients, Makary *et al.*^[22] did report on the surgical outcomes of a large cohort of older patients in which frailty was assessed using a frailty scale based on the Fried frailty phenotype (Table 4). The authors reported that preoperative frailty was associated with an increased risk of postoperative complications. Specifically, patients with moderate or severe frailty had roughly twice (moderate: OR = 2.06, 95%CI: 1.18-3.6; severe: OR = 2.54, 95%CI: 1.12-5.77) the odds of complications compared with non-frail patients. The authors also reported that frailty independently predicted length of stay with moderate or severe frailty having a 44%-53% and 65%-89%, respectively, longer hospital stays than non-frail patients. Of note, the power of frailty to predict worse outcomes was much higher than traditional peri-operative assessments alone (Figure 2). These data emphasize how frailty adds valuable information to standard preoperative risk assessments, yet highlight how defining frailty in the peri-operative period can be challenging.

A full combined geriatric assessment (CGA) can take several hours and includes assessments such as activities of daily living, geriatric depression scores, and timed "up and go" tests^[52]. Specifically, the risk of mortality among patients with frailty ranged from 1.1%-11.7%, with frail patients up to 12 times more likely to die compared with non-frail patients in a recent review on the use of CGA in gastrointestinal surgery^[52]. Due to its time consuming nature, the National Cancer Institute and the National Institute of Aging recommends this scoring system only for patients with special needs who are deemed at high risk^[7]. In addition to CGA, other parameters have been used to assess frailty and sarcopenia in older patients undergoing gastrointestinal surgery. For example, in a large cohort study of 76106 patients from the NSQIP database, Amrock *et al.*^[53] reported that preoperative impaired cognition, low albumin level, previous falls, low hematocrit levels and a high prevalence of comorbidities were associated with an increased 6 mo mortality and post discharge institutionalization among older patients undergoing major abdominal operations. While the authors concluded that preoperative data could help define frailty and predict the geriatric-specific surgical risk, the study failed to provide a clear definition for frailty in gastrointestinal surgical patients. Other studies have suggested that the Charlson index, timed "up and go" tests, Katz score or the Mini cog score, as well as serum albumin levels below 3.4 g/dL and the Braden score all may be associated with postoperative outcomes^[28,54,55]. Each of these parameters have not been shown, however, to improve the risk prediction compared with the Fried Frailty Phenotype when used alone.

Sarcopenia has been proposed as another means to assess frailty. In fact, when Fried *et al.*^[20] first described the frailty phenotype and its association with mortality and morbidity, the potential link between frailty and sarcopenia was noted. Specifically, patients deemed

to be frail who had a concomitant decrease in muscle mass were more likely to suffer from disabilities and a worsening in their mobility vs non-frail patients. Sarcopenia is a syndrome characterized by progressive and generalized loss of skeletal muscle mass and strength. Unlike cachexia, which is typically associated with weight loss due to chemotherapy or a general malignancy-related cachexia syndrome, sarcopenia relates to muscle mass rather than simply weight. As such, while weight reflects nutritional status, sarcopenia - the loss of muscle mass - is a more accurate and quantitative global marker of frailty^[56]. Usually characterized as low muscle mass and low muscle function (strength/performance), sarcopenia is typically defined using an axial cross-sectional image of the psoas muscle at the level of L3^[57,58]. Using this technique, sarcopenia is defined as the total psoas area (TPA), with sarcopenic patients having a smaller TPA^[58]. More recent studies have suggested that assessment of the entire volume of the psoas muscle (TPV) may be a better means to define sarcopenia rather than a single axial image (Figure 3)^[47,59]. In addition, other investigators have suggested the use of dual X-ray absorptiometry as an alternative means to screen for sarcopenia. This tool has not been widely adopted, however, as routine computed tomography is more commonly utilized in patients prior to surgery.

Both the European and the American Society of Ageing have recommended that sarcopenia be recognized as a geriatric syndrome^[57]. In addition, several studies have noted an association between sarcopenia and increased risk of adverse outcomes following surgery^[15,59]. For example, Brant *et al*^[58] reported that patients with sarcopenia were particularly vulnerable in the setting of significant physiologic stressors like major surgery. The importance of sarcopenia in the prediction of outcome after gastrointestinal surgery has been particularly highlighted in several studies^[43,47,59]. The hope is that identification of patients with frailty or sarcopenia who are at high risk of perioperative morbidity can guide patient-physician discussions prior to surgery, as well as identify appropriate patients for "pre-habilitation"^[60].

GASTRO-ESOPHAGEAL MALIGNANCIES

Gastric and esophageal cancer represent a worldwide major health problem. While the incidence in Western countries is relatively low with 18170 and 22220 new esophageal

fact, in 2014 Balducci *et al*^[63] published guidelines on the treatment of older patients with gastro-esophageal malignancies. The authors noted that for individuals whose life expectancy without cancer exceed that with cancer, the estimated risk of chemotherapy complications may reveal those patients in need of additional care and those patients in whom the risk of treatment may exceed the potential benefits. Importantly, the authors noted that the individual's general life expectancy should be defined using the CGA and an assessment of patient frailty.

Table 4 Makary *et al*^[22] did report on the surgical outcomes of a large cohort of older patients in which frailty was assessed using a frailty scale based on the fried frailty phenotype

Characteristic	
Weakness	Weakness should be assessed by grip strength and measured directly with a hand held JAMAR dynamometer (Sammons, Preston Rolyan). Three serial tests of maximum grip strength with the dominant hand will be performed and a mean of the three values will be calculated and adjusted by body mass index and gender. Actual weakness will be defined in the lowest 20 th percentile of a community dwelling adults of 65 yr and older
Shrinking	Shrinking should be defined through a self-report as unintentional weight loss above 10 pounds during the last year
Exhaustion	Exhaustion should be measured by responses following 2 statements from the modified 10 items Center for Epidemiological Studies - Depression scale: "I felt that everything I did was an effort and I could not get going" and "How often in the last week did you feel way?" and will be given the opportunity to reply with 0 = rarely or none of the time (< 1 d); 1 = some or a little time (1-2 d); 2 = a moderate amount of time (3-4 d); and 3 = most of the time. Patients answering either with 2 or 3 will be classified as exhausted
Low activity	Physical activities should be assessed using the Minnesota Leisure Time Activities Questionnaire which includes frequency and duration. The focus should be placed on activities in the past 2 wk prior to operation. Weekly tasks will be converted to equivalent kilocalories of expenditure, and individuals reporting a weekly kilocalorie expenditure in the lowest 20 th percentile for their gender will be classified as having low activity
Slow walking speed	Walking speed should be measured combining 3 trials of walking 15 feet at a normal pace for the patient. Patients with a walking speed in the lowest 20 th percentile, adjusted for gender and height, will be scored as having a slow walking speed

Sarcopenia and gastro-esophageal malignancies

Specific publications on the impact of frailty and sarcopenia on postoperative outcomes following gastro-esophageal surgery are rather scarce (Table 1)^[34,35,63]. In a small study, Pultrum *et al*^[64] reported that esophagectomy was justified in older patients as advanced age alone had only a minor impact on a patients' postoperative course. The authors noted, however, that frailty was much more strongly associated with both short- and long-term outcomes among patients undergoing esophageal surgery. In a separate study, Hodari *et al*^[34] examined a much larger cohort of 2095 patients undergoing esophagectomy and reported that higher frailty scores were associated with increased postoperative morbidity and mortality. In this study, the frailty score was divided into 5 different categories and the incidence of peri-operative mortality incrementally increased with the frailty score, with mortality only 1.8% among patients with a frailty score 0 vs 23.1% among those patients with a frailty score 5 ($P = 0.001$). While the authors assessed several other parameters associated with postoperative outcomes, only age and

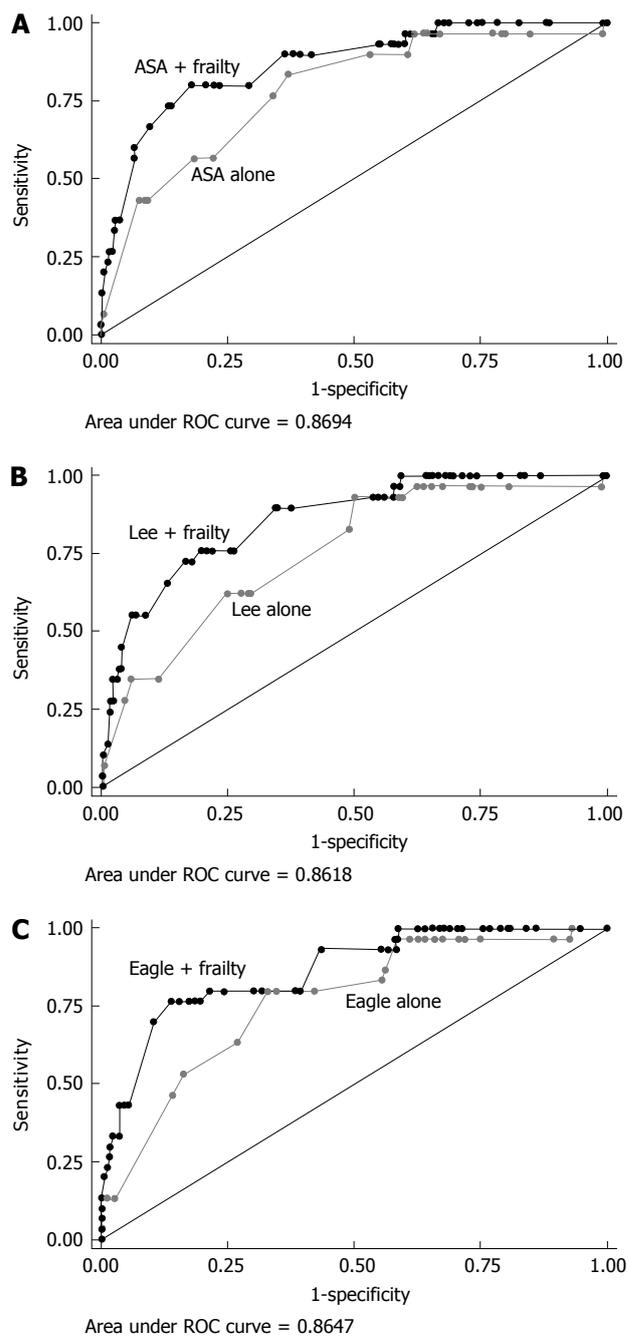

Figure 2 Power of frailty to predict worse outcomes was much higher than traditional peri-operative assessments. A: American Society of Anesthesiologists (ASA); B: Lee; C: Eagle risk indices. Each panel shows the area under the receiver operator characteristics (ROC) curve to demonstrate the ability of the specific risk index to predict surgical complications and discharge to an assisted or skilled nursing facility. Frailty was added to the risk index scoring to demonstrate the combined ability of these indices to predict discharge disposition. Used with permission Makary *et al*^[22], 2010.

frailty were significantly associated with risk of peri-operative morbidity and mortality. Examining a separate cohort of patients undergoing esophageal cancer, Sheetz *et al*^[35] confirmed a strong association between frailty, sarcopenia and peri-operative risk of morbidity among patients undergoing esophagectomy. Using preoperative computed tomography scans in 230 subjects who had undergone transhiatal esophagectomy for malignancy,

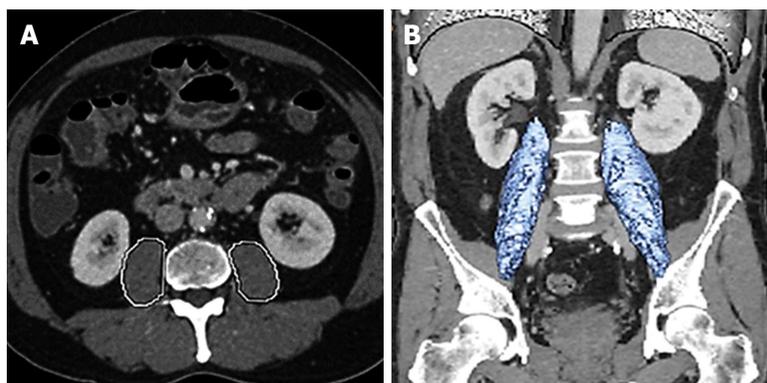

Figure 3 Define sarcopenia rather than a single axial image. A: Total psoas area is measured by circling both psoas muscles at the level of the patients computed tomography where both iliac crests are visible; B: Total psoas volume is measured at the full length of the psoas muscles and normalized for the patients body surface area. Used with permission Amini *et al*^[47], 2015.

the authors assessed lean psoas area (LPA) and correlated it with overall and disease-free survival^[35]. Analyses demonstrated that increasing LPA correlated with both overall and disease-free survival and the authors concluded that core muscle size appeared to be an independent predictor of outcome^[35].

To date, the role of sarcopenia to predict perioperative outcomes among patients undergoing esophagectomy has been evaluated in only a handful of studies^[26,27]. Yip *et al*^[26] studied 35 patients who received neoadjuvant chemotherapy followed by surgical resection for esophageal cancer. The authors noted that changes in computed tomography body composition were associated with outcomes. Specifically, fat mass, subcutaneous fat to muscle ratio and visceral to subcutaneous adipose tissue ratio were each associated with circumferential resection margin. While sarcopenia was more prevalent after neoadjuvant chemotherapy, changes in body composition were not associated with perioperative complication or survival. In a separate study, Awad *et al*^[27] similarly noted marked changes in body composition following neoadjuvant chemotherapy for esophageal cancer. In this study, the authors reported on 47 patients treated with neoadjuvant chemotherapy for esophageal cancer. The proportion of patients with sarcopenia increased from 57% pre-therapy to 79% post-neoadjuvant therapy. Similar to the study by Yip *et al*^[26], no association was demonstrated between sarcopenia and hospital stay, morbidity or mortality. Given the very small number of patients included in the studies by Yip *et al*^[26] ($n = 35$) and Awad *et al*^[27] ($n = 47$), the lack of association between sarcopenia and peri-operative outcomes may have been due to low sample size and a type II statistical error. Future larger studies are necessary to better delineate the impact of sarcopenia on peri-operative and long-term outcomes among patients with esophageal cancer undergoing surgical resection.

Similar to esophageal cancer, gastric cancer patients are at high risk for malnutrition and therefore older patients with gastric cancer may be at a particularly high risk of frailty. In fact, the prevalence of frailty and

sarcopenia among patients with gastric cancer has been reported to be as high as 30% and 38%, respectively^[49,65]. Despite the high incidence, data on the association of frailty, sarcopenia and outcomes of patients after gastric resection are limited. In a review on the topic of gastric cancer surgery, Tegels *et al*^[49] described a strong association between frailty, sarcopenia and increased postoperative mortality after gastric resections. Specifically, the authors highlighted the need for better preoperative risk assessment using comorbidity index, assessment of nutritional status, and frailty assessment. In particular, Tegels *et al*^[65] noted that assessment tools such as the Groningen Frailty Indicator (GFI), Edmonton frail scale, or the Hopkins frailty scale should be used to help identify patients for preoperative optimization using pre-habilitation. In a separate prospective study of 180 patients with gastric cancer, the same authors examined the association of frailty with morbidity and mortality after gastric cancer surgery. In this study, patients scheduled for gastric cancer surgery were preoperatively assessed with the GFI and the Short Nutritional Assessment Questionnaire (SNAQ). Of note, patients with a GFI ≥ 3 had a mortality of 23.3% vs 5.2% in the lower GFI group. Similarly, those patients who scored poorly on the SNAQ had a higher mortality (13.3%) vs those deemed to have better nutritional status (3.2%). The authors concluded that frailty and nutritional status were important factors in preoperative decision making among elderly patients being considered for gastric resection. While the impact of frailty and malnutrition on perioperative outcomes has been examined, no study on the role sarcopenia to predict morbidity and mortality of patients undergoing gastric surgery has been reported to date.

COLORECTAL CANCER

In 2014, 132700 patients were diagnosed with colorectal cancer in the United States. More than half of patients with colorectal cancer are older than 65 years and approximately 70% are diagnosed at early stages, when surgical resection is feasible^[66].

Frailty and colorectal cancer

Among older patients undergoing surgery for colorectal cancer, frailty and sarcopenia have been investigated as predictors of outcome in a small number (Table 2). In particular, pre-operative frailty has been associated with a decline in the patients' activities of daily living and the instrumental activities of daily living after colon resection^[67]. Other studies have noted that frailty can significantly impact peri-operative outcomes. For example, Obeid *et al*^[36] reported on a large group of patients ($n = 58448$) with colorectal cancer derived from the NSQIP database. The authors noted that the proportion of patients who experienced a severe Clavien class IV-V complication following colorectal surgery increased from 5.8% to 56.3% when comparing non-frail vs frail patients ($P = 0.0001$). Frailty was also independently associated with a longer intensive care unit stay and increased peri-operative mortality. In a different study, Neuman *et al*^[37] reported on 12979 patients from the SEER-Medicare database above the age of 80 who underwent a colorectal resection. Older age, male gender, frailty, and dementia were all associated with decreased survival at 1 year. Although only 4.4% of patients were considered frail, this factor had the strongest association with mortality with an odds ratio of 8.4. While the authors concluded that frailty was an important predictor of outcome, the study was limited due to the nature of the administrative data used in the analyses. In a different study that utilized institutional data, Robinson *et al*^[68] reported on 201 subjects, many of whom underwent an elective colorectal surgery. Pre-operative frailty was associated with increased post-operative complications after colorectal surgery (frail 58% vs non-frail 21%); frail patients also had longer hospital stays and higher 30-d readmission rates. Furthermore, frailty has noted to be a good predictor of complications (AUC 0.702). Other authors have noted that an elderly modified Physiological and Operative Severity Score for the enumeration of Mortality and morbidity (E-POSSUM) is also a good tool for predicting mortality after major colorectal surgery in the elderly (AUC 0.86)^[29,31].

Sarcopenia and colorectal cancer

Similar to frailty, the effect of sarcopenia on post-surgical outcomes of patients with colorectal cancer has only been evaluated in a limited fashion. Robinson *et al*^[68] prospectively examined 302 patients who underwent resection of colorectal cancer and noted that psoas density was a better predictor of postoperative complications compared with age, body mass index or preoperative patient comorbidities. The authors reviewed patient computed tomography scans to measure psoas area, density, subcutaneous fat, visceral fat and total body fat. Among the parameters studied, psoas density was found to be the best predictor of surgical complications among patients undergoing colectomy for colon cancer. In a separate prospective study by Lieffers *et al*^[39] that included 234 older patients who underwent

colon resection, sarcopenia was strongly associated with delayed recovery, postoperative infections (23.7% sarcopenic patients vs 12.5% non sarcopenic patients, $P = 0.025$), as well as an increased risk of discharge to a nursing facility (14.3% sarcopenic patients vs 5.6% non sarcopenic patients, $P = 0.024$)^[39]. Similarly, Reisinger *et al*^[50] reported a series of 331 older patients who underwent colorectal cancer surgery and demonstrated that a combination of age related parameters such as frailty, sarcopenia and malnutrition were strongly associated with adverse outcomes. Sarcopenia alone was predictive of 30 d in hospital mortality (8.8% sarcopenic vs 0.7% nonsarcopenic patients, $P = 0.001$). Most recently, Huang *et al*^[30] defined sarcopenia through a combination of monomorphometric measurements and physical performance and used it to define low postoperative outcomes. By this, the authors showed, that including the muscles' functional aspect (handgrip strength and 6-m usual gait speed) to the definition of sarcopenia results in a better prediction for postoperative complications as compared to measurement alone.

HEPATO-PANCREATO-BILIARY MALIGNANCIES

Surgery is commonly used to treat patients with a wide variety of hepato-pancreato-biliary (HPB) diseases. Many of these disease including liver, biliary, and pancreatic malignancies are more common in an aged population. In addition, HPB procedures tend to be complex operations that can be associated with substantial possible morbidity. As such, accurate preoperative assessment of aged patients being considered for HPB surgery is of particular importance.

In 1997, in one of the earlier studies to examine the impact of age on HPB surgery, Fong *et al*^[69] reported on the outcome of 133 patients over the age of 65 years who underwent a hepatic resection. In this study, Fong *et al*^[69] noted that age was an independent risk factor for increased risk of morbidity. Perhaps more importantly, however, the authors noted that major hepatic resection could be performed safely and with good functional outcomes among well-selected aged patients. Over the last several decades, multiple other investigators have similarly reported good outcomes in well-selected older patients undergoing hepatic resection^[70,71]. For example, Reddy *et al*^[71] reported on 856 patients who underwent a major hepatectomy (resection of 3 or more segments) and noted that increasing age was independently associated with postoperative mortality. In fact, each 1-year and 10-year increase in age resulted in an odds ratio of mortality after major hepatic resection of 1.036 and 1.426, respectively. In a separate study of 7764 patients who had colorectal liver metastasis, Adam *et al*^[72] noted that age was associated with outcome, but major resection could be performed in elderly patients with acceptable morbidity. The authors found higher

mortality and morbidity rates in older than in younger patients [3.8% and 32.3% in older, 1.6% and 28.7% in younger patients (both $P < 0.001$)] but did not further investigate frailty or sarcopenia in this cohort. Sixty-day postoperative mortality and morbidity were 3.8% and 32.3%, respectively, compared with 1.6% and 28.7% in younger patients. Of note, 5-year survival was relatively comparable even among very aged patients (70–75 years: 57.8% vs 75–80 years: 55.3% vs > 80 years: 54.1%), suggesting that surgery may have potential benefit even in very well selected aged patients.

Frailty and hepato pancreatico biliary malignancies

While age has been the topic of several investigations, the specific impact of frailty itself has been less well studied. Giovannini *et al.*^[73] suggested that a decrease in serum albumin may be a marker of frailty due to an altered albumin synthesis and the patient's inability to compensate for albumin loss. Unlike frailty, while still limited, several papers have investigated the impact of sarcopenia on outcomes after liver surgery^[40,43,74,75]. Several studies have noted an association between sarcopenia and both short- and long-term outcomes among patients undergoing hepatic surgery^[40,41,43,74,75]. For example, Durand *et al.*^[74] studied whether muscle atrophy was of prognostic value among patients with cirrhosis undergoing surgery. The authors demonstrated that transversal psoas muscle thickness was significantly associated with mortality, independent of Model for End Stage Liver Disease (MELD) score. In a different study, Valero *et al.*^[42] examined whether sarcopenia impacted the risk of post-operative complications following resection or transplantation in patients with primary liver tumors. Among 96 patients, the presence of sarcopenia was an independent predictive factor of post-operative complications, but was not associated with long-term survival. In a study that examined only liver transplant recipients, Englesbe *et al.*^[43] noted that psoas area correlated poorly with MELD score and serum albumin. Central sarcopenia strongly correlated with mortality after liver transplantation, as 1-year survival was 49.7% among transplant recipients with the smallest psoas area vs 87.0% among transplant recipients with the largest psoas area. Kaido *et al.*^[32] reported a similar effect on a cohort of 124 living donor liver transplant patients in 2013. In this study the overall survival rate in patients with low skeletal muscle mass was significantly lower than in patients with normal/high skeletal muscle mass ($P < 0.001$). Other studies have similarly noted that morphometric age correlated with morbidity and mortality after liver transplantation with better discrimination than chronological age^[44,76]. Sarcopenia has similarly been demonstrated to be an important prognostic factor for patients undergoing liver resection for colorectal liver metastasis. Peng *et al.*^[46] reported that sarcopenia was strongly associated with an increased risk of major complications, extended intensive care unit stay, and a longer overall hospital.

Sarcopenia and hepato pancreatico biliary malignancies

Similar to liver resection, frailty and sarcopenia have not been widely assessed in patients after pancreatic operations. Several studies have reported that age is a risk factor for increased morbidity and mortality^[77-79]. For example, in one large study that investigated over three-thousand patients who underwent pancreatic resection in the state of Texas, Riall *et al.*^[77] reported that increased age was an independent risk factor for mortality after pancreatic resection. In fact, in-hospital mortality increased with each increasing age group from 2.4% among patients < 60 years to 11.4% among patients > 80 years. Likewise, postoperative length of stay increased with each increasing age group, going from 11 to 15 d. Of particular interest was the authors' finding that the increase in mortality among older patients was most pronounced among those patients treated at a low vs high volume hospital. While these data and others suggest therefore that age may be associated with outcomes, multiple other studies have noted that pancreatic surgery can be performed safely in well selected older patients^[78-80]. Dale *et al.*^[33] prospectively evaluated the additional value of geriatric assessment in a cohort of older patients undergoing a pancreaticoduodenectomy for pancreatic tumors. Among 76 older patients, significant unrecognized vulnerability was identified using the geriatric assessment. In turn, Fried's exhaustion, a vulnerable elders survey score > 3, as well as a short physical performance battery score < 10 all correlated with an increased risk of severe complication after pancreaticoduodenectomy. As such, the authors concluded that geriatric assessment may help identify older patients at high risk for complication from pancreatic surgery.

Several series have similarly suggested that sarcopenia may be an important predictor of post-operative morbidity and mortality following pancreatic surgery^[45-48]. For example, Joglekar *et al.*^[48] reported a relation between sarcopenia defined by the psoas muscle density and worse outcome after pancreatic resection. In a separate study, Peng *et al.*^[45] examined 557 patients undergoing resection of pancreatic adenocarcinoma and reported on the impact of sarcopenia on outcomes following surgery. Sarcopenia was associated with an increased three year mortality (HR = 1.63, $P < 0.001$) (Figure 4A). Of note, even after controlling for tumor-specific factors such as poor tumor differentiation, margin status, and lymph node metastasis, sarcopenia defined by TPA remained independently associated with risk of long-term death. More recently, rather than assessing sarcopenia using only two-dimensional imaging, the same group reported on the effect of three-dimensional psoas volume (TPV) on outcomes following pancreatic resection^[47]. In this study, Amini *et al.*^[47] noted that more patients were identified as sarcopenic by TPA than TPV. Perhaps more importantly, while TPA-sarcopenia was not associated with a higher risk of postoperative complications (OR = 1.06), TPV-sarcopenia was as strong predictor of post-operative morbidity (OR = 1.79). On multivariate analysis, TPV

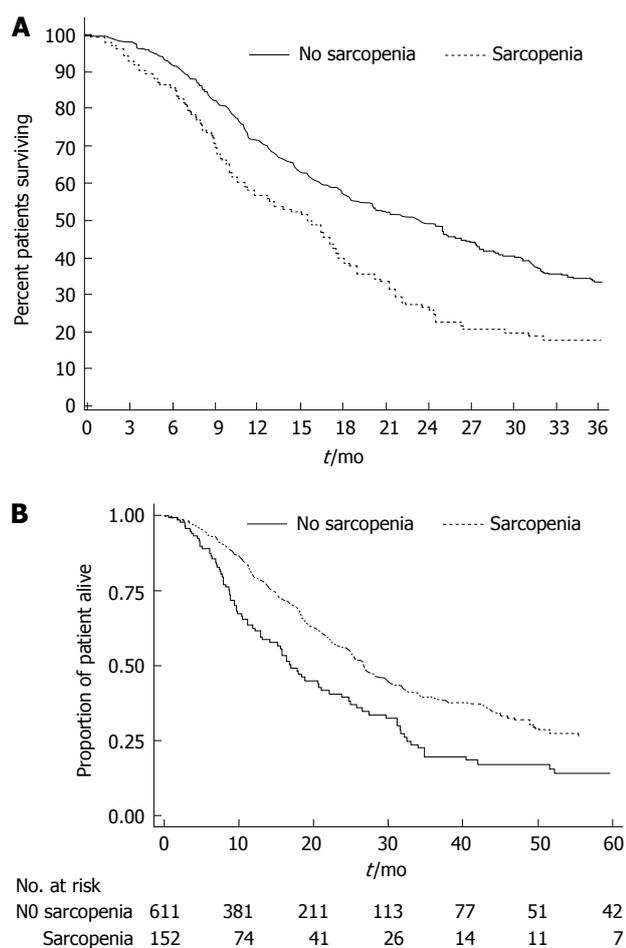

Figure 4 Sarcopenia was associated with an increased three year mortality. A: The presence of sarcopenia was also associated with the risk of death (no sarcopenia, 18.0 mo; 40.0% vs sarcopenia, 13.7 mo; 23.0% vs median, 3-yr survival, respectively; $P = 0.01$) in patients undergoing pancreatic surgery. Used with permission Peng *et al*^[45], 2012; B: The overall survival according to total psoas volume stratified by sarcopenia patients vs no sarcopenia patients quartiles in patients undergoing pancreatic surgeries. Used with permission Amini *et al*^[47], 2015.

- sarcopenia remained an independent risk factor of postoperative complications (OR = 1.69), as well as long-term survival (OR = 1.46) (both $P < 0.05$) (Figure 4B).

CONCLUSION

As the population ages, an increasing number of older patients will require complex gastrointestinal surgical procedures. While chronologic age is an important element in assessing a patient's peri-operative risk, physiologic age is a more important determinant of outcomes. Geriatric assessment tools are important components of the pre-operative work-up and can help identify patients who suffer from frailty. Such data are important, as frailty has repeatedly been demonstrated to be one of the strongest predictors of both short- and long-term outcome following complicated surgical procedures such as esophageal, gastric, colorectal, and HPB resections. Frailty can sometimes, however, be difficult to assess in an accurate and timely manner.

As such, there has been an increasing interest in determining a patient's "morphometric age". Sarcopenia, or wasting of lean muscle mass, has been noted to be an emerging important metric of frailty that is associated with peri-operative outcomes. As demonstrated by the data herein reviewed, screening of patients being considered for gastrointestinal surgery should include an assessment of frailty and sarcopenia to target high risk patients for pre-habilitation. Future studies will need to continue to define the optimal combination of factors (e.g., clinical, performance, and morphometric) to predict optimally a patient's peri-operative risk.

Abstract

This review focuses on the early diagnosis of anal cancer

and its precursor lesions through routine screening. A number of risk-stratification strategies as well as screening techniques have been suggested, and currently little consensus exists among national societies. Much of the current clinical rationale for the prevention of anal cancer derives from the similar tumor biology of cervical cancer and the successful use of routine screening to identify cervical cancer and its precursors early in the disease process. It is thought that such a strategy of identifying early anal intraepithelial neoplasia will reduce the incidence of invasive anal cancer. The low prevalence of anal cancer in the general population prevents the use of routine screening. However, routine screening of selected populations has been shown to be a more promising strategy. Potential screening modalities include digital anorectal exam, anal Papanicolaou testing, human papilloma virus co-testing, and high-resolution anoscopy. Additional research associating high-grade dysplasia treatment with anal cancer prevention as well as direct comparisons of screening regimens is necessary to develop further anal cancer screening recommendations.

Key words: Anal cancer; Secondary prevention; Anal Papanicolaou test; High-resolution anoscopy; Screening

Core tip: Anal cancer is a low prevalence, highly morbid disease. With the success of secondary prevention practices for other human papilloma virus-associated malignancies, screening strategies may similarly decrease rates of anal cancer. No national guidelines formally support screening. This review summarizes possible screening modalities and what further evidence is needed to support routine screening for anal cancer.

INTRODUCTION

Anal cancer is a rare disease whose outcomes continue to underperform those of other malignancies. There are approximately 7000 cases of anal cancer in the United States annually^[1], and the 5-year survival rate is 65.7%^[2]. Unlike other common gastrointestinal malignancies, the incidence of anal cancer is increasing at an average rate of 2.2% per year for the last decade. This increasing rate is above a historical baseline in the 1970s and 1980s where anal cancer incidence remained unchanged^[2,3]. Much of this increase is due to the rise of new high-risk immunocompromised populations in the last three decades, including chronic human immunodeficiency virus (HIV) infected patients and organ transplant recipients. This review will focus on squamous cell carcinoma of the anus, which is responsible for 80% of all anal cancers^[4].

Anal cancer has long been a delayed diagnosis. Historical studies reported a delay of more than two years in diagnosis in more than half of patients^[5], and 44% of patients present with disseminated disease at diagnosis^[2]. This epidemiologic trend is even more troubling when one considers that early stage anal cancer has been shown to respond exceptionally well to low-morbidity chemoradiation therapy while later stage disease often requires highly morbid and quality of life-changing surgical interventions such as abdominoperineal resection with a permanent colostomy for residual primary tumor and groin dissection for inguinal nodal metastases.

Historically, anal cancer was sufficiently rare that population screenings for the disease were not warranted. After 1997, the American Cancer Society dropped its recommendation for annual digital rectal examinations in favor of colonoscopies and sigmoidoscopies for colorectal cancer screening. This further contributed to a lack of screening for anal cancer, in an era where high-risk anal cancer populations were coming into existence.

It has been recognized that certain groups are at substantially higher risks of anal cancer than the general population. The association of sexually transmitted infections and sexual practices with anal cancer has been recognized since the 1980s^[6]. One of the most closely associated sexually transmitted infections has been human papilloma virus (HPV), which was found in 88% of anal cancer patients in a case-controlled cohort^[7] as well as in tissue samples containing anal intraepithelial neoplasia, an anal cancer precursor^[8]. Other risk factors of anal cancer identified include smoking^[9] and organ transplantation^[10].

A number of similarities exist between squamous cell anal cancer and cervical cancer. Both occur at squamocolumnar junction epithelium. The transformation zones of the anal canal and the cervix are both characterized by high turnover epithelium that is thought to be particularly vulnerable to malignancy-inducing genetic alterations^[11]. Both are HPV-associated which is thought to promulgate changes to cells' DNA^[12]. Immu-

nosuppression is also an increasingly important risk factor for both cancers likely due to the increased activity of HPV seen in immunocompromised tissue substrates^[13-15]. Finally, both types of cancer also have widely divergent outcomes for early vs late presenting disease^[16].

Unlike anal cancer, diagnoses of cervical cancer have been markedly reduced in the last 40 years. Between 1975 and 2010, the incidence of cervical cancer has decreased by more than 50%^[16]. This public health success story is largely attributed to the widespread and routine use of cervical cancer screening, primarily employing the cytology-based cervical Papanicolaou (Pap) test^[17]. It is thought that a similar screening effort applied to anal cancer could potentially reverse the disturbing recent trends in disease incidence.

This review focuses on the early diagnosis of anal cancer and its precursor lesions through routine screening. A number of risk-stratification strategies as well as screening techniques have been suggested (Table 1), and currently little consensus exists among national societies (Table 2). No national screening guidelines for anal cancer exist, and the AIDS advocacy groups that note the increased risk of anal cancer in the HIV-positive population differ in their recommended approaches^[18-21]. We provide here a balanced examination of the current clinical science to guide both practitioners and policy-makers in this rapidly developing field.

ANAL CANCER AND AIN PATHOPHYSIOLOGY

Although this review will not cover the cancer cell biology of anal cancer in detail, a general understanding is helpful because it influences the rationale for routine screening. Much of the current consensus on how anal dysplasia evolves is derived directly from cervical cancer literature. In cervical cancer, it is well recognized that the human papilloma virus infection is a necessary step in the development of cervical dysplasia and ultimately invasive neoplasia^[22]. Anal cancer is a more heterogeneous set of malignancies with anal canal tumors that have pathology more similar to squamous cell cervical cancer in addition to perianal squamous cell carcinoma that behaves more like penile or vulvar cancer. Anal canal tumors' similarity to cervical cancer is also shared by the high rate of HPV co-infection - particularly HPV 16 subtypes - in the latter with studies reporting rates over 90% while perianal tumors' HPV co-infection rate vary from 30%-80%^[23-25]. This ongoing close association between HPV and anal cancer has led to parallel frameworks of oncogenesis for both anal and cervical cancer.

Like cervical cancer, anal cancer is thought to most frequently develop at the transformation zone between squamous and columnar epithelium of the anal canal. HPV infects squamous epithelial cells, and the interaction between virion gene expression and cellular growth regulators leads to loss of differentiation and clonal

Table 1 Summary characteristics of anal cancer screening modalities

	DARE	Anal Pap test	HPV testing	High resolution anoscopy
Sensitivity ^[56,57,61,62,101]	Not studied	69%-93%	Alone: 100% Co-testing with Pap ^[49] : 72%-96%	Current diagnostic standard
Specificity ^[56,57,61,62,101]	Not studied	32%-59%	Alone: 16%	Current diagnostic standard
Resource availability	N/A	Ubiquitous	Ubiquitous	Highly selective centers
Provider availability	Universal	Specialty clinics	Specialty clinics	Highly selective centers
Learning curve	Part of usual clinical training	Part of usual clinical training	Part of usual clinical training	> 200 cases
Current consensus ^[52]	Annually, all HIV-positive patients	Annually in highest-risk groups	Alone: No recommendation Co-testing: No recommendation	Second-line screen following positive Pap test

DARE: Digital anorectal exam; HPV: Human papilloma virus; N/A: Not applicable; HIV: Human immunodeficiency virus; Pap: Papanicolaou.

Table 2 Professional society recommendations for anal cancer screening

	Routine screening of general population	Routine screening of high-risk individuals	Assesses modalities for diagnosis	Specific modalities assessed
American Society of Colon and Rectal Surgeons ^[54]	No recommendation	No recommendation	Screening and surveillance	Anal Pap test, high-resolution anoscopy
European Society of Medical Oncology	No recommendation	No recommendation	Surveillance only	Digital anorectal exam, standard anoscopy, computed tomography, magnetic resonance imaging
European Society of Surgical Oncology and Oncology ^[102]				
National Comprehensive Cancer Network ^[103]	No recommendation	No recommendation	Surveillance only	Digital anorectal exam, standard anoscopy
Centers for Disease Control and Prevention ^[104]	No recommendation	No recommendation	Screening and surveillance	Digital anorectal exam, HPV testing
New York State Department of Health ^[52]	No recommendation	All HIV infected adults	Screening only	Digital anorectal exam, anal Pap test, high resolution anoscopy
HIV Medicine Association of the Infectious Diseases Society of America ^[20]	No recommendation	Men who have sex with men, women with a history of abnormal cervical Pap tests, and all HIV-positive persons with genital warts	Screening only	Digital anorectal exam, HPV co-testing, anal Pap test, high resolution anoscopy
British HIV Association ^[21]	No recommendation	No recommendation	Screening and surveillance	Digital anorectal exam, anal Pap test, high resolution anoscopy

proliferation^[12]. These cells have a predictable pattern of stepwise cellular transformation that leads from normal squamous epithelium to low-grade dysplasia to high-grade dysplasia to invasive cancer^[12,26-28].

HPV-associated cellular transformation is characterized by cyclical cellular proliferation and regression. An area of cellular atypia may progress to low-grade dysplasia before then regressing to normal tissue. The occurrence of cancer is when a particular transformed cell line breaks out of this characteristic cycling and linearly progresses to invasive disease^[11].

The natural history of disease progression is largely unknown. Historical reports of the incidence of the progression from premalignant to invasive disease range from 2%-9%^[29-32]. However, more recent series have reported rates as high as 13%-50% in immunocompromised patients managed expectantly^[27,33].

Several case reports point toward anal squamous cell cancer arising in a background of high-grade dysplasia, supporting the dysplasia-to-cancer sequence. Per Scholefield *et al.*^[34] the estimated risk of progression

from anal intraepithelial neoplasia (AIN) to invasive anal cancer is 10% in 5 years. However, this rate needs to be interpreted with caution as progression rates may vary according to such factors as eradication of disease by surgical therapy and the aforementioned risk factors that increase the risk of progression to invasive disease. Furthermore, Simard *et al.*^[35] showed that the incidence of high-grade dysplasia in men in San Francisco has been on the rise - increasing by 11.48% per year between 2000 and 2009.

The basic principle behind screening for anal dysplasia is the early identification of these proliferating cell lines that have established irreversible high-grade dysplasia or local invasive disease. Early stage anal cancer 5-year survival rates exceed 80% while disseminated disease 5-year survival rates are 30%^[2]. Clinical studies demonstrating a morbidity or mortality benefit from routine screening for anal dysplasia are currently ongoing (see "Future Directions"), and the success of such efforts for cervical cancer suggests that further consideration is warranted.

AT-RISK POPULATIONS

Compared to other cancers, anal cancer is rare and no support for general population screening exists. Anal cancer is the 26th most common cancer type in the United States with approximately 7000 cases a year^[1]. Although evidence suggests that the majority of anal cancers are initially asymptomatic^[36], such a low pre-test probability does not make screening tests feasible for the general population.

However, there are populations with disproportionate prevalence of anal cancer that are more conducive to group-wide screening. Immunosuppressed patients are increasingly recognized as one of the groups at highest risk for anal cancer^[13,37]. Much of this recognition has developed over the rise of the HIV/AIDS epidemic in the last three decades. Infection with HIV is associated with a 30-fold increased lifetime risk in anal cancer and a 4-fold increase in 5-year mortality^[37,38]. Although sexual practices - particularly anoreceptive intercourse - have been previously associated with anal cancer, recent studies have shown that the risk of anal cancer in HIV-positive individuals exists independently of sexual practices^[39,40]. The risk of anal dysplasia progression appears to correlate directly with degree of immunosuppression as measured by T cell CD4⁺ count with a cell count less than 200 cells/mm³ most closely associated with increased prevalence^[41-43]. Surprisingly though increased access to highly active antiretroviral therapies has not eliminated the increased risk of anal cancer in the HIV-infected population. It is thought that immune system restoration does not entirely eliminate the increased risk of dysplastic changes and then antiretroviral treated patients are living longer thereby increasing the lifetime interval risk of disease incidence^[44].

Similarly, other immunosuppressed populations share an increased incidence of anal cancer. Increased rates of anal cancer have been identified through controlled studies in kidney^[45,46] and liver transplant recipients^[47]; anogenital malignancy rates after renal transplant are estimated to be 30- to 100-fold higher than the general population^[48].

Currently, no national or international society formally supports routine screening of at-risk populations for anal dysplasia. This lack of recommendation stems from the absence of high-quality studies that demonstrate improved morbidity and mortality for those participating in routine screening. Nevertheless, practice patterns by infectious disease specialists suggest that anal dysplasia screening of high risk individuals is becoming common^[49-51], and influential regional societies like the New York State Department of Health AIDS Institute have begun recommending routine annual examination of the anus in all HIV-infected adults and cytologic testing in ultra high-risk HIV-positive patients such as men who have sex with men (MSM), those with a history of condylomata, and women with cervical or vulvar dysplasia^[52]. Recent population health studies have

even suggested that such selective screening remains inadequate and that anal dysplasia occurs frequently enough in the general HIV-positive population that all should undergo some form of extended screening^[53].

SCREENING MODALITIES FOR ANAL CANCER PREVENTION

Digital anorectal exam

The digital anorectal exam (DARE) is widely considered to be an essential but not sufficient component of any anal cancer screening evaluation. Although the American Society of Colon and Rectal Surgeons does not formally recommend routine screening for anal cancer, a visual perianal skin exam, DARE, and anoscopy are the suggested initial workup for any patient with history or symptoms concerning for anal cancer^[54]. Any abnormal finding necessitates biopsy. There is no evidence that has demonstrated a screening benefit from physical examination and historic surveillance studies with digital examination suggest low sensitivity for recurrent disease^[55]. But the risks to the patient are minimal. The leading guidelines for HIV-infected adults recommend an annual DARE with further screening only if meeting certain high-risk criteria such as MSM, prior history of anogenital condylomas, and women with abnormal cervical or vulvar histology^[52]. As the availability of enhanced low cost screening practices such as the anal Pap test and high-resolution anoscopy become more widely available the accepted adequacy of the DARE as a primary screening test will likely diminish.

Anal Pap test

The cervical Pap test was introduced in the 1960s to help identify premalignant cervical dysplasia that could be intervened upon. Although never demonstrated in a randomized clinical trial, the introduction of the Pap test coincided with a substantially decreased incidence of invasive cervical cancer^[17]. The basis of the test is to collect a swabbed cellular sample that is then collected and prepared on a microscope slide for examination by a pathologist. A number of pathology classification systems have been developed with the modified Bethesda System classification in most contemporary use^[12].

Anal Pap testing was more recently introduced in the 1990s with a similar methodology and grading scheme as a primary screening tool for a premalignant anal dysplasia^[56]. The technique has been well described and is analogous to the cervical Pap test^[52]. Sensitivity and specificity have been shown to be similar to cervical cytology^[57]. Using large cohort databases for retrospective analysis, Markov modeling of the anal Pap test has demonstrated that its role in anal cancer prevention is likely both cost-effective and efficacious^[58].

The test is not without its limitations. Like the cervical Pap test, neither cytologic test has ever been studied in a randomized clinical trial between cytologic screening and

expectant management. The anal Pap test also suffers from a similar inter-rater unreliability of cervical cytologic testing which is then further complicated by varied and evolving classification systems^[59,60]. Sensitivity and specificity estimates range widely from 69% to 93%, and 32% to 59%, respectively^[56,57,61,62]. The anal Pap tests specificity for diagnosing the correct degree of dysplasia is even less accurate with Pap testing routinely reporting low-grade atypia for lesions that ultimately are found to be high-grade dysplasia^[63]. Moreover, sensitivity decreases in the highest risk groups. False-negative cytology results in MSM can be as high as 23% for HIV-negative patients, and 45% for HIV-positive patients^[64]. Such high rates of missed pathology in high-risk populations most needing effective anal cancer screening have led some to suggest that anal Pap tests are inadequate on their own and should be paired with a direct visual modality such as high-resolution anoscopy in order for them to be considered an appropriate screening test^[64]. Even with these limitations, the anal Pap test's low cost, technical ease and familiarity to many primary care physicians, and acceptable sensitivity have supported its role as the most practical screening option currently available^[52,54].

HPV testing

HPV testing is typically performed as part of a Pap test. With modern, liquid-based Pap testing, the same swab sample can be used for both cytology as well as HPV DNA testing^[65].

The necessity of HPV for cervical cancer is well established^[66] and its relationship as a prerequisite for cervical dysplasia has been used as the rationale for routine HPV testing with abnormal Pap test results. The use of HPV testing as a risk stratification tool for cervical dysplasia has become standard practice^[11,67]. Some have even argued that HPV testing as a first-line screening tool for cervical cancer prevention may be sufficient without the need for cytology. Multiple large trials have demonstrated that a single negative HPV test virtually eliminated the risk of death from cervical cancer^[68,69]. The United States Food and Drug Administration approved an HPV primary screening test in 2014^[65].

The role of HPV in anal cancer is thought to be nearly as important, and many studies have routinely assessed HPV status when screening for anal dysplasia^[70-72]. In select high-risk populations, HPV testing has been shown to be an important and clinically useful screening tool in conjunction with anal Pap testing^[73]. Descriptive studies also associate more rapid progression of anal dysplasia with high-risk subtypes of HPV^[42,74,75]. However, early studies have not shown any benefit to anal cancer prevention with or without HPV testing^[76]. More broadly, no guidelines formally recommend HPV testing alone or in combination with Pap testing. Availability of this diagnostic modality is also limited by the lack of coverage by most insurance plans and thereby is a limited offering at most healthcare institutions^[77]. The increasing benefit of HPV testing as part of cervical cancer prevention

practices suggests that the nature and scope of the use of HPV testing for anal cancer prevention will need reconsideration in the future.

High resolution anoscopy

High resolution anoscopy has been proposed as a screening modality that addresses the sensitivity issues of the other methods described above. Modeled off of colposcopy for cervical cancer, high resolution anoscopy uses a high-magnification colposcope with a transparent anoscope to examine the entire anal canal and perianal skin under close visual inspection. Five percent acetic acid is used to identify areas of rapid cell growth; Lugol's solution is employed to improve biopsy yield and accuracy since higher grade dysplastic lesions initially found with acetic acid will not uptake Lugol's unlike low-grade dysplasia^[78]. Originally reported in Europe in 1989^[79], the procedure has been practiced and comprehensively described by its American introducers at the University of California San Francisco since the early 1990s^[78].

The benefits of high resolution anoscopy (HRA) remain unchallenged. Decision models have also demonstrated the superiority of HRA-only screening to combined modalities^[80]. The leading recommendations from the New York State Department of Health AIDS Institute state that HRA be considered standard of care for any patient with prior abnormal anal Pap test^[52]. Its most important contribution being that it effectively addresses some of the limitations of anal cytology-based screening practices^[81]. A longitudinal study of 368 asymptomatic MSM undergoing serial HRAs for a mean of 4.2 years found that 11% of high-grade dysplasia identified with HRA coincided with normal results from an anal Pap test^[82]. In particular, high-risk groups such as HIV-positive MSM have lower sensitivity results from anal Pap testing^[83]. Anal Pap testing may be useful as a way of alerting HRA clinicians to more closely examine suspicious lesions for low- vs high-grade heterogeneity thereby increasing biopsy yields. Some have suggested that HRA and anal Pap test co-testing be performed as a useful quality control measure for HRA^[82,83].

Unfortunately, HRA's usefulness as a screening test is impaired by the logistical needs of its use. Colposcopes are an additional piece of equipment needed for the clinic setting and training for HRA is important^[52]. Surprisingly, HRA has been shown to be cost-effective though with the real obstacle being availability^[80]. Anecdotally, the original group of researchers who brought HRA to the United States note a high degree of dexterity and technical prowess required to effectively visualize the entire anal canal and obtain reliable biopsy specimens^[78]. A new provider logged the first 2 years of cases performed and found that it took approximately 200 cases before results demonstrated no missed high grade lesions found on follow-up^[84]. This substantial learning curve and the lack of practitioners trained formally in residency or fellowship have led to a lack of providers able to provide HRA as a screening option. Hence, HRA is typically utilized as a second-line screening tool for abnormal Pap test or HPV

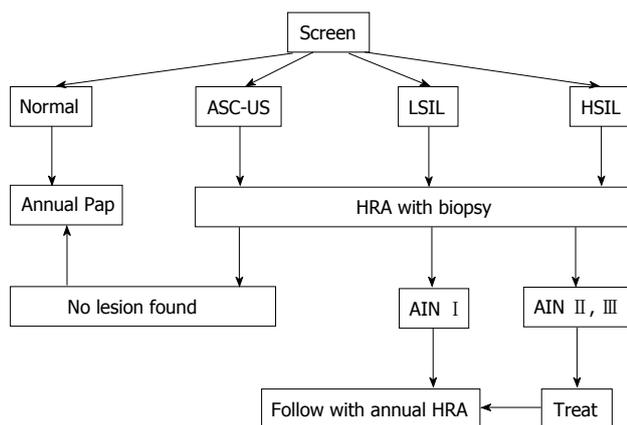

Figure 1 San Francisco algorithm for anal cancer screening of high-risk patients. results^[53,85].

AREAS OF UNCERTAINTY

As described above, the anal cancer prevention literature is rife with screening techniques resulting from rational considerations of cancer biology but with minimal clinical evidence demonstrating their efficacy. This situation is further worsened by the lack of clear-cut guidelines from any national or international society of how best to address this rare but devastatingly morbid malignancy. Some of the most important ongoing clinical questions to be answered are noted here.

First, one of the most critical areas of further research is optimizing both the screening process and post-screen recommendations for a positive result. Until the data provides further guidance on HPV testing or sufficient HRA-trained providers are available to staff screening clinics, the anal Pap smear will remain the standard of care for anal cancer prevention's primary screening modality. What to do with a positive screening test is a matter of ongoing debate. Without formal recommendations, individual expert opinion has driven institutions' screening processes. The most widely disseminated screening algorithm was popularized by researchers at the University of California San Francisco and is reproduced in Figure 1^[29]. The authors' institution uses a modified algorithm that provides HRA screening for all referred patients (Figure 2). The basis of both of these algorithms is that all high-risk patients (*e.g.*, HIV with high-risk sexual history or practices, MSM) get screened annually with an anal Pap test; all atypical cytology results are referred for HRA; and AIN I is followed yearly with HRA while AIN II or III is surgically removed. The diverse modalities for removal of high-grade dysplasia and carcinoma *in situ* are beyond the scope of this review but little guiding evidence exists and most practice is based off of cervical cancer excisional

biopsy techniques.

There is also increasing evidence that the stringent risk stratification currently being employed may be too restrictive. The commonly followed New York State Department of Health's AIDS Institute guidelines for anal cancer screening stratify HIV-positive patients into intermediate risk vs high risk groups. The latter risk stratified group recommends enhanced screening with annual anal Pap tests for any HIV-positive patient who also endorses MSM behaviors, history of anogenital condylomata, or women with history of abnormal cervical or vulvar pathology^[52]. Increasing evidence suggests that HIV-positivity alone affords one a prevalence of approximately 20% for at least some form of anal intraepithelial neoplasia^[39,40,64,86,87]. Such high rates of atypia may be unacceptably high for a population that under current recommendations would only receive a symptoms questionnaire, perianal visual inspection, and digital rectal examination. The previously mentioned high rate of cellular turnover and immunosuppression also suggests that less traditionally screened groups such as all anoreceptive sex practitioners and transplants would both warrant from annual screening as well.

Finally, one other line of inquiry that continues to be considered is the perception of patients who have to undergo these anorectal inspections annually awake and often with tissue samples taken. All of the evidence argues against this concern being a real obstacle to routine screening. Self-performed anal visual inspection^[88], provider-performed digital rectal exam^[89], and anal Pap testing^[90,91] have all been explored with high-risk groups with favorable results. A Toronto study repeatedly screened patients for psychological distress at multiple points throughout the patient's screening algorithm and found less than one-third ever felt negatively distressed throughout the process^[92]. Rather than emotional distress, the greatest patient-oriented obstacles to care appear to be lack of knowledge of increase anal cancer risk and economic barriers to screening^[90,91,93].

FUTURE DIRECTIONS

While controversies remain that will continue to shape the management of anal cancer screening today, there are also a number of expected future developments that may drastically change how we approach anal cancer prevention.

An ongoing Australian study may help address the role of HPV testing in anal cancer screening as well as provide more light on an evidence-based screening plan that incorporates one or more of the modalities described in this review. The Study of the Prevention of Anal Cancer (SPANC) is a 3-year prospective cohort that began recruitment in 2010 with follow-up planned through 2018 that will examine the overlapping roles of digital anorectal exam, HPV testing, anal Pap tests, and HRA^[94]. Each participant will undergo all of these potential screening studies over multiple time points throughout the study, and it is expected that comparisons of sensitivity and

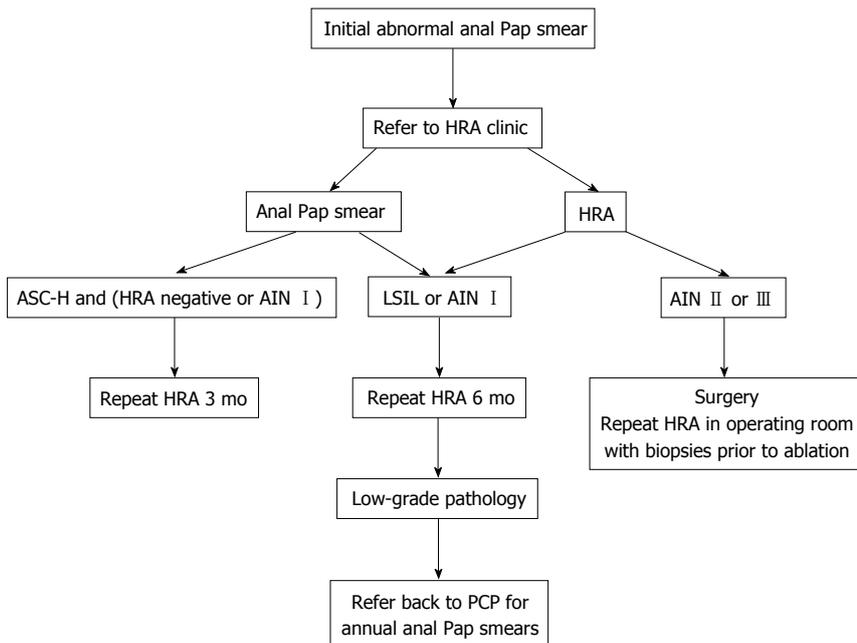

Figure 2 Johns Hopkins Hospital algorithm for anal cancer screening of high-risk patients. Pap: Papanicolaou; HRA: High-resolution anoscopy; ASC-H: Atypical squamous cells of undetermined significance, cannot rule-out high-grade dysplasia; AIN I : Anal intraepithelial neoplasia I ; PCP: Primary care physician; LSIL: Low-grade squamous intraepithelial lesion; AIN II : Anal intraepithelial neoplasia II ; AIN III : Anal intraepithelial neoplasia III.

specificity as well as the practical matters of performing each screen will be better understood. The study selected HIV-positive men over 35 years old living in the Sydney area with a total recruitment of over 350 participants. It is likely that the results of this study will provide a major contribution to the ongoing debate surrounding how best to utilize to the various anal cancer screening modalities at clinicians' disposal.

The ANCHOR Study [anal cancer high-grade squamous intraepithelial neoplasia (HSIL) Outcomes Research] is an ongoing 5-year prospective randomized trial that has the goal of enrolling 5085 patients in the United States. This study aims to follow HIV-positive men over age 35 years with the diagnosis of HSIL over a 5-year period by anal Pap testing and HRA. The two arms of the study include a monitoring arm and a treatment arm for HSIL by ablation through infrared coagulation, with the ultimate goal of determining whether active surveillance with ablative treatment of HSIL will ultimately decrease the incidence of anal cancer^[95].

There are also promising early signs to suggest that anal cancer may be an even more rare disease in the future. The HPV vaccine was developed out of the longstanding consensus that HPV infection is a necessary precursor to cervical cancer. Since its 2006 introduction the HPV vaccine has already been shown to reduce the prevalence of HPV infection among vaccinated populations. Estimating the reduction in cervical cancer cases from the already observed reduced in HPV infection suggests that disseminated vaccination will eliminate more than half of cervical cancers each year^[96]. The similar tumor biology of cervical cancer and anal cancer suggests that HPV vaccination *via* herd immunity and more recent recommendations to vaccinate men

as well will lead to a similar reduction in HPV-associated anal cancer^[97]. There have also been clinical trials to demonstrate the efficacy of the HPV vaccine at reducing anal HPV infection^[98,99]. This supportive evidence helped support a change in the Centers for Disease Control and Prevention's Advisory Committee on Immunization Practice's recommendation to begin routine HPV vaccination of all young males in addition to existing recommendations for female-only vaccination^[100]. If general population uptake of these vaccine-based prevention practices is as successful as the early years suggest, it is likely that there will be dramatic reductions in HPV-associated cancer rates. Changes in prevalence will likely influence what kind of secondary prevention measures are appropriate for anal cancer screening later in life.

CONCLUSION

The low but rising incidence of anal cancer - particularly in vulnerable populations - makes it a concerning and difficult disease to manage with existing evidence-based care. Studies on its diagnosis and management are limited, and nearly all anal cancer guidelines avoid any direct recommendation regarding routine screening. The state of the literature suggests that further descriptive studies will be inadequate to advance consensus. Instead, large randomized clinical trials are necessary to demonstrate the increasing consensus among practitioners that anal cancer screening offers a cost-effective and prevalence lowering intervention in high-risk groups. The SPANC and ANCHOR studies will be helpful in determining whether routine screening through to a cancer diagnosis will ultimately be necessary to build the evidence for a population-wide recommendation.

Abstract

The widespread popularity of new surgical technologies such as laparoscopy, thoracoscopy and robotics has led many surgeons to treat esophageal diseases with these methods. The expected benefits of minimally invasive

surgery (MIS) mainly include reductions of postoperative complications, length of hospital stay, and pain and better cosmetic results. All of these benefits could potentially be of great interest when dealing with the esophagus due to the potentially severe complications that can occur after conventional surgery. Moreover, robotic platforms are expected to reduce many of the difficulties encountered during advanced laparoscopic and thoracoscopic procedures such as anastomotic reconstructions, accurate lymphadenectomies, and vascular sutures. Almost all esophageal diseases are approachable in a minimally invasive way, including diverticula, gastro-esophageal reflux disease, achalasia, perforations and cancer. Nevertheless, while the limits of MIS for benign esophageal diseases are mainly technical issues and costs, oncologic outcomes remain the cornerstone of any procedure to cure malignancies, for which the long-term results are critical. Furthermore, many of the minimally invasive esophageal operations should be compared to pharmacologic interventions and advanced pure endoscopic procedures; such a comparison requires a difficult literature analysis and leads to some confounding results of clinical trials. This review aims to examine the evidence for the use of MIS in both malignancies and more common benign disease of the esophagus, with a particular emphasis on future developments and ongoing areas of research.

Key words: Esophageal disease; Esophageal cancer; Laparoscopic; Robotic; da Vinci; Heller; Reflux disease; Esophageal diverticula

Core tip: Minimally invasive surgery for esophageal diseases is very attractive for reducing potentially serious complications that can occur after conventional surgery. However, if the oncologic long-term results remain the cornerstone of any procedure to treat malignancies, determining the outcomes of surgery for benign diseases requires a deep analysis of published evidence

and a comparison with alternative pharmaceutical or endoscopic treatments.

Bencini L, Moraldi L, Bartolini I, Coratti A. Esophageal surgery in minimally invasive era. *World J Gastrointest Surg* 2016; 8(1): 52-64 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i1/52.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i1.52>

INTRODUCTION

For many years, esophageal surgery has been recognized as very challenging for surgeons and risky for patients^[1-3]. However, subspecialized training of surgeons and a case-load centralization have been shown to reduce both perioperative mortality and the so-called "failure to rescue" rates after a life-threatening complication occurs^[2,4].

This type of surgery is complicated by the deep location of the esophagus in the neck, the posterior mediastinum and the upper abdomen. Moreover, the esophagus crosses all of these sectors very close to major vascular structures, including the carotids, the jugular vein and the aorta, while the trachea and the pericardium have important connections. Furthermore, the absence of a formal serous layer leads to unsafe anastomosis with a great risk of leakage.

All of these issues, together with the older age and comorbidities of many patients affected by esophageal cancer, could explain the disappointing outcomes of patients who are candidates for surgery. In this scenario, the adoption of the concept of a minimally invasive (endoscopic, thoraco-laparoscopic and robotic) approach could represent an attractive and valuable option.

The introduction of the da Vinci[®] Robot system to surgical practice added other benefits in terms of feasibility of the most complex esophageal procedures, which were previously precluded by pure laparoscopy and thoracoscopy procedures.

The proven and unquestionable advantages of minimally invasive surgery (MIS) are mainly represented by a reduction in pulmonary complications, wound infections, postoperative pain, and length of postoperative stay compared to open surgery. A superior cosmetic result is an additional benefit, especially when dealing with benign diseases in younger patients. Another recent field of research has demonstrated the important role of MIS in decreasing the pro-inflammatory and immunologic responses to surgery, which is, hypothetically, related to improved immediate or even long-term oncologic results^[5,6].

However, many of the minimally invasive surgical esophageal procedures failed to reach a consistent level of evidence-based efficacy to enable their routine application^[5]. The evidence-based literature is limited for many reasons. First, there is an intrinsic and well-known difficulty in conducting clinical surgical research.

Second, a relatively low incidence of esophageal diseases (*i.e.*, cancer) compared to stomach and colorectal cancers limits the gain of sufficient experience in Western countries. Finally, the large spectrum of new technologies, including laparoscopy, thoracoscopy, robotics, hybrid procedures and endoscopy, contributes to unclear and confusing results in clinical trials^[7].

We focused this review on minimally invasive surgical procedures, including laparoscopy, thoracoscopy and robotics, for the treatment of the more frequent esophageal diseases, with an emphasis on clinical outcomes rather than on the technical details of each approach. Pure endoscopy, although recognized as the standard of care in some esophageal impairments and as important in many others, does not represent the core focus of article and was treated marginally.

A search of the PubMed, EMBASE and Cochrane databases through March 2015 was conducted, including important cross-matched manual references. Randomized controlled clinical trials (RCTs) and meta-analyses were considered a priority. Data arising from English-written, multicenter, international studies and those with long-term follow-up and oncologic results were also of major interest. A few small studies on the feasibility of the newest procedure were also included.

REFLUX DISEASE AND HIATUS HERNIA

The largest number of medical consultations for esophageal diseases involve symptoms related to hiatus hernia and gastroesophageal reflux disease (GERD). Fortunately, most of the affected patients are managed properly by a medical regiment of proton pump inhibitors (PPIs) and drugs targeted to dyskinesia. However, a subgroup of patients requires further invasive approaches, including endoscopy and surgery, while a few with long-standing disease are at risk of developing cancer.

It is commonly accepted that laparoscopic fundoplication (LF) greatly improves GERD symptoms, and it is considered as the standard operation, although in some patients symptoms can recur, necessitating a return to PPI use^[8]. Interestingly, the best surgical results are achieved in those patients with optimal responses to medical therapy, which reflects an ongoing health-policy and cost-efficacy problem^[9-11]. Morbidly obese patients require peculiar integrated multidisciplinary surgical approaches and will not be considered further in this study.

A debate that has lasted for years still exists on the extent of the stomach wrap (total or partial). The most common approaches are the classical 360° posterior fundoplication [laparoscopic Nissen fundoplication (LNF)], the 270-degree posterior fundoplication [laparoscopic Toupet fundoplication (LTF)], the 180-degree laparoscopic anterior fundoplication (180-degree LAF) and the 90-degree anterior laparoscopic anterior fundoplication (90-degree LAF or Dor fundoplication). All of these partial fundoplications have been adopted to avoid the post-operative negative symptoms associated

with LNF (mainly gas bloating syndrome and dysphagia).

Neither of the two approaches (partial vs total plication) has been demonstrated to be sufficiently superior to justify abandoning the other completely. A recent, updated selective review^[12] concluded that LTF is the therapy of choice for normal-weight GERD patients who qualify for surgery because no better pharmaceutical, endoluminal or surgical alternatives exist to date.

The technical option of performing a laparoscopic 180-degree LAF should be validated compared to the Toupet fundoplication, while the division of the short gastric vessels is not recommended, nor is the use of a boogie or a mesh in the vast majority of patients undergoing surgery^[11]. Interestingly, anti-reflux surgery is considered to be a field for expert surgeons, although no consensus exists on the adequate learning curve^[12].

Most of the benefits of LF for patients suffering from GERD still persist after long-term follow-up. A multicenter Scottish trial^[13] included more than 350 patients randomized to medical management and surgery (or who expressed a preference for one arm over the other) who were followed for five years using structured questionnaires. The authors reported that 44% of those who underwent surgery and 82% of those who had initial medical management were still taking anti-reflux medications. Differences in the REFLUX scores significantly favored the surgery group (mean difference 8.5, 95%CI: 3.9-13.1, $P < 0.001$, at five years). Postoperative complications that required surgical intervention occurred in 3% of patients, while 4% had further reflux-related operations, most often revision of the wrap.

Few rigorous articles have been published on the robotic approach to GERD and most of those compared it to open or laparoscopic techniques. Globally, the updated surgical approach to GERD has led to a hard scientific comparison among medical therapies, the endoscopic approach and surgery using an open, laparoscopic or robotic route. Unfortunately, these types of studies are very difficult (if not utopian) to design and conduct^[7].

One of the largest analyses was that published by Owen^[14], which included more than 12000 patients from an American national database. The group was retrospectively divided into those who received open fundoplication (OF), LF, and robot-assisted fundoplication (RLF). Interestingly, RLF matched favorably with OF in terms of morbidity (5.6% vs 11%; $P < 0.05$), length of stay (LOS) (6.1 ± 7.2 d vs 3.0 ± 3.5 d; $P < 0.05$), intensive care unit (ICU) admissions (11.5% vs 23.1%; $P < 0.05$), and cost (United States \$10644 \pm 6041 vs United States \$12766 \pm 13982; $P < 0.05$), although LF remained superior to RLF when considering the 30-d re-admission rate (1.8% vs 3.6%; $P < 0.05$) and the cost (United States \$7968 \pm 6969 vs United States \$10644 \pm 6041; $P < 0.05$).

A meta-analysis^[15] of 221 patients from six selected RCTs comparing LF and RLF found similar results, with

RLF having a longer duration of surgery, higher costs and similar patient outcomes.

According to the current literature, it is very hard to consider robotic procedures as cost-effective (as compared to standard laparoscopy) when dealing with simple routine operations, such as esophago-gastric junction and functional surgery^[16,17].

Hiatus hernia has several epidemiologic, anatomic and pathophysiological correlations with GERD and its correction is often by LF. Moreover, some patients suffering from hiatus hernias experience gastric volvulus with life threatening complications or become highly symptomatic, which justifies a surgical repair. However, the early minimally invasive approaches could lead to an increased incidence of recurrence compared to traditional open surgery^[18,19]. Currently, laparoscopic mesh crural reinforcement and Collis gastroplasty in selected cases have achieved excellent functional results, with a recurrence rate of less than 20%^[20,21].

From a comprehensive point of view, laparoscopic surgery for GERD and hiatal hernia is considered as a standard of care in most hospitals worldwide. The high grade of effectiveness, together with the proven lower mortality and morbidity, are reasons for abandoning open surgery on a routine basis^[22,23].

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are rare pathologies. The exact incidence is unknown because patients are often asymptomatic, and diagnosis is mostly incidental. Confirmation is based on a barium esophagogram and a thorough endoscopy to exclude the presence of concomitant malignancies^[24,25]. Many cases are acquired pulsion diverticula, caused by an impaired motility that results in higher intraluminal pressure and mucosa herniation through the muscular wall^[25,26].

Zenker's diverticulum (ZD) is the most common type in the esophagus (70%). It usually begins in the upper third, with an estimated prevalence of 0.01%-0.11%^[26] and some age, geographic and gender-related differences^[27].

The choice of treatment for ZD for many years has been an open surgical diverticulectomy with cricopharyngeal myotomy, while an endoscopic myotomy with a rigid or flexible endoscope is a recent emerging option that can be achieved with multiple techniques^[28-32]. Current literature is mostly based on retrospective studies with heterogeneous results, and the gold standard of treatment is not yet established^[33]. However, the endoscopic staple-assisted esophago-diverticulostomy is often considered the first choice of treatment^[34].

Endoscopic repair of ZD is safe and effective, allowing a shorter operative time, a reduction of hospital stay, and a quicker resumption of oral intake^[35-37]. In the available literature, the endoscopic repair has a morbidity rate of up to 4% and a mortality rate lower than 1%. The mean recurrence rate is approximately 6% (0%-22%)^[38].

The traditional surgical techniques consist of a stapled or manual diverticulectomy for larger diverticula associated with a myotomy; a myotomy alone for small diverticula (less than 1 cm); and a myotomy with suspension or inversion for moderate-sized diverticula (1-4 cm)^[39,40]. Despite proven efficacy, open surgery is associated with a high rate of complications (ranging from 3% to 19% depending on the technique), such as pharyngo-cutaneous fistula, mediastinitis, larynx muscles paralysis, recurrence and death (1.6%)^[27,41-43].

The prevalence of epiphrenic diverticula (ED) is approximately 0.015%, and patients are usually elderly men. ED are usually localized in the terminal esophagus and tend to project into the right thoracic cavity, accounting for less than 20% of esophageal diverticula^[44-46]. The remaining 10% of diverticula of the esophagus are located in the mediastinal space.

Because of the high morbidity and mortality rates, treatment of ED is recommended only for selected patients with severe symptoms and a high risk of aspiration pneumonia, rather than being based on the dimension of the diverticular sac itself^[44,46,47].

Surgical treatments of ED include diverticulectomy, myotomy and fundoplication (often partial) due to the higher recurrence rates of diverticulectomy alone^[48]. The procedures could be achieved by a traditional thoracotomy, a thoracoscopy, or a laparoscopic and robotic-assisted transhiatal technique. The minimally invasive approach is generally preferred for its lower morbidity and mortality rates and a similar success rate (83%-100%)^[49].

Fumagalli Romario *et al.*^[50] reported on 30 patients treated with a laparoscopic transhiatal diverticulectomy with only a suture leak (3%) and no recurrence after a median follow-up of 52 mo, while Zaninotto *et al.*^[45] reported on 17 laparoscopic diverticulectomies (associated with myotomy and anti-reflux procedures) and 7 that used a combined laparoscopic-thoracotomy approach. The latter study found 4 leakages (16.6%) and good functional outcomes in all patients.

Unfortunately, most of the studies published are single, monocentric case studies without robust statistical calculations.

ACHALASIA

Achalasia is the most common primary motility disorder of the esophagus and, after GERD, is the second most common functional disorder of the esophagus requiring operative treatment. Most people are diagnosed between the ages of 25 and 60. It initially presents with a difficulty in swallowing that progressively becomes chronic and is not resolved by conventional interventions^[51].

A number of medical and endoscopic treatments, including dilatation and myotomy^[52-55], are available for achalasia with promising results, but a surgical Heller myotomy (HM) with fundoplication has been recognized as having excellent long-term outcomes and is considered as the standard to which others options

should be compared^[56-58].

The goal of myotomy is to improve esophageal emptying by dividing the esophageal and gastric muscle fibers that contribute to the lower esophageal sphincter mechanism. The original operation was developed by Heller^[59] in 1913 and consisted of anterior and posterior esophageal myotomies. Because this approach resulted in excessive gastroesophageal reflux, it later was modified to involve a single myotomy, which still is the mainstay of surgical treatment.

In the early 1990s, Shimi *et al.*^[60] and Pellegrini *et al.*^[61] were the first to describe the use of minimally invasive techniques for the treatment of achalasia. Laparoscopic HM (LHM) has been shown not only to be feasible but also to decrease hospital stay and costs^[57]. The use of LHM spread rapidly, motivating a change in the treatment algorithm for esophageal achalasia^[56]. The standard technique includes both myotomy and fundoplication, while the Dor partial anterior plasty has been shown to be superior to the Nissen total plication^[62]. Most of the patients affected had consistent symptom relief within a few weeks of the operation, with clinical improvements maintained after several years^[63].

Similar to many esophageal procedures, the surgical treatment of achalasia with robotic assistance has been studied^[64]. The first study on a robotic HM (RHM) with a Toupet fundoplication was published by Melvin *et al.*^[65] in 2001. Since then, several larger studies on the use of a RHM have been published^[66-68].

Interestingly, esophageal perforations represent a life-threatening complication but have rarely been studied^[69,70]; the studies that do exist have included immediate repairs with good outcomes. In a meta-analysis of the efficacy of robotic abdominal surgery that included 3 studies relevant to RHM, the authors reported the risk of perforation to be lower with robotic assistance^[71]. It should be noted, however, that the lower perforation rate of RHM may be subject to bias, as most authors compare their results with laparoscopic myotomy cases performed earlier in their learning curve.

Another retrospective multicenter trial suggested decreased esophageal mucosal perforations with the use of a robot (0% vs 16% with conventional laparoscopy; $P < 0.05$) with similar patient outcomes and equal operative times, after an appropriate learning curve^[67]. Huffmann *et al.*^[72] reported a lower rate of esophageal perforations and better quality of life with RHM compared to LHM as well.

From a robust comparative perspective, Shaligram *et al.*^[73] analyzed 2683 patients suffering from achalasia who were treated by open Heller myotomy (OM), LHM, or RHM. No differences in mortality, morbidity, ICU admission, LOS, or 30-d re-admission were observed in the three groups. However, the overall hospital costs decreased in the LHM group (United States \$7441 ± 7897 vs United States \$9415 ± 5515; $P = 0.0028$). Interestingly, when comparing OM and RHM, the authors

found significantly lower morbidity (9.08% vs 4.02%; $P = 0.02$), ICU admission rate (14.01% vs 3.36%, $P = 0.0002$), and LOS (4.42 ± 5.25 d vs 2.42 ± 2.69 d; $P = 0.0001$) in the RHM group. The authors concluded that the RHM group had also a slight improvement in perioperative outcomes compared to the LHM, at the price of increased costs.

Another large review^[74] of LHM vs RHM, which including only 6 RCTs (of low quality), also reported comparable outcomes and increased costs for the robotic technique.

The Society of American Gastrointestinal and Endoscopic Surgeons' guidelines^[75] state that compared with laparoscopy, robotic assistance for the treatment of esophageal achalasia decreases the rate of intraoperative mucosal perforations, but no clear differences in post-operative morbidity, symptom relief, or long-term outcomes have been confirmed to date. Further studies are needed to better establish the role of RHM.

ESOPHAGEAL PERFORATION

Esophageal perforation (EP) is an uncommon situation, although its incidence has increased over the last 20 years. The most common cause is iatrogenic (60% of cases are caused by an endoscopic procedure)^[76,77]. Otherwise, EP can occur spontaneously after vomiting or in cases Boerhaave syndrome or a diseased esophagus (*i.e.*, diverticula, Barrett's esophagus, infective esophagitis, cancer)^[78]. Other rare causes are blunt or penetrating trauma to the epigastrium and ingestion of foreign bodies or caustics. The mortality rate is as high as 60%^[79-81] and is mainly secondary to the onset of a septic shock and the presence of comorbidities^[82].

The ideal management of EP is not yet standardized, and no technique has shown a real superiority over the others. Nevertheless, the number of patients treated aggressively with surgery has been lower over the last several years^[83], while many patients (approximately 25% of EP cases) are being managed non-operatively. Early total parenteral nutrition and antibiotic therapy, in those patients without signs of sepsis, can lead to a medical management success rate of more than 80%^[78].

Endoscopic stenting, associated with or without a percutaneous or surgical thoracic drainage, has a success rate up to 90% in patients with EP due to benign perforations of less than 5 cm or an anastomotic leak with a minimal contamination if treated within 24 h of the perforation^[84-86]. Endoscopic closure of the leak with clips or suture is also effective^[87].

Nevertheless, the surgical approach to EP is still appropriate in case of severe acute sepsis, extended leaks or failure of endoscopic/percutaneous treatments. A feeding jejunostomy is often recommended^[88]. Surgical drainage of the contaminated space, debridement with primary repair, esophageal diversion with delayed repair and esophagectomy with immediate or delayed repair have all been used for several years, with high

morbidity and mortality rates^[78,81,88,89].

Open surgery is widely considered the standard, even though some case studies have reported on the feasibility and safety of laparoscopic^[90-93]/thoracoscopic^[94] primary repair of EP associated with or without stent placement^[95] in hemodynamically stable patients. Again, most of the published studies are monocentric case studies and anecdotal reports with short-term follow-up.

Pleural percutaneous drainage alone may achieve acceptable mortality rates in appropriately selected patients with cervical EP^[96,97], although it is usually associated with thoracoscopy or laparoscopy for complete surgical debridement^[98].

BENIGN AND MALIGNANT TUMORS

Both benign and malignant tumors arising in the esophageal tract are candidates for a minimally invasive approach, although the widespread adoption of minimally invasive techniques has been limited by many challenging technical issues. In addition, the oncologic outcomes remain the foundation of any procedure to cure malignancies, rather than the feasibility itself. Obviously, any laparoscopic or robotic procedure should follow the standards of oncologic surgery, including sufficient margins of resection and extended proper lymphadenectomy^[99].

The need for a surgeon with advanced skills, the availability of instruments and the high case volume together have limited the use of MIS for esophageal neoplasms to few subspecialized centers.

Benign lesions are rare, representing only 20% of all esophageal neoplasms at autopsy, with more than 70% being leiomyoma^[100]. Nevertheless, the anatomic location in the esophageal tract, together with the well-known challenges of esophageal reconstructions, lead to potential life-threatening complications after surgery. A minimally invasive surgical approach would be of crucial interest to limit the risks of perioperative deaths and the length of hospital stay.

Most studies have included a limited number of anecdotal experiences^[101-103] with excellent results from a thoracoscopic or laparoscopic transhiatal enucleation for esophageal leiomyomas. However, the optimal approach should be tailored for each patient according to the location and size of the tumor^[104]. For example, Palanivelu *et al.*^[105], in one of the largest single-center studies (18 cases), reported that leiomyomas are frequently located in the middle and lower third of the esophagus. The author suggested that the proximal ones should be best approached by a right thoracoscopy and the distal ones through an abdominal route. Nevertheless, a laparoscopic transhiatal operation is also feasible to manage benign lesions of the thoracic esophagus^[106,107].

Many of the published studies include very few patients, and those comparing laparoscopic/thoracoscopic procedures with open traditional approaches have poor statistical relevance. However, most studies

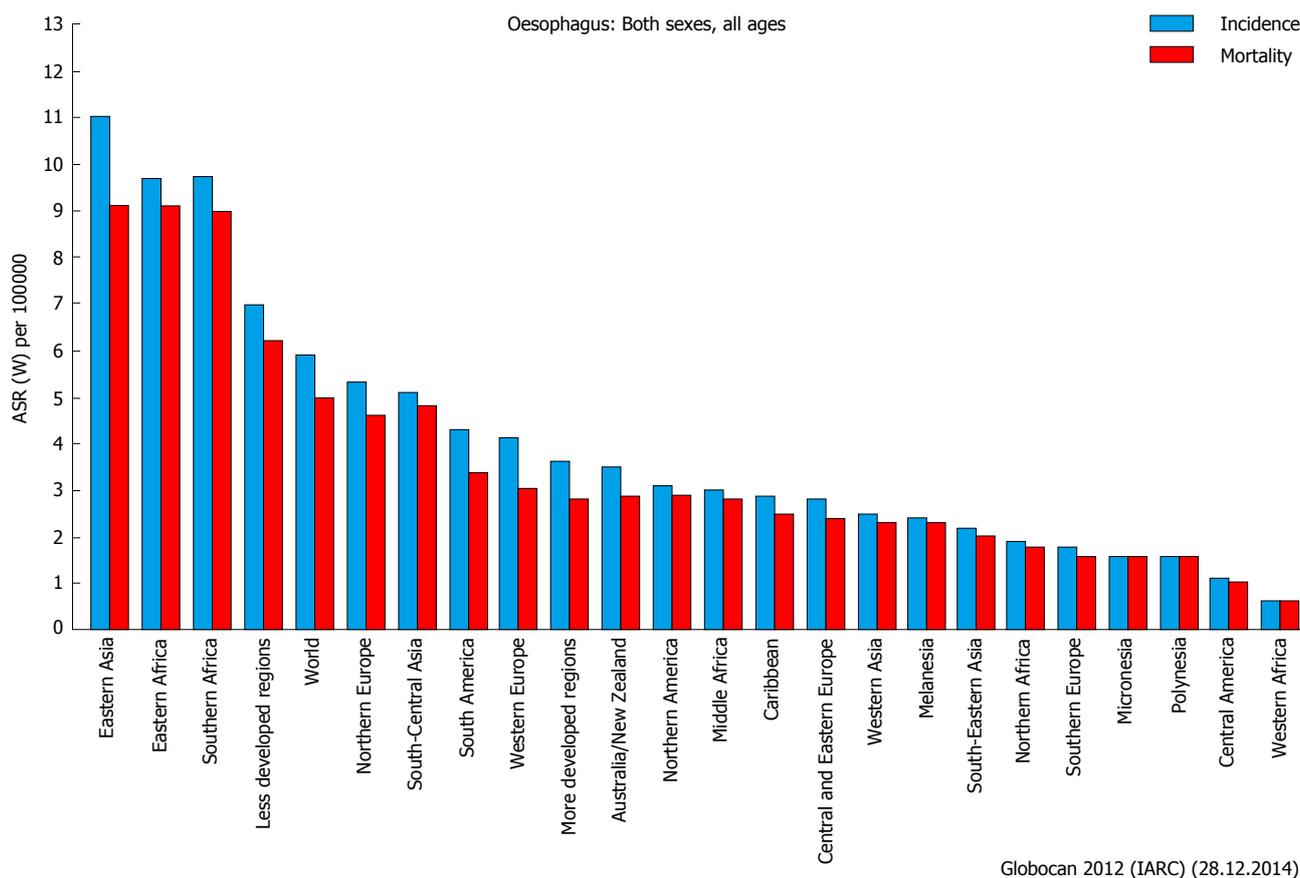

Figure 1 Incidence and mortality rates of esophageal cancer worldwide^[114].

have reported superior results of MIS in terms of reductions of perioperative complications and length of hospital stay^[108,109].

The robotic approach was also described as a procedure very suitable for managing benign esophageal masses that require careful dissection in deep, narrow spaces. Obviously, all these experiences were reported as case studies performed by skillful subspecialized surgeons^[64,110-113].

The different interventions for esophageal benign diseases range from a simple enucleation achieved through a thoracic or an abdominal route to a formal Ivor-Lewis partial esophagectomy. Interestingly, Khalailah *et al.*^[113] reported favorable results of robotic approaches compared to the corresponding open or traditional laparoscopic/thoracoscopic operations (overall complications of 0%, 10% and 13%, respectively). Unfortunately, that retrospective review included fewer than 100 patients in each group, with scarce homogeneity of characteristics and very different approaches.

Cancer of the esophagus is relatively rare in Europe, North America and other developed countries, although it represents a major concern in Eastern Asia, Eastern and Southern Africa, and, generally speaking, in less developed regions (Figure 1). In Eastern Asia, the incidence is almost double than in rest of the world (more than 10 per 100,000 per year)^[114], with some differences in the histopathological features (adenocarcinoma

and squamous). The oncologic outcomes are still disappointing, with a 5-years survival rate of less than 40%^[115]. New adjuvant regimens have been proven to significantly increase the survival after curative surgery, with few or no detrimental perioperative complications^[115,116].

From a comprehensive point of view, the fundamental esophageal cancer cure is always resective surgery with regional lymphadenectomy and (neo) adjuvant chemo or radiochemotherapy. Conversely, many technical debates still exist regarding the opportunity of performing a partial or a total esophagectomy, with or without a transthoracic approach^[117].

In brief, the three-field esophagectomy (McKeown procedure) has been the treatment of choice for esophageal cancer for many years and includes abdominal, thoracic and cervical incisions. The two-field partial esophagectomy with an esophagogastric intrathoracic anastomosis (Ivor-Lewis procedure) has gained popularity in recent years due to comparable oncologic results with the McKeown operation and minor complications. The transhiatal esophagectomy, which avoids the thoracotomy (Orringer procedure), probably offers inferior oncologic outcomes^[118].

In the recent literature, many groups of esophageal surgeons have reported trends in reducing the use of the three-field McKeown total esophagectomy in favor of the two-field Ivor-Lewis partial esophagectomy (except

for cases of cancer arising in the upper third of the esophagus). The significant reduction of perioperative complications, including leaks, recurrent laryngeal nerve injuries, alteration of swallowing and pharyngeal transit, is the major benefit of the limited approach^[119,120].

Despite the different surgical techniques proposed, patients are expected to have a high incidence of complication of up to 60%. Most are pulmonary complications, with an increase in the postoperative stay, costs and mortality^[1,3].

To improve such those disappointing figures, many minimally invasive approaches had been developed, replacing conventional operations with laparoscopy, thoracoscopy or hybrid routes (with open surgery combined), with excellent results^[119,121,122].

The minimally invasive esophagectomy (MIE) is expected to reduce pulmonary impairment, intraoperative bleeding, wound infections and, consequently, length of hospital stay and mortality. Increases in the operative time and of the base costs are the principal concerns^[123].

One recent multicenter (selected hospitals with specific credentials) prospective phase II trial^[124] evaluated the feasibility of MIE in patients with high-grade dysplasia or esophageal cancer with a rigorous protocol. According to the authors' results, surgery was completed in 95 of the 104 patients (91.3%), with a 30-d mortality rate of 2.1%. The major complications were anastomotic leak (8.6%), acute respiratory distress syndrome (5.7%), pneumonitis (3.8%), and atrial fibrillation (2.9%). The 3-year overall survival rate was 58.4% and a locoregional recurrence occurred in only 7 patients (6.7%).

However, the rapid worldwide use of MIS for esophageal cancer has not been followed by a rigorous scientific analysis of results, and the issue of cost-effectiveness is still unresolved^[5,125]. Therefore, large-scale multicenter trials are still lacking, and few studies have had sufficient follow-up to judge the long-term oncologic results.

Aside from the intrinsic difficulty in conducting surgical clinical trials, the challenging learning curve and the numerous technical variables (including the patient's position - prone vs supine or the transoral anvil introduction vs the transthoracic route during an Ivor-Lewis esophagectomy) have jeopardized the results^[126].

One large retrospective cohort study also confirmed the superiority of MIE in terms of postoperative pulmonary complications (13% in the thoraco-laparoscopic MIE group, 38% in the thoracoscopic MIE group, and 39% in the open group)^[122].

Nevertheless, to date, only one prospective, multicenter RCT that including 56 patients and compared open transthoracic oesophagectomy with the minimally invasive approach has been published^[127]. The authors reported that 29% of patients in the open group had pulmonary infections in the first 2 wk compared to five (9%) in the minimally invasive group ($P = 0.005$), while 19 (34%) and 7 (12%) patients in the two groups

had in-hospital pulmonary infections, respectively ($P = 0.005$)^[127]. Another trial to evaluate the benefits of laparoscopic gastric mobilization during Ivor-Lewis intervention is still ongoing^[128].

Conversely, Hanna *et al.*^[129], who selected thirty of the best published papers concerning MIE and open approaches for cancer (including only 1 RCT), found that in most studies a suboptimal lymphadenectomy was described (with the average number of nodes retrieved below 23 considered as the standard) and included a superficial description of the complications that occurred. However, the disease-free survival and the overall survival rates were similar to those achieved by open surgery^[129].

In recent years, robotic-assisted MIE (RAMIE) has been introduced for the treatment of esophagogastric malignancies. The robotic platform would reduce the complexity of the laparoscopic-thoracoscopic maneuvers using endo-wrist arm technology (articulation of the instruments with 7 degrees of freedom). The deeper high-definition 3D vision, the motion scaling and the tremor filtration are other potential advantages of a robotic approach during esophageal dissection, allowing the execution of an extended lymphadenectomy and hand-sewn visceral anastomoses^[130]. Another intriguing advantage of robotic surgery is the reduction of the learning curve (20 procedures in one study^[131]), as compared to standard MIE, which increases the number of surgeons who can gain adequate and specific proficiency.

In the published literature, studies on all three types of esophageal resections (total esophagectomy, partial transthoracic and partial transhiatal resection) using a full robotic or a hybrid approach are available (Figure 2).

For example, Boone *et al.*^[132] reported on 47 robotic three-field total esophagectomies with a pulmonary morbidity of 44% and a postoperative mortality of 6%, which were highly comparable with the results of historical open outcomes in terms of safety and short-term results.

As in standard MIE, the robot-assisted Ivor-Lewis transthoracic esophageal resection has replaced the three-field approach in most cases^[133-135]. The perioperative outcomes and the oncologic parameters reported were highly sufficient to judge the technique to be as safe as traditional MIE and the conventional open approach^[133,136]. From a purely technical point of view, the transthoracic surgical step could be achieved throughout a standard supine or semi-lateral position, while recently some authors^[137] have reported excellent results using the prone position (only a 6% rate of pulmonary complications).

Another peculiar issue of RAMIE is represented by the possibility of performing a hand-sewn intrathoracic esophagogastric anastomosis, which is virtually impossible or very time-consuming for even very skilled laparoscopists due to tremor and anti-ergonomic positions. However, only two papers^[138,139] have specifically addressed the use of RAMIE with a hand-sewn intratho-

Table 1 Recommended approaches to esophageal procedures

racic anastomosis. The authors reported few leakages or cases of stenosis and no significant prolonging of the operative time.

Finally, even a transhiatal esophagectomy is feasible robotically, at the price of a higher complications rate reported in one of the very few anecdotal reports (35% of patients with temporary laryngeal nerve paresis and 25% of patients with self-limiting cervical leaks)^[140].

In conclusion, although the first cases of RAMIE were described in the early 2000s^[69,141], rigorous, well-designed, large comparative studies are still lacking, and none of the existing studies have demonstrated the tangible benefits of robotics over thoraco-laparoscopy or open surgery^[133,142]. Interestingly, a monocentric trial specifically targeted to RAMIE was recently launched^[143].

CONCLUSION

Most of the surgical operations for the treatment of benign and malignant esophageal diseases are suitable for a minimally invasive approach, with the goal of reducing the wide spectrum of perioperative complications.

Thoracoscopy, laparoscopy, hybrid procedures and robotic assistance have been shown to favorably impact pulmonary morbidity and length of hospital stay in many recent papers. However, most of these minimally invasive esophageal procedures were achieved in a limited number of subspecialized centers worldwide and were performed by surgeons with significant experience

in esophageal surgery, advanced laparoscopy and robotics. Interestingly, the hypothesized learning curve for gaining sufficient confidence was more than 30 cases for major operations^[144,145].

In addition, more of the published techniques, although very promising in terms of outcomes and results, are not yet completely validated. An authors' comprehensive opinion of future developments in MIS for esophageal disease is reported in Table 1.

Centralization of the more challenging procedures and rigorous scientific approaches are needed before conventional open surgery can be abandoned completely.

Abstract

Gallstone ileus is a mechanical intestinal obstruction due to gallstone impaction within the gastrointestinal tract. Less than 1% of cases of intestinal obstruction are derived from this etiology. The symptoms and signs of gallstone ileus are mostly nonspecific. This entity has been observed with a higher frequency among the elderly, the majority of which have concomitant medical illness. Cardiovascular, pulmonary, and metabolic diseases should be considered as they may affect the prognosis. Surgical relief of gastrointestinal obstruction remains the mainstay of operative treatment. The current surgical procedures are: (1) simple enterolithotomy; (2) enterolithotomy, cholecystectomy and fistula closure (one-stage procedure); and (3) enterolithotomy with cholecystectomy performed later (two-stage procedure). Bowel resection is necessary in certain cases after enterolithotomy is performed. Large prospective laparoscopic and endoscopic trials are expected.

Key words: Intestinal obstruction; Bouveret's syndrome; Laparoscopic surgery; Endoscopic treatment; Gallstone ileus

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: A review of the symptoms and signs of gallstone ileus is presented. The findings, advantages and limitations of the different diagnostic modalities such as plain abdominal radiographs, upper gastrointestinal

series, ultrasound, computed tomography, magnetic resonance and endoscopy are reviewed. The different surgical options are discussed. Laparoscopic and endoscopic procedures are widely reviewed. Current data on morbidity and mortality are included.

INTRODUCTION

Gallstone ileus is an infrequent complication of cholelithiasis and is defined as a mechanical intestinal obstruction due to impaction of one or more gallstones within the gastrointestinal tract. The term "ileus" is a misnomer, since the obstruction is a true mechanical phenomenon^[1]. Gallstone gastrointestinal obstruction would be an appropriate term.

BACKGROUND

In 1654, Thomas Bartholin^[2] described a cholecysto-intestinal fistula with a gallstone within the gastrointestinal tract in a necropsy study. In 1890, Courvoisier^[3] published the first series of 131 cases of gallstone ileus, with a mortality rate of 44%. In 1896, Bouveret^[4] described a syndrome of gastric outlet obstruction caused by an impacted gallstone in the duodenal bulb after its migration through a cholecysto- or choledochoduodenal fistula. This was the first preoperative diagnosis of the currently known Bouveret's syndrome.

EPIDEMIOLOGY

Gallstone ileus has shown a constant incidence of 30-35 cases/1000000 admissions over a 45-year period^[5]. This entity develops in 0.3%-0.5% of patients with cholelithiasis^[6]. It constitutes the etiologic factor in less than 5% of cases of intestinal obstruction, but up to one quarter of nonstrangulated small bowel obstructions in elderly patients^[7]. In a nationwide study at the United States from 2004 to 2009, only 0.095% of mechanical bowel obstruction cases were caused by a gallstone^[8]. Gallstone ileus has been observed with a higher frequency among the elderly^[1]. Halabi *et al*^[8], recently reported an age range from 60 to 84 years in American patients. A Japanese literature review reported a 13-year-old case as their youngest patient, while a Mexican series included a 99-year-old patient^[9,10]. Accordingly to the predominance of female patients in gallstone disease, the majority of gallstone ileus patients correspond to the female gender, with variable percentages from 72%-90%^[11,12].

PATHOPHYSIOLOGY

Gallstone ileus is frequently preceded by an initial episode of acute cholecystitis. The inflammation in the gallbladder and surrounding structures leads to adhesion formation. The inflammation and pressure effect of the offending gallstone causes erosion through the gallbladder wall, leading to fistula formation between the gallbladder and the adjacent and adhered portion of the gastrointestinal tract, with further gallstone passage^[13,14]. Less commonly, a gallstone may enter the duodenum through the common bile duct and through a dilated papilla of Vater^[15].

The most frequent fistula occurs between the gallbladder and the duodenum, due to their proximity^[11,16,17]. The stomach, small bowel and the transverse portion of the colon may also be involved^[1,13,14] (Table 1). This process might be part of the natural history of Mirizzi syndrome^[18]. Once the gallbladder is free of calculi, it may become a blind sinus tract and contract down to a small fibrous remnant^[19].

In 1981, Halter *et al*^[20] reported a case of gallstone ileus after endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincteromy (ES) and unsuccessful gallstone extraction. Three days later, the patient presented abdominal pain and vomiting. At laparotomy, a 3.5 cm gallstone was removed from the jejunum. To our knowledge, 13 cases of gallstone ileus have been reported after ERCP and ES. This adverse event may occur late after the endoscopic procedure, and should be considered in the differential diagnosis, especially in cases of delayed presentation^[21,22].

Spillage of gallstones during laparoscopic cholecystectomy is not infrequent. Although most of gallstones lost in a previous biliary surgery and lying free in the abdominal cavity are silent, they can cause an intraabdominal abscess and might ulcerate the intestinal wall and gain entrance to the bowel lumen and cause gallstone ileus^[23-26].

Once within the duodenal, intestinal or gastric lumen, the gallstone usually proceeds distally and may pass spontaneously through the rectum, or it may become impacted and cause obstruction. Less commonly if the gallstone is in the stomach, proximal migration can occur and the gallstone may be vomited^[14]. The size of the gallstone, the site of fistula formation and bowel lumen will determine whether an impaction will occur. The majority of gallstones smaller than 2 to 2.5 cm may pass spontaneously through a normal gastrointestinal tract and will be excreted uneventfully in the stools^[1,13,14]. Clavien *et al*^[6] reported an obstructing gallstones size range from 2 to 5 cm. Nakao *et al*^[11] found that impacted gallstones ranged in size from 2-10 cm, with a mean of 4.3 cm. Gallstones larger than 5 cm are even more likely to become impacted, although spontaneous passage of gallstones as large as 5 cm has occurred^[1,14,17]. The largest gallstone causing intestinal obstruction measured 17.7 cm in its largest diameter

Table 1 Frequency of biliary-enteric fistulas in patients with gallstone ileus

Fistula type	Range (%)
Cholecystoduodenal	32.5-96.5

and was removed from the transverse colon^[14]. Multiple stones have been reported in 3%-40% of cases^[6].

The site of impaction can be almost in any portion of the gastrointestinal tract. If the gallstone enters the duodenum, the most common intestinal obstruction will be the terminal ileum and the ileocecal valve because of their relatively narrow lumen and potentially less active peristalsis. Less frequently, the gallstone may be impacted in the proximal ileum or in the jejunum, especially if the gallstone is large enough. Less common locations include the stomach and the duodenum (Bouveret's syndrome), and the colon^[1,7,13,14,17]. The size of the gallstone, a gallbladder inflammatory process compromising the duodenum and a cholecysto-duodenal fistula may cause a gallstone to become impacted in the duodenum^[27] (Table 2).

The presence of diverticula, neoplasms, or intestinal strictures such as secondary to Crohn's disease, decrease the lumen size and may cause the gallstone to impact at the narrowing site^[1,13,19]. Gallstone ileus has been reported at sites of anastomosis after partial gastrectomy and Billroth II reconstruction and after biliointestinal bypass in two cases^[28,29].

Ischemia may develop at the site of gallstone impaction, due to the pressure generated against the bowel wall and the proximal distention. Necrosis and perforation followed by peritonitis may occur^[13].

CLINICAL MANIFESTATIONS

The presentation of gallstone ileus may be preceded by a history of prior biliary symptoms, with rates between 27%-80% of patients^[6,7,10,12,16,30]. Acute cholecystitis may be present in 10%-30% of the patients at the time of bowel obstruction. Jaundice has been found in only 15% of patients or less. Biliary symptoms may be absent in up to one third of cases^[1,6,13,17,25,31].

Gallstone ileus may be manifested as acute, intermittent or chronic episodes of gastrointestinal obstruction. Nausea, vomiting, crampy abdominal pain and variable distension are commonly present^[1,9,13,17,25,32]. The intermittent nature of pain and vomiting of proximal gastrointestinal material, later becoming dark and feculent is due to the "tumbling" gallstone advancement^[12,15]. Therefore, there may be intermittent partial or complete

Table 2 Site of gastrointestinal obstruction in patients with gallstone ileus

Site	Range (%)
Duodenum	0-10.5
Stomach	0-20

intestinal obstruction, with temporary advancement of the gallstone and relief of symptoms, until the gallstone either passes through the gastrointestinal tract or it definitively becomes impacted and complete intestinal obstruction ensues^[13,17]. The character of the vomitus is dependent on the obstruction location. When the gallstone is in the stomach or upper small intestine, the vomitus is mainly gastric content, becoming feculent when the ileum is obstructed.

Particularly, Bouveret's syndrome presents with signs and symptoms of gastric outlet obstruction. Nausea and vomiting have been reported in 86% of cases, while abdominal pain or discomfort is referred in 71%. If the gallstone is not fully obstructing the lumen, the presentation will be of partial obstruction. Recent weight loss, anorexia, early satiety and constipation may be referred. Bouveret's syndrome has also been reported to be preceded by or manifest as upper gastrointestinal bleeding, secondary to duodenal erosion caused by the offending gallstone, with hematemesis and melena, in 15% and 7%, respectively^[17,27,33].

Physical examination may be nonspecific. The patients are often acutely ill, with signs of dehydration, abdominal distension and tenderness with high-pitched bowel sounds and obstructive jaundice. Fever, toxicity and physical signs of peritonitis may be noted if perforation of the intestinal wall takes place. The exam may be completely normal if no obstruction is present at the moment^[1,13,14,27].

DIAGNOSIS

The symptoms and signs of gallstone ileus are mostly nonspecific^[9,16,32]. The intermittency of symptoms could also interfere with a correct diagnosis, if clinical manifestations at the moment correspond to a partial obstruction or distal migration of the gallstone. The "tumbling phenomenon" may be the cause why the patient does not seek medical attention or admittance is postponed. Patients usually present 4 to 8 d after the beginning of symptoms and diagnosis is usually made 3 to 8 d after the onset of symptoms^[1,32]. Cooperman *et al.*^[34] found an average period of 7 d from the onset of symptoms until the hospitalization, and 3.7 d of hospitalization elapsed until surgical intervention. Periods of

Figure 1 Plain abdominal radiograph showing dilated small bowel loops and a high density endoluminal image suggestive of a gallstone (arrow). No pneumobilia is visualized.

several months of symptoms before seeking hospital attention has been reported^[30]. A correct preoperative diagnosis has been reported in 30%-75% of the cases^[6,12,30,35-37]. A high index of suspicion will be helpful, particularly in a female elderly patient with intestinal obstruction and previous gallstone disease; Bouveret's syndrome may be suspected in a patient with gastric outlet obstruction.

Plain abdominal radiograph

Plain abdominal radiographs are of major importance in establishing the diagnosis. In 1941, Rigler *et al*^[38] described four radiographic signs in gallstone ileus: (1) partial or complete intestinal obstruction; (2) pneumobilia or contrast material in the biliary tree; (3) an aberrant gallstone; and (4) change of the position of such gallstone on serial films. The presence of two of the three first signs, has been considered pathognomonic and has been found in 20%-50% of cases^[1,25]. Although pathognomonic, reports of Rigler's triad range from 0%-87%^[30]. A careful inspection for pneumobilia should be performed, since it is present in most patients with gallstone ileus, but sometimes it is identified only in retrospective observation^[25]. Pneumobilia may occur secondary to prior surgical or endoscopic biliary interventions. Therefore, the clinical presentation should be considered when evaluating this radiologic sign^[1]. In 1978, Balthazar *et al*^[39] described a fifth sign, which consists of two air fluid levels in the right upper quadrant on abdominal radiograph. The medial air fluid level corresponds to the duodenum and the lateral to the gallbladder. These authors found that this sign was present in 24% of patients at the time of admission. In Bouveret's syndrome, a dilated stomach is expected to be seen on plain abdominal radiograph, due to the gastric outlet obstruction^[40]. Cappell *et al*^[33], in a review of 64 cases of Bouveret's syndrome, found as relatively common findings pneumobilia (39%), calcified right upper quadrant mass or gallstone (38%), gastric distension (23%) and dilated bowel loops (14%) (Figure 1).

Upper gastrointestinal series

An upper gastrointestinal series may help to identify the

biliary enteric fistula and the level of obstruction^[1]. A secondary sign that may be useful is the identification of oral contrast material within the gallbladder^[41]. Cappell *et al*^[33], in a review of Bouveret's syndrome, upper gastrointestinal series included cholecystoduodenal fistula or pneumobilia (45%), a filling defect or mass in the duodenum (44%), cholecystoduodenal fistula (38%), gastric outlet or pyloric obstruction (27%), distended or dilated stomach (27%), gallstone in duodenum (21%), and duodenal obstruction (12%)^[33].

Abdominal ultrasound

When diagnosis is still doubtful, an abdominal ultrasound (US) will be indicated for gallbladder stones, fistula and impacted gallstone visualization. It may also confirm the presence of choledocholithiasis^[1,42]. The use of US in combination with abdominal films to increase the sensitivity of diagnosis has been advocated. US is more sensitive at detecting pneumobilia and ectopic gallstones. The combination of abdominal films and US has increased the sensitivity of diagnosis of gallstone ileus to 74%^[43]. The most frequent findings in Bouveret's syndrome are gallstone in or near the gallbladder (53%), pneumobilia or cholecystoduodenal fistula (45%), gallstone in duodenum (25%), dilated or distended stomach (15%), and a contracted gallbladder (13%)^[33] (Figure 2).

Computed tomography

Computed tomography (CT) is considered superior to plain abdominal films or US in the diagnosis of gallstone ileus cases, with a sensitivity of up to 93%^[44]. The frequency of Rigler's triad detection is higher under CT examination. In a retrospective study by Lassandro *et al*^[45], Rigler's triad was observed in 77.8% of cases by means of CT, compared to 14.8% with radiographs and 11.1% with US. Bowel loops dilatation was seen in 92.6% of cases, pneumobilia in 88.9%, ectopic gallstone in 81.5%, air-fluid levels in 37%, and the bilio-digestive fistula in 14.8%. Yu *et al*^[44] performed a prospective study where 165 patients with acute small bowel obstruction were evaluated for gallstone ileus, with retrospective identification of three diagnostic criteria: (1) small bowel obstruction; (2) ectopic gallstone, either rim-calcified or total-calcified; and (3) abnormal gallbladder with complete air collection, presence of air-fluid level, or fluid accumulation with irregular wall. Overall sensitivity, specificity and accuracy were 93%, 100%, and 99%, respectively. Rigler's triad was detected only in 36% of cases. These tomographic diagnostic criteria need further prospective validation. Current CT scanners may describe the location of the fistula, offending gallstones and gastrointestinal obstruction with better precision, and helping in therapeutic decisions^[46].

In Bouveret's syndrome, major findings on CT scan are obstruction due to a gastro-duodenal mass or lesion, pericholecystic inflammatory changes extending into the duodenum, gas in the gallbladder, pneumobilia or cholecysto-duodenal fistula, filling defects corresponding to one or more gallstones, thickened gallbladder wall,

Fluid-filled dilated jejunum loops and intestinal pneumatosis are seen (short arrow); C: Endoluminal round-shaped calcium-density images (arrows), and dilated small bowel loops (arrowhead) with pneumatosis (short arrow).

and a contracted gallbladder^[17,27].

CT scan may allow detection of a rim or totally calcified ectopic gallstone without oral contrast administration. This may be done even with non-enhanced CT. Identification of a rim-calcified gallstone may be more difficult with contrast-enhanced CT, compared to total calcified gallstones. Less calcified gallstones could be missed^[44]. Contrast-enhanced CT allows detection of edema and ischemia of the affected gastrointestinal tract site^[44,47]. Given the relevance of possible bowel ischemia, contrast-enhanced CT is of particular importance in management decision making (Figure 3).

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) may be useful in selected cases where diagnosis is not clear after CT. A potential drawback of CT is that 15%-25% of gallstones appear as isoattenuating relative to bile or fluid. Pickhardt *et al.*^[48] described the use of MRCP for diagnosis of Bouveret's syndrome with isoattenuating gallstones. MRCP may be useful in these cases, due to the possibility to delineate fluid from gallstones, which appear as signal voids against the high-signal fluid. This is also a potential advantage in patients unable to tolerate oral contrast material. If sufficient fluid is present in the cholecystoenteric

fistula it could also be depicted. Therefore, MRCP may be particularly useful to confirm the gallstone ileus diagnosis in selected cases^[40]. Magnetic resonance for gastrointestinal obstruction evaluation is also a potential diagnostic option (Figure 4).

Esophagogastroduodenoscopy

In a review of 81 cases of Bouveret's syndrome in whom esophagogastroduodenoscopy (EGD) was performed, the gastroduodenal obstruction was revealed in all of them, but gallstone visualization was possible only in 56 (69%). Among those 56 cases, such gallstones were observed in the duodenal bulb in 51.8%, postbulbar duodenum in 28.6%, pylorus or prepylorus in 17.9%, and in one case the location was not reported. In 31% of cases the gallstone was not recognized because it was deeply embedded within the mucosa. When the gallstone is not visualized, the diagnosis should be strongly suspected when the observed mass is hard, convex, smooth, nonfriable, and nonfleshy, which are all characteristic of a gallstone and may improve the sensitivity of EGD. For such cases, US and CT are the preferred noninvasive diagnostic tests to confirm the endoscopic diagnosis, delineate the gastroduodenal anatomy, and demonstrate a cholecystoduodenal fistula^[33] (Figure 5).

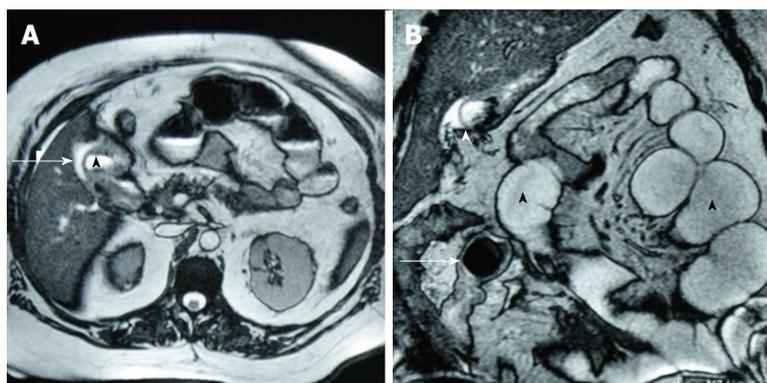

Figure 4 Magnetic resonance cholangiopancreatography findings in a patient with gallstone ileus. A: On T2-MRI, a hyperintense image is identified in the gallbladder bed (arrow), with communication with the duodenal second portion (arrowhead), suggestive of a cholecystoduodenal fistula; B: MRI coronal reconstruction showed dilated small bowel loops with endoluminal air (black arrowheads) and a signal-void round-shaped image, suggestive of a gallstone (arrow). Gallbladder communication with duodenum is observed (white arrowhead). MRI: Magnetic resonance imaging.

TREATMENT

The main therapeutic goal is relief of intestinal obstruction by extraction of the offending gallstone. Fluid and electrolyte imbalances and metabolic derangements due to intestinal obstruction, delayed presentation and pre-existing co-morbidities are common, and require management prior to surgical intervention^[1,19,23,32].

There is no consensus on the indicated surgical procedure. The current surgical procedures are: (1) simple enterolithotomy; (2) enterolithotomy, cholecystectomy and fistula closure (one-stage procedure); and (3) enterolithotomy with cholecystectomy performed later (two-stage procedure). Bowel resection is necessary in certain cases after enterolithotomy is performed.

Enterolithotomy has been the most commonly surgical procedure performed. Through an exploratory laparotomy, the site of gastrointestinal obstruction is localized. A longitudinal incision is made on the anti-mesenteric border proximal to the site of gallstone impaction^[5,6,23]. When possible, through gentle mani-

pulation the gallstone is brought proximally to a non-edematous segment of bowel. Most of the times, this is not possible due to the grade of impaction of the gallstone. The enterotomy is performed over the gallstone and it is extracted. Careful closure of the enterotomy is needed to avoid narrowing of the intestinal lumen and a transverse closure is recommended. Bowel resection is sometimes necessary, particularly in the presence of ischemia, perforation or an underlying stenosis^[6,23]. Manual propulsion of the gallstone through the ileocecal valve should be reserved for highly selected situations because of danger of mucosal injury and bowel perforation^[5,6,23]. Similarly, attempts to crush the gallstone *in situ* can damage the bowel wall and should be avoided^[23]. Multiple gallstones can generally be extracted through a single incision by clearing the gut and moving smaller gallstones towards bigger ones (Figure 6). In cases of sigmoid obstruction, transanal delivery is rarely possible. Sigmoid resection removing the gallstone and the underlying stenosis has been recommended^[6].

The main long-standing controversy in the management of gallstone ileus is whether biliary surgery should be carried out at the same time as the relief of obstruction of the bowel (one-stage procedure), performed later (two-stage procedure) or not at all.

In 1922, Pybus successfully extracted an obstructing gallstone from the ileum, closed the duodenal fistula and drained the gallbladder after removing two additional gallstones from it. In 1929, Holz extracted a gallstone from the sigmoid and after removing a second gallstone that was impacted in the duodenum, he closed a cholecystoduodenal fistula and removed the gallbladder. The author recommended this procedure for patients in satisfactory general condition. In 1957, Welch performed a successful one-stage surgery in a patient who was well prepared after recurrent gallstone intestinal obstruction. The authors suggested the feasibility of the operation under optimal conditions. In 1965, Berliner *et al*^[49] reported three cases managed in a similar manner, and mentioned that when the patient is adequately hydrated with serum electrolytes restored and the procedure

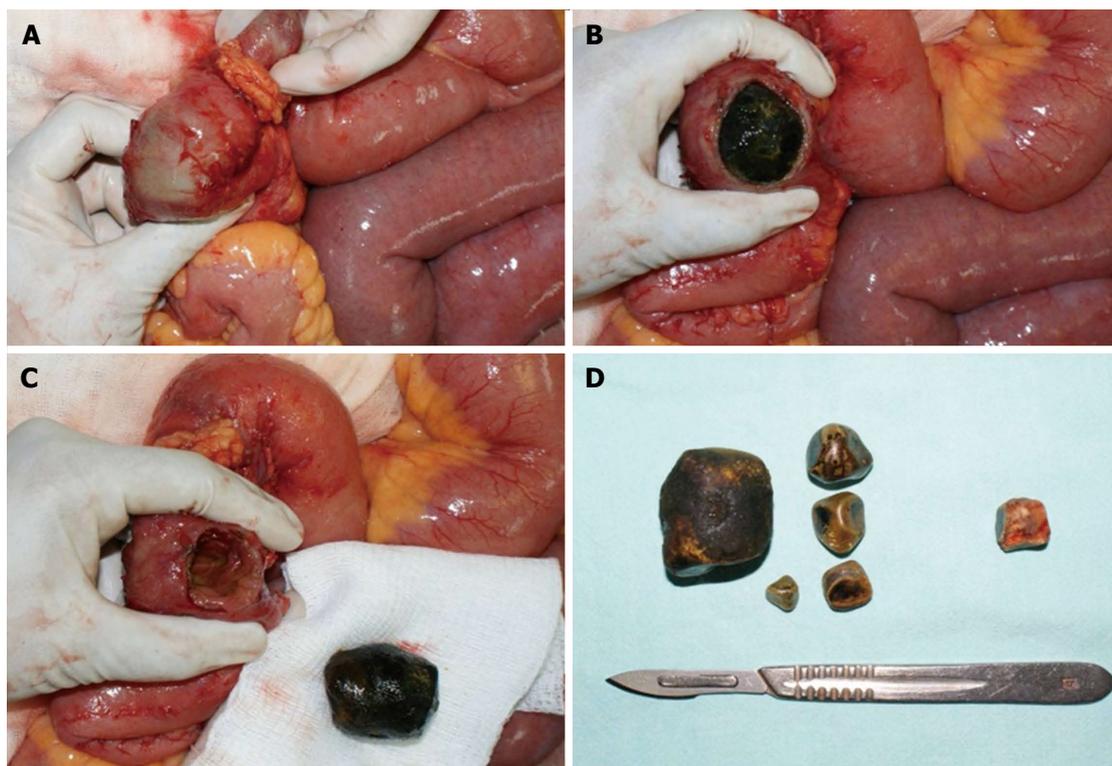

Figure 6 Surgical findings in a patient with gallstone ileus. A: An impacted gallstone was found in distal jejunum. A smaller gallstone proximal to the impacted one is observed; B: Enterotomy over the site of the impacted gallstone; C: Intestinal wall compromise due to gallstone impaction can be observed; D: The offending gallstone, plus four of smaller dimensions found in proximal jejunum. An obstructing gallstone was found and extracted from the common bile duct in the same patient (gallstone on the right).

does not represent a prohibitive operative risk, a one-stage procedure should be considered. In 1966, Warsaw *et al*^[12] reported a series of 20 patients, where enterolithotomy was combined with cholecystectomy and fistula closure in two cases, with cholecystostomy and closure of the fistula in one, and delayed cholecystectomy and closure of the fistula in two. There was no operative mortality. The authors recommend that the one-stage procedure should be considered in selected cases.

Cholecystoenteric fistula closure after the extrusion process has been reported, but if the cystic duct is permanently occluded and any part of the gallbladder mucosa remains viable, it probably remains patent^[15]. The risk of gallstone ileus recurrence is higher than previously reported. The commonly quoted recurrence incidence is 2%-5%, but up to 8% recurrence after enterolithotomy alone has been reported as well; half of these new onset events will present in the following 30 d^[50]. It must be considered that recurrence rates of 17%-33% have been reported^[6,51].

The possibility of recurrent cholecystitis and acute cholangitis has been highlighted^[6,49]. Warsaw *et al*^[12] reported recurrent symptoms or complications in 6 of 18 patients with unrepaired cholecystoenteric fistulas or retained gallbladders. Acute cholangitis has been reported in 11% of patients with cholecystoduodenal fistula and 60% with cholecystocolonic fistula^[6,34]. With a one-stage procedure, further gallstone-related events

are prevented^[12].

A long-term potential complication of biliary enteric fistula could be gallbladder cancer. Bossart *et al*^[52] found a 15% incidence of gallbladder cancer in 57 patients undergoing surgery for such fistulas, compared to 0.8% among all patients having cholecystectomy.

On the other hand, simple enterolithotomy has long been associated with a lower mortality^[7]. As Ravikumar *et al*^[53] observed, this study included patients from 70 published series spanning 40 years, with widely differing lengths of follow-up and evolving surgical techniques during this time period. Consideration should be taken of the fact that the severity of each case has influence on the outcome of any particular surgical procedure, and that mortality is not an absolute consequence of the surgical procedure itself. In the report by Clavien *et al*^[6], when patients were comparable in terms of age, concomitant diseases and APACHE II score, operative mortality and morbidity rates were not significantly different.

In 2003, Doko *et al*^[54] reported a 30 patient series with morbidity of 27.3% in patients undergoing enterolithotomy alone and 61.1% for a one-stage procedure. Mortality was 9% following enterolithotomy and 10.5% after a one-stage procedure. American Society of Anesthesiologists (ASA) scores were similar between the two groups but operating times were significantly longer for the one-stage procedure. Urgent fistula repair was significantly associated with postoperative complications.

The authors concluded that enterolithotomy is the procedure of choice, with a one-stage procedure reserved for patients with acute cholecystitis, gallbladder gangrene or residual gallstones^[6].

In 2004, Tan *et al.*^[55] reported a retrospective study of 19 patients treated by emergency surgery for gallstone ileus. The authors had no preference for either surgical procedure. Enterolithotomy alone was performed in 7 patients and enterolithotomy with cholecystectomy and fistula closure in 12 patients. In the first group, more patients had significant co-morbidity as identified by poorer ASA status (6 patients were ASA III and IV), poorer pre-operative status, and 4 patients were hypotensive in the pre-operative phase. All 12 patients in the one-stage procedure group were ASA I and II and none were hypotensive in the pre-operative phase. Operative time was significantly shorter in the enterolithotomy group (70 min vs 178 min). There were no significant differences in morbidity and there was no mortality in either group.

In 2008, Riaz *et al.*^[56] reported their retrospective experience with 10 patients diagnosed with gallstone ileus. The choice of the surgical procedure was largely determined by the clinical condition of the patient. Five patients underwent enterolithotomy alone (group 1), while the remaining 5 patients underwent cholecystectomy and fistula repair (group 2). In group 1, all patients were hypertensive and diabetic. All patients were hemodynamically-unstable, with metabolic acidosis and pre-renal azotemia. The ASA score was III or above in all patients. In group 2, only 2 patients were hypertensive and all were hemodynamically-stable at presentation with an ASA score of II. There was no operative mortality in both groups.

Many patients with gallstone ileus are elderly, with comorbidities, in poor general condition and have a delayed diagnosis, leading to dehydration, shock, sepsis or peritonitis. Relief of gastrointestinal obstruction by simple enterolithotomy is the safest procedure for these patients^[30,31].

At laparotomy, examination and careful palpation of the entire bowel, gallbladder and extrahepatic bile duct is recommended, in order to exclude gallstones, bile leakage, abscess or necrosis^[1,12,19,57]. Cholecystectomy and fistula repair reduce the need for reintervention and the incidence of complications related to fistula persistence, including recurrent ileus, cholecystitis or cholangitis, but it is justified only in selected adequately stabilized patients in good general condition, such as good cardiorespiratory and metabolic reserve, who are able to withstand a more prolonged operation, unless it has been clearly demonstrated that no gallstones remain in the gallbladder^[6,31,36,58].

Proponents of enterolithotomy alone argue that fistula closure is time consuming and technically demanding. Spontaneous fistula closure can occur when the gallbladder is gallstone-free and the cystic duct remains patent. Some authors have found no risk of cancer when fistula is not managed^[1,6,8].

According to different authors, enterolithotomy alone is the best option for most patients with gallstone ileus. The one-stage procedure should be offered only to highly selected patients with absolute indications for biliary surgery at the time of presentation and who have been adequately reanimated^[7,11,16,31,36,53].

The persistence or appearance of gallstone-related or gastrointestinal symptoms will prompt the need for evaluation. US and contrast gastrointestinal radiology may detect cholelithiasis and fistula persistence in patients who have been treated by enterolithotomy alone^[6,12]. Demonstration of gallstones, the appearance of symptoms, or a persistent cholecystoenteric fistula indicates the need for cholecystectomy, closure of the fistula, and common duct exploration^[12]. It has been emphasized that delayed cholecystectomy as a second procedure is clearly justified only in cases of symptom persistence^[7,31]. The two-stage procedure with scheduled follow-up biliary surgery is not common. Subsequent cholecystectomy and fistula closure are recommended to be performed 4 to 6 wk later^[7,16,32,55]. A mortality rate of 2.94% has been reported in this group of patients^[8].

Laparoscopy

In 1993, Montgomery^[59] reported 2 cases of mechanical intestinal obstruction, which were diagnosed laparoscopically and gallstone ileus was found. In both cases, the affected ileum segment was brought out of the abdominal cavity through a small incision, and through enterotomy the gallstone was removed. Both patients were discharged and only one presented a wound infection, which was successfully treated. In 1994, Franklin *et al.*^[60] reported a case of laparoscopically treated along with cholecystectomy and repair of a cholecystoduodenal fistula.

In 2003, El-Dhuwaib *et al.*^[61] reported a case of gallstone ileus that underwent an emergency laparoscopic enterolithotomy. During follow-up, a cholecystoduodenal fistula and bile duct stones were detected. An elective laparoscopic cholecystectomy with fistula repair, concomitant bile duct exploration, choledocolithotomy and primary bile duct closure were successfully performed. In 2007, Moberg *et al.*^[62] reported a series of 32 patients with gallstone ileus operated laparoscopically in 19 cases with 2 conversions, and by open surgery in 13 cases. There was no mortality. In 2013, Yang *et al.*^[63] reported a case of Bouveret's syndrome, which was successfully treated by laparoscopic duodenal lithotomy and subtotal cholecystectomy. In 2014, Watanabe *et al.*^[64] reported a case of gallstone ileus due to a 4 cm gallstone in the jejunum with presence of pneumobilia. Through single-incision laparoscopic surgery, enterolithotomy was performed. Cholecystoduodenal fistula closure was demonstrated 4 mo after the surgery. The patient had an uneventful postoperative course.

Although experience in minimally invasive surgical treatment of gallstone ileus is still developing, adequate management in low risk patients has allowed successful results. Dilated and edematous bowel represents a

more challenging scenario. According to a recent report, laparoscopy is used only in 10% of surgically managed gallstone ileus cases, with a high conversion rate (53.03%) to laparotomy^[68]. Early recovery and a low mortality are expected from laparoscopic procedures^[65].

Endoscopy

Gallstones causing gastroduodenal or colonic obstruction may be amenable to endoscopic detection and in certain instances to endoscopic extraction. In 1976, Stempfle *et al*^[66] reported a case of cholecystogastric fistula with passage of a gallstone to the stomach leading to massive hemorrhage of gastric mucosa. The gallstone was removed endoscopically and the imminent obstruction could be eliminated. Mucosal bleeding was managed with conservative method. Endoscopic visualization of radiologically detected gallstones in the duodenum has been reported, leading to definitive surgical treatment^[67].

In 1981, Finn *et al*^[68] reported a case of 73-year-old female with gallstone ileus which was diagnosed endoscopically and found 2 gallstones in the duodenal bulb. A cholecystoduodenal fistula was also demonstrated. Immediate surgery was performed. The role of colonoscopy in large bowel obstruction by a gallstone has been reported. In 1989, a report by Patel *et al*^[69] showed the technical difficulty after multiple attempts for gallstone extraction and further surgical extraction, but diagnosis was established. In 1990, Roberts *et al*^[70] reported the removal of a gallstone obstructing the sigmoid colon by means of colonoscopy. In 1985, Bedogni *et al*^[71] reported a successful gallstone extraction in a case of pyloroduodenal obstruction. The initial success rate of endoscopic management was less than 10%^[72]. After endoscopic mechanical lithotripsy (EML), electrohydraulic lithotripsy (EHL), extracorporeal shockwave lithotripsy (ESWL) and endoscopic laser lithotripsy (ELL) have been used alone or in combination for gallstone endoscopic management.

In 1991, Moriai *et al*^[73] reported the combined use of EHL and EML for the treatment of a patient with two 3-cm gallstones in the stomach. The smaller fragments were removed orally. EHL of a gallstone causing gallstone ileus was first reported by Bourke *et al*^[74] in 1997. In 2007, Huebner *et al*^[75] reported two cases managed with EHL alone. This method has the risk of bleeding and perforation due to surrounding tissue damage. In 1997, ESWL was reported by Dumonceau *et al*^[76] who treated two patients with Bouveret's syndrome. All fragments were removed orally, except for one that was left in the stomach of the first patient and caused recurrent ileus. ESWL may need repeated sessions followed by endoscopy. Obesity and distended bowel interposition may be limitations^[77].

The use of Holmium: YAG laser lithotripsy has been reported. An attempt to fragment and retrieve a duodenal gallstone causing Bouveret's syndrome resulted in small bowel obstruction secondary to a fragment. The patient required surgical enterolithotomy^[78]. In 2005, Goldstein *et al*^[79] reported a case of a 94-year-

old patient with two gallstones in the duodenum, which could not be retrieved beyond the upper esophageal sphincter using a Roth net. A holmium: yttrium-aluminum-garnet (Holmium: YAG) laser was used for gallstone fragmentation, with subsequent successful removal^[79]. The main advantage of ELL is the precise targeting of the offending gallstone, with reduced risk of surrounding tissue injury^[80].

One of the potential limitations for endoscopic management of a gallstone is a location out of endoscopic reach. In 1999, Lübbers *et al*^[81] reported the case of a 91-year-old female patient who was unfit for surgery and after location of the gallstone in the upper jejunum, was managed by EML. In 2010, Heinzow *et al*^[82] reported the case of an 81-year-old female patient who suffered from gallstone ileus of the ileum. Peroral single-balloon enteroscopy allowed the successful endoscopic removal of the obstructing gallstone. Single and double balloon enteroscopy constitutes a recent means of endoscopically directed therapy.

A colonic location of an obstructing gallstone may be endoscopically managed in selected patients. In 2010, Zielinski *et al*^[83] reported a case of endoscopic EHL of a 4.1 cm gallstone in the sigmoid colon. A gallstone impacted at the ileocecal valve was successfully managed by Shin *et al*^[84] using EHL by means of colonoscopy in a patient with liver cirrhosis (Child-Pugh class B). The fragments were retrieved with snare and forceps.

These non-operative endoscopic methods should be considered in elderly and high risk patients^[6]. A potential complication of endoscopic treatment is the possibility of distal impaction of gallstone fragments^[17].

MORBIDITY

Previously, the most common postoperative complication has been wound infection. In 1961, Raiford^[15] observed a 75% global rate of wound infection. Localized peritonitis, respiratory complications, phlebitis, recurrent obstruction due to residual gallstones and cholangitis were also observed. In more recent series, the global rate of postoperative complications has been reported in the range of 45%-63%^[6,30,31,36,55]. Wound infection continues to be the most common complication, with rates of 27% and 42.5%, as reported by Clavien *et al*^[6] and Rodríguez Hermosa *et al*^[30] respectively. Several authors have reported no significant differences of postoperative complications between those patients treated by enterolithotomy or enterolithotomy, cholecystectomy and fistula closure^[6,31,36,55]. Martínez Ramos *et al*^[36] found a 100% complication rate among patients requiring intestinal resection. Global immediate complications were greater when the diagnosis was made during the surgical procedure than when it was made prior to surgery. If relapsing gallstones ileus is not considered, less common postoperative complications have been wound dehiscence, cardiopulmonary and vascular complications, sepsis, intestinal and biliary fistulas, and urinary tract infections^[6,31,55].

Currently, the most common postoperative complication is acute renal failure, which was seen in 30.45% of patients, followed by urinary tract infection (13.79%), ileus (12.42%), anastomotic leak, intraabdominal abscess, enteric fistula (12.27%), and wound infection (7.73%)^[8].

MORTALITY

Gallstone ileus is predominantly a geriatric disease, and as many as 80%-90% of patients have concomitant medical illnesses. Hypertension, diabetes, congestive heart failure, chronic pulmonary disease and anemia are the most common comorbidities^[8]. These associated conditions need to be considered, as they may affect the results of treatment^[1].

Mortality rates were reported as high as 44% at the late 1800's, while in the first half of the twentieth century these rates maintained between 40%-50%^[3,19]. In the 1990's, considerable reductions in mortality were observed to 15%-18%, to current rates of less than 7%^[7,8]. Specifically, simple enterolithotomy has long been associated with an 11.7% mortality compared to 16.9% for the one-stage procedure (enterolithotomy plus cholecystectomy and fistula closure)^[7].

As described by Kirchmayr *et al.*^[85], four main reasons might be responsible for the high number of lethal courses. First of all, gallstone ileus is a disease of the elderly. Second, concomitant diseases, such as cardiorespiratory diseases and/or diabetes mellitus are frequent. Third, because of uncommon symptoms diagnosis is difficult and a mean delay of 4 d from the beginning of symptoms to hospital admission is reported. Fourth, postoperative recovery is also hampered; age-related complications such as pneumonia or cardiac failure are more frequent than surgery associated complications.

In the study by Halabi *et al.*^[8] of 3268 gallstone ileus cases who underwent surgical management, an overall mortality rate of 6.67% was observed. The authors noted that fistula closure, performed during the initial procedure, was independently associated with a higher mortality rate than enterolithotomy alone. When bowel resection was indicated, it was also associated with a higher mortality rate than enterolithotomy alone. When analyzing by surgical procedures, the mortality rates were 4.94% for the enterolithotomy alone group, 7.25% for the enterolithotomy plus cholecystectomy and fistula closure group, 12.87% for the bowel resection group, and 7.46% for the bowel resection and fistula closure group. However, if consideration is made of the fact that bowel resection is not exactly an option but a requirement due to the bowel segment conditions instead, the mortality for those patients undergoing enterolithotomy alone or bowel resection is actually 6.53%.

In summary, gallstone ileus or gallstone gastrointestinal obstruction represents less than 1% of gastrointestinal obstruction cases, with a higher frequency

among the elderly. Computed tomography has proven to be the most accurate diagnostic modality, but diagnostic criteria validation is required. Surgical relief of obstruction is the cornerstone of treatment. Given the high incidence of comorbidities in these patients, a good judgement in selecting the surgical procedure is required. Enterolithotomy remains the mainstay of operative treatment. A one-stage cholecystectomy and repair of fistula is justified only in selected patients in good general condition and adequately stabilized preoperatively. Specific criteria for a one-stage procedure remain to be established. A two-stage surgery is an option for patients with persistent symptomatology after enterolithotomy surgery. Large prospective studies of laparoscopic and endoscopic-guided procedures are expected.

Abstract

Gastroesophageal reflux disease (GERD) is a very common disorder with increasing prevalence. It is estimated that up to 20%-25% of Americans experience symptoms of GERD weekly. Excessive reflux of acidic often with alkaline bile salt gastric and duodenal

contents results in a multitude of symptoms for the patient including heartburn, regurgitation, cough, and dysphagia. There are also associated complications of GERD including erosive esophagitis, Barrett's esophagus, stricture and adenocarcinoma of the esophagus. While first line treatments for GERD involve mainly lifestyle and non-surgical therapies, surgical interventions have proven to be effective in appropriate circumstances. Anti-reflux operations are aimed at creating an effective barrier to reflux at the gastroesophageal junction and thus attempt to improve physiologic and mechanical issues that may be involved in the pathogenesis of GERD. The decision for surgical intervention in the treatment of GERD, moreover, requires an objective confirmation of the diagnosis. Confirmation is achieved using various preoperative evaluations including: ambulatory pH monitoring, esophageal manometry, upper endoscopy (esophagogastroduodenoscopy) and barium swallow. Upon confirmation of the diagnosis and with appropriate patient criteria met, an anti-reflux operation is a good alternative to prolonged medical therapy. Currently, minimally invasive gastroesophageal fundoplication is the gold standard for surgical intervention of GERD. Our review outlines the many factors that are involved in surgical decision-making. We will review the prominent features that reflect appropriate anti-reflux surgery and present suggestions that are pertinent to surgical practices, based on evidence-based studies.

Key words: Gastroesophageal reflux disease; Decision-making; Fundoplication

INTRODUCTION

The prevalence of gastroesophageal reflux disease (GERD) in the United States has appreciably increased in the last few decades, making it one of the most common chronic diseases^[1]. It is estimated that up to 20%-25% of Americans experience symptoms of GERD weekly^[2]. Interestingly, most patients that present to their primary care doctor with typical GERD symptoms, such as heartburn and regurgitation, never undergo formal diagnostic evaluation and are managed with non-surgical therapy such as proton pump inhibitors (PPI) long-term^[3]. In accordance with the American Gastroenterological Association and the American College of Gastroenterology, patients with symptoms suggestive of GERD should undergo an 8-wk empiric treatment regimen with a PPI^[4]. Non-responders should undergo esophagogastroduodenoscopy (EGD) as well as esophageal pH monitoring if EGD reveals no abnormalities^[4]. On the other hand, patients with extraesophageal symptoms are much more difficult to diagnose and should undergo pH monitoring sooner in the diagnostic algorithm^[5]. Unremitting GERD can result in complications including esophagitis with scarring and stricture formation, Barrett's esophagus and cancer, specifically adenocarcinoma. These types of symptoms may often require daily medication, which can be a significant adverse impact on the patients' quality of life^[6].

PATHOPHYSIOLOGY AND SYMPTOMATOLOGY

In simple terms, GERD results from failure of the distal esophageal reflux barrier^[7,8]. During normal physiologic swallowing, relaxation of the lower esophageal sphincter (LES) and crura occur which in turn allow the food bolus to enter the stomach. Furthermore, the LES and crura relax during belching to allow gas venting. If the LES relaxes separately from initiation of a swallow, these

relaxations are termed transient lower esophageal relaxations (TLESRs)^[7,8]. It has been shown that abnormal TLESRs result in an enlarged cross sectional area at the gastro-esophageal junction resulting in increased reflux of gastric contents and gas. These TLESRs are rather important as they likely result in 90% of reflux episodes^[7,9]. Hiatal hernias appear to increase the degree of reflux during TLESRs. In patients with severe reflux esophagitis, a hypotensive LES seems to be the etiology rather than abnormal TLESRs^[7,10]. If the LES pressure is < 10 mmHg, reflux tends to occur with more frequency. If the LES pressure is < 4 mmHg, however, free reflux occurs^[7,11,12].

The most common symptom of GERD is heartburn, which is said to be caused by the stimulation and activation of mucosal chemoreceptors in the distal esophagus^[3]. Other typical esophageal symptoms include regurgitation which, in addition to heartburn, reflect dysfunction of the reflux barrier. Extra-esophageal symptoms include cough, asthma, and chest pain. Additional testing, including combined impedance/pH monitoring, should be performed if GERD is thought to be the cause of any atypical symptom and/or the patient has been on long-term medical treatment and surgery is being considered^[8,13,14].

MANAGEMENT OF GERD

Surgical vs medical management of GERD

Medical options for patients with GERD include antacids, histamine-receptor antagonists or PPI therapy^[4]. Studies comparing medical management of GERD to surgical therapy have shown that anti-reflux operations are an effective alternative to medical treatments, even for patients with good symptom control on pharmacologic therapy^[15].

Furthermore, fundoplication results show significantly less acidic content and increased LES pressure compared to medical treatment alone. Fundoplication is associated with a high level of patient satisfaction and improved quality of life in patients with chronic GERD. According to the guidelines written by the American Society for Gastrointestinal and Endoscopic Surgeons (SAGES), surgical procedures for GERD are curative in 85%-93% of cases^[16]. In review of a meta-analysis comparing open vs laparoscopic surgery, a total of 16.2% of the patients in the open group and 14.7% in the laparoscopic group used acid suppression drugs post-operatively^[17]. As advancements in the field of laparoscopy have been made, minimal invasive operations have been established as the gold standard in the surgical treatment of this condition^[8].

Indications for anti-reflux surgery

The most frequent indication for anti-reflux operations symptoms refractory to pharmacological therapy^[18]. It is critical, however, to have physiological testing showing pathological acid reflux exists. SAGES guidelines suggest

that surgical intervention may be appropriate in patients who have failed medical management, decide for surgery despite successful medical management, have complications of GERD such as Barrett's esophagus and/or peptic stricture, have medical complications attributable to a large hiatal hernia, or have "atypical" symptoms such as asthma, hoarseness, cough, chest pain, dental erosions or aspiration and reflux documented on 24 h pH monitoring^[16]. It is important to note, however, that operative intervention to alleviate GERD should be performed after the diagnosis of GERD has been objectively confirmed and should only be considered in individuals who meet the aforementioned criteria. In the subset of patients who do indeed respond to pharmacologic therapy but are either unable or unwilling to take daily medication, anti-reflux surgery will likely prove quite beneficial. It has been estimated that up to 40% of patients do not respond to PPI therapy^[4]. There have been studies showing poor resolution of reflux symptoms after surgery in patients who do not respond to acid reducing medications. An eleven year follow-up study reported response and lack of response to acid reducing medications were associated with 77.1% and 56.0% success rates of laparoscopic Nissen fundoplication (LNF) respectively^[19]. Despite the potential of suboptimal results, failure of pharmacologic therapy in the treatment of GERD still remains an operative indication. In one study reviewing long-term outcomes after anti-reflux surgery, at 69 mo, the majority of patients maintained improvement or resolution of heartburn (90%), regurgitation (92%), and dysphagia (75%) when compared to before laparoscopic reflux surgery. The results were less satisfactory in patients with extraesophageal symptoms such as hoarseness (69%) and cough (69%)^[20]. Few absolute contraindications to an anti-reflux exist except the presence of esophageal cancer or Barrett's mucosa with untreated high-grade dysplasia. A long-term outcome 5-year follow-up study evaluating anti-reflux surgery in patients with Barrett's esophagus that included patients with low-grade dysplasia, short and long-segment Barrett's showed reflux symptoms were absent in 67 of 85 patients (79%) after surgery^[21]. In regards to resolution of Barrett's, low-grade dysplasia regressed to nondysplastic Barrett's in 7 of 16 (44%), and intestinal metaplasia regressed to cardiac mucosa in 9 of 63 (14%). High-grade dysplasia and adenocarcinoma were prevented in all 97 patients^[21].

Preoperative considerations

Preoperative objectives should identify the proper patients for anti-reflux surgery after appropriately evaluating symptoms and diagnostic studies. Proper selection of patients optimizes outcomes. Initial evaluation must include a thorough history and physical exam. It is important for the surgeon to focus on the duration of symptoms, type of reflux symptoms and causation/temporal relationship of symptoms. Studies have shown that patients with typical symptoms, in comparison to

those with atypical symptoms, have a better response to fundoplication. A 10-year follow-up study reported 85% percent of patients with typical symptoms had a successful outcome after LNF, compared to only 41% with atypical symptoms^[19]. Furthermore, patients who experience exaggerated symptoms when supine rather than standing tend to have better outcomes after fundoplication as well. In the supine position, transient lower esophageal relaxation periods increase. Studies have shown that fundoplication reduces TLRSR frequency by 50% and thus decrease reflux events^[22,23]. After a detailed history and physical examination is performed, important preoperative studies to consider are: (1) Upper endoscopy (EGD): Endoscopy has a high specificity (95%) for diagnosing GERD as the operator can note visual and histopathologic changes of the esophageal mucosa. Moreover, the operator is able to take biopsies of the mucosa that are essential in ruling out other etiologies or complications of reflux. Biopsies of the mucosa are necessary to diagnose and exclude other non-reflux esophageal disorders such as eosinophil esophagitis, *Helicobacter pylori*, Barrett's esophagus or esophageal cancer. As stated previously, if high-grade dysplasia or esophageal cancer is noted on endoscopy, the surgeon cannot perform anti-reflux surgery. If, however, low-grade dysplasia or intestinal metaplasia is noted, the surgeon should proceed with the procedure as studies have shown resolution and regression to cardiac mucosa. Despite its' high specificity, endoscopy lacks sensitivity in the diagnosis of GERD as up to half of patients with GERD will have normal endoscopic findings^[24]. EGD is also useful to visualize the presence of a hiatal hernia. If a hiatal hernia is discovered pre-operatively, the surgeon must repair the hiatal hernia prior to performing the wrap; (2) pH monitoring: As stated previously, non-responders to pharmacologic therapy should undergo EGD as well as esophageal pH monitoring. pH monitoring can be a very valuable tool to objectively establish a diagnosis of GERD and is the gold standard for pathologic acid reflux^[25]. A 24-h or 48-h intra-esophageal study can be done to evaluate the patient's pH levels during daily life, and thus assess reflux patterns as well as determining the patients' ability and frequency of clearing acid. Multiple devices are available for use in pH monitoring. Two specific devices include a 24 h transnasal catheter placement and BRAVO wireless esophageal pH probe monitoring, both of which have been proven effective to accurately diagnose GERD^[5]. It is necessary that the patient discontinue his/her acid suppression medication for a minimum of 1 wk for the pH monitoring to be accurate. If the patient is unable to stop the medication, referral for an impedance test should be done^[26]. Most studies have shown an elevated DeMeester score indicates pathological reflux. Impedance testing can distinguish between acidic and nonacidic reflux. Impedance testing, however, is prone to interpretational error so it is not optimal^[27]; (3) Esophageal manometry is used to identify dysmotility of the esophagus, for example, achalasia. Some surgeons

will determine the type of surgery necessary for the patient based on their manometry results (Nissen vs partial). However, there is overwhelming data showing even with poor motor function of the esophagus, a Nissen fundoplication provides the best results by effective blockade of reflux, which is most likely, the cause of poor dysmotility^[28,29]. Our group has shown that compared to patients with good motor function, patients with poor motor function tend to have longer short-term dysphagia, yet at the 3-mo follow-up period, both groups behaved similarly; and (4) Barium swallow: Perhaps not useful to all surgeons, a barium swallow can help to better understand the anatomy of esophagus and stomach. A barium swallow can prove valuable in patients with various anatomical abnormalities such as a shortened esophagus or hiatal hernias. Hiatal hernias affect the competence of the LES, in turn, impeding the ability to clear acid in the esophagus. It is prudent that the surgeon recognizes hiatal hernias preoperatively as it is necessary to repair them during any anti-reflux operation. A barium swallow study can also determine if the patient has esophageal dysmotility. For example, the diagnosis of achalasia is supported by barium swallow findings including dilation of the esophagus, a narrow esophago-gastric junction with "bird-beak" appearance, aperistalsis, and poor emptying of barium^[30].

SURGICAL TECHNIQUES USED TO TREAT GERD

Laparoscopic vs open technique for GERD

A laparoscopic, transabdominal approach is preferred for the vast majority of patients undergoing anti-reflux surgery. Rarely, transthoracic and open abdominal approaches are required and may be considered for patients undergoing revision of their former anti-reflux operations^[31]. However, reoperation surgery typically can be performed laparoscopically. Perioperative morbidity was found to be significantly lower (65%) after laparoscopic compared with open fundoplication^[32]. Laparoscopic fundoplication is associated with longer operative times but shorter hospital stays^[17]. In turn, conversion rates to open surgery were less than 5%^[17]. Laparoscopic fundoplication is preferred over open surgery because it is associated with shorter hospital stay, decreased pain, postoperative wound infections and abdominal wall hernia formation^[17]. Additionally, using the laparoscopic approach, surgeons have the advantage of seeing all the hiatal structures in a magnified fashion. In a 10-year randomized trial comparing LNF to conventional Nissen fundoplication (CNF or open technique), it was noted that twice as many patients required reoperation after CNF, including a much higher number of incisional hernia corrections. The 10-year effectiveness of LNF and CNF is comparable in terms of improvement of GERD symptoms, PPI use, quality of life, and objective reflux control seen on impedance studies. Thus, the long-term results from this trial

lend level 1 support to the use of LNF as the surgical procedure of choice for GERD^[33]. Regardless of the type of fundoplication performed, the aim of the operation is the same: Re-create and restore the normal physiologic functionality of the LES, reconstruction of the hiatus when necessary and repair of any hiatal hernia if present.

Partial vs total fundoplication

In the United States, in comparison to Europe, a 360° fundoplication is the most common anti-reflux operation performed. European surgeons, however, favor a partial fundoplication operation. Many prospective, randomized, controlled studies have evaluated both 360° and 270° fundoplication procedures and have shown similar short- and long-term efficacy^[34,35]. Despite these findings, proponents of the Nissen fundoplication argue its superiority over the partial fundoplication. Advocates for the partial fundoplication argue that their patients have fewer symptoms of bloating and retain their ability to vomit. In one randomized control study, there were noted to be a higher rate of postoperative dysphagia, flatulence, and bloating in total fundoplication as compared to partial fundoplication^[36]. There were not, however, significant differences between the two modalities in the continuing postoperative incidence of heartburn, esophagitis or persistent acid reflux. A similar proportion of patients experiencing excellent long-term outcomes were seen in both partial and Nissen fundoplication^[34,36]. Another study reported at 10 years, 89.5% patients who had undergone laparoscopic fundoplication were free of significant reflux (93.3% after Nissen, 81.8% after Toupet). Thus, Nissen patients did better than Toupet patients, although the difference was not statistically significant^[34].

Anterior (Dor) vs Nissen fundoplication

Prospective, randomized controlled studies comparing 120-degree anterior fundoplication vs Nissen fundoplication showed anterior fundoplication to be associated with less postoperative dysphagia, 74% in the Nissen group and 95% in the anterior fundoplication group after 24 mo follow up^[36]. However, this technique was shown to be less effective for controlling reflux over time. In addition, more patients required reoperations for reflux control after anterior fundoplication^[37].

Toupet vs Nissen fundoplication

There have been several randomized control studies comparing Toupet fundoplication to Nissen fundoplication. Studies have shown lower rates of post-operative dysphagia after a Toupet fundoplication when compared to results after a Nissen fundoplication - around 8.5% vs 13.5% respectively^[38]. There were no differences, however, in the percentage of patients affected by heartburn comparing the two procedures^[38]. Regarding the operative technique, recent findings have shown that the length of the wrap is important when performing a Toupet fundoplication. For example, a 3.0 cm Toupet vs 1.5 cm Toupet proved to better control reflux. The

Table 1 Comparison of advantages and disadvantages in different types of funduplications

	Advantages	Disadvantages
Nissen fundoplication	Very effective in controlling reflux over long periods of time	Increased flatulence, bloating and dysphagia
Anterior (Dor) fundoplication	Less postoperative dysphagia	Recurrent symptoms over time requiring more reoperations
Toupet fundoplication	Less postoperative dysphagia	Surgeons need to be mindful of length of wrap as it determines quality of reflux control

length of the wrap in a Nissen fundoplication, however, did not influence reflux control, rather mild dysphagia rates were higher for the 3.0 cm wrap (8.8%) compared to the 1.5 cm wrap (21.2%) at the 12-mo follow up^[39]. Five years after the operation, mild dysphagia rates in the Nissen fundoplication groups were equivocal, 9.7% in the 1.5 cm wrap and 7% in the 3.0 cm wrap^[39]. More level 1 evidence with longer follow up periods is required to determine whether Nissen fundoplication is superior to Toupet fundoplication in terms of patient outcomes (Table 1).

Use of robotic surgery in treating GERD

The use of robotic surgery for managing GERD has been shown to be a viable and safe option, with similar outcomes when compared to laparoscopy after one year follow up. Robot-assisted LNF is comparable to traditional laparoscopy in terms of complications, mortality and length of hospital stay. Robotic Nissen fundoplication is advantageous as the surgeon has improved ergonomics, visualization, comfort, and autonomy. The only disadvantages seen with robotic assisted surgeries were reported to have longer surgical times (131.3 min vs 91.1 min laparoscopically), and generally higher costs when compared to laparoscopic surgery^[40].

KEY OPERATIVE STEPS IN ROBOTIC NISSEN FUNDOPLICATION

Positioning

Supine position with arms out on arm boards.

Incision and exposure

Veress technique is used to enter the abdominal cavity 13 cm subxiphoid and 5 working ports are placed under direct visualization. A Genzyme liver retractor is placed to retract the left lobe of the liver superiorly and laterally. The patient is placed in steep reverse Trendelenburg, and the robot (DaVinci Xi) is docked and the working instruments are placed.

Procedure

Dissection begins with the takedown of the gastrohepatic ligament using a vessel sealer all the way to the right crus that is clearly dissected off the esophagus. The short gastrics are then taken all the way through the angle of His until the left crus is clearly defined. Right and left crus are clearly delineated, and the esophagus is identified. A Penrose drain is placed around the esopha-

gus and the posterior vagus after clearly identifying this window. Dissection is carried into the chest, allowing for complete reduction of the esophagus, and after which the hiatus is closed using V-Loc and 3-0 silk sutures.

The fundoplication is then performed around a 56 bougie taking a distal and proximal bite of the esophagus. The bougie is then removed. Posterior pexy is then performed to the right crus with 2 sutures. An anterior pexy is performed to the right and left crus.

Penrose is removed as is the Genzyme retractor.

The robot is undocked and the ports were removed under direct visualization.

The skin is approximated using fine absorbable sutures in a subcuticular manner.

Special situations

GERD in morbidly obese patients and surgical technique: There is a direct association between obesity and gastroesophageal reflux. The prevalence of GERD is higher with people that have higher body mass index (BMI), and linearly increases with increased BMI. Some studies have shown fundoplication surgeries for morbidly obese patients to have a higher rate of failures compared to normal weight patients^[19]. Other studies, however, have showed equivalent outcomes in obese and normal weight patients^[41,42]. One of the many lifestyle alterations suggested by physicians to aid in the treatment of GERD is weight loss. Morbidly obese patients following Roux-en-Y gastric bypass (LRYGB) have improved reflux symptoms after losing weight^[43]. One prospective study quoted 94% resolution of reflux symptoms 9-mo after patients underwent LRYGB^[44]. Essentially, the LRYGB procedure helps the patient lose weight and improve reflux symptoms as well. Thus, it is the procedure of choice for many surgeons treating morbidly obese patients with GERD.

Revisional surgery for failed anti-reflux surgery

The failure rate of fundoplication ranges from 3% to 16%^[45]. Not every patient who has failed anti-reflux surgery needs reoperation. It is important for the surgeon to determine whether a physiologic or anatomic failure can be ameliorated surgically. The most common indications for reoperation are a "slipped" fundoplication or herniation of the wrap into the mediastinum^[45,46]. Laparoscopic re-operative anti-reflux surgery is a viable and safe option for patients. While it is effective, re-operative surgeries have higher complication rates compared to primary repairs such as gastric or esophageal perforation^[45]. The re-operation should be done

in the same manner as the primary fundoplication. Revisional surgery, compared to primary repair, requires longer operative times (mean duration of reoperation was 177.4), is correlated with higher conversion rates to an open approach and has higher complication rates^[47]. Patient satisfaction after revisional surgery is generally high (89%) with resolution of heartburn symptoms in almost 80% of patients and resolution of regurgitation in 85% of patients, 18 mo after surgery^[48].

CONCLUSION

GERD is a very common disorder with increasing prevalence. Excessive reflux of acidic gastric contents has a multitude of symptoms for the suffering patient including heartburn, regurgitation, cough, and dysphagia. There are also associated complications of GERD including erosive esophagitis, Barrett's esophagus, stricture and adenocarcinoma. Surgical intervention is often necessary in those who fail medical therapy, are non-compliant or wish to discontinue long-term medical therapy, have complications secondary to GERD, or present with extra-esophageal symptoms. There are various types of anti-reflux operations that have been quite successful in treating GERD and restoring competence in an otherwise incompetent LES, while at the same time repairing a potential hiatal hernia. Laparoscopic fundoplication is the gold standard for surgical treatment of severe GERD and results in approximately 95% patient satisfaction. Robotic Nissen fundoplication is also very advantageous with good outcomes. In regards to the specific type of fundoplication, the Nissen fundoplication has overall improved outcomes when compared to partial wraps. Before entertaining a surgical approach, it is important that the surgeon take all necessary preoperative measures to ensure surgery is the appropriate choice for the patient. The surgeon must also take into consideration special situations such as obese patients or those that are in need of a revisional anti-reflux procedure.

Abstract

Colorectal cancer is one of the most common cancers in western society and malignant obstruction of the colon accounts for 8%-29% of all large bowel obstructions. Conventional treatment of these patients with malignant obstruction requiring urgent surgery is associated with a greater physiological insult on already nutritionally replete patients. Of late the utility of colonic stents has offered an option in the management of these patients in both the palliative and bridge to surgery setting. This has been the subject of many reviews which highlight its efficacy, particularly in reducing ostomy rates, allowing quicker return to oral diet, minimising extended post-operative recovery as well as some quality of life benefits. The uncertainty in managing patients with malignant colonic obstructions has led to a more cautious use of stenting technology as community equipoise exists. Decision making analysis has demonstrated that surgeons' favored the use of stents in the palliative setting preferentially when compared to the curative setting where surgery was preferred. We aim to review the literature regarding the use of stent or surgery in colorectal obstruction, and then provide a discourse with regards to the approach in synthesising the data and applying it when deciding the appropriate application of stent or surgery in colorectal obstruction.

Key words: Self-expanding metallic stent; Stenting; Surgery; Colorectal cancer; Large bowel obstruction; Radiology

INTRODUCTION

Despite the accumulation of data on stent insertion, the choice of stent or surgery as the most appropriate modality in the management of colorectal obstruction presents a constant decision dilemma. When cure is possible we want that, but with minimal morbidity. In a group of patients who are prone to higher rates of morbidity and mortality, this can be problematic and full of uncertainty.

This review takes an approach to review the primary and secondary outcomes established in the literature regarding the use of stent or surgery in colorectal obstruction, and then create discourse and a structured approach in regards to synthesising the data and applying it when deciding the appropriate application of stent or surgery in colorectal obstruction.

Colorectal cancer is one of the most common cancers in western society and malignant obstruction of the colon accounts for 8%-29% of all large bowel obstructions^[1]. Other causes of large bowel obstruction include uterine, ovarian, gastric, breast, bladder and kidney malignancies^[2]. Conventional treatment of these patients with malignant obstruction requiring urgent surgery is associated with a greater physiological insult on already nutritionally replete patients. This is associated with mortality in 15%-34% of patients and morbidity in 32%-64% of patients^[3]. Of late the utility of colonic stents has offered an option in the management of these patients. The first being used by Dohmoto *et al*^[4] in 1991. Tejero *et al*^[5] described the use of colonic stents as a "bridge to surgery" in 1994. This has been the subject of many reviews which highlight its efficacy, particularly in reducing ostomy rates, allowing quicker return to oral diet, minimising extended post-operative stay and some quality of life (QoL) benefits^[6]. Xinopoulos *et al*^[7] demonstrated that self-expanding metallic stent (SEMS) placement represents an alternative approach to colostomy for patients with inoperable malignant colonic strictures. The uncertainty in managing patients with malignant

colonic obstructions has led to a more cautious use of stenting technology as community equipoise exists^[8].

PATIENT AND DISEASE FACTORS

Regarding the location of obstructing colonic malignancy, Fiori *et al*^[9] in 2004 reported that 63.6% of obstructing malignancies occur in the rectum and 36.3% in the rectosigmoid/sigmoid colon. Sankararajah *et al*^[10] in 2005 observed 37% in the rectosigmoid, 21% in the sigmoid colon, 16% at the splenic flexure, 16% in the descending colon, 5% in the rectum and 5% in the ascending colon. van Hooft *et al*^[11] in 2008 observed 76% obstruction in the rectosigmoid and 24% obstruction in the descending colon. With the majority of obstructing pathology being on the left side, this makes these lesions amenable to endoscopic intervention. Sankararajah *et al*^[10] demonstrated malignant stricture length to be in the range of 3-7 cm meaning that all these lesions are within "stentable" range. Fiori *et al*^[9] and van Hooft *et al*^[11] collected data on patient ASA level with all patients included in their trials being ASA 1 to 3. The majority of the patients were in the ASA 2 category.

MORBIDITY OF SURGERY V STENT

While decision making with regards to the utility of stents in patients with metastatic disease may be easier for the treating clinician, this decision is more difficult to make for patients with local disease. A recent randomised controlled trial (RCT) by Young *et al*^[6] reported that in a population of patients with incurable metastatic large bowel obstruction, stent use was associated with faster return to diet, decreased stoma rates, reduced post-procedure stay, and some QoL benefits.

The decision with regards using a stent in patients with non-metastatic malignant bowel obstruction is one that is fraught with indecision due to the theoretical risk of perforation converting a once potentially curable disease to incurable^[12,13]. However this risk needs to be balanced with multiple other factors, principally being the patients pre-existing morbidities and the need for emergent surgical intervention. In this day, with highly trained endoscopists, the more imminent risk of perforation is much lower in some centres than the reported 4%.

Efficacy

The efficacy of SEMSs as a tool in the treatment of malignant colonic obstruction has been demonstrated well over the past few years. Many randomised control trials have supported their use and hence should be considered a valid option in the treatment of this condition (Table 1).

The 2011 review by Sagar *et al*^[14] reported an clinical relief of obstruction in the colonic stenting group to be approximately 0.66 d compared to 3.55 d in the emergency surgery group, with an overall success rate of 86%. In Ho's review in 2012, the placement of

Table 1 Summary of the studies included in this review

Ref.	Centres and aim	No. of patients (stenting/surgery)	Stenting morbidity	Surgery morbidity	Stenting mortality	Surgery mortality	Stenting efficacy
Fiori <i>et al</i> ^[9]	Single centre, palliation	11/11	0	1/11 (9%)	0	0	100%
Xinopoulos <i>et al</i> ^[27]	Single centre, palliation	15/15	0	0	0	0	93%
van Hooft <i>et al</i> ^[111]	Multicentre, palliation	11/10	11/11 (100%)	5/10 (50%)	3/11 (27%)	0	82%
Sankararajah <i>et al</i> ^[100]	Single centre	9/9	2/9 (22%)	6/9 (67%)	1/9 (11%)	1/9 (11%)	78%
Cheung <i>et al</i> ^[23]	Single centre, bridge to surgery	24/24	2/24 (8%)	17/24 (71%)	0	0	83%
van Hooft <i>et al</i> ^[24]	Multicentre, bridge to surgery	47/51	25/47 (53%)	23/51 (41%)	9/47 (19%)	9/51 (18%)	70%
Ho <i>et al</i> ^[15]	Single centre, bridge to surgery	20/19	7/20 (35%)	11/19 (35%)	0	3/19 (16%)	70%
Young <i>et al</i> ^[6]	Multicentre, palliative	26/26	10/26 (38%)	14/26 (54%)	0	0	79%

self expanding metallic stents took a median time of 35 min (range, 20-80 min). Seventy percent patients (14/20) had been stented successfully. Following stent placement, they resumed a diet after approximately day 2 and were discharged about day 4. Six out of 20 patients failed stenting with the main cause being the inability to pass the guide wire across the stenotic cancer (4/6 cases)^[15]. This technical success was also noted in the review by Khot *et al*^[16]. It may be overcome with the use of a pediatric nasogastroscope^[17].

Both Tan *et al*^[18] and Zhang *et al*^[19] reviews demonstrated that a higher primary anastomosis rate and lower morbidity rate was achieved in the group receiving colonic stents.

In the study by Ho *et al*^[15] stented patients were sent home significantly sooner than in the emergency surgery groups, with medial length of stays at 6 d vs 8 d respectively ($P = 0.028$). Furthermore, they demonstrated significantly better outcomes for the stenting group that went on to have elective surgery compared to the group randomized to have emergency surgery^[14].

A recent metaanalysis by Zhao *et al*^[20] emphasized that there is limited data on the long term survival of patients with malignant left sided colonic obstruction when comparing emergency surgery with semi-elective use of stents. With limited data, recommendation was made for more studies on the topic^[20].

BLOCKAGE

Blockage of stents principally affects patients who have long term stent insertion in the palliative setting. In the review by Khot *et al*^[16], the overall, reobstruction occurred in 52 of 525 (10%) cases with only three patients in the "bridge to surgery" group having reobstruction. The reasons of reobstruction in these patients included tumour in-growth in 32 (62%), stent migration in seven (13%) and faecal impaction in 13 (25%)^[16]. These issues with obstruction of the stent can be managed expectantly with surveillance being tailored to the patient's condition. In general, patients who are having the stent as a bridge to surgery would very rarely experience obstruction. Patients with palliative stent insertion who are not candidates for surgery would present the main group with tumor related blockage and this may be managed expectantly with re-stenting of the

lesion.

STOMA RATES

A major advantage of colonic stent placement is the reduction of stoma formation rates^[5,6,9,11,21]. This represents a significant improvement in the patient outcomes with relation to physical recovery and overall QoL issues. In the meta-analysis by Cennamo *et al*^[22], the permanent stoma creation rate was 38/152 (25%) in the stent group and 78/162 (48.1%) in the surgical group; the pooled analysis showed a significantly higher rate in the surgical group^[20]. In the RCT by Young *et al*^[6], none of the 19/26 patients in the stent group who were successfully stented required a stoma while 24/26 in the surgery group required a stoma to be fashioned ($P < 0.001$).

PERFORATION RATES

The decision of using a stent in patients with non-metastatic malignant bowel obstruction is one that is fraught with indecision due to the theoretical risk of perforation converting a once potentially curable disease to incurable. However this risk needs to be balanced with multiple other factors, principally being the patients pre-existing morbidities and the need for emergent surgical interventions. In four trials, no stent related perforation was noted (Young *et al*^[6] 2015, Cheung *et al*^[23] 2009; Fiori *et al*^[9] 2004; Sankararajah *et al*^[100] 2005). In two of the RCTs by Khot *et al*^[16] 2011 and van Hooft *et al*^[24], a perforation rate of 4% was noted. Khot *et al*^[16] states that this rate was significantly associated with balloon pre-dilatation. With Van Hooft's study the large number of centres^[24] involved in the study may not have allowed a standardisation in the technique and also local expertise may vary considering that some centres contributed one patient over the two year period.

DEATH

In malignant obstruction of the colon, emergency surgery is associated with a high mortality rate of 10%-30%, when compared to < 5% rate in elective surgery for colorectal cancer^[25,26]. Three meta-analyses^[14,18,19],

Table 2 Surgeons' treatment preferences in different clinical scenarios (Suen *et al*^[8])

Clinical scenarios	Level of clinical certainty			Evidence of community equipoise?
	Surgery (%)	Undecided (%)	Stent (%)	
1 70yo; partial obstruction; metastatic cancer; ASA score 4	8	12	80	N
2 70yo; complete obstruction; metastatic cancer; ASA 4	9	8	82	N
3 50yo; partial obstruction; metastatic cancer; ASA 4	15	10	75	N
4 50yo; complete obstruction; metastatic cancer; ASA 4	12	8	80	N
5 70yo; partial obstruction; metastatic cancer; ASA 1	51	19	30	Y
6 70yo; complete obstruction; metastatic cancer; ASA 1	40	13	47	Y
7 50yo; partial obstruction; metastatic cancer; ASA 1	60	17	23	Y
8 50yo; complete obstruction; metastatic cancer; ASA 1	51	14	35	Y
9 70yo; partial obstruction; curable cancer; ASA 4	66	15	19	Y
10 70yo; complete obstruction; curable cancer; ASA 4	41	13	46	Y
11 50yo; partial obstruction; curable cancer; ASA 4	73	10	17	N
12 50yo; complete obstruction; curable cancer; ASA 4	50	11	39	Y
13 70yo; partial obstruction; curable cancer; ASA 1	96	4	0	N
14 70yo; complete obstruction; curable cancer; ASA 1	79	12	9	N
15 50yo; partial obstruction; curable cancer; ASA 1	96	4	0	N
16 50yo; complete obstruction; curable cancer; ASA 1	87	9	4	N

did not show any advantage in terms of post-operative mortality between the emergency surgery and stenting groups. In the recent RCT by Young *et al*^[6], similar mortality figures were noted in both groups, noting that this patient population was palliative. A review of the United Kingdom National Audit showed that patients undergoing surgery for left-sided colonic obstruction had an operative mortality rate of 12.9%^[27]. The mortality rate with stenting being a lot lower at 1%, giving evidence that it is a safe method to decompress a patient as a bridge to surgery^[16].

COST

The cost of stents utility needs to be weighed up against many factors. They may represent an expensive option in isolation, however overall they represent a cost-effective option in the treatment of malignant obstruction of the colon. A study from the United Kingdom demonstrated the cost of a palliative stent was fifty percent less than surgical decompression and that the expense of 'bridge to surgery' was reduced by twelve percent with compared to a two stage procedure^[28]. In the review by Fiori *et al*^[9], the median hospital stay was 2.6 d for stent group and the median hospital stay was 8.1 d for the stoma group.

Other factors such as QoL, faster return to normal bowel function and significantly less physiological insult make stenting a much more cost-effective option. Further, the additional costs of outpatient stoma care should also not be forgotten^[16].

QOL

Increasing evidence has been published with regards to the QoL of patients undergoing stents and surgical intervention for the management of malignant bowel obstruction. In the study by van Hooft *et al*^[24] (2011), primary outcome of global health status was recorded and no significant difference was noted between the two groups. More recently, Young *et al*^[6] (2015) observed

that 15/26 (58%) patients in the stent group patients were recorded as having an increased QoL from baseline to one week compared to 7/26 (27%) of the surgery group ($P = 0.02$). The surgery group had significantly lowered QoL compared to the stent group from baseline to 1 and 2 wk ($P < 0.001$ and $P < 0.012$), and from baseline to 12 mo ($P = 0.01$) in favor of the stent group, while both reported reduced QoL^[6]. There were no significant differences in whether the patient had an increased or decreased QoL at any other time point.

DECISIONS

The treatment of patients with stenting technology is one that has traditionally being fraught with concern by the treating clinician. A recent study by Suen *et al*^[8] demonstrated that there would be limitations in conducting a future randomised controlled trial to assess the use of colonic stenting especially in the curative setting. Surgeons' favored the use of stents in the palliative setting preferentially when compared to the curative setting where surgery was preferred (Table 2).

In the management of physiologically poor patients (ASA > 3) with complete bowel obstruction, SEMS is the preferred initial intervention of choice. This allows the patient to be physiologically optimised for subsequent interventions and also increases the chance of a one-stage resection. The morbidity of emergency surgery can be as high as 51% with an associated mortality rate of 16%^[29]. With the greatest concern of colonic perforation being reported at 4% in previous trials, and modern day trials are quoting this at 0% with increasingly experienced interventionalists and safe methodology^[6]. This low rate of perforation and the benefits of stenting with lower stoma formation rates, lower perioperative morbidity and quicker recovery/return to community should make SEMS a valid tool in the management of malignant complete bowel obstruction^[23].

In the fit patient with curable disease, surgery is more often preferred as the intervention of choice due

to the improved physiologic parameters aiding in a better outcome and potential for one stage resection.

Considering the myriad of clinical scenarios and variables, the overall judgement, stenting technology offers an alternate tool to the clinician in the management of large bowel obstruction, with safe and effective outcomes.

The present body of evidence regarding stent insertion demonstrates its role, but to more clearly define its use in areas of uncertainty and community equipoise would require large multi-centre RCT's. Such trials may be necessary, but will be hard to complete with the difficulties of recruiting patients to trials where treating clinicians still hold conservative views as to the merits of stent or surgery.

Abstract

Esophageal carcinoma (EC) is a highly lethal malignancy

with a poor prognosis. One of the most important prognostic factors in EC is lymph node status. Therefore, lymphadenectomy has been recognized as a key that influences the outcome of surgical treatment for EC. However, the lymphatic drainage system of the esophagus, including an abundant lymph-capillary network in the lamina propria and muscularis mucosa, is very complex with cervical, mediastinal and celiac node spreading. The extent of lymphadenectomy for EC has always been controversial because of the very complex pattern of lymph node spreading. In this article, published literature regarding lymphatic spreading was reviewed and the current lymphadenectomy trends for EC are discussed.

INTRODUCTION

Esophageal carcinoma (EC) is one of the most common cancers and an important cause of cancer-related deaths in the world. It is an aggressive disease with a poor prognosis and a rapidly increasing incidence. The overall 5 years survival is 10%, ranging from 15% to 40% after surgery. Although multimodal therapy, including neoadjuvant chemotherapy or chemoradiotherapy with esophagectomy, has improved the long-term survival, surgery is also regarded as the standard treatment for resectable EC^[1-4]. Lymph node status has been recognized as the most important independent factor that influences the prognosis of EC. The 7th edition of the TNM staging system showed that an increasing number of metastatic lymph nodes is associated with a poorer prognosis^[5,6]. Therefore, the outcome of surgery depends on lymphadenectomy as well as the primary tumor invasion in EC.

However, the extent of lymphadenectomy in EC is still considerably controversial. There have been two primary opinions in recent years. Some agree with a three-field lymphadenectomy and hold that it is essential to achieve improved postoperative survival by resectioning adequate lymph nodes in the neck because cervical lymph node metastases have been documented as approximately 20% to 40%. Others argue that two-field lymphadenectomy is enough to dissect all the possible metastatic lymph nodes, including recurrent nerve chain lymph nodes from the superior mediastinum up to the neck, with less perioperative complications and the same outcome^[7-10]. A consistent lymphadenectomy strategy has yet to be established.

In this review, we hope to offer some references about the extent of lymphadenectomy through describing the pattern of the lymphatic spreading.

THE ANATOMICAL LYMPHATIC SYSTEM OF THE ESOPHAGUS

The lymphatic drainage system of the esophagus is very complex because of an abundant lymph-capillary network in the lamina propria and muscularis mucosa, deep to the basement membrane. In total, lymphatic spreading has two modes, including penetrating the esophageal wall transversally and shifting longitudinally upwards (cervical lymph glands) and downwards (abdominal lymph glands). However, the longitudinal lymphatic flow is much more abundant than the transverse flow^[11,12]. In detail, there are three pathways for lymph node metastasis in EC. One is spreading longitudinally along the submucosal lymphatic networks to regional and non-regional lymph nodes; another passes transversely through the muscularis propria to regional lymph nodes; and the last penetrates perpendicularly through the muscularis mucosa to the thoracic duct and the venous system^[13]. Moreover, some studies show the presence of lymphatic drainage

and an anatomical correlation between the right recurrent laryngeal nerve nodes and cervical lymph nodes in EC, which suggests that tumor cells from the midthoracic level reach the right recurrent laryngeal nerve nodes through submucosal lymphatic vessels in the early stage. Meanwhile, it seems that lymphatic routes communicating with periesophageal lymph nodes generally originate from the intermuscular area of the muscularis propria and connections between the submucosal and intermuscular areas do not exist. Thus, once the primary tumor infiltrates the submucosa of the esophagus, the lymph node metastasis might apparently increase^[14-16].

PATHWAYS OF ESOPHAGEAL LYMPHATIC SPREADING

According to many published data, the upper mediastinal and perigastric areas are the most common areas for lymph node metastasis in EC. However, lymph node metastasis in different areas may vary with the location of the primary tumor^[17,18].

For upper thoracic EC, tumor cells usually spread upwards to upper mediastinal and cervical nodes. As for middle thoracic EC, lymphatic flow drains primarily both up and down into the cervical, upper mediastinal, periesophageal and perigastric nodes. With regard to lower thoracic EC, the perigastric area is the most important^[17,18]. Another study of endoscopic injection of technetium-labeled rhenium colloid into the esophageal wall also demonstrated that lymphatic flow of the upper and middle third of the esophagus drains mainly to the neck and upper mediastinum, with the lower third draining mainly into the abdomen^[19]. These studies generally reach a consensus.

On the other hand, Akiyama *et al.*^[20] showed that the frequency of cervical and upper mediastinal lymph node metastasis, including recurrent laryngeal nerve chains, was 46.3% in cases of thoracic EC. Shiozaki *et al.*^[21] reported that the rates of cervical lymph node metastasis with positive recurrent laryngeal nerve nodes was 22.2%, 51.9% and 50.0% in upper, middle and lower third thoracic EC, respectively. The rate of the recurrent laryngeal nerve lymph node metastasis with positive cervical lymph nodes was 51.2%, in contrast to 13.9% of patients with negative cervical nodes^[22]. Tabira *et al.*^[23] demonstrated that the 5 years survival was 21% with recurrent laryngeal nerve nodes metastasis, in contrast to 47% with negative recurrent nerve nodes. Therefore, it is generally accepted that recurrent laryngeal nerve chain nodes, especially the right side, should be intensively dissected in surgery for EC to improve survival, regardless of the location of the tumor^[20-24].

In addition to the location, the tumor histological type and invasion depth may be worth considering, well known as influencing factors on the prognosis for EC^[25-29]. In contrast to esophageal squamous cell carcinoma

ma with lymphatic spreading more widely, the lymphatic flow of esophageal adenocarcinoma is primarily into the lower posterior mediastinum, the pericardial region and along the lesser gastric curvature. Distant metastasis is rarely found^[28,30]. Based on the anatomical lymphatic drainage system, lymph node metastasis in EC is usually present in the upper mediastinum and perigastric area, known as skip metastasis, with the tumor not penetrating through the submucosa. If the tumor reaches the muscularis propria, the rate of periesophageal lymph node metastasis will increase rapidly for the middle and lower thirds of the mediastinum^[18].

LYMPHADENECTOMY FOR EC

Lymph node metastasis is the most important prognostic factor in EC and the number of metastatic nodes is closely related to survival. More and more studies have reported that the number of positive nodes independently determines survival rather than the area of metastatic lymph node in EC^[5,31-35]. Tachimori *et al.*^[18] showed that the overall postoperative survival did not differ between the areas of metastatic lymph nodes. According to their multivariate analyses, the number of metastatic nodes was the most predictive factor for survival, not the area. Similarly, Zhang *et al.*^[31] reported that the number of metastatic lymph nodes was significantly associated with survival for esophageal squamous cell carcinoma. The 5 years survival rates of patients with none, one and two or more positive lymph nodes were 59.8%, 33.4% and 9.4%, respectively. Therefore, the 7th edition of the TNM staging system identified the number of metastatic lymph nodes for N stage in EC^[6]. Apparently, the more lymph nodes are dissected, the lower the possibility of missing positive lymph nodes. The 7th edition also intensively requested that at least twelve lymph nodes should be removed for an accurate and reliable N classification in EC on account of several detailed research outcomes^[36,37]. However, only considering the number regardless of the area of metastatic lymph nodes is not enough. For the same number of positive lymph nodes, the prognosis between one and more distribution areas is different^[38,39].

Considering both outcome of lymphadenectomy and perioperative complications, the controversy about the extent of lymphadenectomy for EC has developed: Two or three-field?

The three-field lymphadenectomy was initiated in Japan. According to a prospective randomized trial, high neck recurrence rates in patients with esophageal squamous cell cancer were reported, suggesting that it was necessary to add neck dissection^[40]. After that, it was known that lymph from the upper third of the esophagus mainly flows upwards to the superior mediastinum and neck, whereas lymph from the middle and lower third of the esophagus flows downwards *via* the mid and inferior mediastinum to the left gastric and celiac nodes^[41]. A nationwide study showed that

the rate of lymph node metastasis was significantly increased with adding cervical dissection of three-field lymphadenectomy (58.7% of two-field vs 72.9% of three-field). Moreover, not only the rate of cervical nodes metastasis, but also the rate of mediastinal nodes metastasis was evidently increased^[42]. Meanwhile, Lerut *et al.*^[8] showed that the overall morbidity was 58%, 5 years disease-free survival was 46.3% and 5 years overall survival was 41.9% after three-field lymphadenectomy. Other research reported that the 5 years survival rate after three-field dissection was in the range of 40%-50%^[42,43]. However, some demonstrated that no survival benefit was found in patients undergoing cervical nodal dissection compared to esophagectomy with three-field vs two-field lymphadenectomy^[44]. Several recent meta-analyses suggested a priority of three-field lymphadenectomy for EC, especially for tumors with lymph node metastasis. However, the incidence of complications such as anastomotic leakage and recurrent laryngeal nerve palsy increased following three-field lymphadenectomy^[45,46].

CONCLUSION

Lymph node metastasis is a key factor that affects both surgical treatment and prognosis in patients with EC. Thus, reasonable lymphadenectomy becomes very important, offering a better treatment outcome and accurate staging. However, lymphatic channels within the esophagus are very complex, resulting in variable lymphatic spread and skip metastases in EC. Generally, upper mediastinal and perigastric areas are worth more consideration. Based on current studies, it seems that three-field lymphadenectomy for EC is being gradually accepted by more and more people, with more extensive lymphadenectomy and higher survival. However, there are more postoperative complications in three-field lymphadenectomy compared to two-field. Therefore, more studies have recently focused on identifying optimal patients for each pattern of lymphadenectomy. Considering complications, tumor stage and lymphatic spreading of the esophagus, limiting factors in the application of three-field lymphadenectomy, may be a poor physical condition, systemic disease stage and lower mediastinal, including the esophagogastric junction, carcinoma of the esophagus. Although more strict clinical trials are needed to compare two and three-field lymphadenectomy, it is essential to attempt to decrease surgical traumatic injury of esophagectomy with lymphadenectomy while ensuring the extent of lymph node dissection in EC.

Abstract

AIM: To determine the effect of single-incision laparoscopic colectomy (SILC) for colorectal cancer on short-term clinical and oncological outcomes by comparison with multiport conventional laparoscopic colectomy (CLC).

METHODS: A systematic review was performed using MEDLINE for the time period of 2008 to December 2014 to retrieve all relevant literature. The search terms were "laparoscopy", "single incision", "single port", "single site", "SILS", "LESS" and "colorectal cancer". Publications were included if they were randomized controlled trials, case-matched controlled studies, or comparative studies, in which patients underwent single-incision (SILS or LESS) laparoscopic colorectal surgery. Studies were excluded if they were non-comparative, or not including surgery involving the colon or rectum. A total of 15 studies with 589 patients who underwent SILC for colorectal cancer were selected.

RESULTS: No significant differences between the groups were noted in terms of mortality or morbidity. The benefit of the SILC approach included reduction in conversion rate to laparotomy, but there were no significant differences in other short-term clinical outcomes between the groups. Satisfactory oncological surgical quality was also demonstrated for SILC for the treatment of colorectal cancer with a similar average lymph node harvest and proximal and distal resection margin length as multiport CLC.

CONCLUSION: SILC can be performed safely with similar short-term clinical and oncological outcomes as multiport CLC.

Key words: Single-incision laparoscopic surgery; Single-incision laparoscopic colectomy; Colorectal cancer

Core tip: The aim of this review is to determine the effect of single-incision laparoscopic colectomy (SILC) for colorectal cancer by comparison with multiport conventional laparoscopic colectomy (CLC). A total of 15 studies with 589 patients who underwent SILC for colorectal cancer were selected. No significant differences between the groups were noted in terms of

short-term clinical and oncological outcomes, but there was a reduction in the conversion rate to laparotomy in the SILC group. We concluded that SILC can be performed safely with similar short-term clinical and oncological outcomes as multiport CLC.

Hirano Y, Hattori M, Douden K, Ishiyama Y, Hashizume Y. Single-incision laparoscopic surgery for colorectal cancer. *World J Gastrointest Surg* 2016; 8(1): 95-100 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i1/95.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i1.95>

INTRODUCTION

Many surgeons have attempted to reduce the number and size of ports used in laparoscopic surgery in order to decrease parietal trauma and improve cosmetic results, and single-incision laparoscopic surgery (SILS), in which the laparoscopic procedures are completed using trocars placed in a single umbilical incision, has recently been developed^[1].

Since the oncologic safety of laparoscopic colectomy in cancer patients has been proven in randomized trials^[2], laparoscopic surgery has steadily become a safe and practical treatment option for these patients, even those with malignant disease of the colon and rectum.

Single-incision laparoscopic colectomy (SILC) is a challenging procedure. Although it seems to be safe and feasible, there is insufficient clinical evidence to confirm this. Moreover, it is unclear whether SILC is able to achieve satisfactory oncologic results in colorectal cancer patients compared to multiport conventional laparoscopic colectomy (CLC).

The aim of this systematic review is to compare the short-term clinical and oncological outcomes following SILC and multiport CLC.

MATERIALS AND METHODS

Data search

An electronic search was performed using MEDLINE databases from 1966 to 2014. The search terms were "laparoscopy", "single incision", "single port", "single site", "SILS", "LESS", and "colorectal cancer". The authors performed the electronic searches in December 2014. Publications were included if they were randomized controlled trials, case-matched controlled studies, or comparative studies, in which patients underwent single-incision (SILS or LESS) laparoscopic colorectal surgery. Studies were excluded if they were non-comparative, or not including surgery involving the colon or rectum.

Articles were selected if the abstract contained data on patients who underwent SILC for colorectal diseases in the form of randomized controlled trials (RCTs) and other controlled or comparative studies. Conference abstracts were excluded. To avoid duplication of data,

articles from the same unit or hospital were excluded. Reports including benign colorectal diseases or reports with fewer than 10 cases of SILC and review articles were excluded from this study. Data extracted for this study were taken from published reports, and authors were not contacted to obtain additional information. The flow chart of the selection process is summarized in Figure 1.

Results of the literature research

By using the above search strategy, a total of 162 potentially relevant citations were found. After the exception of 125 duplicate citations, we excluded 86 articles irrelevant to the surgical specialty and 26 relevant articles by reviewing titles and abstracts. Fourteen publications were selected for review of the full text^[3-17] and 11 articles including benign colorectal diseases were excluded from this study. There were 13 comparative studies, including 5 case-matched ones, between SILC and conventional laparoscopic procedures. There were two RCTs in the selected literature^[10,11].

RESULTS

The literature search identified one randomized controlled trial and 13 case-matched control or comparative studies^[3-17]. In total, 1559 colorectal resections were included, 589 by SILC and 970 by CLC. Table 1 describes basic demographic data from each study, including patient age, male-female ratio, body mass index, and colorectal surgical procedure breakdown (right, left, or total). There were no differences in patient characteristics in all studies.

The incidence of postoperative mortality was reported in 13 studies, 0% and 0.11% in the SILC and CLC groups, respectively. The incidence of postoperative morbidity was reported in 14 studies, 15.1% and 18.1% in the SILC and CLC groups, respectively.

The average operative time was described in 14 of the included studies. Takemasa *et al.*^[16], in their case-matched series, reported that operation time was significantly shorter in the group treated by right-sided SILC ($n = 69$) than in the group treated by right-sided CLC ($n = 69$) (168 ± 32 min vs 179 ± 32 min, respectively, $P = 0.046$). The average estimated blood loss was described in 14 studies; there were no significant differences in all reports.

Thirteen studies described conversion to open surgery, which was 0.92% in the SILC group and 3.04% in the CLC group. An additional 13.3% of SILC procedures required the insertion of an additional port to allow completion of the operation (Table 2).

Fourteen studies reported the average length of hospital stay. Poon *et al.*^[11] reported that the median hospital stay in the SILC group was shorter than that in the CLC group in their study.

Poon *et al.*^[11] found that the SILC group had a consistently lower median pain score than the CLC group during the whole postoperative course, and the

SILC: Single-incision laparoscopic colectomy; CLC: Conventional laparoscopic colectomy.

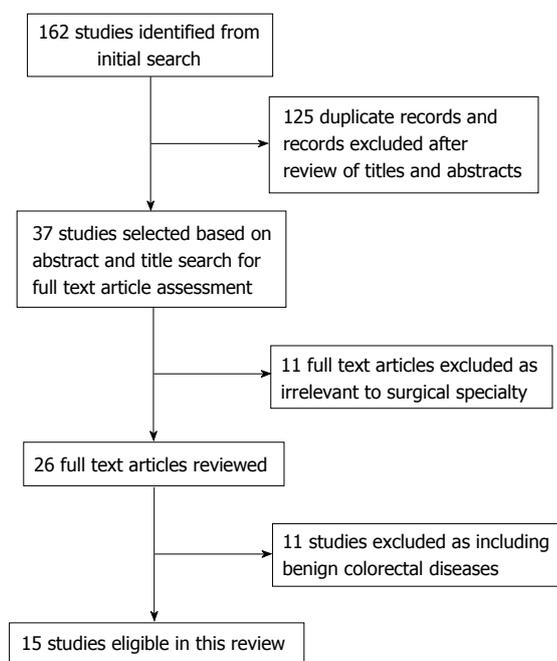

Figure 1 Flow chart of the selection process for studies included in the systematic review.

difference was statistically significant on day 1 [0 (0-5) vs 3 (0-6), respectively, $P = 0.002$] and day 2 [0 (0-3) vs 2 (0-8), respectively, $P = 0.014$]. Takemasa *et al.*^[16] also revealed that postoperative pain was significantly lower with SILC than that with CLC in their case-matched study (4.2 ± 2.7 vs 5.1 ± 3.3 , respectively, $P = 0.01$). Lu *et al.*^[9], however, reported that postoperative pain scores were significantly higher in the SILC group than those in the CLC group (3.07 ± 1.14 vs 2.41 ± 0.63 , respectively, $P < 0.001$).

Kim *et al.*^[3] showed that postoperative recovery was faster in the SILC group in terms of shorter time duration before first flatus (SILC vs CLC; 2.5 ± 1.2 d

vs 3.2 ± 1.8 d, $P = 0.004$), earlier initiation of free oral fluids (1.8 ± 2.2 d vs 2.6 ± 1.7 d, $P = 0.000$) and of a solid diet (4.2 ± 2.9 d vs 6.5 ± 2.7 d, $P = 0.000$), less frequent usage of parenteral narcotics (2.2 ± 3.2 times vs 3.5 ± 4.0 times, $P = 0.029$), and shorter hospital stay (9.6 ± 9.6 d vs 15.5 ± 9.8 d, $P = 0.000$) (Table 3).

With regard to oncologic clearance, 14 studies reported average lymph node harvest. The length of proximal resection margin was reported in 7 studies, and that of distal was reported in 8 studies. The mean number of harvested lymph nodes and proximal and distal resection margins did not differ significantly between the two groups. Papaconstantinou *et al.*^[5] reported that the mean follow-ups were 13 and 21 mo for the SILC and CLC groups, respectively ($P < 0.001$), with 2 (8%) recurrences in each group, and no port-site recurrences or deaths. Disease-free survival at 1 year was 92% for both groups. Yun *et al.*^[15] reported that the mean follow-up periods were 24.5 mo for the SILC group and 26.4 mo for the CLC group ($P = 0.098$), with 6 recurrences in the SILC group (9.1%) and 3 recurrences in the CLC group (3.2%) ($P = 0.120$). One death occurred in the CLC group. Disease-free survival at 24 mo did not differ significantly between the 2 groups (89.7% vs 96.3%, $P = 0.120$) (Table 4).

DISCUSSION

Natural orifice transluminal endoscopic surgery (NOTES) has recently been developed as a new less invasive type of surgery; however, NOTES is technically challenging, and the currently available instruments need to be improved. As a bridge between traditional laparoscopic surgery and NOTES, SILS was developed to further minimize the invasiveness of laparoscopic surgery by reducing the number of incisions required. SILS can be performed by refining existing technology, and it does not require the surgeon to learn any new skills.

SILC: Single-incision laparoscopic colectomy; CLC: Conventional laparoscopic colectomy.

SILC for colon cancer was first described by Bucher *et al.*^[18] and Remzi *et al.*^[19] in 2008. Although many authors have reported that SILC provides a better cosmetic result with similar perioperative results, the procedure remains somewhat controversial. Several studies of SILC were designed to include both cancerous and noncancerous lesions, such as adenoma, diverticulitis, and inflammatory disease. The aim of this review of 14 studies was to compare short-term clinical and oncological outcomes from SILC with those of CLC only for colorectal cancer.

The major findings of the analysis showed no significant differences between the groups in terms of mortality or morbidity. Operative time was also similar between the groups. The benefits of a minimally invasive approach were enhanced within the SILC group as reflected by a reduction in estimated blood loss and length of hospital stay. The incidence of conversion to an open procedure was also significantly reduced in the SILC group (SILC 0.92% vs CLC 3.04%, $P = 0.016$); however, 13.3% of SILC procedures required the insertion of an additional port to allow completion of the operation. The oncological safety of SILC for the treatment of colorectal cancer, as evidenced by similar average lymph node harvest as well as proximal and distal resection margin length, was comparable to that of CLC.

The patient populations for both groups were similar in terms of age, body mass index, and right vs left colorectal procedures. However, male gender was significantly less in the SILC group, which implies a degree of selection bias may have been present in the studies included and thus represents a significant confounder in the interpretation of the short-term outcomes presented.

Reduction of postoperative pain is an important benefit associated with a minimally invasive approach to surgery. The transition from an open to a laparoscopic procedure was revolutionary and associated with large improvements in postoperative pain. Although Poon *et al.*^[11] and Takemasa *et al.*^[16] revealed reduction of pain scores following SILC compared to CLC in their studies, the evolution from a conventional multiport laparoscopic approach to a single-incision technique is less dramatic and may only result in incremental improvements in postoperative pain.

The oncological surgical quality of a SILC approach was demonstrated by a similar average lymph node harvest and proximal and distal resection margins compared to those of CLC. With regards to survival, Papaconstantinou *et al.*^[5] reported that the mean follow-ups were 13 and 21 mo for the SILC and CLC groups, respectively, and that the recurrence rates and disease-free survivals (DFSs) at 1 year were equivalent in both groups. Yun *et al.*^[15] showed that the mean follow-up periods were 24.5 mo for the SILC group and 26.4 mo for the CLC group, and that the recurrence rates and DFSs at 2 years did not differ significantly between the two groups. Comparison of long-term survival follow-

ing SILC and CLC for colorectal cancer is clearly an important area for future research.

Despite this present review being the largest analysis on comparison between SILC and CLC for colorectal cancer to date, there are important limitations that must be acknowledged. Currently, only 2 RCTs have been published on this subject, and therefore, important confounding factors, including patient medical comorbidities, may not be evenly distributed between the groups, thus influencing the results generated. Furthermore, there was a wide range in surgical techniques and devices used that were included in the SILC group.

In conclusion, SILC for colorectal cancer can be performed safely with similar short-term clinical and oncological surgical outcomes to multiport CLC. In the future, RCTs with a large number of cases are necessary to determine the role of SILC in long-term clinical and oncological outcomes.

COMMENTS

Background

Single-incision laparoscopic surgery, in which the laparoscopic procedures are completed using trocars placed in a single umbilical incision, has recently been developed, since the oncologic safety of laparoscopic colectomy in cancer patients has been proven in randomized trials, laparoscopic surgery has steadily become a safe and practical treatment option for these patients, even those with malignant disease of the colon and rectum. Single-incision laparoscopic colectomy (SILC) is a challenging procedure. Although it seems to be safe and feasible, there is insufficient clinical evidence to confirm this. Moreover, it is unclear whether SILC is able to achieve satisfactory oncologic results in colorectal cancer patients compared to multiport conventional laparoscopic colectomy (CLC).

Innovations and breakthroughs

Aim to determine the effect of SILC for colorectal cancer on short-term clinical and oncological outcomes by comparison with multiport CLC.

Applications

SILC for colorectal cancer can be performed safely with similar short-term clinical and oncological surgical outcomes to multiport CLC. In the future, randomized controlled trials with a large number of cases are necessary to determine the role of SILC in long-term clinical and oncological outcomes.

Peer-review

The article is very interesting and good enough, focused details are well described and may show a step forward in the field of minimally invasive surgery.

Abstract

Sensitized patients tend to have longer waiting times on the deceased donor list and are at increased risk of graft loss from acute or chronic rejection compared to non-sensitized candidates. Desensitization protocols are utilized to decrease the levels of alloantibodies and to convert an initial positive cross-match to prospective donors into a negative crossmatch. These procedures are mostly available in the setting of living donation. Due to the elective nature of the procedure, desensitization protocols can be extended until the desire result is obtained prior to transplantation. We present two cases of successful desensitization protocol applied to living donor intestinal transplant candidates that converted to negative cross-match to their donors. We present two cases of intestinal transplant candidates with a potential living donor to whom they are sensitized. Both cases underwent successful transplantation after desensitization protocol. No evidence of humoral rejection has occurred in either recipient. Living donor intestinal transplantation in sensitized recipients against the prospective donors provides the ability to implement a desensitization protocol to convert to negative cross-match.

Key words: Living donor; Positive crossmatch; Intestinal

transplant; Desensitization protocol; Donor specific antibody; Plasmapheresis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Intestinal transplant candidates are frequently sensitized and waiting longer on the list. Living donation of intestine has been successful and allows for time to immunologically prepare sensitized recipient prior to transplant to achieve higher degree of success.

INTRODUCTION

Allosensitization represents a common problem for patients awaiting small bowel transplantation. In this patient population, allosensitization occurs often consequent to multiple blood transfusions administered during complex abdominal procedure, eventually leading to short bowel syndrome.

The presence of donor specific antibodies to the human leukocyte antigens (HLA) antibodies augments the risk of either acute or chronic immune mediated graft loss^[1]. In kidney transplantation, removing anti-HLA antibodies by a combination of plasmapheresis, immunoglobulins (IVIG) and immunosuppression have been successfully applied to prevent antibody-mediated rejection (AMR). However, this approach can logistically only be applied in the context of elective living donor transplantation.

Outcomes after living donor small bowel transplantation in experienced centers are comparable to those obtained with cadaver grafts^[2]. The elective nature of living donor intestinal transplantation offers the opportunity for the use of desensitization protocols in highly sensitized patients. Herein, we present the first report of two successful small bowel transplants after desensitization protocol in recipients with a positive cross-match (CM) to their prospective living donors.

CASE REPORT

Case one

A 13-year-old Caucasian male was diagnosed of pseudo-papillary tumor of the head of the pancreas with vascular encasing of portal vein and superior mesenteric artery. He underwent a Whipple procedure with vascular resection and reconstruction. Twelve months later, the patient presented with acute bowel ischemia secondary to superior mesenteric artery thrombosis and underwent

nearly total enterectomy and extended right colectomy. The patient was placed on total parenteral nutrition (TPN) as he was left with less than 5 cm of intestine. Given the young age of the patient and the high sensitization we suggested living donor small bowel transplant.

The other of the patient, 36-year-old in perfect health without previous abdominal surgeries, volunteered as a potential donor for intestinal transplantation. The donor evaluation process was carried out according to our standard protocol previously reported^[3].

Due to the multiple blood transfusions required during the events leading to transplantation, his Panel Reactive Antibodies (PRA) was 67% for class I and 100% for class II. He had strong donor specific antibodies (DSA) at locus A × 11:01 (MFI = 7359). The initial CM was positive by flow cytometry technique with pronase treatment at + 55 channel shifts for T cell and + 40 for B cell (negative CM less than + 17 channel shift); the standard cytotoxic CM was negative. The patient underwent seven plasma exchange treatments before the planned transplant procedure, each followed by IVIG at the dose of 100 mg/kg. The final flow cytometry CM remained weakly positive, with + 19 channel shifts for T cell and + 23 channel shift for B cell; the standard CM stayed negative. At the time of transplant our recipient was 36.7 kg (the 10th percentile in the growth chart) and fully dependent on total parenteral nutrition. The transplant event was successful; the 180 cm ileal graft was revascularized through anastomosis to the aorta and the vena cava. Proximally, the bowel graft was anastomosed to the stomach and distally to the residual colon; a loop ileostomy was created for graft monitoring.

Induction immunosuppression consisted of methylprednisolone taper along with of five doses of thymoglobulin (100 mg/kg) and 5 plasmapheresis treatments every other day followed by IVIG (125 mg/kg based on ideal body weight) on alternative days. He was closely monitored with ileoscopy and graft biopsy for surveillance of rejection weekly for a month, biweekly for another 2 mo and monthly thereafter. There was no evidence of rejection in any of the biopsies over two years follow-up.

Two months post-transplant, his course was complicated by an Epstein barr virus positive post-transplant lymphoproliferative disorder (PTLD) involving lymph nodes in both sides of the diaphragm. He was successfully treated with reduction of immunosuppression, antiviral therapy, Rituximab (375 mg/m²) weekly for total of 6 doses and Cytoxan (600 mg/m²) every 21 d for a total of 6 doses.

Nine months after transplant, he had successful ileostomy reversal and his TPN was completely discontinued. He is currently fully supported by unrestricted oral diet and his most recent weight is 51.7 kg (the 18th percentile of his peers) at 2 years follow up; he remains in remission from PTLD. His maintenance immunosuppression consists of prednisone 5 mg daily and low dose Tacrolimus with target levels of 4-6 ng/mL.

Case two

A 56-year-old Caucasian female with history of scleroderma complicated by intestinal pseudo-obstruction, underwent several intestinal resections and diverting ileostomy. Unfortunately, an injury to the superior mesenteric vessels occurred during one of the surgical procedures, resulting in near total enterectomy and extended right colectomy. At the time of presentation to our center, she was TPN-dependent for 6 mo, with high output tube duodenostomy; she was underweight at 42.2 kg with a body mass index (BMI) of 17 kg/m².

Her daughter, a healthy 36-year-old female ABO compatible, with a BMI of 24 kg/m², volunteered as a potential donor. The recipient was sensitized with a PRA class I 80% and class II 26%; no DSAs were identified. While the standard cytotoxic CM was negative, the flow cytometry CM was negative for T cell but positive for B cell with + 69 channel shifts. Desensitization was conducted by three plasma exchange treatments prior to transplant followed by IVIG, obtaining a completely negative flow cytometry and standard CM at the time of transplant.

A donor ileal graft of 190 cm was transplanted successfully in the recipient with our standard technique. Thymoglobulin (3 mg/kg) was given intraoperative and followed by three more doses (1.5 mg/kg) on alternate days to plasmapheresis; Tacrolimus was initiated the day prior to procedure with rapid taper of steroids to 10 mg daily by post-operative day 5. Endoscopic surveillance at previously described intervals during the initial 6 mo follow up revealed no evidence of rejection. The patient has had successful ileostomy reversal at 6 mo and is tolerating oral intake; she is no longer on supplemental TPN.

DISCUSSION

Small bowel transplantation is an accepted treatment for patient with irreversible intestinal failure with life-threatening complications of TPN. At the end of 2014, there were approximately 250 patients listed for bowel transplantation in the United States. For candidates wait-listed in 2010, the median time to transplant was 14.9 mo for those younger than 18 years and only 2.8 mo for those aged 18 years or older^[4]. The United Network of Organ Sharing does not report separately the waiting time on sensitized candidates for bowel transplantation, but experience in kidney recipients suggests potentially longer waiting times^[5]. Importantly, transplant outcomes performed on recipients receiving total parenteral nutrition for less than one year are significantly better than those on TPN of a year or longer^[6].

In the current literature there are limited publications concerning small bowel transplantation in CM positive recipients. While intestinal transplantation has a higher rejection rate than most other solid organs (42% in the first year)^[4], antibody mediated rejection (AMR) is not well characterized and understood in this set of patients.

In other solid organs, the presence of C4d staining in the biopsies is indicative of AMR but this may not apply to intestinal transplants^[7].

Recently, virtual crossmatch has been successfully used to facilitate allocation of intestinal grafts specifically in the subgroup of sensitized candidates^[8]. With this strategy, the group at Georgetown University has achieved 80% successful allocation with negative cross-match in sensitized recipients compared to 86.7% in non-sensitized, minimizing the discard rates of suitable organs originating out of state. However, sensitized patients with elevated PRA achieving a negative CM showed a survival disadvantage. The 1-year graft survival was lower in the sensitized group at 66.7% compared to 85.2% in the group with low PRA^[8]. Although the authors did not observe a statistically significant difference between the two groups, likely due to a small sample size, the discrepancy is clinically concerning. The study also did not comment on specific therapy to reduce the levels of alloantibodies.

Experience in other solid organ transplantation such as kidney or heart indicates that outcomes in sensitized recipients are inferior to those observed in non-sensitized patients. Sensitized patients exhibit higher rejection rates, lower graft and patient survival^[9]. Similarly, in intestinal transplantation, the risk of AMR has been reported to be higher in sensitized recipients and in those developing *de-novo* DSA. Diagnosis of AMR should be based on clinical suspicion in the presence of DSA or increased PRA since intestinal biopsy may not be conclusive^[10,11]. Independent risk factors for worse outcomes in intestinal transplantation are: recipient PRA more than 20%, liver-sparing grafts and absence of recipient splenectomy^[12]. Persistence of DSA after transplantation or *de-novo* formation of DSA result in increased risk of graft loss due to rejection (58% and 47% respectively). The risk of graft loss in patients without DSA was 8% and 13% in those clearing DSAs after transplant. Liver containing grafts are immunoprotective, effectively clearing pre-formed antibodies and reducing the risk of *de-novo* formation, but the recipients with persistent DSA after transplantation correlated with lower graft survival despite the presence of the liver^[13]. Additionally, the rates and aggressiveness of rejection are worse in isolated intestine vs transplant containing liver graft^[14].

Contrary to these results, Kubal *et al.*^[15] recently reported similar 3-year survival rates in small bowel transplantation (67% in positive CM vs 65% in negative CM). The also did not found a significant difference in the incidence of acute rejection between liver sparing and liver containing grafts (30% vs 29%). Additionally, the use of anti-interleukin-2 antibody as part of the induction therapy was noted to significantly reduce the rate of rejection overall.

Protocols to desensitize recipients continue to evolve and emerging therapeutic strategies allow successful positive CM transplantation^[16]. The application in small bowel transplantation is not widely reported but the use of Bortezomib during induction in sensitized candidates has been suggested^[13]. Performing surveillance DSA

to identify patients at risk, especially those without a concomitant liver, and rapidly initiate treatment with a combination of plasmapheresis, IVIG may optimize outcomes^[17,18]. The use of Bortezomib to treat resistant rejection was successful in one case report^[19].

The only Desensitization protocol reported in wait list candidates to intestinal transplantation used escalating doses of IVIG according to the level of response in reducing the PRA level and included plasmapheresis or mycophenolate mofetil as the final step. The rate of rejection was found to be similar to non-sensitized recipients and the waiting time was also reduced on patients responding to the protocol^[20].

Our center is experienced in living donor small bowel transplantation and the elective nature of the procedure offers several advantages, especially in the sensitized candidates. We can optimize the immunological condition prior to transplantation with current desensitization protocols existing in other solid organs, mostly in kidney transplantation. As noted before, the risk antibody mediated rejection is increased in patients with elevated PRA, *de-novo* DSA formation and those with positive B cell CM. We realize that the CM was weak prior to desensitization, especially in the second case, and resulted in easier conversion to a negative CN. The one-year follow-up on both patients without rejection episodes are encouraging and suggest that pretransplant plasmapheresis may effectively prevent humoral rejection in sensitized intestinal transplant recipients. We acknowledge this is a very short follow and follow up DSA surveillance studies may be necessary to confirm the success of this protocol.

In conclusion, living donation offers the possibility to initiate therapy to optimize the immunological condition at the time of transplant, converting to a negative CM sensitized intestinal transplant recipients to their prospective donors.

COMMENTS

Case characteristics

Two patients with short bowel syndrome treated with living donor intestine transplantation.

Clinical diagnosis

Both cases present highly sensitized making their chances for a deceased donor transplant unlikely.

Differential diagnosis

Sensitization can be from autoantibodies or atypical antibodies and not identified in by donor specific antibodies (DSA) studies.

Laboratory diagnosis

Cross-match and DSA studies performed.

Pathological diagnosis

Biopsies taken from the intestinal mucosa were normal.

Treatment

They underwent desensitization protocol and elective intestine transplant.

Related reports

Intestinal transplant candidates are frequently sensitized and tend to wait for an organ longer than non-sensitized patients. Living donation is a scheduled procedure allowing for desensitization protocol to be completed prior to transplantation. This is not available when a deceased organ is offered. Desensitization protocols are applied frequently for sensitized patients before receiving a kidney transplant from live donors. The application to prospective recipient of intestine is novel.

Term explanation

Desensitization protocols can turn positive crossmatch into negative and allow for successful transplantation.

Experiences and lessons

This is a two cases report with limited follow up, but successful so far in both recipients. Post-transplant lymphoproliferative disorder is a risk in patients receiving high immunosuppression as the desensitization protocol.

Peer-review

This is a manuscript that presents a valuable potential solution to the shortage of small bowel grafts, particularly in the setting of patients who are sensitized. The authors provide an interesting hypothesis for larger studies.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, In Sook Lee, MD, Associate Professor, Department of Radiology, Pusan National University Hospital, Busan 602-739, South Korea

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Aim of the study is to comprehensively review the

latest trends in laparoscopic complete mesocolic excision (CME) with central vascular ligation (CVL) for the multimodal management of right colon cancer. Historical and up-to-date anatomic-embryological concepts are analyzed in detail, focusing on the latest studies of the mesenteric organ, its dissection by mesofascial and retrofascial cleavage planes, and questioning the need for a new terminology in colonic resections. The rationale behind Laparoscopic CME with CVL is thoroughly investigated and explained. Attention is paid to the current surgical techniques and the quality of the surgical specimen, yielded through mesocolic, intramesocolic and muscularis propria plane of surgery. We evaluate the impact on long term oncologic outcome in terms of local recurrence, overall and disease-free survival, according to the plane of resection achieved. Conclusions are drawn on the basis of the available evidence, which suggests a pivotal role of laparoscopic CME with CVL in the multimodal management of right sided colonic cancer: performed in the right mesocolic plane of resection, laparoscopic CME with CVL demonstrates better oncologic results when compared to *standard* non-mesocolic planes of surgery, with all the advantages of laparoscopic techniques, both in faster recovery and better immunological response. The importance of minimally invasive *meso-resectional* surgery is thus stressed and highlighted as the new frontier for a modern laparoscopic total right mesocolectomy.

Key words: Right sided colonic cancer; Complete mesocolic excision; Central vascular ligation; Laparoscopy; Quality of surgical specimen; Oncologic outcome

Core tip: Laparoscopic complete mesocolic excision

(CME) with central vascular ligation (CVL) is based on resection of the colon within its intact and inviolate mesocolon with high tie ligation, so to improve the quality of the resection specimen produced; up-to-date anatomo-embryological concepts are analyzed in detail, focusing on the latest studies of the mesenteric organ, its dissection by mesofascial and retrofascial cleavage planes, and questioning the need for a new terminology in colonic resections. The rationale behind the CME with CVL is explained and particular attention is paid to the current surgical techniques. The impact on local recurrence, disease-free and overall survival is reviewed. Current literature about laparoscopic CME with CVL demonstrated better quality of the surgical specimen produced and significant survival advantage when compared to standard non-mesocolic resections, stressing the importance of meso-resectional surgery, especially when performed with minimally invasive techniques: higher surgical quality, faster recovery and better immunological response may in fact contribute to better long term oncologic outcome.

Siani LM, Garulli G. Laparoscopic complete mesocolic excision with central vascular ligation in right colon cancer: A comprehensive review. *World J Gastrointest Surg* 2016; 8(2): 106-114 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i2/106.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i2.106>

INTRODUCTION

At the end of the 19th century, Emil Theodor Kocher^[1,2], was the first to theorize oncologic resections based on removal of the involved organ along with its lymphatic drainage; this concept was shortly after substantiated by Miles *et al*^[1] and Jemison *et al*^[2] for rectal and colonic cancer respectively. Yet, the real revolution in oncologic surgery was performed seventy years later by Heald *et al*^[3], who introduced the concept of total excision of the mesorectum (TME), the primitive embryological dorsal mesentery of the rectum: Dissection in the mesorectal plane yields an intact fascial-lined specimen containing all the vasculo-lymphatic pathways and lymph nodes, and reduces the risk of an involved circumferential resection margin (CRM)^[3,4]. The embryological right plane of dissection, graded by the pathologist, has been shown to be independently related to the risk of local recurrence, disease free and overall survival^[5,6], so to promptly became the central part of any multimodal treatment of rectal cancer^[7].

In 2009, Hohenberger *et al*^[8] translated the concept of TME to colonic cancer, noting that traditionally more favorable oncologic results of colon neoplasia was eventually overtaken by rectal cancer: Multimodal strategies, not yet applied to colonic tumors, and a more radical surgical approach performed along embryonic planes of development with higher quality

specimens, produce better oncologic outcome; thus, complete mesocolic excision (CME) with central vascular ligation (CVL) was theorized, standardized and eventually validated by several studies^[9,10].

The concept of complete excision of the involved organ along with its primitive mesentery, associated to central ligation of the supplying blood vessels, is progressively gaining acceptance as the next step towards a modern surgical oncology; surgical resection of the primitive embryological mesentery is in fact pivotal for optimal local clearance. The primitive mesentery is the embryological envelope where the neurolymphovascular structures develop within a double-layered mesenchymal fibrofatty tissue and the initial pathway for cancerous diffusion: Its intact, complete excision is thus essential to clear residual disease in the surgical field, with consequent impact on local control.

Furthermore, CVL allows for an extensive lymph node dissection along the feeding vessels, with significant effect on regional recurrence and systemic dissemination, as shown by improved survival in stage I-III colonic cancers treated with enhanced lymph node harvesting^[11,12].

Blending Complete Mesocolic Excision with CVL is thus the logical step in gaining the highest loco-regional control, removing both the intact mesocolon and the apical nodes, with relevant impact on long term outcome. To take advantage of minimally invasive techniques, laparoscopic approach to CME with CVL seems the natural consequence in the evolution of this procedure.

ANATOMO-EMBRYOLOGICAL CONCEPT OF THE MESOCOLON

The mesocolon is the adult remnant of the primitive dorsal mesentery^[13-19]. In the 5 mm embryo (approximately 32 d), the colon develops within a dorsal mesentery for all its length; an approximately 270° counterclockwise rotation of the primitive mid-gut along the axis of the superior mesenteric artery (SMA) causes the folding of the dorsal mesentery, originating the future mesocolon^[13-19].

In 1885, Treves^[20] stated that the right mesocolon fuses with the primitive posterior parietal peritoneum, with the consequent obliteration of the space between these embryonic structures. This view of mesenteric obliteration through a process of fusion was than refuted in the early '900 by the study of Carl Toldt^[21] and Congdon^[22], who affirmed that the mesentery of the colon persists in adulthood not only at the level of the transverse and sigmoid colon, but all along its length, being separated from the posterior parietal peritoneum by a loose areolar connective plane referred to as Toldt's fascia. Later on, Goligher^[23] described the possibility of stripping back the colon and its meso towards the midline, restoring the primitive embryological disposition

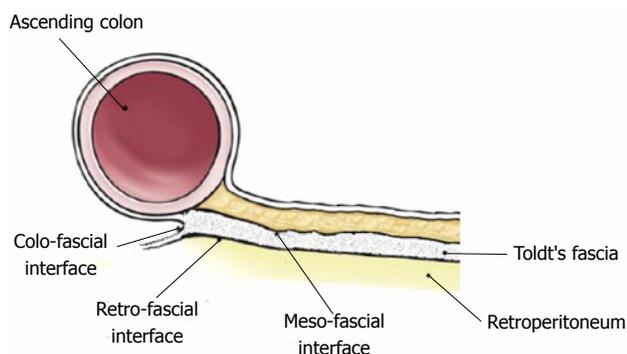

Figure 1 Depiction illustrating the relationships between the mesocolon, Toldt's fascia (schematically exaggerated for descriptive purpose) and the retroperitoneum. Meso-fascial interface is the apposition between the Toldt's fascia and the overlaying mesocolon; Retro-fascial interface is the apposition between the Toldt's fascia and the underlying retroperitoneum.

before its rotation, confirming the Toldt's and Congdon's remarks.

Contemporary view of the mesenteric organ

The increasing focus on the quality of the surgical specimen as an independent variable in the outcome of cancer surgery stresses the need for a more detailed knowledge of the mesocolon anatomy.

Recent papers demonstrated that the mesocolon persists in adulthood as a distinct anatomic structure, continuous from the ileocecal valve to the rectosigmoid junction, with well defined mesocolic, fascial, and retroperitoneal components and related mesofascial (the apposition between the Toldt's fascia and the overlaying mesocolon) and retrofascial (the apposition between the Toldt's fascia and the underlying retroperitoneum) interfaces (Figure 1): These latter are crucial for surgical planes in mesocolic and colonic mobilization^[24,25].

Furthermore, recent studies^[26,27] investigated the mesocolon by light and electron microscopy: Its structure is homogeneous across all locations and is composed of adipocyte lobules separated by thin fibrous septae layered by mesothelium, with lymphatic channels within this lattice; unexpectedly, a further connective, highly cellular submesothelial layer exists between surface mesothelium and the adipocytes.

A detailed appraisal of the lymphatic network within the mesocolon by immunohistochemical analysis^[28], showed that lymphatic vessels occur within both submesothelial connective tissue and interlobular septations, on average every 0.14 mm and within 0.1 mm from the mesocolic surfaces, generating a rich lymphatic network; the authors stressed that breaching the mesocolic surface extensively disrupts this lymphatic network. In the same study, lymphatic vessels were also identified within the Toldt's fascia, with no direct communication with those in the mesocolon, and whose clinical significance (independent or integral part of the mesocolon) should be investigated with further dedicated works: In fact, in mesofascial separation,

mesocolon and fascia are surgically separated with the Toldt's fascia left *in situ* (Figure 2A), whereas in retrofascial separation the mesocolon/fascia complex is separated from the underlying retroperitoneum (Figure 2B); both separations are integral to CME as shown by Hohenberger *et al*^[8], but the exact role of lymphatic channels within the Toldt's fascia could define only retrofascial separation as an oncologically correct plane of resection.

Time for a new terminology?

Some authors^[29-32] advocated the need for a new terminology in describing the mesocolon and its related surgical procedures: Visceral and parietal fascia, pre-renal fascia, parietal plane, somatic fascia may ingenerate confusion and should be standardized in the modern view of the mesenteric organ.

A surgical plane is defined as the interface between two contiguous structures, and in resectional colonic surgery the planes are (1) mesofascial; (2) retrofascial; and (3) colofascial, as shown in Figure 1. In keeping with this, a terminology of total or partial right (left) mesocolectomy has been proposed, being more informative than right (left) hemicolectomy or ileocolic resection because entirely derived for the current anatomical appraisal of the mesenteric organ anatomy.

THE RATIONALE BEHIND

There are three essential components of CME with CVL: (1) development of a mesofascial or retrofascial plane to mobilize an intact and inviolate mesocolon as an intact package; (2) CVL with high tie to maximize the vertical lymph node dissection (central spread); (3) adequate length of bowel to remove pericolic lymphnodes, maximizing the longitudinal lymphnode harvesting (longitudinal spread).

CME allows for removal of the entire envelope of the primitive dorsal mesentery along the anatomic-embryological avascular cleavage planes, and is therefore fundamental for a true radical R0 resection, as the meso contains the whole potential routes of metastatic spread through lympho-vascular, neuroperineural and fibro-fatty tissues^[8-10]. The mesocolon must be excised as an intact, inviolate package as any breach of its surface and underlying structures threatens the radial margin and disrupts the lymphatic network of the meso-structure with consequent *spillage* of neoplastic cells within the surgical field, enhancing the risk of local recurrence. This concept stresses further the need for a correct surgical plane of resection to maximize the local clearance, exactly the same way we conceptually perform TME for rectal cancer: To reduce to reduce the risk of an involved CRM and minimize the risk of local failure^[7].

CVL is essential in obtaining an adequate regional control and impact on survival. The latest 2010 JSCCR guidelines recommends D2 dissection for clinically

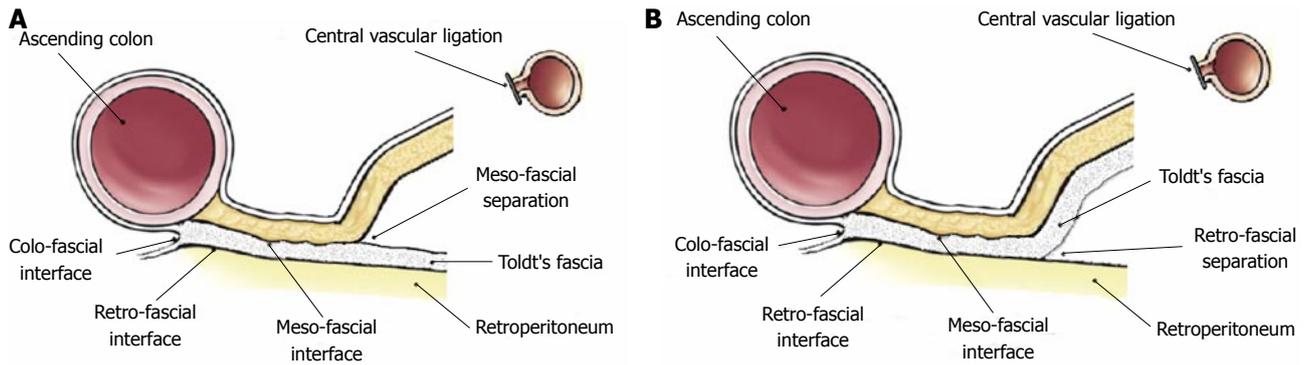

Figure 2 Depiction illustrating the meso-fascial (A) and retro-fascial (B) separation performed in the medial to lateral approach for laparoscopic right meso-colectomy. In Meso-fascial separation (A), the plane of dissection lies between the inferior leaf of the mesocolon and the underlying Toldt's fascia (schematically exaggerated for descriptive purpose), separating both components of the meso-fascial interface. In Retro-fascial separation (B), the plane of dissection lies between the Toldt's fascia and the posterior parietal peritoneum covering the retroperitoneum, separating both components of the retro-fascial interface. Both dissections end with colo-fascial separation.

early stages colorectal cancers and D3 dissection for more advanced disease: Impressive results in terms of local recurrence and patients survival have been reported^[33,34], also by Western authors who claim CME with CVL for right colonic cancer as oncologically effective as D3 right hemi-colectomy performed in Eastern Countries^[8,35,36]. CVL could be crucial in micro-metastatic clearance of central nodes, which are frequently missed by routine histological examination^[37], and thus responsible for loco-regional recurrence and systemic dissemination^[34]. For cancers located in the hepatic flexure and proximal transverse colon, possibly because of an embryological coalescence of mesenteric fascia, metastatic nodes incidence of about 5% for subpyloric station and about 4% for right gastroepiploic arcade has been reported^[38]: Central transection of middle colic vessels, ligation of right gastroepiploic vessels at the origin, 10 to 15 cm of greater omentectomy off the tumor and removal of subpyloric nodes could be beneficial, especially in advanced stages (clinically T3c-d and T4)^[8,39], as shown in Figure 3.

Blending CME with CVL is thus the logical step to ensure the best loco-regional control: CME maximizes the local clearance of the surgical field both increasing the chance for an uninvolved CRM and limiting any neoplastic spillage; CVL enhances regional control, removing apical nodes along the surgical trunk of the superior mesenteric vein (SMV), preventing regional recurrence and systemic dissemination: This is probably plausible for cancer without spread beyond the primitive *meso-structure*, as macroscopic involvement of apical nodes carries a poor outcome, independently from the extension of the surgical resection^[40].

SURGICAL TECHNIQUE OF LAPAROSCOPIC COMPLETE RIGHT MESO-COLECTOMY

Patient is administered general anesthesia and placed in

the supine or lithotomy position; a pneumoperitoneum is maintained at 10-12 mmHg using CO₂. The first step is always a thorough exploration of the abdominal cavity and peritoneal washing for cytology.

Once created the working space, a medial to lateral technique is generally adopted: The ileocolic vessels are stretched so to delineate the Treves arcade, and peritoneal incision is commenced at the base of the created peritoneal fold; dissection of the anterior peritoneal leaf is performed along the left margin of the SMA, with transection of the ileocolic and of the inconstant right colic vessels at their roots. An *en-bloc* lymphadenectomy of the anterior aspect of the SMV from the ileocolic vessels to the gastro-colic trunk of Henle is preformed (D3 lymph node dissection).

The anatomico-embryological plane along the Toldt's fascia is sharply divided from medial to lateral and from bottom to top along the meso-fascial or retro-fascial plane, sometime mobilizing the duodenum, as suggested by Hohenberger *et al*^[8], but usually dissecting along the plane between the intact dorsal mesocolon of the hepatic flexure and the Fredet's pre-duodenopancreatic fascia; the meso-fascial or retro-fascial interface must be carefully identified and components separated without breaching of either, respecting the integrity of the right mesocolon and of the retroperitoneal structures such as right ureter and gonadal vessels. The dissection stops at the lateral aspect of the right colon (right lateral peritoneal fold) exposing the colo-fascial interface, which will be separated later.

In case of caecum or ascending colon cancer, the stretched transverse mesocolon is progressively transected with central ligation of the right branch of the middle colic vessels and the colon is stapled 10 cm off the tumor (Total Right Meso-colectomy; Figure 3, blue lines); for hepatic flexure or proximal colon transversum cancers, middle colic and right gastroepiploic vessels are ligated at their roots, subpyloric lymph nodes are removed, 10 to 15 cm of greater omentum off the tumor is excised and colon stapling is carried out just

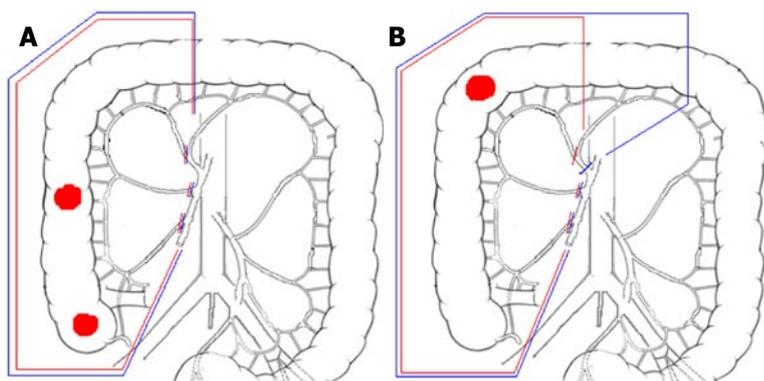

Figure 3 Schematic drawing illustrating the difference between extent of colon resection and lymph node harvesting between D3 right hemicolectomy according to 2010 JSCCR guidelines (red lines) and complete mesocolic excision with central vascular ligation according to Hohenberger's rules (blue lines). A: Cancer located in the caecum or ascending colon; B: Cancer located in the right (hepatic) flexure.

proximal to the splenic flexure (Total Extended Right Meso-colectomy; Figure 3, blue lines).

The hepatic flexure is mobilized by severing the lateral hepatocolic peritoneal fold, with the double components of the superior attachment (right phrenocolic ligament) and the medial attachment (cholecystoduodeno-colic ligament); division of these peritoneal folds demonstrate the colo-fascial interface at this level, which can be easily mobilized.

The right lateral peritoneal fold and the ileocecal peritoneal folds (caecal ligaments) are progressively severed to obtain complete mobilization of the specimen.

The ileum is stapled at 10-15 cm from the ileocaecal valve and the specimen is extracted within a plastic bag through a protected mini-Pfannestiel incision; side-to-side mechanical intracorporeal or extracorporeal anastomosis is fashioned.

Variants to laparoscopic classic CME with CVL

Some authors proposed their experience with modification of the classical approach in CME and CVL: Cho *et al*^[41], adopted a modified CME in respect to 3 major aspects: (1) non performance of Kocherization as described in the original paper of Hohenberger *et al*^[8]; (2) clearance of the pre-renal soft tissue behind Gerota's fascia for T3/4 cancer; and (3) tailored resection of the mesentery and mesocolon according to tumor location.

Feng *et al*^[42] proposed a hybrid medial approach prospectively compared to a completely medial approach: The hybrid approach is based on a first up-to-bottom dissection (section of the gastrocolic ligament and dissection of the middle colic vessels and Henle's trunk) blending with a subsequent classical medial-to lateral bottom-to-top approach; the study demonstrated less time for CVL and fewer vessel-related complications, especially for the pancreatico-duodenal vessels.

Matsuda *et al*^[43] also stressed a cranio-to-caudal approach for total right meso-colectomy, noting that lymph node dissection around the middle colic vessels is technically demanding and potentially exposed to severe intra-operative bleeding: The author suggests a caudal traction of the mesocolon to detect the origin of the middle colic vessels, maneuver suitable for detecting easily various types of middle colic vein

branching and thus reducing the risk of Henle's trunk and/or pancreatico-duodenal vessels injury.

QUALITY OF THE SURGICAL SPECIMEN

Laparoscopic CME with CVL, when performed in the right mesocolic plane, produces high quality surgical specimens. A grading system was developed in the CLASICC trial^[44], with the aim to compare laparoscopically assisted surgery with open resection for colorectal cancer; it was based on translation of the grading system used in the MRC CR07 trial for rectal cancer^[45]: (1) mesocolic plane of resection (“good” plane of surgery; intact, inviolate mesocolon with a smooth peritoneal-lined surface); (2) intramesocolic plane of resection (“moderate” plane of surgery; irregular breaches in the mesocolon, none reaching down to the muscularis propria of the viscus); and (3) Muscularis propria plane (“poor” surgical plane; disruption of the mesocolon down to the muscularis propria).

In the initial study of West *et al*^[46], the *mesocolic plane* translated into a higher quality of the surgical specimen: Wider cross-sectional tissue around the muscularis propria (mean 2181 ± 895 mm² compared to muscularis propria plane with a mean of 1447 ± 913 mm²; *P* = 0.0003), longer distance between the tumor and the mesocolic/retroperitoneal resection margin (44 ± 21 mm vs 21 ± 12 mm for muscularis propria plane, *P* < 0.0001), longer distance between the tumor and the high vascular tie and greater lymph node yield. The same group, in 2010 compared the quality of specimen between the Erlangen and Leeds experience, by precise tissue morphometry and grading of the surgical plane, concluding that CME with CVL routinely performed in Erlangen yields wider mesocolic area (19657 mm² vs 11829 mm²; *P* < 0.0001), longer large bowel (median, 314 mm vs 206 mm; *P* < 0.0001) and ileal (median, 83 mm vs 63 mm; *P* = 0.003) segment, higher distance between the tumor and the high vascular ties (131 mm vs 90 mm; *P* < 0.0001) and more lymph nodes harvested (median, 30 vs 18; *P* < 0.0001), reflecting in higher quality of the surgical specimens and better oncologic outcome^[9]. In 2012, CME with CVL was compared to Japanese D3 resection,

Ms: Mesocolic plane; NMs: Non-mesocolic planes; CVL: Central vascular ligation; Ctl: Control; NR: Not reported.

benchmark for highest survival reported in worldwide literature: Even in this case, CME with CVL showed wider mesocolic area (17957 mm² vs 8309 mm², $P < 0.001$), longer bowel segment (324 mm vs 162 mm, $P < 0.001$) and greater nodal yield (32 vs 18, $P < 0.001$), but equivalent distance between the tumor and the high vascular tie not statistically different (100 mm vs 99 mm; $P = 0.605$), translating in similar impressive long term survival^[10].

RESULTS

The higher quality of surgical specimen translates in better long term oncologic outcome, with significant impact on local recurrence rate, disease free and overall survival: In the pioneering studies of West^[46,9,10], Mesocolic plane of surgery and high tie ligation showed a non-stratified 15% survival advantage at 5 years when compared to *non-mesocolic planes* of resection; interestingly, the survival boost was even more remarkable in the subset analysis for stage III patients, with an increased survival by 27% at 5 years.

These results were confirmed in subsequent studies comparing the different planes of resection, both in open^[8-10,35,36,47] and laparoscopic surgery^[40,48-55], reflecting a significant interest for the brilliant results of CME with CVL. Recently, two important studies further substantiated the effect of the correct plane of resection in colonic cancer: A systematic review on 5246 patients revealed a local recurrence rate, 5 years overall and disease free survival of 4.5%, 58.1% and 77.4% respectively^[56]; and in 2015, a well structured population-based study by the Danish Colorectal Cancer Group^[57] demonstrated a better disease-free survival

for patients with stage I-III colonic cancer, suggesting that both laparoscopic and open CME with CVL may significantly improve outcome.

Unfortunately, these numerous studies (the most relevant reported in Table 1) have significant statistical power limitations, being predominately retrospective and non-homogeneous, so that at the moment a definitive high level of evidence cannot be drawn and thus no strong grade of recommendation may be assigned. This highlights the need for sufficiently powered randomized trials, to definitively address the issue and affirm with conclusive evidence that CME with CVL represents the gold standard in the surgical management of (right) colonic cancer.

CONCLUSION

The current evidence shows the equivalence in terms of tissue morphometry, quality of the surgical specimen and long term oncologic results between laparoscopic and open techniques^[39,43,46,52,55-57], but with laparoscopic approach offering all the advantages of minimally invasive surgery, both in faster recovery and in less immunological stress response which could affect long term outcome^[58-62].

In the multimodal management of right sided colonic cancer, laparoscopic CME with CVL is progressively gaining a pivotal role on the base of high quality surgical specimen, better local recurrence rate, better 5 years overall and disease-free survival when compared to less radical planes of surgery.

Laparoscopic CME with CVL should be regarded as the new frontier of a modern, *meso-resectional* oriented surgery, with all the advantages of minimally

invasive techniques, which allow for faster recovery and better immunological stress response: Higher quality of yielded surgical specimen, less complications when the laparoscopic procedure is *embedded* in an Enhanced Recovery After Surgery program^[63-72] and better immuno-competence due to less surgical stress^[58-62], may thus collectively contribute to better long term oncologic outcome.

Yet, in the absence of high level of evidence which precludes strong grade of recommendation, laparoscopic CME with CVL should be intensely investigated with highly powered, well structured prospective studies, so to define its role in the modern, multimodal management of right colonic cancer.

Abstract

Inflammatory bowel disease (IBD) is a chronic intestinal illness of autoimmune origin affecting millions across the globe. The most common subtypes include ulcerative colitis (UC) and Crohn's disease. While many medical

treatments for IBD exist, none come without the risk of significant immunosuppression and in general do not have benign side effect profiles. Surgical intervention exists only as radical resection for medically refractory UC. There exists a dire need for novel treatments that target the inherent pathophysiologic disturbances of IBD, rather than global immune suppression. One avenue of investigation that could provide such an agent is the interaction between certain dietary elements and the aryl hydrocarbon receptor (AHR). The AHR is a cytosolic transcription factor with a rich history in environmental toxicant handling, however, recently a role has emerged for the AHR as a modulator of the gastrointestinal immune system. Studies have come to elucidate these effects to include the enhancement of T_H cell subset differentiation, interactions between enteric flora and the luminal wall, and modulation of inflammatory interleukin and cytokine signaling. This review highlights advancements in our understanding of AHR activity in the digestive tract and how this stimulation may be wrought by certain dietary "micro-nutriceuticals", namely indole-3-carbinol (I3C) and its derivatives. Greater clarity surrounding these dynamics could lead to a novel diet-derived agonist of the AHR which is not only non-toxic, but also efficacious in the amelioration of clinical IBD.

Key words: Inflammatory bowel diseases; Aryl hydrocarbon receptor; Mucosal immunity; Dietary phytochemicals; Autoimmune diseases

Core tip: Inflammatory bowel disease (IBD) is a chronic illness with a paucity of safe and effective treatments, either medically or surgically. The aryl hydrocarbon receptor represents a novel target for future treatments of IBD using dietary ligands of the receptor. Many studies have examined the interplay between the aryl hydrocarbon receptor and gastrointestinal mucosal immunity, though there remains a gap in the understanding of how dietary ligands can modulate

this activity. Our objective was to highlight elements of current literature focusing on aryl hydrocarbon receptor biology, IBD, and how their interplay can be activated with dietary “micronutriceuticals”.

INTRODUCTION

The incidence of inflammatory bowel disease (IBD) such as ulcerative colitis (UC) and Crohn’s disease (CD) has been increasing worldwide; it is now estimated that between 1 and 1.3 million Americans are currently diagnosed with IBD^[1,2]. This increased incidence is possibly due to currently unidentified environmental factors, which interact with an inherent genetic predisposition^[3]. IBD is a family of chronic inflammatory conditions primarily involving the digestive tract, and often having additional extra-intestinal manifestations. The unique chronic inflammatory milieu maintained by IBD predisposes patients to non-adenomatous colorectal cancer as well as small bowel adenocarcinoma^[4]. To date there is no accepted etiology or preventive measures for these conditions. Even more, there exists no cure aside from radical surgery for refractory ulcerative colitis^[5].

The medical management of IBD currently stands at topical intestinal anti-inflammatories, systemic immunosuppression/immunomodulation, and novel biologic agents. The response rates, or rather the percentage of IBD patients experiencing true and deep remission using currently available treatment, is notoriously low. Only just recently have gut-specific monoclonal antibody inhibitors such as vedolizumab, which targets the integrin $\alpha 4\beta 7$ receptor, been approved for the treatment of IBD, possibly ushering in an age of targeted therapies^[6]. However, many if not all of the current treatment modalities for IBD have significant side effect profiles, exorbitant cost, or both^[7,8]. A prospective avenue of treatment for IBD that avoids many of the pitfalls of current therapy involves modulating mucosal inflammation using bioactive phytochemicals delivered by the diet. In fact, it has been reported that diets rich in fruits and vegetables are protective of IBD, which may indicate a role for future diet-derived treatments^[9,10]. The ideal treatment would have influences on gut barrier permeability, innate GI inflammation, and mucosal immunity, all pathophysiological hallmarks of IBD.

One potential mediator of anti-inflammatory dietary compounds is the aryl hydrocarbon receptor (AHR). The AHR is a chaperoned cytosolic protein that has been found to influence transcription after binding to an

exogenous ligand^[11]. It is a member of the basic helix-loop-helix transcription factor family as well as the Per-Arnt-Sim protein homology that regulates environmental adaptation to ligand exposure^[12,13]. Once bound, the AHR can shed its cytosolic chaperones, heterodimerize with the aryl hydrocarbon receptor nuclear translocator, bind to specific xenobiotic response elements within the genome, and induce downstream genes *via* transcriptional activation (Figure 1)^[14,15]. The canonical function of the AHR exists as an environmentally responsive “sensor” which acts to detoxify its own ligands *via* upregulation of phase I and phase II enzymes, most notably the cytochrome P450 superfamily^[16]. Its biology has been most famously attributed to the metabolism of dioxin, or 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)^[17]. In addition to its roles in toxin handling, recently the AHR has been implicated in inflammatory pathways, tumorigenesis, and immune regulation within the intestines^[18-20]. These downstream effects of AHR activity have been linked to manipulations of T-cell response, interleukin (IL) production, as well as altered cytokine function^[21]. All of these phenomena have been found to contribute in some way to regulation of intestinal immunity, mucosal integrity, and alterations to the microvasculature of the intestine, which are all pathological disturbances inherent to IBD^[22]. While it is known that AHR biology is linked to the development and progression of IBD, it is yet to be determined if the AHR can be manipulated in such a way to exert a preventative, protective, or even therapeutic role in IBD *via* dietary ligands^[23].

The well-studied dietary component indole-3-carbinol (I3C) has been recognized as a precursor to a host of AHR ligands that are active in the gut. The compound glucobrassicin (precursor to I3C) is found in high concentrations in the Brassica family of vegetables which includes broccoli, cabbage, and Brussels sprouts (Figure 2)^[24]. Mastication-induced enzymatic hydrolysis of glucobrassicin produces I3C in the mouth. I3C then dimerizes to 3,3'-diindolylmethane (DIM) in the presence of gastric HCl as well as indole [3,2-b] carbazole (ICZ) among others further down in the GI tract^[25]. It is known that DIM is the molecule which exerts more robust effects on the AHR, not its parent I3C^[24]. AHR activation has been found to modulate activity of intraepithelial lymphocytes, preserve lymphoid organs in the gut, and maintain mucosal homeostasis^[26,27]. Moreover, DIM-supplemented diets have been shown to attenuate colonic inflammation as well as suppress colitis-associated tumorigenesis in mice^[28]. This effect may be due to the ability of DIM to modulate various inflammatory cell actions in the gut lining^[29]. What is known for certain is that dietary AHR ligands are able to induce the receptor within the gut epithelium as well as globally^[30]. These recent advances in the understanding of the effects of AHR stimulation *via* dietary ligands may lead to diet-derived novel anti-inflammatory agents which combat the inherent disturbances of IBD.

This review highlights current knowledge on AHR

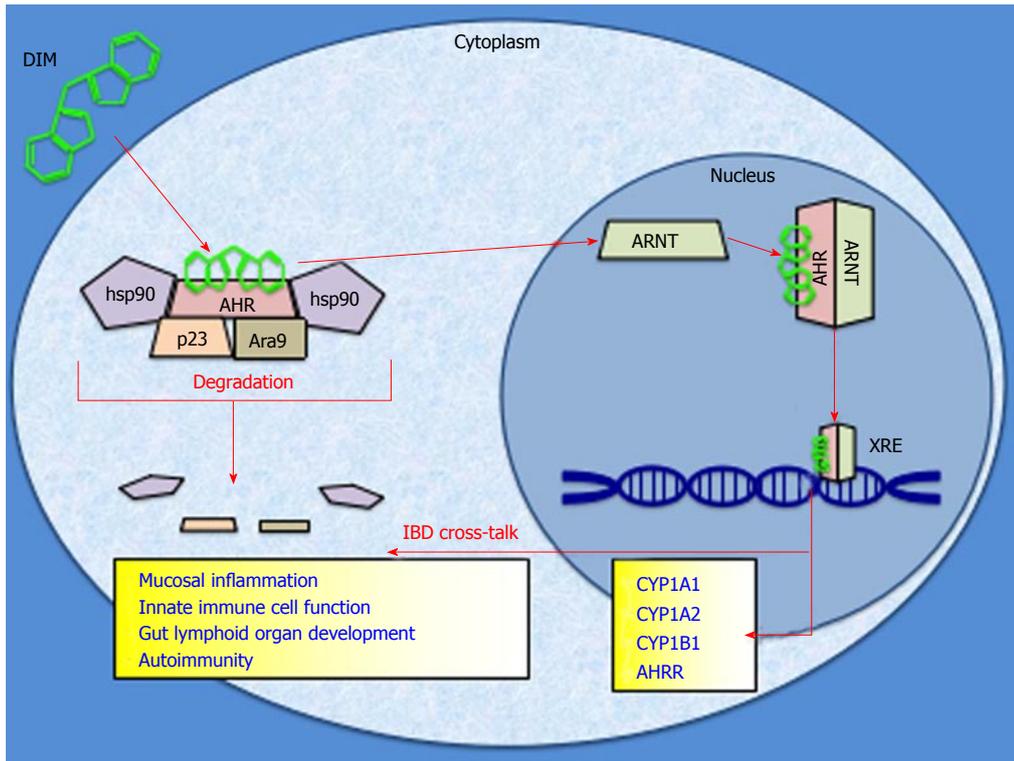

Figure 1 The aryl hydrocarbon receptor signaling pathway is depicted with 3,3'-diindolylmethane as a model agonist. Upon binding to a ligand, aryl hydrocarbon receptor (AHR) sheds its cytosolic chaperones and translocates to the nucleus to heterodimerize with aryl hydrocarbon receptor nuclear translocator (ARNT). This complex binds to the xenobiotic response element (XRE) within the genome and drives transcription of cytochrome P450 detoxifying enzymes. Proposed avenues of cross-talk with inflammatory bowel disease pathology are listed. IBD : Inflammatory bowel disease.

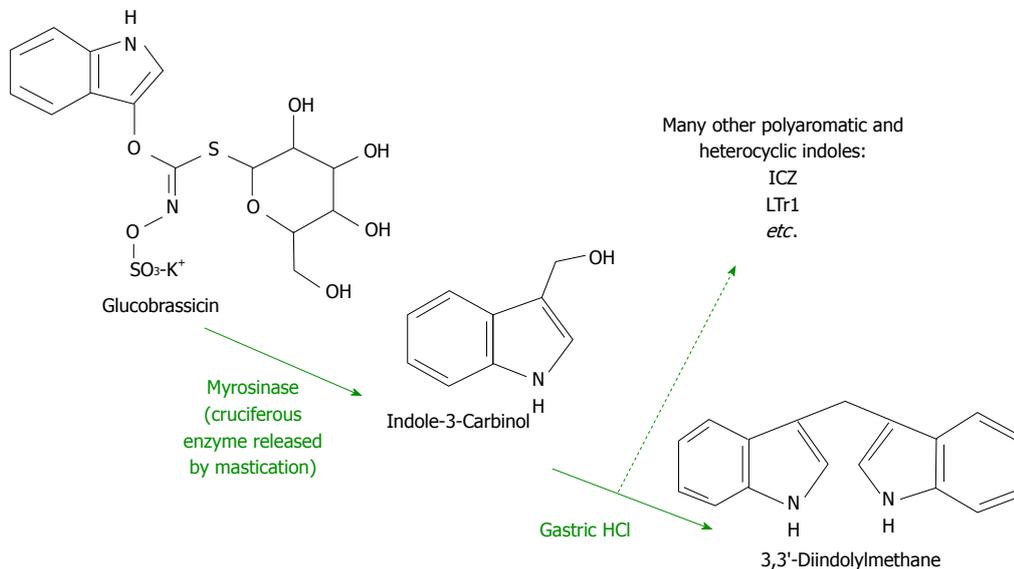

Figure 2 Presented is a simplified model for glucobrassicin digestion. I3C is freed from glucobrassicin by the mastication-released enzyme myrosinase. Gastric HCl drives dimerization of I3C to 3,3'-diindolylmethane, as well as other indole complexes that are released to the duodenum and distal digestive tract. I3C: Indole-3-Carbinol.

stimulation in the context of IBD, especially as it relates to dietary stimulation of the receptor. Continued study of the manipulation of the unique gastrointestinal inflammatory milieu associated with IBD could eventually lead to both novel therapeutics as well as

diet-modifying strategies. Due to the apparent benign side effect profile of dietary AHR ligands, clinical application of this knowledge could reduce iatrogenic immunosuppressive morbidities associated with current IBD treatment as well as improve overall disease

control.

LITERATURE SEARCH

A systematic literature search was conducted using PubMed and Google Scholar for "aryl hydrocarbon receptor", "AHR", "IBD", "ulcerative colitis", "3,3'-diindolylmethane", "indole-3-carbinol", and "mucosal immunity". Searches containing relevant synonyms and combinations of the above terms were also utilized. Eighty-nine relevant references were identified and cited within this review. Included studies ranged from basic science investigations to clinical trials.

IN VITRO INVESTIGATION OF THE AHR, DIETARY LIGANDS, AND IBD

The biology of the AHR is well studied in numerous *in vitro* models, however, recently the common understanding of the AHR solely acting as a toxicological sensor that upregulates detoxification enzymes has been challenged^[31]. Interactions between the receptor and dioxin (TCDD) have always been the cornerstone of mechanistic and physiologic AHR studies, however it is now known that there is a wide compendium of exogenous chemicals that operate *via* the AHR^[32-34]. In fact, it is micronutritional chemicals such as the indole family including I3C and DIM that have recently been identified as the bridge between AHR signaling and anti-inflammatory as well as chemoprotective effects in the gastrointestinal system^[35]. These chemicals have been found to enhance mucosal integrity, maintain intraepithelial lymphocyte populations, as well as sensitize the GI tract to certain populations of enteric flora^[36,37]. In contrast, TCDD treatment has been found to weaken mucosal immunity in the gut^[38]. This would present a possible bifunctional role for the AHR and IBD. Further investigation of these actions is warranted to elucidate their role within the inherent disturbances of IBD. An important step in understanding the role of both the AHR and its dietary ligands is to examine their roles modulating inflammation *in vitro*.

Research surrounding the aryl hydrocarbon receptor and various aspects of immunity has recently exploded, especially concerning the effects of dietary ligands. First, it is important to note that not only has DIM been found to activate the AHR *in vitro*, but has also been found to elicit multiple chemoprotective responses in various intestinal cell lines^[39-42]. In addition to its ability to upregulate the AHR in cells of the digestive tract, DIM treatment also modulates immune cell activity. For instance, DIM treatment suppresses the inflammatory response of murine macrophages *in vitro* *via* downregulation of TNF- α , IL-6, and IL-1 β ^[43]. These effects and more were also found when murine dendritic cells were treated with I3C. This protocol prompted a downregulation of TNF- α , IL-6, and IL-1 β as well as an upregulation of IL-10^[44]. These are important

findings as activated macrophages as well as these inflammatory cytokines, especially TNF- α , play key roles in the pathogenesis of IBD^[45-49]. In fact, many of the most widely used biologic agents for the treatment of IBD are anti-TNF- α antibodies^[50].

In addition to various cytokine and interleukin abnormalities, IBD has also been linked to various T-cell populations and their relative size and function in the GI tract^[51]. Two distinct populations that have been linked to IBD disease activity are T-regulatory cells (T_{reg}) and T_H17 T-cells^[52-54]. The action of T_{reg} cells has been found to be protective, while T_H17 cell activity has propagated inflammatory damage in IBD. It is well established that the aryl hydrocarbon receptor modulates various populations of immune cells, which has implications for the future treatment of IBD^[55]. In fact, AHR stimulation *via* natural ligands has been linked specifically to upregulated T_{reg} cell activity and inhibition of T_H17 cell activity^[27,55-57]. These effects have been further proven to be AHR-dependent^[58]. Another immunomodulatory effect of *in vitro* AHR stimulation comes as a consequence of T_{reg} cell biology. AHR activity enhances T_{reg} differentiation and thus increases the population of immunoregulatory/anti-inflammatory cell populations that are responsive to IL-10^[59]. This is not only important because, as mentioned earlier, DIM treatment of murine immune cells leads to the induction of IL-10, but also because IL-10 has a firmly seated role in the pathophysiology of IBD. Mice null for IL-10 have been found to be deficient in various immunoregulatory functions in the GI tract^[59]. Even more, in a small trial, patients with CD responded favorably to treatment with recombinant IL-10 producing microbes^[60]. Further study of the interaction between dietary AHR ligands and immune cell function could lead to a better and more targeted understanding of their interplay.

There exists a large battery of cellular cascades and signaling pathways enhanced, inhibited, or modulated by the actions of dietary indoles such as I3C and DIM, though there remains a gap concerning a full understanding of their anti-inflammatory effects^[61]. Further *in vitro* protocols focusing solely on the interaction between the AHR and certain "micronutriceuticals" like I3C and DIM could one day lead to a better understanding of their cellular effects in the context of IBD.

IN VIVO INVESTIGATION OF THE AHR, DIETARY LIGANDS, AND IBD

The AHR has been extensively studied *in vivo*, mainly through the use of murine models null for the AHR to better understand its unique role in toxicology. Previous research has suggested the need to better understand the potential immunological function of AHR across various disciplines^[62]. The AHR has been previously implicated as an important autoimmune target *in vivo* as it alters expression of the T_H17 cell subset and

associated cytokines in response to environmental toxins in the intestine^[56,63]. Perhaps one of the most interesting avenues of research linking environmental exposures to altered immune response *via* the AHR can be found in the pathogenesis of IBD^[21]. To best study the complex interaction of environmental factors and AHR expression in the context of immune function in the gut, many *in vivo* models have been developed to pick apart this inflammatory environment.

Due to the historical classification of AHR as the dioxin receptor, many models have been developed using TCDD treatment after induction of IBD. Dextran sulfate sodium (DSS) is a commonly employed agent to induce colitis in murine models, and multiple studies have shown that pre-treatment with low dose TCDD can prevent inflammation associated with colitis and/or reduce inflammation when administered after the onset of colitis in mice^[57,64]. A similar study using trinitrobenzenesulfonic acid (TNBS)-induced colitis in mice as a model for CD, showed that animals treated with TCDD recover quicker and experience less colonic damage than those that are untreated^[43]. While these studies show promise for the role of AHR in IBD, dioxin is a carcinogen that is highly persistent in tissue, leading to efforts to identify novel AHR ligands with low toxicity for use *in vivo*.

As a non-toxic agonist of the AHR, β -naphthoflavone (β NF) has shown great potential in attenuating colitis through reducing the histological score in both wild-type and AHR null mice with varying severities of DSS-induced colitis^[65]. Perhaps even more interesting is the use of an endogenous mammalian AHR ligand such as the non-toxic tryptophan byproduct 6-formylindolo(3,2-b)carbazole (FICZ), which has been shown to protect mice from DSS-, TNBS-, and T-cell transfer-induced colitis through reduced inflammatory cytokine levels and lack of IL-22 induction^[18]. While these compounds attenuate colitis without the potential toxic side effects of TCDD, research into the use of dietary phytochemicals as AHR ligands is of even greater interest for the treatment of IBD^[66]. One study showed that the AHR is induced by phytochemicals derived from plants of the Brassicaceae family, which includes broccoli, cabbage, kale, and others. It was found that this AHR activation is required for development of ROR γ ^t-expressing innate lymphoid cells (ILCs), as shown by increasing pools of these cells when mice are fed a diet supplemented with I3C, a product of glucobrassicin breakdown^[6]. Another study established a role for I3C in controlling bacterial colonization of the gut, sustaining immune function, and protecting epithelial barrier organization as it pertains to colitis severity^[27]. I3C remains a compound of great interest for the treatment of IBD, but the activity of I3C in the diet is most likely dependent on the activity of DIM, the dimer product of I3C hydrolysis by gastric acid. DIM would make up the majority of the indole load that reaches portions of the intestinal tract distal to the duodenum.

DIM has previously been shown to alleviate hepatic

inflammation through shifting of diet-induced T_H17 dominance to T_{reg} dominance^[67]. These data were further supported in studies where DIM was shown to attenuate experimental colitis as determined by pathological findings in mouse models, including evidence that DIM works through the AHR to decrease the T_H17 cell population while increasing the number of T_{reg} cells^[29,68]. In DSS-induced colitis experiments, DIM has been shown to attenuate the disease by reducing the clinical severity of colitis, including prevention of colonic shortening and weight loss in addition to dramatically decreasing the number of tumors in AOM/DSS treated mice, which provide a common model of colitis-associated colorectal cancer^[28].

In vivo models to study the AHR and IBD remain warranted, as there are numerous unidentified factors that affect progression of the disease. In particular, the interaction between immune cells and the gut microbiome is of growing interest to the research community. For example, AHR null mice succumb to infection by *Citrobacter Rodentium* because the absence of AHR signaling leads to a lack of ROR γ ^t+ ILCs that consequently do not produce enough IL-22^[69]. Furthermore, the balance between ILCs and T_H17 cells regulated by AHR has been shown to control the composition of commensal flora^[69]. In fact, the menaquinone precursor 1,4-dihydroxy-2-naphthoic acid, an AHR ligand produced by *Propionibacterium freudenreichii* has been shown to inhibit DSS-induced colitis in mice and is even commercially available in Japan as a dietary supplement that holds promise as an IBD treatment agent^[70]. These findings are critical to the continued study of IBD, as interactions between dietary factors and various states of colonic dysbiosis have been shown to contribute to disease progression^[71,72].

HUMAN AND CLINICAL INVESTIGATION OF THE AHR, DIETARY LIGANDS, AND IBD

While there is a wealth of data and analysis surrounding the aryl hydrocarbon receptor and DIM in both tissue culture and murine models, there are few studies in humans related to IBD, clinical or otherwise. Some correlations have been made however, and these have prepared the way for many potential future studies. Arsenescu *et al.*^[23] found that AHR activity is upregulated in colonic biopsy tissue in IBD patients when compared to healthy controls. Even more, this increased activity mirrored that of IL-8, a neutrophil chemotactic that is elevated in IBD patient tissues^[23,73]. Conversely, it has also been reported that biopsies from patients with CD exhibit downregulated levels of AHR, which is thought to be due to T_H17 cell infiltration of inflamed tissue in CD^[18]. This underscores the inherent bifunctionality of the AHR. Even though there are few studies which investigate human tissue, they do provide some exciting

evidence to a role for the AHR in human IBD.

There are not currently any clinical trials using DIM for any form of IBD. However, there are multiple chemopreventive and chemotherapeutic trials using both DIM and its parent I3C in the context of a variety of neoplasms. These trials aimed to treat, prevent, or modulate hormone response in breast cancer, vulvar epithelial neoplasia, cervical intraepithelial neoplasia, and recurrent respiratory papillomatosis^[74-77]. Again, while these examples are outside the realm of IBD, they do serve to prove that a clinical trial using I3C and/or DIM is biologically feasible in humans. In addition, there have been multiple studies which have analyzed the pharmacodynamics of these compounds in humans, which provide groundwork to one day optimize dosing protocols for trials aimed at IBD^[78-80]. One pharmacokinetic and safety investigation established that not only are I3C and DIM non-toxic at doses ranging from 200-800 mg daily, but also that in most of the participants tissue concentrations over 1 mmol/L were observed^[81].

What all of this work has done is prove that both I3C and DIM have some form of biologic and therapeutic activity in humans. Whether or not this activity is the result of AHR stimulation remains to be seen. Moving forward, a clinical trial utilizing these phytochemicals to combat IBD is warranted. The concept of using natural chemicals to treat intestinal inflammation is not new. Curcumin, the biologically active derivative of the spice turmeric, has been found to modulate numerous inflammatory, oxidative, and tumorigenic pathways in various tissues, including the colorectum^[82-85]. Numerous *in vitro* and *in vivo* studies have propelled curcumin into multiple IBD-related clinical trials. The first of these investigations was a very small pilot study which discovered that in IBD patients curcumin treatment lowered both erythrocyte sedimentation rates and CD Activity Index scores vs placebo^[86]. More recently, Hanai *et al*^[87] found in their RCT that curcumin performed well vs placebo for maintenance therapy of mild-moderate ulcerative colitis. While oral delivery proved to have therapeutic activity, curcumin enemas have also been employed in the treatment of distal colitis with similarly efficacious results^[88]. In relevance to the paradigm of I3C/DIM acting *via* the aryl hydrocarbon receptor, curcumin as well as other dietary phytochemicals have been found to modulate AHR activity^[89]. These trials of curcumin provide relevance to investigating the therapeutic potential of natural dietary chemicals such as I3C and DIM in the context of IBD.

CONCLUSION AND FUTURE DIRECTIONS

The complex and often dangerous treatment of IBD is a dilemma faced by gastroenterologists and colorectal surgeons alike. The intricate inflammatory milieu of IBD presents many avenues for potential targets to attenuate the inherent autoimmunity of the condition. In order to better understand the role that dietary

ligands of the AHR play in attenuating IBD, potential avenues of study should focus on the aryl hydrocarbon receptor as it pertains to intestinal barrier function, immune regulation, and inflammation. To achieve this, portions of the IBD phenotype would be isolated and measured under AHR stimulation by a dietary agonist such as I3C or DIM. Also, the binding affinities of these compounds to the AHR in an array of gastrointestinal tissues must be established in order to localize the cell and tissue types where these agents will achieve the most robust response. Another important line of inquiry is to delineate the molecular cross-talk between AHR stimulation and the numerous other pathways previously identified as those that drive IBD. More globally, tissue-specific AHR activity should be investigated in order to ascertain off-target effects of treatment with a dietary AHR agonist. Finally, the most rigorous examination of these agents would be a randomized controlled trial of I3C or DIM for the treatment of IBD within the Phases set by the FDA. However, incorporation of dietary AHR ligands into human clinical studies demands a crystal clear picture put forth by exhaustive *in vitro* and *in vivo* murine models as to how these compounds exert their effects. Throughout these various investigations, it would remain important to delineate additional molecular pathways engaged by these dietary ligands in addition to the AHR in order to better understand their complete mechanisms of action.

Further investigation of how IBD-related cascades can be manipulated exogenously, perhaps *via* the AHR, could one day lead to diet-derived and well-tolerated regimens for those with ulcerative colitis and CD. That being said, it must be appreciated that the AHR is only one of many potential signaling cascades that may influence the IBD phenotype in humans. The characterization of a diet-derived agent, AHR agonist or not, that targets the hallmark imbalances in IBD without compromising host immune function would revolutionize current medical treatment modalities and save many from radical surgical intervention.

Abstract

Associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) is a novel approach in liver surgery that allows for extensive resection of liver parenchyma by inducing a rapid hypertrophy of the future remnant liver. However, recent reports indicate that not all patients eligible for ALPPS will benefit from this procedure. Therefore, careful patient selection will be necessary to fully exploit possible benefits of ALPPS. Here, we provide a comprehensive overview of the technical evolution of ALPPS with a special emphasis on safety and oncologic efficacy. Furthermore, we review the contemporary literature regarding indication and benefits, but also limitations of ALPPS.

Key words: Liver tumor; Resection; Hepatectomy; Staged; Portal vein embolization; Future liver remnant; Liver hypertrophy; Liver failure; Morbidity; Mortality

INTRODUCTION

Associating liver partition and portal vein ligation for staged hepatectomy (ALPPS), initially known as “*in situ* split”, was first performed in September 2007, and until today, more than 600 procedures have been performed worldwide^[1-4]. ALPPS has shown to have a promising efficacy regarding the induction of a rapid liver hypertrophy, thereby increasing the resectability of previously unresectable liver malignancy^[5]. Furthermore, a sufficient volume increase can also be achieved by liver partition after unsuccessful portal vein embolization (PVE)^[6,7].

Since the pioneering publication of Schnitzbauer *et al.*^[1] in 2012 with the first 25 cases in a multicentric study, considerable experiences have been obtained. A technical evolution of this novel procedure has been observed during the last four years. This was accompanied by a better understanding of the importance of patient selection, not only to minimize morbidity and mortality, but also to achieve the most oncological benefit^[8].

This review was performed to report a current overview on the development of the ALPPS procedure. The review is based on personal experience from our institute as well as a detailed analysis of the international literature of the last four years.

LANDMARKS

The pioneer case and the first multicenter study

The pioneer case of ALPPS was performed in September 2007 by Dr. Schlitt at the University Hospital Regensburg, Germany in a young patient with hilar cholangiocarcinoma (CCA)^[2]. During the exploration, the surgeon decided to perform a left hepaticojejunostomy to relieve the cholestasis of the future liver remnant (FLR), which was considered too small for a one stage right trisectionectomy. To provide an access to the left bile duct, the liver was transected along the falciform ligament. The right portal vein was ligated to enhance the hypertrophy of the remnant liver. The patient recovered so well that a computer tomography (CT) was performed at the postoperative day (POD) 8, showing a 94% gain of the future remnant liver volume. Thus the second stage operation was successfully performed on POD 9.

This method was found to be reproducible and was soon adopted by many other surgeons around the world. In 2012, Dr. Schnitzbauer reviewed the first 25 cases of this novel concept of 2-staged hepatectomy in five German university hospitals between September 2007 and January 2011^[1]. The indications were patients with either primary or secondary liver malignancy, who underwent a right trisectionectomy with a preoperative left lateral lobe to body weight ratio of less than 0.5%. After a median interval of 9 d (range, 5 to 28 d) from *in situ* splitting and right portal vein ligation (PVL), a CT volumetry was performed, indicating a median

increase in volume of 74% (range: 21% to 192%). The procedure was then completed on the same or following day without drop-out. None of the patients developed irreversible liver failure after surgery. Sixteen patients (68%) experienced perioperative complications^[1]. In-hospital mortality was 12%, the six-month median overall survival was 86%.

The above procedure was considered as a novel concept representing one of the most promising advances in oncological liver surgery by the editors of the *Annals of Surgery*^[3]. The new strategy was found to elegantly address the most feared complication following major hepatectomy, postoperative liver failure (PHLF). The amount of hypertrophy induced by this procedure is unparalleled by any other techniques. Moreover, the rapid regenerative response offers additional significant advantages. For example, tumor progression is unlikely during this short period, and there are less adhesions during the second stage operation. Furthermore, this procedure thereby allows a faster recovery for the patient, with the possibility to resume chemotherapy earlier. The acronym “ALPPS” was proposed to describe this novel approach: “Associating Liver Partition and Portal vein ligation for Staged hepatectomy”^[3].

ALPPS registry

The ALPPS registry was initiated by Dr. De Santibanes, Dr. Lang and Dr. Clavien in 2012 to achieve a more systematic exploration of this new surgical procedure^[9]. It is an internet-based international registry for cases performed using the above method. The headquarter is located at the Department of Surgery, University Hospital Zurich, Switzerland. To establish the registry, an electronic case report form using the clinical trials software SECUTRIAL (Interactive System, Berlin, Germany) was presented to selected experts worldwide for approval (Scientific Committee of the ALPPS Registry). Any center willing to report patients in the registry is given access through the internet. The aim of the registry is to systematically and uniformly collect information from multiple centers worldwide^[10]. Despite of a possible reporting bias, the registry enables surgeons to study a larger population to overcome shortcomings inherent to small case series reports. In 2014, the first report by the registry consisted of a total of 202 patients from 41 centers, provided complete data sets of procedures and 90 d survival status^[10]. Till July 8th, 2015, 583 cases performed worldwide were enrolled into the registry.

The first consensus meeting on ALPPS

In February 2015, the first ALPPS consensus meeting was held by Dr. Oldhafer and Dr. van Gulik in Hamburg, Germany. Nearly all groups with vast experience in the ALPPS approach were invited to participate as faculty. The key points consisted of indications, preparations, techniques and outcomes. The two-day meeting provided the community a scientific base for future decision-making. The video and slides are available at the

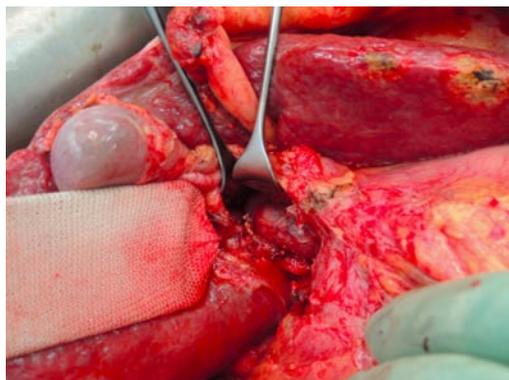

Figure 1 Exposure of the portal vein by lifting the common bile duct and right hepatic artery using a lid retractor. Here the right portal vein branches were transected.

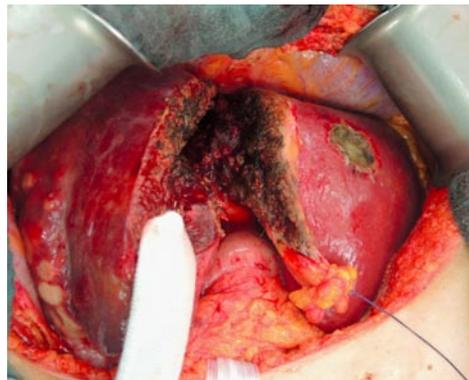

Figure 2 Liver parenchyma transection along the falciform ligament.

official website (www.alpps.com). The meeting not only summarized the development and the limitations of ALPPS, but also inspired the ideas and promoted the cooperation between international centers. The summary of the consensus meeting is yet waiting for publication.

EVOLUTION OF THE SURGICAL TECHNIQUE

Classical ALPPS

The first operation (right portal vein transection and in situ liver splitting): During the first operation, an exploration is carried out to exclude extrahepatic tumour dissemination. Resectability is determined if the remnant segments 2 and 3 have adequate inflow as well as outflow. Tumour involvement of segments 2 and 3 is no contraindication as long as it could be safely resected without tumour residual. The next step is the dissection of the hepatoduodenal ligament. A cholecystectomy is optional. In patients without tumour infiltration of the gall bladder, a cholecystectomy is usually carried out. After lifting the common bile duct and right hepatic artery by a lid retractor, the right portal vein and main portal vein is exposed (Figure 1). At this stage, the main right portal vein branch could be transected after suture ligation at the distal end and continuous suture, *e.g.*, with 5/0 Prolene at the proximal end. In patients with trifurcation of the portal vein with separate entry of the right anterior and posterior sectional branches, the anterior and posterior portal veins should be divided separately.

The umbilical portion of the left portal vein is exposed by dissecting the umbilical fissure. The portal branches of segment 4 are ligated and divided at its origin. The hepatic artery, the bile duct and the right hepatic vein are dissected and identified with rubber bands. Subsequently, transection of the liver parenchyma along the falciform ligament is performed (Figure 2). The falciform ligament could also be kept in the future remnant side for re-fixation of the left lateral lobe at the diaphragmatic dome if technically

possible. Intraoperative ultrasound should be performed to confirm the absence of right portal flow at the end of the operation. Silicone sheeting or drainage could be applied to separate the two parts of the liver and the surrounding organs in order to prevent strong adhesion among the above mentioned structures. Closed drainage is placed in the liver hilum. An intraabdominal swab should be taken for microbiological analysis at the end of the operation.

Postoperative management after the first operation:

The patient is usually transferred to the intermediate care unit and discharged to the normal ward according to the postoperative course. Prophylactic antibiotics are given as single shot intraoperatively. If any bacteria are isolated from the intraoperative swab, the antibiotics should be given until the second operation. In patients with stented bile duct, antibiotics and antimycotics are administered during the whole postoperative phase.

One week after the first operation, depending on the logistics, an abdominal CT scan (native phase) is performed for re-evaluation of the liver volume (Figure 3). When the future liver remnant/total liver volume ratio (FLR/TLV) is more than 30%, the second operation, *i.e.*, right trisectionectomy, could be carried out on the next available operation day. If the FLR/TLV is less than 30%, a repeat CT scan would be carried out in an interval of seven days, and the second operation being postponed accordingly.

The second operation (right trisectionectomy):

After relaparotomy, the silicone sheeting or drainage is removed. An intraabdominal swab is taken for microbiological analysis for orientated antibiotic therapy if indicated. The hilar structures are easily identified by the rubber bands, and the right hepatic artery, right hepatic ducts (or the left hepatic duct when extrahepatic bile duct should be resected) and the right and middle hepatic veins are transected (Figure 4). Liver segment 1 could be preserved in patients with non-perihilar CCA without tumour involvement.

After removal of the transected liver, a lymphadenectomy could be conducted at this stage. Biliodi-

Figure 3 Computed tomography scan before associating liver partition and portal vein ligation for staged hepatectomy in a patient with intrahepatic cholangiocarcinoma and on day 10 after liver partition. A: The future liver remnant consisted of segment 2 and 3 with volume of 347 mL (23% of the standardized total liver volume); B: Showing the hypertrophy of the segment 2 and 3 with volume of 610 mL (41% of the standardized total liver volume).

gestive anastomosis is followed when resection of the extrahepatic bile duct is indicated in patients with perihilar CCA. The postoperative treatment after the second operation is the same as for the patients undergoing any major hepatectomy.

ALPPS variations

Improvement of patient safety by different approaches of *in situ* liver splitting: One of the major differences between traditional PVE and ALPPS in liver partition is that the latter, has a liver splitting along the transection line of the FLR. To simplify the first operation, three methods were developed to achieve liver partition without physically splitting the liver: Tourniquet compression, radiofrequency ablation (RFA) or microwave ablation.

The use of a tourniquet to ensure parenchymal compression and intrahepatic collateral occlusion along the future transection line was first described by Robles *et al.*^[11]. He used a 1 cm deep groove to place and tighten a 3 mm Vicryl tourniquet, after which ultrasound confirmed occlusion of the vessels between the two parts. This technique was termed Associating Liver Tourniquet and Portal Ligation for Stage Hepatectomy (ALTPS)^[11]. In 22 patients undergoing ALTPS procedure, FLR at 7 d increased by a median of 61% (range: 33% to 189%).

Jiao *et al.*^[12] used in-line radio frequency (Habib Sealer, LH4X, Rita) to create a virtual liver partition in combination with portal vein ligation. The RFA produce a precise avascular area up to 1 cm wide. In the initial report of five patients, Radiofrequency-Assisted Liver Partition with Portal Vein Ligation could significantly increase the FLR by a median of 62.3% (range: 53.1% to 95.4%) after 21.8 ± 9.4 d.

Similar to RFA, Cillo *et al.*^[13] used microwave ablation on segment 4 in the first stage operation to complete the liver partition. The authors reported that this technique could minimize the risk of neoplastic left lobe invasion and limit portoportal shunts. They observed a 78% FLR growth, performing the second stage after 10 d.

All three techniques could be performed laparoscopically^[13,14]. However, superiority of these procedures

to the classic ALPPS approach regarding safety has not been confirmed apart from case reports.

Improvement of patient safety by partial ALPPS:

To avoid bile leak from incidental transection of the segment 4 bile duct and to avoid segment 4 ischemia due to transection of the segment 4 artery or middle hepatic vein occlusion, non-total parenchymal transection was carried out systematically in the author's institute (Figure 5) and selectively in other institutes^[15-17].

The group of De Santibanes identified total parenchymal transection as an independent predictor of postoperative complications during ALPPS. They found that most complications in patients with total parenchymal transection were surgical complications following the first stage. Avoiding total parenchymal transection might be related to the better outcomes in terms of liver-related complication in these patients^[15]. The Zurich group observed in an experimental model that partial (75%-80%) transection of the liver triggered a similar degree of hypertrophy of the FLR compared to complete transection. On the basis of experimental observation and clinical implications, they switched from a complete to a well-defined partial transection (> 50% of the transection surface) in 2013^[16]. In partial-ALPPS, a median hypertrophy of 60% was observed, compared to 61% after classic ALPPS approach, within a median time of 7 d. To facilitate communication among clinicians, Petrowsky *et al.*^[16] proposed to standardize the name of ALPPS with non-total parenchymal transection at stage 1 operation as "partial-ALPPS".

Improvement of patient safety by selecting different planes of liver splitting:

Various modifications of ALPPS that alter the specific segments comprising the FLR have been described, including right hepatectomy ALPPS (segment 2-4 as FLR), left hepatectomy ALPPS (segment 5-8 as FLR), central hepatectomy ALPPS (segment 4, 5 and 8 as FLR)^[18]. Liver partition in different extent of hepatectomy is aimed to increase the FLR, thereby avoiding post-hepatectomy liver failure.

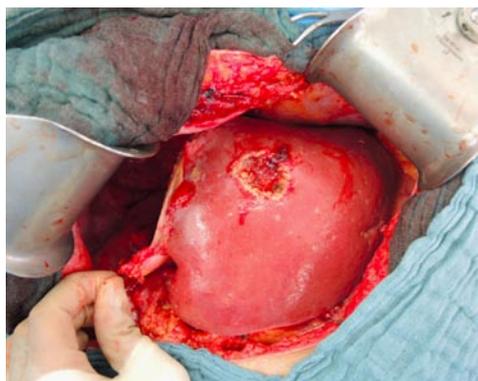

Figure 4 Completion of right trisectionectomy.

Recently, the concept of a monosegmental ALPPS has been addressed^[19,20]. The authors proposed to name such procedures, leaving only a one-segmental FLR in the context of ALPPS, according to the remnant liver segment using third-order segment terms, for example "Segment 2 ALPPS", "Segment 3 ALPPS", "Segment 4 ALPPS" and "Segment 6 ALPPS". Among 333 patients, 12 underwent monosegment ALPPS hepatectomies in six centers, all for extensive bilobar colorectal liver metastases (CRLM). Four patients experienced liver failure, but all recovered. There was no mortality. Complications higher than Dindo-Clavien IIIa occurred in four patients with no long-term sequelae. The authors concluded that extreme liver resections for CRLM based on a single segment liver remnant are feasible and safe using the novel monosegmental ALPPS technique, a new surgical tool in the management of extensive CRLM^[20].

Improvement of patient safety by imaging study and liver function test: The estimation of the postoperative liver function is mainly based on the remaining liver volume and liver function blood tests. Volumetric measurement of the intended FLR by CT or MRT is routinely carried out prior to the second stage operation. A FLR/TLV ratio exceeding 30% in patients with normal liver or higher than 40% in patients with parenchymal disease is preferred^[8]. In the author's institute, a FLR to body weight ratio over 0.6% in patients with normal liver, or more than 0.8% in patients with preexisting parenchymal damage is used as a threshold, additionally to FLR/TLV ratio for performing the second stage operation. Otherwise, the operation is postponed for another week or even cancelled.

Tanaka *et al.*^[21] performed technetium-99 m galactosyl human serum albumin (99mTc-GSA) scintigraphy single-photon emission computed tomography (SPECT)/CT with 3-dimensional volume-rendering fused images preoperatively and at 7 d after the first surgical procedure. They found that the increase in functional FLR calculated at 7 d after the liver partition by ALPPS was similar to functional FLR at 3 wk after the liver partition by PVE alone (52.1% vs 59.2%). In the group of De Santibanes, hepatobiliary scintigraphy was performed in patients with borderline sufficient FLR

Figure 5 Partial associating liver partition and portal vein ligation for staged hepatectomy. The non-total liver parenchymal transection is indicated by the clips, left along the liver split area in a computed tomography scan performed on day 10 after the liver partition.

volume after first stage operation, or when there were doubts regarding functional sufficiency. The regional FLR function was determined by quantifying 99mTc-dimethyl iminodiacetic acid uptake during 10 min (liver uptake phase) after intravenous injection^[15]. They found this method to be helpful to decide the best timing of the second stage operation in four patients of this series. In those four patients with delayed hypertrophy, an increase of the FLR function over time was observed, although there was no significant volume increase. These findings suggested that in some patients, the recommended waiting time until second stage operation may be shorter than indicated by volumetric parameters alone.

Lau *et al.*^[22] described an intraoperative indocyanine green (ICG) clearance assessment to estimate the function of the future liver remnant. After complete parenchymal transection, Bulldog vascular clamps were applied to occlude the right hepatic artery and the portal vein, and ICG clearance was carried out. They found the plasma disappearance rate was 7.9%/min and with a 15 min residual (R15) amount of 30.6% during the first stage operation. During the second stage operation 14 d later, the plasma disappearance rate increased to 12.1%/min and an R15 of 16.3% was observed. They concluded that intraoperative ICG clearance allows for the direct assessment of the actual future liver remnant function. However, since no safe cut-off levels were suggested, future validation studies would be necessary.

Improvement of patient safety by other modifications: In the International ALPPS Registry, 35% of centers did not use any coverage on the raw surface after liver transection, 26% used a plastic sheet, 26% TachoSil, and 16% of centers still used a plastic bag (of a total 192 patients). The use of a plastic bag or plastic sheeting to cover the cut area and prevent adhesions is not an essential component of ALPPS^[10,23]. In the author's institute, Penrose drainages are routinely used to separate the raw surface after liver transection as well as to avoid collections in case of a bile leak (Figure

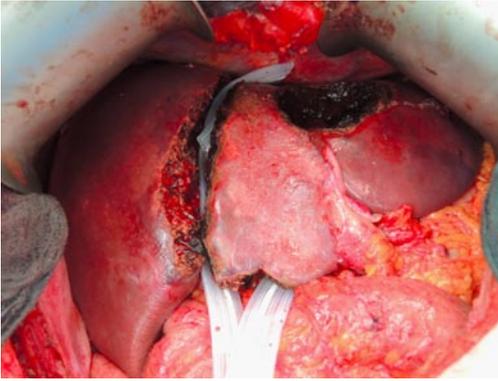

Figure 6 The future liver remnant was separated by two Penrose drains from the right liver lobe in a patient with bilobar colorectal liver metastases during the first stage operation. Three lesions at the left hemi-liver were resected.

6). However, the most important aspect to avoid bile leak and consecutive infection is not to perform *in situ* splitting in patients with dilated bile duct or cholangitis^[24].

Improvement of surgical approach under oncological aspects: The classic approach of ALPPS includes full mobilization of the liver and dissection of the liver hilum^[1]. Aloia *et al*^[25] criticized that ALPPS was supposed to be an “all-touch” technique that would reduce the oncological efficacy to treat liver malignancy. This comment was addressed by two technique refinements: “anterior approach” and “hybrid ALPPS”, to improve the efficacy of surgical oncology as well as to reduce the adhesion at the second stage of the operation^[26,27]. An analysis of the registry data found that in 37% (66/175) of patients that underwent transection during the first stage of ALPPS, an anterior approach was applied. However, caution has to be taken while applying the anterior approach due to the inability to achieve optimal vascular control during this technically complex procedure^[23]. “Hybrid ALPPS” was developed in authors’ institute to treat advanced gall bladder carcinoma in two patients^[27]. *In situ* split of the left lateral liver lobe was combined with postoperative right-PVE as a hybrid procedure. The authors concluded that hybrid ALPPS provided rapid hypertrophy of the FLR for a right trisectionectomy in case of tumor infiltration of the RPV or biliary bifurcation, while allowing to adhere to the non-touch principles. A similar procedure was performed by Robles *et al*^[28] by using a tourniquet-technique and sequential PVE to achieve liver partition in a patient with perihilar tumor burden.

Despite lacking sufficient data for a statistical analysis of disease-free or overall survival, non-touch technique is possible, and should therefore be applied for the resection of hepatic malignancy in ALPPS. Furthermore, hybrid ALPPS combining non-physical liver split and sequential PVE could be employed to reduce the rate of bile leak in patients with dilated bile duct.

Summary: Current results on safety and efficacy

Among the preliminary reports, ALPPS showed a high morbidity (59% to 68%) and mortality (12% to 12.8%)^[1,29]. In the first report of the international ALPPS registry, 90 d mortality was 19/202 (9%). Severe complications including mortalities (Clavien-Dindo \geq IIIb) occurred in 27% of patients^[10]. In experienced centers, including the authors’ institute, a much lower rate of major morbidity (13.6% to 14%) and mortality (0% to 6.6%) have been reported^[15,17]. As is the case with many new techniques, there will be an inherent learning curve, and lower rates of morbidity and mortality will be observed, along with further technical improvements and standardization of the ALPPS procedure.

ALPPS has been found to result in faster FLR growth in comparison with PVE alone^[30]. In a recent systemic review with a total of 295 patients, the FLR hypertrophy was 84%, with a confidence interval (CI) of 78%-91%^[31]. This high efficacy in inducing FLR hypertrophy was confirmed universally by the published case series and the international ALPPS registry. Moreover, in contrast to a failure rate of 20%-30% after PVE due to inadequate hypertrophy or disease progression^[32] (97%CI: 94%-99%) of all patients underwent stage one operation of ALPPS completed the procedure. Furthermore, histological complete resection (R0) was achieved in (91%CI: 87%-94%) of these patients^[31].

BENEFITS OF ALPPS

To decrease the risk of grade C PHLF

Similar to PVE and 2-stage hepatectomy, the aim of ALPPS is to decrease the risk of grade C PHLF after major liver resection in otherwise too small FLR. Beside a more rapid FLR hypertrophy induced by ALPPS, this approach can also be used in cases of failed portal vein occlusion (PVO) or an anticipated extremely small FLR^[33]. For an early prediction whether a patient will obtain a sufficient FLR, the concept of kinetic growth rate (KGR) or degree of hypertrophy has been introduced^[34]. Growth rate was shown to be a predictor of PHLF. Patients with low KGRs are unlikely to benefit from PVO only and could thus be candidates for ALPPS. Another group of patients who might be especially suitable for ALPPS are those with “extremely low” FLRs, who, given the boundaries of growth achieved with PVO, are unlikely to reach a FLR volume deemed necessary for resection.

In the first report of the international ALPPS registry, a median KGR of 2% FLR or 30 mL FLR per day have been observed^[10]. The second stage operations were performed at 10 d (interquartile ranges, 8 to 15) after the liver partition. Only 9% (16/202) of patients experienced liver failure according to the 50-50 criteria^[35]. Within them PHLF was regarded as the main cause of mortality in 8 patients^[10].

To provide more chance of R0 resection

Resection of a large tumor load in the liver may result in an excessive removal of hepatic parenchyma leading to PHLF and associated complications^[36]. ALPPS not only allows for resection in patients with very small anticipated FLR that would not be possible with conventional techniques, but also enables surgeons to proceed with multi-staged resections in a short interval before a substantial tumor progression^[17]. PVO is burdened with a considerable failure rate, and only about two thirds of patients will eventually be eligible for a subsequent curative resection due to tumor progression during the waiting interval between the two stages, or failure of the FLR to grow^[37-39]. A retrospective multicenter study was carried out to compare the rate of complete tumor resection after ALPPS vs conventional two-stage approaches^[5]. Eighty-three percent (40/48) of ALPPS patients achieved complete resection compared with 66% (55/83) in the PVO group. Seventeen percent (8/48) of ALPPS patients failed to achieve the primary endpoint due to mortality ($n = 7$) or incomplete resection (R1, $n = 1$). The author concluded that ALPPS offers a better chance of complete resection in patients with primarily unresectable liver tumours^[5].

Evidences of oncological benefits compared to other two-stage liver resection when R0 achieved

Colorectal liver metastasis: Colorectal liver metastasis (CRLM) is the most common indication for ALPPS as indicated in the first report of the international ALPPS registry^[10]. To compare the benefits of ALPPS to conventional 2-stage hepatectomy by PVO, evaluation of resection rate, postoperative mortality, as well as disease-free survival (DFS) or/and overall survival (OS) are necessary.

Resection rate, the resection rate for CRLM by traditional two-stage liver resection, either PVE or PVL, was reported to be 52%-80%^[40-42]. Non-resectability was mainly due to progression of metastasis^[40,41]. ALPPS avoided this type of drop-out by effectively inducing a sufficient liver hypertrophy within 6 to 15 d^[33]. A retrospective study carried out by Tanaka *et al*^[21] found that at first hepatectomy, Ki67 expression was evident in 28.2% \pm 42.7% of tumor cells in the ALPPS group and 51.7% \pm 35.6% in the conventional 2-stage group ($P = 0.09$). However, at second hepatectomy, expression of Ki67 was detected in 20.5% \pm 24.7% and 54.5% \pm 26.9% of patients in the ALPPS and in the conventional 2-stage group respectively ($P = 0.01$)^[21]. Therefore, the reduced expression of Ki67 in tumors resected during the second stage in the ALPPS group may indicate an oncologic benefit from ALPPS, as the short period between the two interventions helps to avoid the risk of tumor progression. Of note, in a recent review on the treatment of CRLM, the resection rate by ALPPS was reported to be about 97.1%^[33].

Postoperative mortality, PVO is a well-established, state of art procedure for patients with insufficient FLR

whereas ALPPS is still among the phase of exploration. Therefore, a comparison of these two procedures should be done when the learning curve of ALPPS is overcome. According to the first report of the international registry data, mortality of ALPPS for CRLM is 8%, and 5.1% in CRLM- patients younger than 60 years of age^[10]. In experienced centers, including the authors' institute, nil mortality after ALPPS for CRLM has been reported^[17].

DFS/OS, the 1 and 2-year DFS for patients undergoing ALPPS for CRLM from the ALPPS registry is 59% and 41% respectively^[10]. Overall survival is 86% at six months postoperatively, dropping to 59% at 2 years^[10]. Similar to the high recurrence rate despite a survival advantage observed in patients with advanced CRLM (> 4 metastases) undergoing traditional resection^[43-45], high recurrence rates have also been reported in patients undergoing ALPPS^[5,33,46]. In some case series, the recurrence of CRLM after ALPPS was quite early. For example, in the 7 patients reported by Oldhafer *et al*^[41] recurrence was observed after 3, 6, 7, 8, 11, 13 and 13 months respectively following ALPPS procedure^[46]. However, to date there is no direct comparison of DFS in patients undergoing PVE or ALPPS. Of note, two RCTs investigating ALPPS vs conventional two-stage hepatectomies for CRLM were recently launched (clinicaltrials.gov-identifier NCT01775267 and NCT01842971).

To get the best benefit of ALPPS, Hernandez-Alejandro *et al*^[17] proposed selecting the group of patients with biologically favorable CRLM. The inclusion criteria for ALPPS in their group were (1) no evidence of extrahepatic disease; (2) good functional capacity Eastern Cooperative Oncology Group performance status grade 0 or 1 and (3) complete or partial response to systemic chemotherapy after 6 cycles. In the 14 patients reported in this series, recurrence developed in 2 patients after a median follow-up of 9.4 mo. Overall survival at the time of follow-up was 100%^[17].

Hepatocellular carcinoma: An aggressive surgical approach in patients with locally advanced hepatocellular carcinoma (HCC) has been reported to yield an acceptable long term outcome that is significantly better than that of patients with unresectable HCC treated with Sorafenib^[47-49]. In this view, the ALPPS procedure could yield a better outcome and further expand the number of patients undergoing radical major liver resection for HCC in liver cirrhosis that were previously considered non-resectable, compared to non-surgical treatment^[49].

Chan *et al*^[50] reported the largest case series with 17 patients having HCC on the basis of chronic hepatitis B infection. Selection criteria included Child-Pugh A liver cirrhosis, indocyanine green retention rate < 20% at 15 min, FLR/sTLV (standardized total liver volume) < 40%, and platelet count $\geq 100 \times 10^9/L$. After a median of 6 d, a hypertrophy of the left FLR by 48.7% with a FLR/sTLV ratio of 38.5% (preoperative FLR/sTLV 24.2%) was noted. All patients proceeded to second-stage hepatectomy. Major surgical complications

¹Interval: Median days from the stage 1 to CT scan; ²Morbidity: Clavien-Dindo classification was applied; FLR: Future liver remnant; PHLF: Post-hepatectomy liver failure according to 50-50 criteria (35).

(Clavien–Dindo grade III or above) occurred in 11.8% of patients ($n = 2$), and in-hospital mortality rate was 5.9% ($n = 1$). No follow-up data were reported. Chan *et al*^[50] concluded that ALPPS could also promote liver hypertrophy in patients with chronic liver diseases, with a similar safety profile compared to other established series. Another case series by Vennarecci *et al*^[51] suggested that the ALPPS procedure could be very useful in a subgroup of patients with HCC and venous thrombosis. In their series, portal hypertension or liver cirrhosis more than Child-Pugh A was considered as a contraindication^[49,52]. However, data regarding the long term outcome of ALPPS in patients with HCC are still very limited, and further reports on the use of the ALPPS in this setting are expected^[49].

Perihilar cholangiocarcinoma: Although the first case of ALPPS was successfully performed in a patient with hilar CCA, high rates of major postoperative complication and mortality were found in this population after ALPPS^[10]. Li *et al*^[24] first questioned the benefit of ALPPS in treatment of perihilar CCA. The authors found that patients undergoing ALPPS for perihilar CCA were at a high risk of intraabdominal infection and bacteraemia as the diseased liver and stented biliary system were not removed between the two operations. Two of three patients with hilar CCA received ERCP and a stent before referral. Both of them had postoperative intraabdominal bacterial infections, and eradication of bacteria failed. The deaths of those two patients account for the 22% mortality observed in the cohort of 9 ALPPS patients from this series. Thus, the authors considered the combination of a stented biliary system and cholestatic liver with low potential of regeneration as a contraindication for ALPPS. This opinion has been

shared with the HPB community, in which caution has aroused against the use of ALPPS for hilar tumors^[8,53].

Other indications: The other indications of ALPPS comprised of intrahepatic cholangiocarcinoma, gallbladder cancer, neuroendocrine tumors and other liver metastases. Because of the limited number of cases, no high quality evidence on the oncological benefit other than increased resectability is available^[5,8,10].

Summary - current status of oncological benefit by patient selection

The ALPPS procedure was developed to decrease the morbidity and mortality related to PHLF, to avoid drop-out in patients undergoing conventional two-stage liver resection and to achieve histopathological complete tumor resections (R0) in otherwise non-resectable patients. Although contemporary reports have highlighted the importance of patient selection in avoiding perioperative morbidity and mortality, suitable indications for the ALPPS approach remain to be determined^[17]. Till date, there is no clear evidence for the oncological benefit of ALPPS in treatment of CRLM over other procedures as long as R0 resection is achieved. For patients with hilar CCA, ALPPS should be considered with extreme caution due to the aforementioned safety issue. For other indications, there are no ongoing studies comparing ALPPS with non-surgical treatment in term of overall survival.

CONCLUSION

ALPPS is a pertinent alternative approach to the conventional two-stage liver resection after PVE or PVL. In selected cases, it could even increase the resectability of

previously unresectable liver malignancy by promising rapid hypertrophy of the FLR (Table 1). With the evolution of surgical technique, proper patient selection for ALPPS has been found to be the key element to achieve the best oncological results.

Abstract

Up to 10% of acute colonic diverticulitis may necessitate

a surgical intervention. Although associated with high morbidity and mortality rates, Hartmann's procedure (HP) has been considered for many years to be the gold standard for the treatment of generalized peritonitis. To reduce the burden of surgery in these situations and as driven by the accumulated experience in colorectal and minimally-invasive surgery, laparoscopy has been increasingly adopted in the management of abdominal emergencies. Multiple case series and retrospective comparative studies confirmed that with experienced hands, the laparoscopic approach provided better outcomes than the open surgery. This technique applies to all interventions related to complicated diverticular disease, such as HP, sigmoid resection with primary anastomosis (RPA) and reversal of HP. The laparoscopic approach also provided new therapeutic possibilities with the emergence of the laparoscopic lavage drainage (LLD), particularly interesting in the context of purulent peritonitis of diverticular origin. At this stage, however, most of our knowledge in these fields relies on studies of low-level evidence. More than ever, well-built large randomized controlled trials are necessary to answer present interrogations such as the exact place of LLD or the most appropriate sigmoid resection procedure (laparoscopic HP or RPA), as well as to confirm the advantages of laparoscopy in chronic complications of diverticulitis or HP reversal.

Core tip: With the aim to improve surgery outcomes, laparoscopy has been increasingly performed in complicated diverticulitis. Despite the absence of solid proofs and under the condition of large expertise, it is an appropriate approach for the surgical management of both elective and emergent situations related to complicated diverticulitis. Moreover, the laparoscopic

lavage drainage represents a previously unknown modality of treatment of purulent peritonitis. Validation of these data by large-scale randomized controlled trials is mandatory to build future therapeutic algorithms on which general surgeons can rely in their daily practice.

INTRODUCTION

Colonic diverticulosis is mainly an acquired disease with an age-dependent prevalence, ranging from 5% at 30 years to 60% at 80 years^[1]. Acute diverticulitis occurs in 4%-25% of cases^[2,3] of which 8%-35% present with perforated disease^[4]. Generalized peritonitis from colonic diverticulitis (graded as Hinchey 3 and 4^[5]) is a life-threatening situation requiring immediate surgical intervention^[2,6,7]. Designated by Hartmann's procedure (HP), resection of the affected diverticular colon segment, closure of the rectal stump and formation of an end colostomy has been considered the treatment of choice for many years^[8-13]. However, morbidity and mortality rates of 24% and 19% as well as high risk of permanent stoma^[14-18] have pushed general surgeons to look for surgical alternatives with better outcomes.

In colorectal surgery, large-scale prospective studies have confirmed the superiority of laparoscopy over the open approach in terms of lowered postoperative morbidities, reduced postoperative pain, improved respiratory function and shortened hospital stay^[19-22]. Based on that, laparoscopy has been considered as the preferred approach for the elective treatment of diverticular disease^[1,23,24]. In 2006, however, the European Association of Endoscopic Surgeons^[25] and the American Society of Colon and Rectal Surgeons^[23] expressed their opposition to the routine usage of laparoscopy in the acute setting. Due to insufficient data confirming validity of the presumed advantages in emergent surgery, the laparoscopic approach was estimated not to be appropriate for the management of complicated perforated diverticulitis.

Since then, worldwide increasing experience in colorectal and minimally invasive surgery has broadened applicability of laparoscopy to abdominal emergencies, hypothesizing that the advantages observed in the elective setting can be translatable to acute situations^[26]. Several recent studies claim the benefits of laparoscopy over the open approach when performed by experienced surgeons in selected patients with perforated diverticulitis^[25,27-31].

Virtually all procedures for complicated diverticular disease have been achieved under laparoscopy. Since its first description almost twenty years ago^[32], the

laparoscopic reversal of HP has been progressively performed promising reduced morbidity and mortality^[33,34]. Similarly, sigmoid resection and primary anastomosis (RPA) with or without derivating loop ileostomy (DI) has been repeatedly performed in diverticular peritonitis^[35]. Furthermore, during the last ten years, we have been observing the emergence of the laparoscopic lavage drainage (LLD), a previously unknown technique for the management of purulent peritonitis^[36,37].

In parallel, laparoscopy is being increasingly performed for elective surgeries related to complicated diverticulitis. The most common examples are the reversal of HP and the sigmoidectomy for chronic complications (such as fistula, inflammatory stenosis and phlegmon).

Nonetheless, despite worldwide application, laparoscopic surgery for complicated diverticulitis mostly relies on empirical experience. A precise consensus based on level 1 evidenced data has not yet been established to determine the exact status of laparoscopic techniques in this field.

This review aims to provide a critical appraisal of currently available data concerning the laparoscopic approach in both emergent and elective settings of complicated diverticulitis. We will focus on ongoing randomized controlled studies (RCTs) that are expected to provide clear practical recommendations for emerging techniques. Perspectives for future research will also be suggested to assist tomorrow's surgeons in their decision making when addressing these situations.

LITERATURE RESEARCH

A bibliographic search was performed in PubMed and Cochrane library for case series and comparative studies published from January 1995 to July 2015. RCTs were recorded from the official web site www.clinicaltrials.gov. The following medical subject heading (MeSH) terms were searched for titles and abstracts in the English or French languages: Diverticulitis; acute; emergent; laparoscopy; lavage; drainage; peritonitis; purulent; stercoral; fecal; complicated; perforation; Hinchey; Hartmann. The "related articles" function was used to enlarge the search. A manual search of the reference lists was also performed to identify additional relevant studies. The first two authors separately classified the selected articles into elective, emergent and future situations. Subsequently, relevant articles were discussed and discrepancies of findings were resolved with agreement of both authors. Overlapping publications were identified and only the most recent paper was selected for the review.

DISCUSSION

Emergent surgery

Laparoscopic surgery for failed medical treatment: Diverticulitis complicated by pericolic and/or

pelvis abscess (Hinchey 1 and 2) are most often managed conservatively with intravenous antibiotics more or less combined to percutaneous drainage^[1,38,39]. In case of failure, an emergent surgery may be indicated for sepsis control and resection of the diseased colon. Available data are, however, limited to a single-institutional retrospective series^[40] which has been recently updated^[41]. When comparing outcomes of the laparoscopic approach (24 patients) to those of laparotomy (18 patients), laparoscopy was associated with a 4-fold decrease in overall complication rate, faster bowel movement, shorter hospital stay and comparable rate of RPA despite a longer operative time. In the laparoscopy group, RPA could be achieved in all but one patient and conversion to open surgery occurred in 2 patients. In regard to these encouraging results and motivated by the scarcity of data on this specific aspect of colonic diverticular surgery, RCTs are needed to confirm the suggested benefits of laparoscopy in this group of patients.

LLD: First described in 1996^[42,43], the procedure consists of a laparoscopic exploration of the abdominal cavity followed by lavage with heated saline serum and drainage of the diseased colon for the next several days. The need for extensive adhesiolysis in search of the colonic perforation remains controversial^[44]. In a prospective multi-institutional study^[45], 92 patients underwent laparoscopic peritoneal lavage for Hinchey 2 or 3 diverticulitis. All patients but two had complete clinical resolution. One patient required subsequent colonic resection whereas the other required percutaneous drainage for pelvic abscess. Mortality and morbidity rates were 3% and 4%, respectively. After a median follow-up period of 36 mo, only two patients were readmitted with acute diverticulitis successfully treated with antibiotics. The authors concluded that LLD can be a reasonable alternative to HP for Hinchey 3 perforated diverticulitis. Another prospective study^[46] found that LLD offers the advantages of shorter operative time and hospital stay, reduced estimated blood loss and better postoperative outcomes compared with laparoscopic HP. Including all stages of complicated diverticulitis (mainly Hinchey 3), only 2.1% of patients undergoing LLD were converted to open HP, and 6.4% were reoperated for uncontrolled sepsis. Almost half of the patients who received LLD underwent subsequent sigmoid resection, but the reasons were not mentioned. Such favorable results (low morbidity and mortality rates, high chance of sepsis control, avoidance of stoma and bowel salvage) have been constantly reported in case series and systematic reviews^[37,44,47-53]. Soon after and despite robust evidence, LLD was cited in national and international scientific committees' reports as a potential therapeutic option for purulent peritonitis of diverticular origin^[1,54,55].

Preliminary results of the DILALA prospective randomized trial have been recently published after complete accrual^[56]. Although the primary endpoint

(the number of reinterventions) could not be assessed because of incomplete follow-up, this trial showed a higher than usual mortality rate of 7.7% after LLD. This result was comparable to that found in the open HP group. Both procedures provided comparable complication profiles, but LLD resulted in shorter operative time, shorter time in the recovery unit and shorter hospital stay. Recently, the enthusiasm toward LLD has been hindered by the results of the LOLA group within the Ladies trial confronting LLD to sigmoidectomy in Hinchey 3 diverticulitis^[57]. This multicenter RCT has been prematurely terminated because of significantly increased in-hospital major morbidity or mortality in the lavage group compared with sigmoidectomy. Surgical reinterventions accounted for most of these adverse events. However, mortality rate was unaltered (9% in the LLD group vs 14% in the sigmoidectomy group), and sepsis was successfully controlled in 76% of cases (vs 90% in the sigmoidectomy group). In the long-term, there was no difference in the incidence of major morbidity or death between the two groups (37% vs 40% in the LLD and sigmoidectomy groups, respectively). LLD allowed salvage of the sigmoid in almost half of the cases and avoided stoma formation in three-quarters of the patients. In contrast to the resection procedure, LLD allows bowel salvage and avoids stoma but requires a multi-step careful surveillance and timely management. The authors conclude that peritoneal lavage cannot be favored over sigmoid resection as a routine intervention for purulent peritonitis of diverticular origin. Instead, it may be an alternative approach to sigmoidectomy with similar length of stay and long-term outcome in select patients. From this standpoint, in the Dutch Collaborative study group^[58] as well as in another study^[59], age older than 80 years, American Society of Anesthesiologists grade 3 or above, multiple comorbidities, immunosuppression, high C reactive protein and/or high Mannheim peritonitis index were associated with increased risk of failure after LLD. Currently, there are two ongoing RCTs comparing LLD to sigmoidectomy^[60,61]. The results are eagerly awaited to provide further evidence about expected outcomes after LLD and to identify criteria for patients who would preferably benefit from each technique.

In contrast to the enthusiasm for LLD in purulent peritonitis, this approach is not commonly admitted for Hinchey 4 diverticulitis. The presence of a visible perforation in the colon has always represented the limit of application of the technique^[42,62]. In his prospective study, Myers *et al.*^[45] stated that stercoral peritonitis constitutes an indication for conversion to open HP. Conversely, Liang *et al.*^[46] reported very encouraging results despite the inclusion of more than 10% of Hinchey 4 peritonitis in his prospective study. Many authors agree that LLD cannot be accepted unless perforation of the colon is formally ruled out^[45,53]. Conversely, others propose suturing the colonic hole if stercoral peritonitis is not evident^[59]. The diagnosis of stercoral peritonitis on explorative laparoscopy

excluded patients from both of the available randomized controlled trials^[56,57]. This condition is presumed to significantly modify the results observed with purulent peritonitis. In fact, the high reintervention rate found in the Ladies trial is mostly attributed to the misdiagnosis of stercoral peritonitis. To optimize outcomes after peritoneal lavage, the authors pushed toward a meticulous search for colon perforation. In all cases, the adoption of LLD in emergency settings, abdominal exploration for generalized peritonitis, pelvic dissection in inflammatory conditions and possible suture of a diseased colon require that the surgeon have a minimum of colorectal and minimally invasive skills before he can propose this conservative approach^[51,58].

Sigmoidectomy: Primary anastomosis and

HP: Supported by considerable improvement in the perioperative care, RPA (without or without DI) has been proposed as an alternative to HP in emergent situations. A comparison of these two techniques has mostly enrolled patients undergoing open procedures before the widespread application of laparoscopy in emergent colorectal surgery. In fact, several comparative studies, systematic reviews and meta-analyses favored RPA over HP in respect to reduced mortality and morbidity rates, shorter cumulative operative time and hospital stay, more frequent stoma reversal and reduced cost^[63-76]. Even without DI, RPA was shown to be preferable than HP for purulent peritonitis^[70,72,77]. These studies, however, suffer from marked heterogeneity and selection bias with low-risk patients mainly undergoing RPA, whereas HP is offered to high-risk elderly patients^[63,74]. A recent RCT showed that for Hinchey 3 and 4 diverticular disease, the main differences between RPA with DI and HP occur during the stage of stoma reversal^[78]. When both stages (colonic resection and stoma reversal) were combined, the rates of overall complications, severe complications and mortality (13% in HP vs 9% in PA) were similar in both groups. In contrast, when the reversal procedure was considered alone, HP was associated with lower stoma reversal rate (58% vs 90%), more frequent severe complications (20% vs 0%), and longer operative time and hospital stay. The main flaw of this RCT would be the lack of information about the adopted approach (laparoscopic or open) for the reversal of the stoma. This issue is of paramount importance because laparoscopy has been proved to decrease the morbidity of HP reversal in several case series and systematic reviews^[79-86]. The elevated rate of severe complications during stoma closure in the HP group may have been overemphasized by the open approach *per se*.

This evidence raises the question whether the laparoscopic HP may offer advantages over the open approach in terms of reduced morbidity and mortality in the acute setting of perforated diverticulitis. To improve the outcome after open HP, we have been among the first to show the feasibility of a laparoscopic two-staged strategy for complicated diverticular disease.

Despite conversion in 19% of cases, this approach offered adequate control of sepsis with low rates of mortality (3%) and morbidity (23%)^[33]. Similarly, in a small case series, Agaba *et al.*^[34] described favorable outcomes after laparoscopic HP for Hinchey 3 and 4 diverticulitis. Recently, a propensity-matched analysis of the ACS NSQIP database failed to show a decrease in postoperative morbidity and mortality when HP was performed under laparoscopy compared with the open approach. This study, however, suffers from substantial imperfections in methodology such as retrospective data acquisition and lack of analysis of pertinent variables that might substantially interfere with the results^[26].

To clarify the role of laparoscopy in emergent sigmoidectomy, Mbadiwe *et al.*^[87] retrospectively analyzed the ACS NSQIP database. In a total of 11981 patients, a bivariate analysis showed that patients undergoing laparoscopy experienced lower rates of complications with both RPA (14% vs 26%, $P < 0.001$) and HP (30% vs 37%, $P = 0.02$). The laparoscopic approach was associated with decreased mortality rate for patients undergoing RPA (0.24% vs 0.79%, $P < 0.001$). The reduced complication rate after laparoscopic RPA was confirmed in the multivariate analysis^[87].

To provide a high level of evidence in the present era of widespread use of laparoscopy for colorectal disease, a well-built RCT is highly desirable comparing laparoscopic RPA (with or without DI) with a two-step laparoscopic HP (sigmoid resection and stoma closure) in perforated complicated diverticulitis. Not only outcomes of both procedures will be clarified but also identification of precise criteria would define the subgroups of patients who will benefit more from each technique. Based on this perspective, the results of the ongoing DIVA section of the Ladies trial are keenly awaited to provide us with level 1 evidence about the preferable laparoscopic attitude in Hinchey 4 complicated diverticulitis^[57].

Elective surgery

Based on solid proofs from a large-scale meta-analysis^[88] and RCTs^[89,90], international committees have adopted laparoscopy as the preferred approach for elective sigmoidectomy after acute diverticulitis^[1,23,24]. Compared with an open procedure, the laparoscopic modality offers a significant decrease in major complications and morbidity, less blood loss, fewer analgesic requirements, shorter hospital stay and improved quality of life.

Conversely, in early experience, laparoscopy was contraindicated for the treatment of diverticular chronic complications (stricture, fistula and persistent phlegmon) because severe inflammation and distorted anatomy exposes the patient to high risks of bleeding and adjacent organ trauma (bladder, left ureter, female genital organs)^[11,91]. With increasing experience, the laparoscopic approach has been progressively accepted as an alternative to open surgery but its routine usage in chronic complications remains controversial^[92].

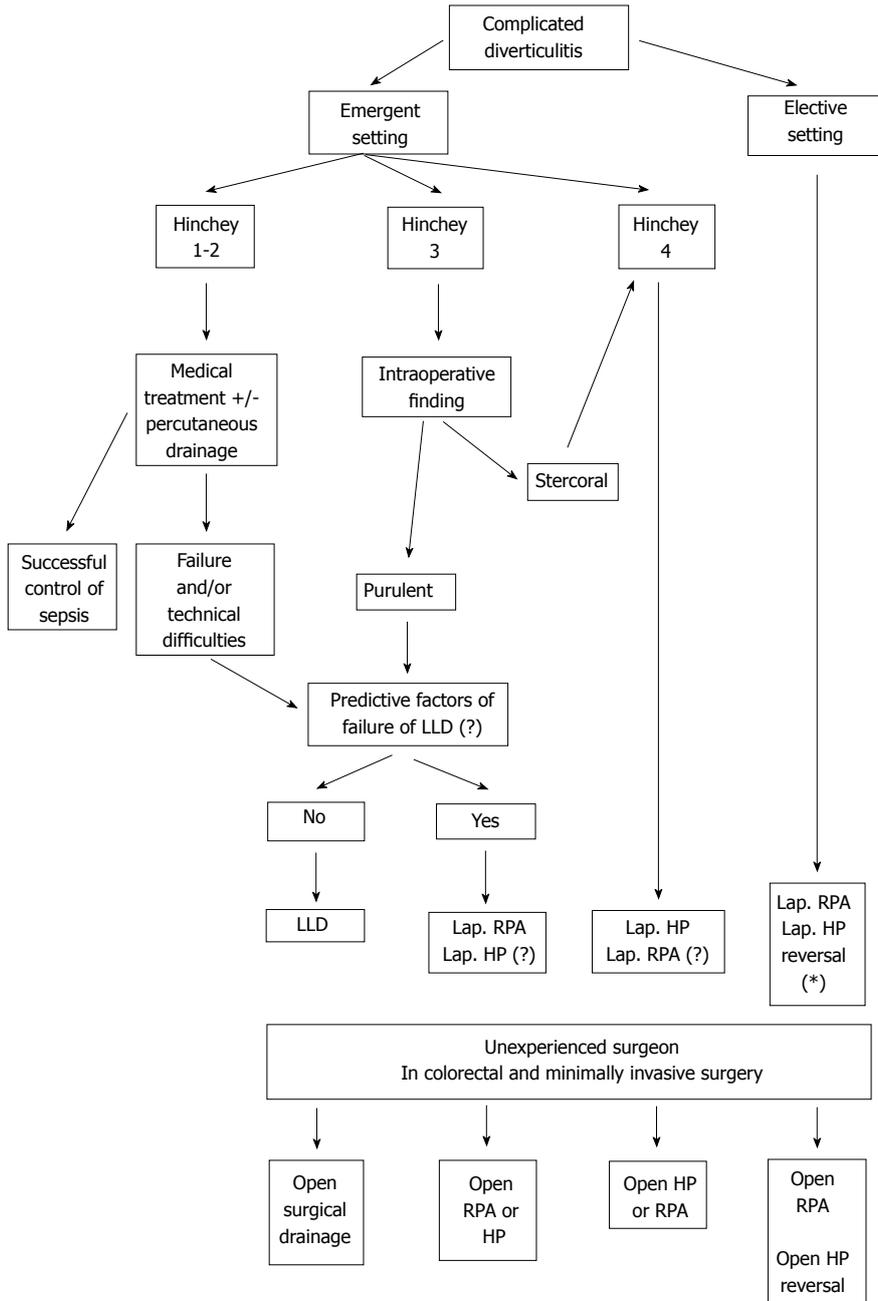

Figure 1 Algorithm for the laparoscopic management of complicated colonic diverticulitis. Lap: Laparoscopic; LLD: Laparoscopic lavage drainage; RPA: Resection with primary anastomosis; HP: Hartmann's procedure; (?): Data that need to be elucidated in RCTs, (*): Data that need confirmation in RCTs.

Because presently available data mostly rely on small retrospective series and case reports, several controversies cannot be fully elucidated. In a descriptive case series, Le Moine *et al*^[93] suggested that chronic complicated diverticulitis increases the risk of conversion to laparotomy in elective laparoscopic sigmoidectomy. This effect has been recently disproved by two comparative studies^[94,95] which stated that surgeons' expertise in minimally invasive and colorectal surgery is the principal determinant of morbidity and conversion rates in complicated cases. This evidence outlines that accumulating experience during the last ten years has inevitably challenged previously accepted knowledge.

Colonic fistula is the most reported late compli-

cations of diverticular disease, although available data is scarce and confined to retrospective case series. In recent systematic reviews^[96,97], the laparoscopic approach was judged to be feasible and safe for the treatment of colovesical fistulae. However, due to a lack in methodology and/or a limited number of patients, the studies failed to show superiority of laparoscopy over the open approach. Furthermore, the conversion rate could not be determined and the predictive factors of its occurrence were not discussed^[96]. This issue has been addressed in a previous case series including 31 patients conducted over 10 years. The overall conversion rate was approximately 30% but declined to 10% during the second half of the study period^[98].

This finding is consistent with the statement of Abbas *et al*^[99] that similar rates of conversion, morbidity and mortality can be expected with laparoscopy regardless of the presence of colonic fistula. Therefore, the current surgical management of colonic fistula relies on poor data derived from empirical experiences in open surgery. The most salient example is the adoption of a single-stage procedure as the preferred surgical option despite the absence of solid proofs confirming its superiority^[98].

During this study, we noticed a striking lack of high quality papers dedicated to the issues of inflammatory phlegmon and stricture. Information on the most appropriate treatment in these situations is thus absent. If low incidence of such cases is the cause of this shortage, prospective enrollment of patients in large multi-institutional databases might be the solution to build precise therapeutic algorithms on which tomorrow's general surgeons can use for the treatment of their patients.

Finally, with the emergence of LLD as a conservative modality for complicated perforated diverticulitis, controversies have arisen about the need for systematic elective sigmoidectomy after the diseased organ has been saved. In a recent systematic review^[44], rehospitalization was observed in 7% of patients who underwent LLD. More than half of them presented with a new episode of diverticulitis, 21% with generalized peritonitis, 10% with colovesical fistula and 7% with undetected colon cancer. At this stage of experience, the present data lack sufficient proof to know whether LLD can be regarded as a definitive treatment or a bridge to elective laparoscopic sigmoidectomy^[100]. If LLD becomes widely admitted, well-built RCTs will be necessary to answer these questions and to determine the best candidates for bowel sparing.

CONCLUSION

In conclusion, accumulated empirical experience during the last two decades shows that laparoscopy is undeniably a promising adjunct in the management of complicated colonic diverticulitis. Analysis of presently available data also highlights the urge to build large-scale prospective RCTs in order to elucidate the exact benefits of laparoscopy and to define patients who are the best candidates for each approach. Like the ongoing trials NCT01019239 and NCT01047462, solid data are particularly awaited in order to clarify the exact place of LLD and to determine the most appropriate sigmoid resection procedure (laparoscopic HP or RPA) in Hinchey 3 and 4 peritonitis. The advantages provided by laparoscopy in chronic complications of diverticulitis and HP reversal also need to be confirmed. In the absence of precise recommendations, we suggest the following algorithm that may assist general surgeons in their decision-making when dealing with complicated colonic diverticulitis (Figure 1).

Abstract

Minimal access surgery has revolutionised colorectal surgery by offering reduced morbidity and mortality over open surgery, while maintaining oncological and

functional outcomes with the disadvantage of additional practical challenges. Robotic surgery aids the surgeon in overcoming these challenges. Uptake of robotic assistance has been relatively slow, mainly because of the high initial and ongoing costs of equipment but also because of limited evidence of improved patient outcomes. Advances in robotic colorectal surgery will aim to widen the scope of minimal access surgery to allow larger and more complex surgery through smaller access and natural orifices and also to make the technology more economical, allowing wider dispersal and uptake of robotic technology. Advances in robotic endoscopy will yield self-advancing endoscopes and a widening role for capsule endoscopy including the development of motile and steerable capsules able to deliver localised drug therapy and insufflation as well as being recharged from an extracorporeal power source to allow great longevity. Ultimately robotic technology may advance to the point where many conventional surgical interventions are no longer required. With respect to nanotechnology, surgery may eventually become obsolete.

Key words: Colorectal surgery; Robotic surgery; Endoscopy; Robotics; Nanotechnology; Microtechnology; Rectal neoplasms; Colonic neoplasms

BACKGROUND

The objective of robotic surgery is allowing us to operate in challenging environments or to achieve levels of performance we would otherwise not be capable of. Surgeons interact with their environment by using their senses to gather information (perception), combining these inputs with their pre-existing knowledge and experience (processing) to change the environment (action). A robot may augment any or all of these aspects in order to improve the final outcome.

Over the last two decades colorectal surgery has dramatically changed due to the widespread implementation of laparoscopic surgery. Laparoscopic surgery offers comparable oncological outcomes^[1], but with improved post-operative recovery^[2]. The move towards minimal access surgery has, however, put challenges upon the surgeon's perceptive and action abilities with a resultant increased reliance on processing abilities required to make up for these deficits. Robotic assistance in minimal access surgery aims to make up for some of the practical shortcomings of laparoscopic surgery, providing assistance to the surgeon with improvements to perception, processing and action.

This aim of this review is to summarise the current benefits and shortcomings of robotics in colorectal surgery and endoscopy and to identify how the implementation of developing robotic technology may shape the future of colorectal surgery.

ESTABLISHED ROBOTIC COLORECTAL SURGERY

At present the Da Vinci Robot (DVR) (Intuitive Surgical) is the most widely used platform for robot assisted laparoscopic colorectal surgery. It consists of a high definition three-dimensional camera system allied to a patient "sidcart" that allows instruments to be delivered and controlled. The surgeon sits at a separate control module (Figure 1) that delivers three-dimensional images and allows remote control of the sidcart-mounted effectors.

The DVR addresses some of the limitations of conventional laparoscopic surgery by allowing dexterity in 7 planes of movement within a limited space, static ports, filtering of physiological tremor and variable motion scaling. The potential drawbacks of the system include lack of tactile feedback, prolonged operative time and financial cost, including initial outlay, consumables and servicing of equipment.

The attributes of the DVR make it suitable for assisting in precision surgery within confined spaces such as the pelvis and use of the DVR for radical prostatectomy is now widespread in the United Kingdom

Figure 1 Surgeon interaction with the Da Vinci robot control module.

for this reason. Robotic prostatectomy is now seen as the primary treatment for localised prostate cancer, delivering equivalent oncological outcomes with decreased morbidity^[3,4], but equivocal improvement in sexual function^[5].

The practical challenges of pelvic surgery for prostate cancer are similar to those encountered in rectal surgery, particularly when performing total mesorectal excision (TME). It has been demonstrated that laparoscopic TME offers equivalent oncological outcome with faster recovery and less morbidity than open surgery^[2,6]. However, it is technically demanding with higher conversion rates seen in the obese and during low rectal surgery^[7].

Comparative studies have suggested an improved TME grade following robotic TME^[8,9] and it is hypothesised that the improved precision of surgery enables the TME plane to be more accurately preserved, offering greater preservation of the pelvic autonomic nerves resulting in improved urinary and sexual function with some evidence of short-term benefit^[10]. Rates of conversion are often used as a surrogate marker of operative difficulty and a systematic review of case-controlled studies identified that conversion rates may be lower in robotic assisted cases, although this was not statistically significant^[11].

The Robotic vs Laparoscopic Resection for Rectal cancer trial is the first international, multi-centre randomised controlled trial to compare laparoscopic with robotic TME. The results of 471 participants have been presented at the European Society of Coloproctology, September 2015 and demonstrated no statistically significant difference in oncological clearance, patient outcome or conversion to open surgery between the two groups. These findings may impact the usage of the DVR in TME as it seems that the increased financial cost of robotic usage is not offset by improved surgical outcomes.

There are several centers performing robotic ventral mesh rectopexy. It has been argued that the increased dexterity of the instruments of the DVR facilitates dissection and more precise suturing of the mesh^[12]. There are few studies that compare outcomes between laparoscopic and robotic ventral mesh rectopexy, however functional improvements with respect to obstructive defaecation symptoms have been noted in patients having robotic surgery^[13].

The COST and COLOR trials demonstrated that laparoscopic surgery offers oncological and survival outcomes commensurate with open surgery in colonic tumors^[14,15]. Decreased morbidity and length of hospital stay have also been shown^[1,16,17]. The improved dexterity the robot offers has demonstrable benefit when performing intracorporeal anastomosis^[18], but the benefits of robotic over laparoscopic colonic surgery however are less well established and no benefit of has been demonstrated when comparing laparoscopic to robotic right hemicolectomy^[19]. Robotic left hemicolectomy can be used as training platform to practice mobilization of the left colon and splenic flexure as part of robotic anterior resection.

Currently there appears to be little evidence to support the use of DVR type robots in conventional multiport trans-abdominal surgery. The development of transanal endoscopic microsurgery (TEM) and single port laparoscopic surgery (SPLS) limits a surgeons dexterity still further and these fields may be particularly suited to robotic augmentation.

COLORECTAL ROBOTIC SURGERY UNDER DEVELOPMENT

Robotic surgical technology is expensive- initial outlay, maintenance and purchasing disposable equipment contributes to the financial expense that must be justified by reproducible cost effectiveness. This currently restricts robotic surgery to larger institutions that are able to absorb these costs and provide high utilisation in circumstances where financial gains can offset expenditure. Therefore developments in colorectal robotics over the next decade will concentrate on the widening application of robotics to other colorectal disciplines, such as endoscopy, single port surgery and transanal surgery and minimisation of cost.

Single port robotic laparoscopic surgery

SPLS offers improved cosmesis and less post-operative discomfort compared to that seen in multiport laparoscopic surgery^[20]. SPLS restricts the triangulation and retraction easily achieved in multiport surgery. This can be managed utilising conventional straight instruments that are crossed intracorporeally or by using curved or articulating instruments such as the Autonomy Lapro-angle^[20]. The technique is associated with equivalent oncological outcomes^[21], but a systematic review of colorectal SPLS found conflicting evidence regarding

Figure 2 Robotic single port laparoscopic surgery module designed by Intuitive Surgical. ©[2015] Intuitive Surgical, Inc.

demonstrable improvements in patient recovery and length of stay^[22].

Robotic assisted SPLS systems offer superior triangulation, without the need for crossing instruments, while incorporating other robotic technology. The Da Vinci Si Surgical Robot (Intuitive Surgical) has obtained FDA approval. It incorporates remote centre technology that reduces interference between instruments in addition to a three dimensional camera, motion scaling and removal of tremor (Figure 2). Evidence has been published demonstrating the feasibility of robot assisted SPLS in right hemicolectomy^[23] but to date no advantage of robot assisted over conventional SPLS has been demonstrated. Alternative robotic SPLS platforms are in the prototype stage, including the Single Port Orifice Robotic Technology robotic SPLS module (Titan Medical) which is predicted to cost a third of the Da Vinci system, although data on efficacy is awaited^[24].

Robotic transanal surgery

TEM offers similar practical challenges to SPLS and has become established as an effective method of removing non-advanced distal rectal lesions and may be oncologically superior to conventional transanal excision^[25]. Initially described in 2011, a SILS (Covidien) port was placed in the anus and the Da Vinci machine deployed as for SPLS^[26]. The first cohort study of sixteen patients managed with robotic TEM reported that the procedure was technically feasible but did not offer comparative data with conventional TEM. Use of the robot added an additional €1000 per procedure in disposables alone^[27].

Robotic transanal total mesorectal excision (RT-TME) is an alternative method of TME where the standard abdominal component of an anterior resection is completed laparoscopically before the DVR is introduced transanally to complete the TME in a retrograde fashion. This method facilitates distal rectal dissection in patients who are obese or who have narrow pelvises^[28]. A study of twenty patients did not compare RT-TME to conventional TME but demonstrated the feasibility of the approach in distal rectal cancers^[29].

Improving current laparoscopic technology

Modifying and augmenting existing laparoscopic surgical instrumentation to offer additional degrees of movement, tactile or haptic feedback may narrow the gulf between laparoscopic and robotic surgery with potentially significant cost savings. Movement of conventional laparoscopic instruments is restricted by the fulcrum of movement existing at the point of entry into the abdomen. The Radius Surgical System (RSS, Tuebingen Scientific) has been in circulation for over ten years and offers an additional fulcrum at the tip of the instrument to allow a greater degree of movement. As with the DVR, it offers 7 degrees of freedom for a significantly lower financial outlay although the extent of its distal joint articulation is reduced^[30].

The RSS generally offers tools for suturing and manipulation, rather than dissection and there is no mechanism for removing surgeon tremor or changing the ratio of hand to instrument movement. Results suggest a shorter learning curve compared to the DVR^[31] and it has been demonstrated that they can be used in sutured intracorporeal colorectal anastomosis with encouraging results^[32]. The parallel development of reliable laparoscopic stapling devices has, however, generally obviated the need for an advanced suturing instrument, which may account for the lack of take up of the RSS system. The Autonomy Laparo-angle (CambridgeEndo) is a simpler system offering a range of graspers, scissors and needle holders that can articulate at a distal joint allowing a greater degree of movement not offered by conventional laparoscopic instruments. However, to date there is no published evidence of its use in colorectal surgery.

Robotic endoscopy

Developments in robotic endoscopy have focused on automatic endoscope propulsion and improved endoscopic instrumentation. Balloon endoscopy mimics the movement of an earthworm, using coordinated inflation and deflation of a series of balloon to advance the camera and it has been successful in small bowel enteroscopy^[33]. Current research focuses on providing propulsion at the endoscopic tip to pull the scope through the colon, reducing discomfort and procedure duration. Development of legged locomotion allows efficient propulsion and a steering capability, but risks iatrogenic injury from the traction of the legs on the colonic surface. New generations of microscopic leg effectors aim to minimise injury while offering sufficient propulsive force for effective motion^[34].

Capsule endoscopy utilises passive propulsion to traverse the GI tract and has proved successful in endoscopic practice, particularly in visualisation of the small bowel. The purely passive locomotion is also a drawback and does not allow retrograde motion to recheck areas of incomplete examination. Capsules with active control could be steered to closely examine certain areas, release medications and

perform diagnostic or therapeutic interventions but they are limited by size as they must be swallowed. Size constraints currently preclude independently self-propelled capsules.

Vectoring using external magnets allows the capsule to remain as small as possible and was originally described using a hand-controlled external magnet^[35]. To offer accurate and reproducible magnetic control requires a generated magnetic field utilising a series of magnets under computer control and offering very high positional accuracy at the cost of extensive magnetic equipment^[36]. Early trials demonstrate that the technique is feasible but movement is restricted by collapsed bowel with no method of insufflation available and there are no reports from trials in human subjects^[37].

Endoscopic mucosal resection is an established method of endoscopic piecemeal removal of sessile polyps or superficial cancers less than 20 mm in diameter that would otherwise require surgical excision^[38]. Endoscopic submucosal resection (ESR) can be applied to larger lesions and aims to remove a greater depth of tissue in a single specimen. This allows more accurate histological examination and reduces the risk of recurrent disease^[39]. Although initially developed for the management of upper gastrointestinal lesions, the procedure has shown great promise with respect to colonic lesions greater than two centimeters in diameter^[40]. The procedure is technically challenging and relies on the application of tension to the target lesion to allow careful dissection, which is challenging with conventional endoscopic instruments.

A number of flexible multi-tasking platforms are available that consist of conventional endoscope video technology with an enhanced multichannel intervention system allowing two working instruments operated mechanically or robotically. The Master and Slave Transluminal Endoscopic Tool (MASTER) is a robotic endoscopic surgical system that introduces a two-channel endoscope with two slave robotic effectors possessing nine degrees of freedom. The system allows separation of the endoscopic control and instrument control to allow two operators to work together in tandem^[41]. The MASTER was originally developed for Natural Orifice Transluminal Endoscopic Surgery (NOTES) but has been tested in ESR in animal models with success^[42]. A trial of the MASTER system in ESR in human subjects was planned but results have not been published yet.

POTENTIAL FUTURE OF ROBOTIC COLORECTAL SURGERY

The ultimate aim of minimal access surgery is for surgery to be completed *via* natural orifices without any disruption to the normal functioning of the patient. Ultimately the development of nanotechnology may make this a reality but in the meantime the direction

of minimal access surgery is to further minimise access without compromising surgical outcome and to improve patient safety.

Advanced instrumentation

The Image-Sensing Navigated and Kinematically Enhanced (i-SNAKE) is an instrument delivered *via* a standard laparoscopic port. The distal end of the instrument possesses an articulated section carrying a camera, driven by a hybrid motor design, allowing a greater degree of flexion compared to cable actuators used in a conventional flexible endoscope^[43]. In addition, there are two flexible surgical arms driven by cables that can carry a range of instruments and there is an additional channel that allows an instrument to be passed through the articulated section. The three arms are delivered *via* a 15 mm trocar and the arms are extended once safely within the peritoneal cavity.

Flexible robots such as this are required to operate in highly angulated positions while maintained sufficient control to allow careful dissection and to produce enough force to manipulate tissue. The i-SNAKE can retroflex completely, allowing tubal ligation from a vaginal NOTES approach^[44]. The suitability of the platform for conducting intraluminal interventions such as ESR and Per-Oral Endoscopic Myotomy have been assessed^[45] and it is would be anticipated that this technology could be used to augment SPLS and intraluminal colorectal interventions.

Haptic feedback

Haptic feedback describes the conveying of information from the robotic effector, now also functioning as a receptor, back to the surgeon. The aim is to provide "transparency", where the surgeon feels that they are contacting the patient directly, rather than *via* a robotic mechanism^[46]. To achieve this level of feedback requires transmission of information regarding temperature, texture, force and vibration, and may not be technically feasible. Other industries make use of limited forms of haptic feedback, but surgery offers the unique challenges of size limitation, sterilisability and cost implications over existing technology. An economical approach would be to modify existing technology with feedback sensors and effectors^[47], but this may make integration with complex technology such as the DVR challenging.

Colorectal surgery demands soft tissue differentiation, the careful manipulation of tissues and suturing, all of which benefit from haptic feedback. The TELELAP ALF-X (SOFAR) is a surgical robot that offers haptic feedback in a smaller package compared to the DVR^[48]. The TELELAP ALF-X provides haptic feedback by exerting forces on the surgeon's hands- this requires a complex system of processors and actuators to achieve adequate fidelity and is therefore inherently complex. An alternative approach would be to relay haptic information to the surgeon by an auditory or visual representation of force feedback. Lab studies

have demonstrated that color-coded visual display of stitch tension improves consistency in tension applied to ligatures^[49,50].

To provide haptic feedback in the seven degrees of freedom that the DVR offers would be even more challenging. Given the wide uptake of the DVR it may be unlikely that institutions will invest in another robot simply to take advantage of haptic feedback when the surgeon feels it may be helpful. Therefore a successful haptic feedback system would most likely have to be integrated with the DVR, or operate in parallel with it.

A force-sensing adaptor for the Da Vinci Robot has been developed with some success in lab testing but there are no data from *in vivo* tests^[51]. A wireless palpation probe is an alternative that could be used both in robotics and conventional laparoscopic surgery. This battery operated unit can be introduced *via* a port and used to measure indentation pressure and depth in order to characterise tissues. Initial porcine studies used the probe to serially palpate a porcine liver to produce a "stiffness map" that could be used to guide subsequent resection^[52].

Tactility

Open surgery offers a uniquely tactile experience that is significantly dampened by minimally invasive surgery. Haptic feedback may offer some gross information on tissue resistance, but not the degree that the surgeon requires for accurate tissue differentiation. The technology to provide tactile transparency does not currently exist and may not do so for some time due to the technical complexity of detecting, processing and displaying such information.

Instruments for the detection of gross tactile information in minimal access surgery have been developed and tested in order to locate arteries and detect blood flow, in identifying the inferior mesenteric artery for example. The tools, such as TactArray (Pressure Profile Systems) carry multiple pressure sensitive receptors that may be applied to the tissues producing graphic representations of the tactile feedback detected^[53]. An alternate approach would be to use intracorporeal Doppler ultrasonography as a proxy to assess the tissue instead or relying on tactile feedback. This has already been demonstrated in laparoscopic nephrectomy^[54] but has not been utilised in colorectal surgery.

Capsule endoscopy

Diagnostic capsule endoscopy has proven itself as a diagnostic modality and is already in widespread use. Further development of this technology in the future will look to expand its diagnostic and therapeutic possibilities. Wireless capsule endoscopy is limited by the lack of a conventional insufflation system and the resultant lack of bowel distension limits diagnostic capability. Preliminary studies have demonstrated the feasibility of a wireless insufflation capsule utilising liquids or powders to produce gaseous insufflation^[55]. There have been no published results from animal

studies but this demonstrates the widening functionality of capsule intervention.

As capsule endoscopes become more complex they will become limited by their power storage capacity. Complex luminal processes such as delivery of topical chemotherapy, brachytherapy or treatments for inflammatory bowel disease may require capsules to remain inside the body for a prolonged period of time. Therefore an alternate source of power may be necessary. Magnetic induction offers a method of transmitting power to a device within the body from an external charger over a prolonged period of time without causing deleterious effects^[56].

Micro- and nanotechnology

Nanotechnology offers opportunities to investigate and intervene at the cellular level and may ultimately lead to a step change in the conduct of colorectal surgery over the next fifty to one hundred years. Currently machine actuators limit the minimum size of machines to a few millimetres- too large to be injected into the circulation for example, but alternative avenues for micro-interventions have been investigated.

Minimally invasive biopsy retrieval has been demonstrated using "micro-grippers". These tools possess minuscule biopsy tools that close in response to a change in temperature and are also composed of a ferromagnetic alloy. These tools were injected into the common bile duct during an endoscopic retrograde cholangiopancreatography in a live porcine model, allowed to sit for ten minutes to allow the grippers to close in response to change in temperature before being retrieved by a catheter with a magnetic tip^[57]. The retrieved tissue was assessed and deemed suitable for cytological analysis. Potentially this technology could be adapted for use as a non-invasive diagnostic aid in colonic conditions such as inflammatory bowel disease.

Nanobot technology in medicine aims to deliver therapy at the cellular level and may have particular importance in the treatment of cancers. Mechanical actuators and processors are not viable at this scale and therefore the robots are genetically engineered bacteria that allow cellular-level interactions, containing ferromagnetic granules that allow steering and propulsion using magnetic fields. Microbot technology and its application in medicine are likely to radically change how we view therapeutics. The ranges of possible applications include targeted therapy, material removal, deployment of structures, such as stents and telemetry^[56]. Although currently in its infancy, this aspect of robotic technology has the greatest potential to revolutionise how we manage colorectal pathology in the future.

CONCLUSION

The development of minimal access surgery has spurred the creation of robotic assistance in order to aid surgeons to overcome the shortcomings of this surgical technique. The breadth of robotic advancement

considered in this review demonstrates that robotic colorectal surgery has advanced far beyond its original brief of surgeon assistance. The potential advancements within this field will allow utilisation of minimal access surgery in a wider range of increasingly technically challenging environments and could fundamentally change the way surgeons manage their patients.

Abstract

Chronic radiation proctopathy (CRP) is a troublesome

complication of pelvic radiotherapy. The most common presentation is rectal bleeding. CRP symptoms interfere with daily activities and decrease quality of life. Rectal bleeding management in patients with CRP represents a conundrum for practitioners. Medical therapy is ineffective in general and surgical approach has a high morbidity-mortality. Endoscopy has a role in the diagnosis, staging and treatment of this disease. Currently available endoscopic modalities are formalin, potassium titanyl phosphate laser, neodymium:yttrium-aluminum-garnet laser, argon laser, bipolar electrocoagulation (BiCAP), heater probe, band ligation, cryotherapy, radiofrequency ablation and argon plasma coagulation (APC). Among these options, APC is the most promising.

Key words: Endoscopic treatment; Radiation proctopathy; Proctitis; Argon plasma coagulation; Cryotherapy; Radiofrequency ablation; Formalin; Laser; Bipolar probe; Pelvic radiotherapy

Core tip: The objective of this review is to critically analyze the available data and our experience with this disease, with suggestions for daily practice and further research. In our view, laser treatment is an obsolete technology and can be abandoned. The bipolar probe (BiCAP) is very well indicated for patients with implantable electronic devices. The best way to use formalin is still unknown. More studies with band ligation, cryotherapy and radiofrequency ablation are still needed. Argon plasma coagulation has emerged as the front-runner, due to its ease of use, affordability, better-defined settings, effectiveness and low risk of complications.

INTRODUCTION

Chronic radiation proctopathy (CRP) is recognized as injury to the rectum and/or colon due to radiotherapy for the treatment of pelvic malignancies; it occurs when clinical symptoms persist or appear months to years after therapy (median 6-12 mo). The sigmoid colon may also be affected^[1,2]. The term radiation proctitis is a misleading term since epithelial damage to the rectum due to radiation is associated with minimal or no inflammation^[1,3]. Cancers of the cervix, prostate, rectum, bladder, testicles and uterus are commonly treated with pelvic irradiation. Among these, prostate malignance is the most frequent^[1].

The incidence of CRP has yet to be ascertained due to the lack of prospective studies and variability in the definition and classification systems used for the condition^[1,2]. However, it is estimated to range from 2% to 20%^[3,4]. The method of radiation delivery is an important predictor of the risk for radiation proctopathy^[2,5]. The rate of colorectal complications with brachytherapy is lower compared to external beam radiation^[6]. The use of newer conformal radiation therapy techniques maximizes the dosage directed to the tumor while minimizing the dosage of radiation to the rectum^[6,7]. CRP may be more frequent in patients with inflammatory bowel disease, diabetes, hypertension or peripheral vascular disease and in those who develop severe acute proctopathy^[2].

CRP should be suspected in patients who develop symptoms such as diarrhea, urgency, tenesmus or bleeding, usually 6 mo or more after pelvic radiation exposure. Hematochezia occurs due to oozing from a friable, ischemic mucosa, and the rupture of radiation-induced telangiectasias and can lead to anemia and the need for blood transfusions^[1-3,8]. Symptoms are non-specific and the diagnosis requires exclusion of other etiologies of colitis^[3,4]. Diagnosis can be confirmed by colonoscopy or sigmoidoscopy^[7]. Endoscopic findings of CRP are mucosal pallor, telangiectasias, spontaneous hemorrhage, edema and friability. Less frequent findings are ulcers, strictures and fistulas^[9]. A scoring system has been developed for the endoscopic evaluation of radiation proctopathy severity, based on three factors: The presence of fresh blood, the telangiectasia distribution and the surface area involved^[10]. Although biopsies are not diagnostic, they can rule out other causes of proctopathy such as inflammatory bowel disease or infection and can grade the mucosal damage^[11,12].

TREATMENTS FOR CRP

In patients with CRP, the management should be based upon the severity and pattern of symptoms and experience within the treatment center^[13].

Therapy for CRP includes medical, endoscopic and

surgical therapies. Medical therapy includes: Use of non-steroidal anti-inflammatory drugs, sucralfate, short chain fatty acids, metronidazole, pentoxifylline, vitamins (A, C and E), and hyperbaric chamber treatment; all have been described with limited success. In a small study, vitamin A also showed some benefits on functional symptoms^[14], although the effect of retinol on rectal bleeding was not evaluated^[15]. Enemas of sucralfate are safe and well tolerated and have become the best medical therapeutic option^[7,15,16].

The management of patients with symptomatic CRP remains essentially empirical because there are only a few randomized trials, in addition to the difficulty of grading symptoms, endoscopic severity and response to therapy. However, some concepts regarding the management of these patients have been suggested: Treatment for hematochezia is in general better if it involves a sclerosing agent or a topical cautery to obliterate telangiectatic mucosal vessels; non-steroidal anti-inflammatory drugs have a limited role in treatment; large rectal ulcers, strictures, fistulas, abscesses and intractable bleeding generally require surgical management^[1,15]. However, surgical therapy has high morbidity and mortality rates^[16].

ENDOSCOPIC TREATMENTS FOR CRP

The main objective of endoscopic therapies of CRP is to achieve control of blood loss, leading to improvements in quality of life by reducing the requirement for blood transfusions, iron replacement and hospital admissions, resolving anemia and hematochezia^[10,16]. Endoscopic therapy using potassium titanyl phosphate (KTP) laser, argon laser, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, BiCAP, heater probe, endoscopic band ligation (EBL), cryotherapy, radiofrequency ablation (RFA) and argon plasma coagulation (APC) have been reported^[15,16]. Formalin is a miscellaneous technique with aspects of medical and endoscopic approaches. However, Cullen *et al*^[17] described instilling formalin into the rectum during flexible sigmoidoscopy, and it shall be included in the endoscopic treatment group. Endoscopic treatment can also be used for radiation-related strictures^[7].

Formalin therapy

Formalin therapy for CRP is based on its use in patients with hemorrhagic cystitis^[18]. Since Rubinstein's work, in 1986, reported the first successful CRP treatment using a rectal wash with formalin, many authors have published on the treatment of hemorrhagic CRP using this therapy^[19]. Formalin functions as a local sclerosant and causes chemical cauterization of telangiectasias.

According to an email survey with members of the American Society of Colon Rectal Surgeons, formalin is the most popular method to treat CRP. Of the 327 respondents, 85% favored to formalin, while 42% used APC. Only 25% of practitioners reported using sucralfate (more than one modality could be chosen)^[20].

Success rates vary from 27% up to 100%^[16-23]. This

difference can be explained by the wide variability in application technique and concentration^[21]. Formalin can be administered as an enema, irrigation in small aliquots, or soaked pledgets of cotton wool applied under rigid sigmoidoscopic, proctoscopic or flexible endoscope guidance^[17,22]. Sedation may be needed, but because of pain due to the procedure, most authors reported the use of general anesthesia for this procedure. Formalin therapy can be repeated for two or three more applications until symptomatic improvement, especially with the cessation of rectal bleeding. Ulcers due to formalin application preclude repeating the procedure^[18].

Patel *et al.*^[19], in a retrospective study, evaluated the combination of oral vitamin A with formalin application. The addition of vitamin A led to a significant decrease in the number of formalin sessions and a significantly shorter time for resolution. Supplementation with vitamin A also has a better success rate in controlling rectal bleeding than formalin alone (94% vs 64%).

There are also two small studies comparing formalin with APC. Yeoh *et al.*^[21] suggested that formalin and APC had similar success in managing hemorrhagic CRP. Nevertheless, Alfadhli *et al.*^[22] concluded that APC was significantly more effective (78.5% vs 27.2%, $P = 0.017$) and safer ($P = 0.001$) than formalin.

The advantages of formalin application include low cost, wide availability and good efficacy in general^[23]. Despite this, high rates of complications have been reported, including chemical colitis, anorectal pain, anal and rectal strictures, rectal perforation, fissures, incontinence and diarrhea^[16,18]. Further studies are needed to determine the optimal method of delivery.

Laser therapy

Lasers cause thermal destruction by tissue absorption of laser light and have been used to coagulate radiation proctopathy related vascular lesions in small retrospective series. The KTP laser, the Nd:YAG laser and the argon laser have been effectively used for CRP. A laser fiber is advanced into the working channel of a regular endoscope and is activated by the endoscopist, generating several laser pulses. The depth of thermal effect is dependent on the duration of pulses, power setting and light wavelength. Multiple sessions are generally required. Laser therapy usually decreases rectal bleeding, transfusion dependence and the frequency of hospitalization^[24,25].

Complications secondary to deeper thermal injury, which include strictures, transmural necrosis, perforations and fistulas, occur in up to 15% of patients. Intervals between sessions of at least a few weeks and using the least amount of energy for ablation are recommended to avoid complications^[26].

Chapuis *et al.*^[24] described the combination of formalin and Nd:YAG laser in 34 patients with CRP. The patients underwent an endoscopic Nd:YAG laser session and then were treated with formalin application. The authors reported that bleeding ceased in 25 patients

(74%) with no major complications.

Compared with other ablative devices, lasers are unwieldy and far more expensive. Other considerations include availability, safety issues and limited portability^[25]. The use of lasers in the treatment of CRP has declined^[27].

Heater probe and BiCAP - contact therapy

BiCAP and heater probe are contact methods for CRP treatment. The heater probes have Teflon-coated heating components at the extremity of a plastic catheters that deliver standardized energy over set times. The BiCAP probes have pair of electrodes (negative and positive) at its end through which current is passed using the tissue as a conduction surface^[3,16]. No current is passed through the tissues to either a distant or local electrode; for this reason, the induced electromagnetic field is insignificant^[28]. Both devices are directed in the setting of active bleeding^[16]. In contrast to BiCAP, heater probe mucosal injury is based on direct heat application rather than electrical current. Both probes have an irrigation port^[25].

The heater probe and BiCAP have advantages. They cause less tissue injury (in comparison to laser therapy), permit tangential application of cautery, and are both relatively inexpensive and widely accessible^[11]. They are also considered the best methods to use in patients with electronic devices, such as pacemakers and defibrillators^[28]. The disadvantage of both methods is char formation on the tip of the probe, requiring catheter retrieval and repeated cleaning^[7,11,16].

In a randomized prospective trial by Jensen *et al.*^[29], 21 patients with chronic recurrent hematochezia and anemia due to CRP were followed for 12 mo. Nine patients were treated with heater probe and 12 with BiCAP (power of 10-15 W). A median of four sessions was required. Severe bleeding episodes were significantly reduced after BiCAP (75% vs 33%) and heater probe (67% vs 11%) treatment without a statistically significant difference between the methods. The decreased rate of bleeding was accompanied by hematocrit improvement in both groups. There were no major complications.

A retrospective study evaluated 55 patients treated with three sessions of BiCAP (power of 30 W) and sucralfate enemas. The authors concluded that BiCAP was effective in stopping bleeding from telangiectasias, decreasing recurrence, hospital stay and blood requirements (especially in the group of more severe patients). Unfortunately, there were no comments about complications and follow-up in this study^[30].

We recently published a prospective randomized trial comparing APC and BiCAP for rectal bleeding due to CRP. Fifteen patients were enrolled in each group. BiCAP was performed using a 7Fr Gold probe (Wilson-Cook, Winston-Salem, United States) and a high frequency generator (ERBE ICC 200; Electromedizin, Tübingen, Germany). The power setting was 50 W. Coagulation was achieved by applying light pressure with the

probe directly into each telangiectasia. Success was considered as the eradication of all abnormal vessel, and failure as the requirement for more than seven sessions or the need for other therapeutic modality. The complete eradication success rate was 93.3% for BiCAP after a mean of 2.9 sessions, vs 80% at 3.7 sessions for APC ($P > 0.05$). Ten of 15 (66.7%) patients had minor complications, mainly transitory anal and abdominal pain. One developed symptomatic stenosis (successfully managed with a fecal emollient). Five patients presented major or hemorrhagic complications (two patients had both minor and major complications). There were no statistical differences between the groups regarding complications when categorized as major ($P = 0.169$) or minor ($P = 0.068$). Nevertheless, the total rate of complications was significantly higher in the BiCAP group ($P = 0.003$, with power 97.4%). No other more severe adverse events, such as fistulas, extensive necrosis, bowel explosion or perforations were noticed in this study. The frequency of complications was evidently superior than those reported so far. Many potential factors can account for such a difference: Most prior studies have been retrospective and underestimated the real incidence of complications; in our study, BiCAP was used at a higher power setting; our patients had a meticulous follow-up; most of the complications were minor and all of them were managed on an outpatient basis. We concluded that APC and BiCAP are both effective for hemorrhagic CRP. There are probably no significant differences between the two methods. Even though, APC seemed to be safer than BiCAP in our study, further research with a larger sample size is necessary to assess complication rates and determines the best therapeutic choice^[31].

Endoscopic band ligation

Endoscopic band ligation (EBL) was introduced in 1986 and is currently considered the endoscopic method of choice for the prevention of esophageal varices bleeding^[32]. As far as we know, there is only one paper published on the use of EBL as a treatment for CRP^[33]. The authors reported one patient who had been treated with APC sessions with no success. EBL was performed with a gastroscope and a standard multiband ligation kit. Three bands were placed in the first session and two during the second session (interval of 20 d between the first and second sessions). The procedure was well tolerated. A lower gastrointestinal endoscopy 45 d after the completion of treatment showed no evidence of ongoing CRP^[33]. This was the first experience using this technique, and more data are needed to make further conclusions.

Cryotherapy

Cryospray ablation, similar to APC, is a non-contact therapeutic method by the application of liquid nitrogen or carbon dioxide gas at extremely cold temperatures^[8,16]. Cryoablation has been used to treat esophageal early cancer and high-grade dysplasia^[8].

Limited data exist on the efficacy of this technique for treating vascular lesions^[25]. In a few studies, endoscopic cryoablation was performed in patients with CRP^[34-38].

Cryotherapy is performed with a catheter passed through the working channel and its tip is positioned around 0.5 to 1.0 cm from the end of the scope. The spray is applied for 5 s directly onto the mucosa. The freeze/thaw cycle is repeated for a total of three series (total of 15 s) per involved area. A decompression tube with ports spanning the distal 35-40 cm is inserted over a Savary-like guide wire. Suction *via* the decompression tube is applied for the period of cryospray application to protect against over-insufflation^[8,35]. Despite this care, one patient was reported with a cecal perforation caused by malfunction of the decompression tube. For this reason, the procedure was adapted to reduce treatment time and carry out full colonoscopy after the cryotherapy for bowel decompression^[35]. Difficulties include the field of view with frosting of the lens, and management around the decompression tube. Using a friction-fit mucosectomy cap reduces the chance that the catheter will adhere to the surface and improves access to difficult areas^[39].

The required number of sessions ranges from one to four. In one study, the endoscopic score considerably improved, as well as hematochezia and rectal pain. Symptomatic improvement was observed in 80% of patients^[35].

The cryospray generators currently on the market are more cumbersome and less mobile than most APC and the radiofrequency units, and need maintaining a supply of liquid nitrogen, which lasts around 2 wk in the holding tank. Therefore, therapies for rare findings, mainly in a lower volume service, may be more difficult. One possible advantage of cryospray over the heat-generating ablative techniques is that colonic lavage is not required to reduce the probability of gas ignition. However, studies in animals showed that the depth of tissue destruction may be deeper with cryospray than that achieved by RFA, and it is unknown whether this could lead to fistulas, abscesses and strictures or whether cryospray is inherently less prone to such complications. Furthermore, the quickly expanding gas requires adequate venting, which may be difficult for proximal lesions in the sigmoid^[16].

Studies using cryospray for CRP remain experimental and anecdotal. These initial case reports support the use of cryotherapy for the treatment of CRP. In spite of this, there has been no prospective study comparing cryotherapy with other methods such as APC, regarding the durability of results, safety and efficacy. Supplementary research is required to confirm the superiority or even utility of cryospray^[16].

RFA

RFA is a newer endoscopic technique. The Halo RFA system uses two different types of probes with a closely spaced arrangement of electrodes, which thermally ablate tissue. The depth of injury (0.5-1 mm)

is dependent on the power, density and duration of contact. A generator connects to either a 360° Halo catheter or a 90° Halo catheter to provide circumferential or more focused ablation^[40]. The FDA (United States Food and Drug Administration) approved the RFA for the treatment of Barrett's esophagus and for gastric hemostatic applications. RFA reaches large areas in a superficial way, suggesting that analogous benefits could be applied in the rectum and colon^[41].

Recently, a number of studies have evaluated the safety and efficacy of RFA for CRP treatment^[40-45]. RFA is generally performed on outpatients using a single use Halo90 electrode catheter (BARRx/Covidien, Sunnyvale, United States) that is passed through a standard gastroscope. A gastroscope is used instead of a colonoscope because Halo devices are designed for a gastroscope, and because retroflexion is easier using a gastroscope, especially with the RFA catheter attached. During the ablation procedure, the Halo90 catheter is mounted in the 6 o'clock position (as opposed to the 12 o'clock location usually used for the ablation of Barrett's esophagus). To promote hemostasis, the coagulum in treated areas is not scraped off. The endoscope and device are removed for cleaning every eight applications in order to preserve electrode surface effectiveness for subsequent areas treatment. Ablations are performed about 1 mm proximal to the dentate line (to prevent sensory injury to the anal mucosa) and restricted to a short length (less than 6 cm to the dentate line). The procedure is repeated as needed until complete rectal mucosa ablation is achieved. Based on prior studies, an energy density of 12-15 J/cm² at a power density of 40 W/cm² was selected, which showed no transmural damage at these settings^[8,41,43].

Generally, the procedure is well tolerated with mild anorectal pain was reported in 12% of sessions. One of 39 patients presented with significant anorectal bleeding (endoscopic exam demonstrated arterial-like hemorrhage from a vessel in a shallow erosion at a place of excessive ablation) and was treated with a single hemostatic clip^[41]. After one or two RFA sessions, hemostasis was achieved with a significant decrease in clinical symptoms and an increase in the hemoglobin concentration^[8,41,43]. Thus, RFA seems to be safe and effective to treat CRP. The benefits of RFA include re-epithelialization with the prevention of rebleeding without stenosis and ulceration that may be more frequently observed in other thermal methods. The narrowly spaced bipolar array of the RFA catheter confines the radiofrequency energy penetration, restricting the RFA lesion to the superficial mucosa, in this manner avoiding deep tissue injury. In conclusion, RFA permits much broader areas of tissue to be treated at the same time compared to the point-by-point approach required with the bipolar or heater probes, or even with APC. Similar to APC, the equipment is transportable and can be utilized in different places. The BARRx units also deliver a consistent energy to the surface by using a well defined and a reproducible

ramp-up of energy. This diminishes the likelihood of over-treatment and operator-dependence that may lead to ulcerations or perforations^[16]. However, despite these theoretical advantages, some statements should be made before RFA is considered the treatment of choice for CRP. First of all, these studies were retrospective and conclusions are limited by the lack of a control group. They were also non-powered and even considering all published works, only a few dozen patients with CRP have been treated with RFA. Another important limitation is that no sigmoid or proximal rectal lesions were ablated, thus safety in those areas (with a thinner wall) remains uncertain. The cost of the RFA energy generator (applicable in only a few indications) and the price of the Halo catheter can be another drawback. Therefore, additional controlled studies are required to compare RFA to other therapeutic modalities for CRP.

APC

APC is a non-contact thermal method using ionized argon gas to deliver a monopolar high-frequency current, which efficiently coagulates tissue. APC is applied to tissue until a white coagulum appears, and then the endoscope and catheter are maneuvered in a vertical or circumferential linear pattern to coagulate additional tissue. The depth of tissue destruction is limited due to increased resistance and decreased current flow through coagulated tissue^[39]. Once the tip makes contact with the target tissue, it works as a monopolar probe and it can cause deeper damage. And contact between the tissue and tip may also result in the infusion of extraluminal or submucosal gas. Due to repeated contact with the mucosa, a coagulum may also develop on the extremity of the catheter, which needs intermittent removal of the probe for manual cleaning^[25].

The second-generation equipment (VIO/APC2) integrates numerous improvements over the first-generation device. The total effectiveness of the method was improved by 30% ± 50%, so lower power settings can be utilized to create the same thermal effects and, conversely, the same power settings may produce deeper and more extensive tissue injury than expected. Three different modes are now available on the apparatus: Forced, pulsed and precise. Forced mode provides continuous output and corresponds to the settings on the earlier system. Pulsed mode delivers an intermittent current with two alternative effects: Effect 1 pulses nearly every second with a higher energy output following each pulse, while effect 2 pulses around 16 times per second with a lower energy output *per pulse*. The latter may be preferred when superficial treatment of large surface areas is desired. Precise mode uses an integrated regulation system to control the flow. This results in a more superficial depth of damage compared to the other settings^[39].

APC has been used to treat a wide spectrum of bleeding lesions in the gastrointestinal tract^[25]. However, CRP is really a niche for APC^[46]. An impressive

number of studies evaluated APC efficacy and safety for the treatment of CRP, with more than 500 patients enrolled^[15,21,31,47-52]. Thus, APC is certainly the best-studied technique in the management of this disease. Nevertheless, until now, there has been no consensus regarding the best APC settings (gas flow rate and power). Power settings reported in the literature range from 25-80 W and flow from 0.6-2.5 L/min^[8,15]. Gheorghie *et al.*^[53] compared two different power settings: 23 patients were treated with 60 W and 19 patients with 50 W. They concluded that there was no statistical significance concerning the efficacy and safety of APC application between the 60 W and 50 W power setting, although rectal stenosis was described only in patients treated with the higher power setting. Sato *et al.*^[52] using a porcine rectal wall *ex vivo*, found that the optimal setting was 40 W with 1.2 L/min gas flow and a two-s application, which was enough to treat submucosal vessels but did not affect the muscle layer.

More spread lesions commonly need repeated applications per session and several treatments. The mean number of sessions varies from 1 to 3.7 with a calculated overall cumulative mean of 2.13 sessions per patient (median: 2)^[16,31]. APC session intervals range from every 2 d to every 8 wk^[15,16]. APC improves rectal bleeding in 80%-90% of cases as well as symptoms of tenesmus, diarrhea and urgency in 60%-75% of cases^[16]. Follow-up ranged from 2 to 60 mo^[15]. Recurrences have been reported, which responded to additional rounds of APC therapy^[16,31].

Ulcers after APC can be considered an effect of thermal injury to already damaged, compromised more fragile and tissue, with poorer healing. Ulcer incidence may be affected by the flow rate and power settings of the argon gas, way of application, interval between sessions, and number of sessions subsequent to ulcer development, which may delay ulcer healing due to repeated thermal damage. The fact that rectal ulcers are not clinically problematic denotes they should not be considered a complication or an absolute contraindication to APC, nor do they necessarily need any further endoscopic follow-up^[16,54]. However, it is advisable that in the presence of a large ulcer (> 1.0 cm), treatment should be delayed.

The overall reported complication rate with APC has been variable^[16], probably due to the lack of a standard technique, variation in the criteria for defining complications and different follow-up periods. The most common procedure-related complication is rectal or anal pain with or without tenesmus, which is most probable to occur following treatment near the dentate line, and habitually resolves spontaneously within a few days, with or without regular analgesics^[16,31]. A method described by Coriat *et al.*^[55], using a transparent cap attached to colonoscope tip, improved visualization of the upper part of the anal canal and of low rectal lesions without retroflexion and a proper distance for safe and effective APC use. Vagal symptoms, cramping and

abdominal bloating related to luminal distension have also been reported. One potential drawback of using APC is the risk of excessive bowel distention from the quick instillation of argon gas. It is recommended that, whenever available, a two-channel endoscope should be utilized so that the insufflated argon gas can be removed periodically, associated with a low flow rate^[16].

Overall, the frequency of asymptomatic rectal strictures is 4.3%^[16]. Although some eschew treating in a circumferential manner to avoid stricture formation, the results of Villavicencio *et al.*^[56] seem to indicate otherwise. It is likely that the long trawl back technique is more associated with rectal strictures than single-shot procedures with separated spots^[57-59]. Ben-Soussan *et al.*^[59] reported three cases of colonic explosion in two poorly prepared patients. The pathophysiology of the explosion remains unclear but an accumulation of bowel gas (methane and hydrogen) at potentially explosive concentrations due to poor preparation could be the cause. Theoretically, intestinal gas production could also be influenced by the presence of fermentable products in the administered enema. In the Ben-Soussan study^[59], the enema used (disodium phosphate and monosodium phosphate) did not contain any fermentable agent likely to increase gas production and facilitate colonic explosion. Thus, these authors concluded that rather than the type of preparation, the presence of stools above the telangiectasias constituted the main risk. In our previous study, we also used enema preparation before the APC session and did not encounter any colonic explosions^[31]. As far as we know, no other explosions have been recently reported in the literature.

Bacterial translocation of endogenous microbial flora into the bloodstream may occur during any endoscopic procedure. We prospectively evaluated the frequency of bacteremia following APC during CRP treatment. A total of 21 patients were included and 30 APC sessions were performed. Bacteremia was found in two patients (6.67%). In one case, the isolated bacterium was *Staphylococcus hominis*, and regarded as a contaminant. Another patient had two different microorganisms (*Rhodotorula sp.* and *Streptococcus bovis*). None had infectious symptoms^[50].

There are few comparative studies using APC. One of them compared two different power settings^[53] and the other compared oral sucralfate with placebo following APC; the authors stated that additional sucralfate treatment did not influence clinical or endoscopic outcomes^[49]. Only four studies have compared APC with other therapy for CRP. Two compared APC with formalin (vide formalin section)^[21,22], one with hyperbaric oxygen^[48] and our study assessed APC vs BiCAP (see contact method)^[31]. The results of these preliminary studies show that APC is at least as effective and safer than other treatments. However, more comparative studies with larger series, especially between APC and the newest techniques (RFA and cryotherapy) are needed for definite conclusions.

DISCUSSION

CRP is a troublesome complication with an adverse effect on quality of life. The most common complaint is rectal bleeding. Most available data come from uncontrolled, undersized studies with short-term follow-up. Satisfactorily powered, randomized trials comparing different modalities are lacking, and an optimal management strategy has yet to be determined.

Vitamin A had some benefits on functional symptoms, but has not been studied regarding blood loss. Sucralfate enema seems to be the best medical therapy and is well tolerated and secure^[15,16]. There is not enough data to support the use of other medical options in daily practice^[1-3,8]. Surgical management is associated with high morbidity and mortality and should be considered a last resort. Fewer than 10% of patients eventually require surgery, which is usually for intractable bleeding, perforations, strictures and fistulas^[6,7]. In this scenario, endoscopic treatment is becoming increasingly popular^[31].

Besides the therapeutic aspects, endoscopy plays a role in diagnosis and grading and in ruling out another sources of bleeding, especially malignancy^[3,4,11]. Full colonoscopy is recommendable for all patients with rectal bleeding. Due to the risk of fistula formation, rectal biopsies should be performed judiciously. If necessary, they should be directed to the lateral and posterior walls to avoid irradiated areas^[11].

Patients considered to be ideal candidates for endoscopic treatment are those with transfusion dependency, chronic hematochezia, refractory to medical management, no tumor recurrence, no other bleeding source, and no fistulas, ulcerations or strictures^[18]. It is still controversial that patients with occasional hemorrhage without anemia should be treated endoscopically. We think that at least one endoscopic session during the first diagnostic colonoscopy is a reasonable approach. Presumably, it will resolve once and for all these milder cases^[60]. Of course, this and subsequent treatments (if necessary) should be tailored to the patient's preferences.

Nowadays, we agree with other authors in advocating a four to 6 wk interval between sessions^[46,59,61]. It is likely that the ischemic rectal mucosa needs this minimal amount of time to recover from thermal or chemical injury^[1-3,8]. We agree with John Lee^[46] that repeating endoscopy is not necessary in the absence of symptoms.

Good bowel preparation is crucial for endoscopic therapy. We currently recommend complete anterograde bowel preparation for all treatment sessions. Because enemas can cause trauma to a friable mucosa, and many patients with CRP have fecal incontinence^[21], retrograde preparation may be more difficult and provide worse results. Because feces above the lesions are the main risk for bowel explosion^[59], in cases of poor preparation, the procedure should be postponed or vigorous washing must be done. In the presence of

significant oozing, adrenaline solution (1:10000) should be sprayed over the mucosal surface^[31].

Like other invasive procedures, there is a debate about antibiotic, antiplatelet and anticoagulant prophylaxis with endoscopic therapy for CRP. The current American Society for Gastrointestinal Endoscopy guidelines do not mention the use of antibiotics in this patient condition (CRP) nor in this procedure (endoscopic ablation)^[62]. Tam *et al.*^[57] suggested the use of antibiotics for immunocompromised patients before APC for CRP. Postgate *et al.*^[63] made this recommendation for all patients. However, in our study, the incidence of bacteremia after APC for CRP was low (6.67%), similar to the mean frequency of bacteremia associated with colonoscopy in the literature (4.4%). Therefore, APC for CRP may be considered a low-risk method regarding infectious complications, and does not demand the prophylactic administration of antibiotics^[50]. Unfortunately, until now, no other study like ours has been done with other endoscopic techniques for CRP. Chrusciewska-Kiliszek *et al.*^[47] suggested that antiplatelet drugs can play a protective role against ulcer formation after APC. In our study, we found a negative impact of antiplatelet medication, with a statistically significant higher number of APC sessions being required to eradicate telangiectasias in patients using aspirin ($P = 0.047$) (unpublished data). Kaassis *et al.*^[61] also reported a higher number of treatments in patients using anticoagulants. In the Karamanolis *et al.*^[64]'s study recurrence was higher in those using an anticoagulant or aspirin ($P = 0.02$). The present European Society of Gastrointestinal Endoscopy guidelines recommend that clopidogrel or aspirin can be continued in patients undergoing APC for vascular lesions (recommendation grade C). In the lack of appropriate studies, no recommendation can be made for patients taking a combination of thienopyridines and aspirin^[65].

Another issue is whether concomitant medical treatment improves the results of endoscopic treatment. Patel *et al.*^[19] demonstrated that adding vitamin A enhances the effectiveness of formalin application (see the section on formalin treatment). On the other hand, combined oral sucralfate for 4 wk with APC was not better than APC alone in improving the overall disease severity score (see APC section)^[49]. Two possible reasons for the absence of an effect of sucralfate are the short-term period of use and the oral route. Kochhar *et al.*^[66] identified a good response with enemas with a 77% response in 4 wk and 92% response in 16 wk. Studies using oral vitamin A and sucralfate enemas (or both) for longer periods in association with different endoscopic modalities are welcome, especially in patients with intractable bleeding.

Intractable bleeding is traditionally managed surgically. Nonetheless, when surgery is needed, most studies have demonstrated poor outcomes (because a diversion rarely controls the bleeding completely), as well as high complication (15%-80%) and mortality (3%-9%) rates^[6]. Therefore non-surgical strategies

are desirable. Some authors described the success of a second endoscopic modality when the first one had failed^[22,33,56,67]. So a cross-over (two endoscopic methods) or a combined (medical plus endoscopic treatments - see above) schemes may avoid surgery in some patients.

A variety of endoscopic techniques for treating CRP were evaluated and discussed in this review. The choice of treatment should be based on the availability and experience of each center^[13]. If there is more than one method at hand, some considerations can be made. Laser therapy is an obsolete technology and should be abandoned. Contact methods, especially BiCAP, are very well indicated for patients with pacemakers and other implantable devices. The best way to use formalin is still unknown. More studies with EBL, cryoablation and RFA are still needed. APC has emerged as the front-runner due to its ease of use, affordability, better-defined settings, efficacy and safety. Perhaps in the future, the results of the second generation APC device will improve further.

Abstract

AIM: To analyze outcomes in patients who underwent liver transplantation (LT) for hepatocellular carcinoma (HCC) and received autologous intraoperative blood salvage (IBS).

METHODS: Consecutive HCC patients who underwent LT were studied retrospectively and analyzed according to the use of IBS or not. Demographic and surgical data were collected from a departmental prospective main-

tained database. Statistical analyses were performed using the Fisher's exact test and the Wilcoxon rank sum test to examine covariate differences between patients who underwent IBS and those who did not. Univariate and multivariate Cox regression models were developed to evaluate recurrence and death, and survival probabilities were estimated using the Kaplan-Meier method and compared by the log-rank test.

RESULTS: Between 2002 and 2012, 158 consecutive patients who underwent LT in the same medical center and by the same surgical team were identified. Among these patients, 122 (77.2%) were in the IBS group and 36 (22.8%) in the non-IBS group. The overall survival (OS) and recurrence free survival (RFS) at 5 years were 59.7% and 83.3%, respectively. No differences in OS ($P = 0.51$) or RFS ($P = 0.953$) were detected between the IBS and non-IBS groups. On multivariate analysis for OS, degree of tumor differentiation remained as the only independent predictor. Regarding patients who received IBS, no differences were detected in OS or RFS ($P = 0.055$ and $P = 0.512$, respectively) according to the volume infused, even when outcomes at 90 d or longer were analyzed separately ($P = 0.518$ for both outcomes).

CONCLUSION: No differences in RFS or OS were detected according to IBS use. Trials addressing this question are justified and should be designed to detect small differences in long-term outcomes.

Key words: Cell saver; Cancer; Hepatocellular carcinoma; Liver transplantation; Recurrence

Core tip: This study addresses an alternative option for allogeneic blood transfusion during liver transplantation (LT) for hepatocellular carcinoma (HCC). The autologous blood salvage in LT, in our series, did not impact recurrence or death. This suggests that autologous blood transfusion should be considered an option avoiding the deleterious effects of allogeneic blood transfusion. Overall, we do believe that our data claim for trials looking for non-inferiority comparing the two modalities of blood transfusion in patients who underwent LT for HCC. We do believe that further studies are justified and should be designed to detect small differences in long-term outcomes.

Does autologous blood transfusion during liver transplantation for hepatocellular carcinoma increase risk of recurrence? *World J Gastrointest Surg* 2016; 8(2): 161-168 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i2/161.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i2.161>

INTRODUCTION

Autologous intraoperative blood salvage (IBS) is used routinely in many surgical specialties to minimize the effects of intraoperative bleeding, avoiding the risks of allogeneic red blood cell (RBC) transfusion. A recent cochrane review showed a 40% reduction in the requirements for allogeneic blood transfusion with cell salvage^[1]. IBS has been generally used in liver transplantation (LT), although it is not usually recommended in patients with hepatocellular carcinoma (HCC) since there is a putative risk of reinfusion of neoplastic cells. The IBS is an alternative to allogeneic blood transfusion but it remains a controversial technique in oncologic procedures since it could represent an uncertain risk of malignant cell reinfusion^[2-5].

The circulation of viable neoplastic cells in the IBS device and their detection in the leukocyte depletion filter (LDF) have been proved, and LDF has been used as an effective method to clean the RBC component before infusing it back^[5-9]. Although the rationale to use LDF to block neoplastic cells back by the IBS device has been investigated on experimental studies, the clinical relevance analysis over patients who underwent LT for HCC has been restricted to a single study^[5]. In the latter case, no differences were observed in recurrence between patients who received IBS and those who did not. However, it was not possible to rule out the possibility that this result was a consequence of a small sample size.

The aim of this study was to evaluate if the use of IBS for HCC patients who underwent LT increases the risk of tumor recurrence. To our knowledge, this is the largest series addressing this question in this population.

MATERIALS AND METHODS

Subjects and data collection

Patients submitted to LT for HCC at Hospital das Clínicas of University of São Paulo Medical School (HCFMUSP) were analyzed from a prospectively maintained database containing demographic, clinical, operative, pathological, and follow-up data and studied retrospectively. Permission was obtained from the informed consent statement and institutional review board according to the institutional policy for protected health information.

All patients presented in this analysis were initially considered to meet the Milan criteria or UCSF criteria^[10,11]. Patients who had detectable extra-hepatic disease during the pre- or intraoperative course and patients with a concurrent second neoplasm were not included. Patients who did not present HCC in the specimen were excluded with the exception of those previously treated with radiofrequency or chemoembolization. Pre-operative imaging modalities to evaluate the extent of intrahepatic disease and to exclude extra-hepatic metastatic sites included

computed tomography and/or magnetic resonance imaging of the chest, abdomen, and pelvis. Model of end-stage liver disease (MELD) scores were calculated using laboratory results collected prior to the LT. The MELD score was calculated using the standard UNOS formula: $MELD = 3.78 \times \ln(\text{bilirubin}) + 11.2 \times \ln(\text{INR}) + 9.57 \times \ln(\text{creatinine}) + 6.43$, where bilirubin and creatinine are in mg/dL units and INR is the international normalized ratio. The MELD score was analyzed separately as both continuous and categorical variables (*i.e.*, ≥ 20 vs <20).

The estimated blood loss was not fully available and thus it was not described and analyzed. The intraoperative decision to transfuse either allogeneic or autologous blood was consensual between the surgeon and the anesthesiologist. It was based on hemodynamic status, blood loss, hemoglobin concentration and patient's comorbidities.

Follow-up time was calculated from the date of LT to the date of last clinical encounter captured by the HCFMUSP medical record system or the date of death. Recurrence-free survival (RFS) was calculated from the LT to the first detected recurrence or last follow-up without recurrence. Overall survival (OS) was calculated based on the survivorship status (deceased or alive) at last follow-up.

Blood salvage processing

The blood from the surgical field was collected using a Cell Saver auto-transfusion device (Fresenius C.A.T.S, Terumo Cardiovascular Systems, Germany) and anticoagulated with heparinized saline and stored. The RBC component of aspirated blood was centrifuged and washed with heparinized saline. The RBC concentrates were filtered through an LDF (FTS-RC202, Shuangweibio Corp., Nanjing, China). Processed RBCs were transfused back to the patient when appropriate.

Statistical analysis

Statistical analyses were performed using the Fisher's exact test and the Wilcoxon rank sum test to examine covariate differences between patients who underwent IBS and those who did not. Values are expressed as median (interquartile) or percentage, as appropriate. Survival probabilities were estimated using the Kaplan-Meier method and compared using the Log-Rank test. A Cox regression model was developed to determine factors independently associated with death. The use of IBS was included in the multivariate analysis regardless of its univariate significance. Other factors that were significantly associated with outcomes by univariate analysis (inclusion criterion, $P \leq 0.1$) were entered into a multivariate analysis to test for significance of IBS adjusting for possible confounders. For recurrence assessment, no Cox regression was used since the number of events per variable was not appropriated^[12,13]. A P value < 0.05 was considered significant for univariate and multivariate analyses. All statistical analyses were conducted using STATA v 9.0

(Stata Corp, College Station, TX).

RESULTS

Between January 2002 and September 2012, 158 consecutive patients who underwent potentially curative LT for HCC were included. One hundred and twenty-two (77.2%) patients in the IBS group and 36 (22.8%) patients in the non-IBS group were compared. Patients and clinicopathological presentation were compared between groups and are summarized in Table 1. Briefly, the demographic and clinicopathological characteristics were comparable between the two groups. The only significant difference was the presence of liver cirrhosis, which was more prevalent in the non-IBS group (100% vs 84.8%, $P = 0.014$).

Survival analysis

The median follow-up time for all patients was 27 mo; 25 mo for the group who received IBS and 32 mo for the group who did not ($P = 0.049$). The median follow-

up time for survivors was 38 mo; 37 mo for the group who received IBS and recurred and 41 mo for the group who did not ($P = 0.017$). The estimated 3- and 5-year OS rates were 68% and 59.7%, respectively. When OS was adjusted for the use of IBS or not, no difference was detected ($P = 0.51$), as depicted in the Figure 1A. The univariate and multivariate analyses for death were performed and are shown in Table 2. Briefly, no differences were detected according to MELD either as a continuous variable (recurrence, $P = 0.633$; death, $P = 0.286$) or as binominal, as demonstrated in Tables 2 and 3. Only elevated Edmond-Steiner degree of tumor differentiation (III-IV) remained significant for the risk of death, as shown in Table 2. The estimated 3- and 5-year RFS rates were 87.7% and 83.3%, respectively. When RFS was adjusted for the use of IBS or not, no difference was detected ($P = 0.953$; Figure 1B). The univariate analysis for recurrence is shown in Table

3. Briefly, elevated Edmond-Steiner degree of tumor differentiation (III-IV), pre-operative alpha-feto protein level equal to or higher than 100 ng/dL and presence of microsatellite lesions were independent predictors of recurrence, as demonstrated in Table 3.

Regarding the group of patients who received IBS (122 patients), the infusion volume was additionally analyzed as a continuous variable, and no differences were found in either recurrence ($P = 0.512$) or death ($P = 0.055$), as demonstrated in Figure 2A and B. Analyses of outcomes at 90 d or longer were performed and no differences in recurrence ($P = 0.518$) or death ($P = 0.518$) were detected (Figure 2C and D).

DISCUSSION

The IBS is largely accepted as an option for blood transfusion. However, the contra-indications are based on

the use of contaminated blood as in chronic diseases like hepatitis or other viral infections, bile infection or colonization, and intra-operative contamination^[4,8]. The same rationale is applied to avoid tumor dissemination in patients with liver cancer already identified. Although this apprehension has been justifying its practice, no clear relation between the use of IBS and cancer recurrence has already been proved. Operations with high blood loss including cancer surgery have been demanding IBS use, however retrospective series did not show any suggestive association between the increase of recurrence and IBS use^[14].

Concerning HCC patients, IBS use was described in a few series for resection and LT. One series described no increase in recurrence with IBS, showing no differences in higher stages and even better results for patients who used IBS in early stage disease^[15,16]. Two series of LT, respectively, with 31 and 40 patients in the IBS groups vs 16 and 96 patients as control group, were described^[17,18]. Despite the theoretical risk of tumor cell

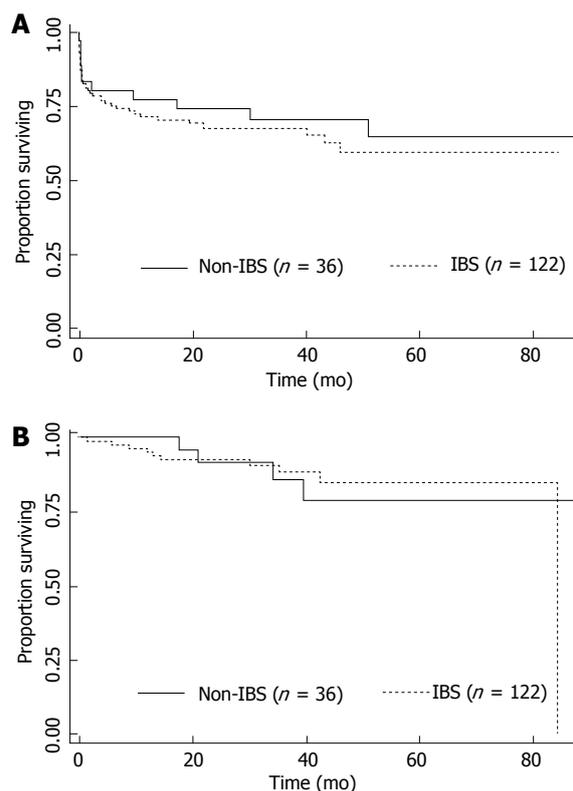

Figure 1 Kaplan-Meier estimates of survival from the date of liver transplantation according to the use of autologous intraoperative blood salvage. A: Overall survival ($P = 0.51$); B: Recurrence free survival ($P = 0.953$). IBS: Intraoperative blood salvage.

dissemination, the recurrence rates were not increased by IBS use in both series^[17,18].

The purpose of our study was to compare long-term outcomes for patients undergoing LT for HCC who received IBS or not. In our study population, the groups were comparable except for the remarkable presence of cirrhosis in the IBS group. As expected, patients with cirrhosis are technically challenging and the blood loss is usually elevated, more justifying IBS. With regard to oncologic outcomes, the use of IBS or not was not significantly associated with recurrence or death. The predictors associated with recurrence were presence of satellite lesions and elevated Edmond-Steiner tumor degree. This was also an independent predictor of death in the multivariate model. The principal finding of this study is that in a large patient population from a single institution there were no measurable differences in outcomes based on the IBS use for patients who underwent LT for HCC.

Regarding only the IBS group, differences in the volumes infused were associated with death but not with recurrence, as depicted in Figure 2. The volume infused changed when the time point of 90 d was used. In the earlier period, higher volumes were associated with death but not with recurrence. This performance translates the IBS volume as surrogate of estimated blood loss, which is an independent predictor of mortality and transfusion as well^[19]. Patients in the earlier

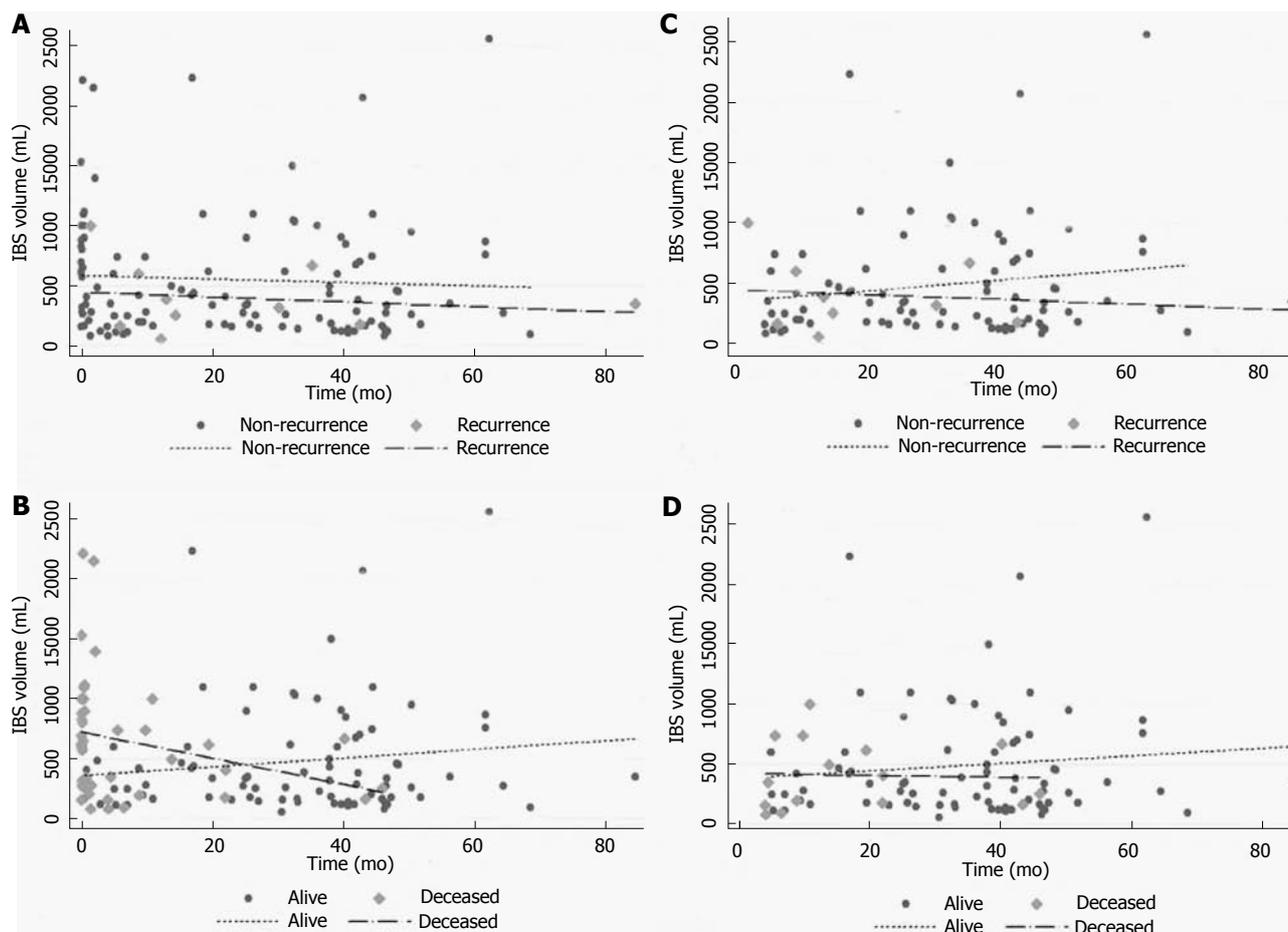

Figure 2 Scatter plots of the infusion volume of autologous intraoperative blood salvage over time. Overall distribution (total, $n = 122$) according to the time for recurrence (A: Recurrence, 10/91) and death (B: Death, 41/92). Distribution at 90 d and longer according to the time for recurrence (C: Recurrence, 9/91) and death (D: Death, 15/92). IBS: Intraoperative blood salvage.

period died in a short follow-up period and they could not have presented recurrence. With regard to longer follow-up (90 d or longer), the IBS volumes fit similarly for the distribution of recurrence or death. Long-term outcomes were not affected for the IBS volume in our series.

The limitations of the study are those associated with the immeasurable biases seen in all retrospective studies. We recognize that selection bias based on several nonobjective, undocumented criteria may have contributed to some of the differences between the two study groups. The estimated blood loss was not fully available and thus it was not described or analyzed.

The major finding of this analysis is the lack of any association between the use of IBS and oncologic outcomes. The results of this study should not be misinterpreted as an endorsement for the IBS use for all cancer patients. On the contrary, our data claim for more translational and clinical investigations of this issue. The operative hemorrhage in LT remains significant and blood transfusion is often demanded. The IBS should be applied as much as necessary, however the rationale of tumor cell reinfusion is a common concern^[4,14,17,18,20-22]. Studies *in vitro* and retrospective series suggest that the use of LDF is effective enough

to avoid tumor cell recirculation^[5-7]. We believe that this finding is convincing and perhaps it is a reasonable explanation for no differences in recurrence or death in our series, since the LDF was used in all cases.

Moreover, a recent meta-analysis, including only non-randomized trials, showed an increase of risk for death and recurrence in patients with HCC who received allogeneic blood transfusion during hepatic resection^[23]. Patients in the allogeneic group had a 16% more chance of recurrence at 5 years as well as a 60% more chance of all-case death in the same period. The reasons for the worse outcomes remain uncertain but it has been assumed that suppressive effects in the host immune system may have been responsible. The postulated mechanisms are allogeneic mononuclear cells; leucocytes-derived soluble mediators; and soluble HLA peptides circulating in allogeneic plasma inducing the host immune suppression^[24]. These effects could be prevented by the autologous transfusion^[24].

In summary, the present study shows that in a large consecutive series of patients undergoing LT for HCC in this single institution, there were no measurable differences in RFS or OS between patients who received IBS or not. With the lack of randomized clinical trials comparing the use of IBS for oncologic patients, its use could

be considered a reasonable option for individualized patients. Based on these data, a trial looking for no inferiority comparing the use of IBS and conventional blood transfusion for LT for HCC is justified and should be designed to detect small differences in outcomes.

COMMENTS

Background

Blood transfusion is usually necessary for liver transplantation (LT). Intraoperative blood salvage has generally been used in LT to avoid deleterious effect of allogeneic blood transfusion. However, autologous blood transfusion has not been recommended in patients with hepatocellular carcinoma (HCC) since there is a putative risk of reinfusion of neoplastic cells.

Research frontiers

Although there is a putative risk of reinfusion of cancer cells into circulation during surgery, there is no data yet demonstrating that it would really impact on oncologic outcomes. This study did not demonstrate impact on clinical and oncologic outcomes. However, since the data are retrospective, our finding claims for trials looking for no inferiority comparing the two modalities of blood transfusion in patients who underwent LT for HCC, to detect small differences in outcomes.

Application

This study addresses an alternative option for allogeneic blood transfusion during LT for HCC. The autologous blood salvage in LT, in this series, did not impact recurrence or death. This suggests that autologous blood transfusion should be considered an option avoiding the deleterious effects of allogeneic blood transfusion.

Innovations and breakthroughs

The use of intra-operative blood salvage would have immunological and economic impact during postoperative course. Circulating cancer cells were already demonstrated, however it also seems that leucocyte filters are safe enough to block those cells. Then, the use of auto-transfusion devices associated with leucocytes filters seems to be a potential resource to help patients who undergo LT for HCC

Terminology

IBS: Autologous intraoperative blood salvage; HCC: Hepatocellular carcinoma; LDF: Leucocyte depletion filter; LT: Liver transplantation; MELD: Model of End-Stage Liver Disease; OS: Overall survival; RFS: Recurrence free survival; RBC: Red blood cell.

Peer-review

Autologous IBS is generally used in liver transplantation to minimize the effect of intraoperative bleeding. However, the peripheral blood of HCC patients may be contaminated with cancer cells or cancer-inducing virus, which can lead to potential risks of recurrence. In this study, authors investigated the association between the intraoperative use of IBS and survival of HCC patients. According to the data of a postoperative follow-up cohort, they reported that the use of IBS cannot influence the survival of HCC patients. This is an interesting study and is useful for clinicians.

Abstract

A 26-year-old woman was referred to our hospital because of abdominal distention and vomiting. Contrast-enhanced computed tomography showed a blind loop of the bowel extending to near the uterus and a fibrotic band connecting the mesentery to the top of the bowel, suggestive of Meckel's diverticulum (MD) and a mesodiverticular band (MDB). After intestinal decompression, elective laparoscopic surgery was carried out. Using three 5-mm ports, MD was dissected from the surrounding adhesion and MDB was divided intracorporeally. And subsequent Meckel's diverticulectomy was performed. The presence of heterotopic gastric mucosa was confirmed histologically. The patient had an uneventful postoperative course and was discharged 5 d after the operation. She has remained healthy and symptom-free during 4 years of follow-up. This was considered to be an unusual case of preoperatively diagnosed and laparoscopically treated small-bowel obstruction due to MD in a young adult woman.

Laparoscopic surgery for small-bowel obstruction caused by Meckel's diverticulum. *World J Gastrointest Surg* 2016; 8(2): 169-172 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i2/169.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i2.169>

INTRODUCTION

Meckel's diverticulum (MD) is one of the most common congenital anomaly of the gastrointestinal tract that results from an incomplete obliteration of the omphalomesenteric duct^[1,2]. It has an incidence of 1%-2% among the general population, and most cases remain asymptomatic^[2]. The rate of developing complicated MD is reported to be about 4% throughout lifetime^[3], which comprises bleeding, inflammation or obstruction.

Intestinal obstruction may occur in cases where there is a volvulus or an internal hernia around a diverticulum, intussusception, or incarceration of the diverticulum in an inguinal (Littre) hernia^[1]. However, as its symptoms, such as abdominal pain, distention, vomiting or constipation, are so non-specific, it may be difficult to make a correct diagnosis, and exploratory laparotomy is often required.

Here we report a case of small-bowel obstruction caused by MD that was diagnosed preoperatively using multi-dimensional contrast-enhanced computed tomography (CECT) and treated by elective laparoscopic surgery.

CASE REPORT

A 26-year-old woman was admitted to our hospital complaining of abdominal pain and recurrent vomiting. She had been hospitalized because of ovarian hyperstimulation syndrome 2 years previously, and had also suffered an episode of small-bowel obstruction 1 year prior to admission, which had been diagnosed as food impaction. She had no episode of hematochezia.

Physical examination demonstrated abdominal distention, with a soft abdomen and no tenderness or rebound pain. Her bowel sounds were hyperactive. Results of a hematologic examination were normal, and a urine pregnancy test gave a negative result.

Abdominal plain X-ray examination demonstrated a ladder-like series of distended small-bowel loops (Figure 1). Multi-dimensional CECT showed a blind-ending U-shaped loop of bowel in the pelvis and a fibrotic band connecting the mesentery to the blind end of the bowel, suggesting MD and a mesodiverticular band (MDB) (Figure 2). A change in the caliber of the ileum was

Figure 1 Abdominal plain X-ray examination demonstrated a ladder-like series of distended small-bowel loops.

Figure 2 Contrast-enhanced computed tomography (coronal section image) showing a blind loop of the bowel extending near the uterus (arrowhead) and a fibrotic band connecting the mesentery to the top of the bowel (arrow) suggesting Meckel's diverticulum and a mesodiverticular band. The terminal ileum appeared to be conglutinated to the band and a change in caliber was ascertained.

evident adjacent to the band.

We diagnosed the patient as having small-bowel obstruction, probably caused by adhesion to the MDB of MD, without any sign of vascular compromise.

A long tube was placed and her small intestine was successfully decompressed. After the tube had been removed, scintigraphy with 99mTc-Na-pertechnetate was performed, and this revealed uptake in the lower abdomen (Figure 3).

Although surgical treatment was proposed, the patient expressed a wish to temporarily leave hospital because of pressing business matters. She was therefore discharged after 1 wk of hospitalization.

Two months after discharge, we performed elective laparoscopic surgery using three 5-mm ports. MD was dissected from the surrounding adhesion and MDB was divided intracorporeally. Then subsequent Meckel's diverticulectomy was performed extracorporeally *via* a 2 cm mini-laparotomy. The postoperative course was uneventful and the patient was discharged on postoperative day 5, and she has since remained healthy and symptom-free during 4 years of follow-up.

Histological examination confirmed the presence of

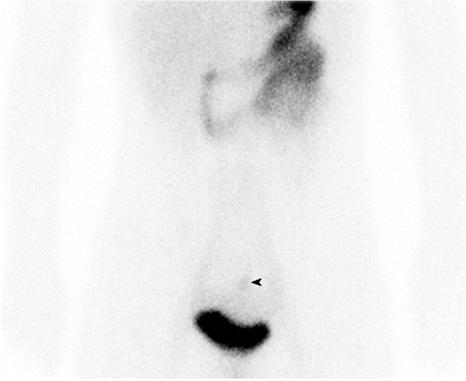

Figure 3 ^{99m}Tc -Na-pertechnetate revealed uptake in the lower abdomen (arrowhead).

a MDB (Figure 3) and heterotopic gastric mucosa in the mucosa of the diverticulum (Figures 4 and 5).

DISCUSSION

MD is an innate anomaly of the gastrointestinal system caused by incomplete closure of the omphalomesenteric duct^[1]. MD was so named in 1809 after its discoverer, the German anatomist Johann Friedrich Meckel. The presence of MD can be explained in terms of intrauterine evolution of the bowel. The omphalomesenteric duct is the embryonic communication between the yolk sac and the developing midgut. By the 10th week of embryogenesis, the omphalomesenteric duct becomes a thin fibrous band. However, incomplete atrophy of the omphalomesenteric duct may result in a variety of anomalies, they are, umbilicoileal fistula, omphalomesenteric duct cyst or MD^[4].

The diverticulum originates from the antimesenteric border of the small bowel, within 40-100 cm of the ileocecal valve^[4,5]. Blood is supplied *via* the vitelline artery, which is a branch of the ileocecal artery. The diverticulum is ordinarily lined by intestinal mucosa, but the heterotopic gastric mucosa or pancreatic tissue was frequently observed by the histological examination^[4,5].

Reportedly, 25% of MD become symptomatic

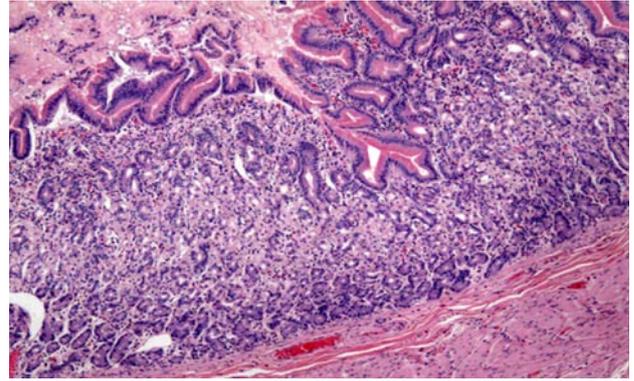

Figure 5 Histological features of the diverticulum. Heterotopic gastric mucosa was seen in the mucosa of the diverticulum (hematoxylin-eosin staining, $\times 100$).

throughout the lifetime^[4]. Bleeding, inflammation or obstruction are the main cause of complication^[2]. Statistically, hemorrhage is the most common presentation in children aged 2 years or younger^[6], whereas intestinal obstruction is the commonest presentation among adults^[7]. Intestinal obstruction due to MD is the most common presentation in adults and the second most common in children^[6,7].

The clinical symptoms are non-specific; patients may have abdominal pain and distension, vomiting or constipation. MD-related small-bowel obstruction occurs so infrequently that most articles have reported only small series or isolated cases. Moreover, many patients with MD have non-specific abdominal symptoms, often making a correct preoperative diagnosis difficult, especially in an emergency setting^[8,9].

The present case illustrates that abdominal CECT has the potential to identify the MDB and MD as the cause of small-bowel obstruction. Multi-dimensional CECT, especially in the coronal view, may yield more information about the cause of the small-bowel obstruction and the presence of a MDB. CECT is less invasive and speedier than other examinations such as Tc scintigraphy, interventional radiology or a gastrointestinal series, and therefore is more preferable in an emergency setting, yielding information about the cause of the small-bowel obstruction, such as internal hernia or other intestinal mass. CECT can also reveal the presence of strangulation. In the present case, we were able to confirm by CECT that there was no sign of vascular compromise, enabling us to start intestinal decompression in preparation for elective laparoscopic surgery.

Laparoscopic surgery for MD has been widely used recently. However, as it is not clear whether laparoscopic surgery is preferable to laparotomy in the setting of small-bowel obstruction^[10], we performed intestinal decompression first. MD can be resected either extracorporeally or intracorporeally^[9,11]. Although some reports have indicated intracorporeal laparoscopic diverticulectomy, we selected laparoscopy-assisted diverticulectomy *via* a small incision in the lower abdomen to allow palpation of the MD, thus helping

to rule out any mass or thickening of the base, and allowing a more complete assessment for the presence of any ectopic gastric mucosa^[12].

In conclusion, we successfully treated MD causing small bowel obstruction by laparoscopic surgery. Multi-dimensional CECT may yield to detect both the etiology of small-bowel obstruction and the presence of strangulation in such unusual settings.

COMMENTS

Case characteristics

A 26-year-old woman with past history of small bowel obstruction presented with abdominal pain and recurrent vomiting.

Clinical diagnosis

Physical examination demonstrated abdominal distention, with a soft abdomen and no tenderness or rebound pain. Her bowel sounds were hyperactive.

Differential diagnosis

Small bowel obstruction due to food impaction, due to internal hernia, or due to intestinal tumor.

Laboratory diagnosis

All labs were within normal limits.

Imaging diagnosis

Multi-dimensional contrast enhanced computed tomography showed a blind-ending U-shaped loop of bowel in the pelvis and a fibrotic band connecting the mesentery to the blind end of the bowel, suggesting Meckel's diverticulum (MD) and a mesodiverticular band (MDB).

Pathological diagnosis

MDB and heterotopic gastric mucosa in the mucosa of the MD.

Treatment

Long tube decompression and subsequent laparoscopic diverticulectomy.

Related reports

MD occurs with an incidence of 1%-2% among the general population, and most cases remain asymptomatic. Complications result most commonly from bleeding, inflammation, or obstruction.

Term expression

The MDB is an embryologic remnant of the vitelline circulation which carries the arterial supply to the Meckel's diverticulum. In the event of an error of involution, a patent or nonpatent arterial band persists and extends from the mesentery to the apex of the anti-mesenteric diverticulum.

Experiences and lessons

This is a successful case of small-bowel obstruction caused by MD that was

diagnosed preoperatively using multi-dimensional contrast-enhanced computed tomography and treated by elective laparoscopic surgery.

Peer-review

This is an interesting report on a rare etiologic factor of bowel obstruction in young adults.

Abstract

Pneumatosis intestinalis (PI) often represents a benign condition that should not be considered as an argument for surgery. We report a patient with PI and obstructing intussusception who underwent urgent colectomy and review the literatures regarding PI with intussusception. A 20-year-old man presented at our hospital with a 3-d intermittent lower abdominal pain history. He underwent steroid therapy for membranoproliferative glomerulonephritis for 4 years. Computed tomography revealed ascending colon intussusception with air within the wall. Intraoperative colonoscopy revealed numerous soft polypoid masses with normal overlying mucosa and right hemicolectomy was performed. Histological examination of colonic wall sections revealed large cysts in the submucosal layer. The pathological diagnosis was PI. Nine cases of intussusception associated with primary PI have been reported. Although primary PI often represents a benign condition that should not be considered as an argument for surgery, if the case involves intussusception and obstruction, emergent laparotomy should be considered.

INTRODUCTION

Pneumatosis intestinalis (PI) is a rare condition characterized by the presence of gas within the wall of the gastrointestinal tract. This condition can result from a wide variety of pathologies, including chronic obstructive lung disease, collagen diseases, necrotizing enterocolitis in premature infants, intestinal infections, ischemic bowel disorders, and immunosuppressive drug therapy^[1]. PI often represents a benign condition that should not be considered as an argument for surgery^[2]; however, immediate surgery may be required in some life-threatening circumstances such as the presence of bowel obstruction, perforation, or ischemia^[3].

Here we describe a case of PI in the ascending colon with obstructing intussusception for which urgent surgery was performed, and review the available published literature on PI with intussusception. Written informed consent was obtained from the patient.

Search strategy

The literature search strategy for this study was based on published systematic review guidelines^[4]. Literature databases such as PubMed MEDLINE (National Library of Medicine) were searched from 1980 to 2015 using the following medical subject headings: "PI (or Pneumatosis cystoides intestinalis)" and "intussusception" or "PI (or Pneumatosis cystoides intestinalis)" and "invagination". In addition, references within the retrieved articles were reviewed. We identified 24 manuscripts using this search strategy and selected 8 case reports for this review. Nineteen articles were excluded because their content was not applicable to this review and 7 articles were excluded because they were not written in English.

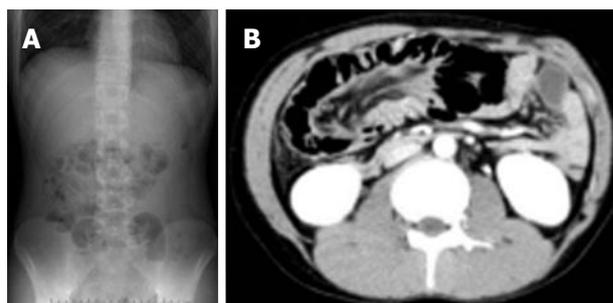

Figure 1 Abdominal radiograph. It showing multiple distended loops of small bowel with fluids and multiple air pockets (A) and computed tomography showing multiple gas-filled cysts, a streaky collection of air in the bowel wall, and an intussusception of the colon (B).

Figure 2 Intraoperative findings showed intussusception of the ascending colon with palpable soft polypoid masses.

CASE REPORT

A 20-year-old man presented our hospital with a 3-d history of intermittent lower abdominal pain. He had been on steroid therapy (methylprednisolone 25 mg/d) for membranoproliferative glomerulonephritis for 4 years. A physical examination revealed tenderness in the lower right quadrant of the abdomen. His body temperature was 37.7 °C and pulse was 81 beats per minute. All serum levels tested were within the normal range, with the exception of serum total bilirubin (1.5 mg/dL; normal range, 0.3-1.2 mg/dL). White blood cells (WBCs) (21000/μL), hemoglobin concentration (17.1 g/dL), and the C-reactive protein concentration (0.5 mg/dL) were also elevated, indicating acute inflammation and dehydration, with a level of base excess of 2.4 mmol/L. Abdominal X-ray showed multiple air-filled lucencies in the right upper quadrant and multiple distended loops of small bowel with fluid (Figure 1A). Computed tomography (CT) revealed intussusception of the ascending colon with air within the wall (Figure 1B). We performed an urgent laparotomy under the diagnosis of acute abdomen with obstructing intussusception. The colo-colic intussusception that was caudal to the polypoid lesion easily resolved using Hutchinson's maneuver and soft polypoid masses were palpable from the cecum to the ascending colon (Figure 2). Intraoperative colonoscopy revealed the presence of numerous soft polypoid

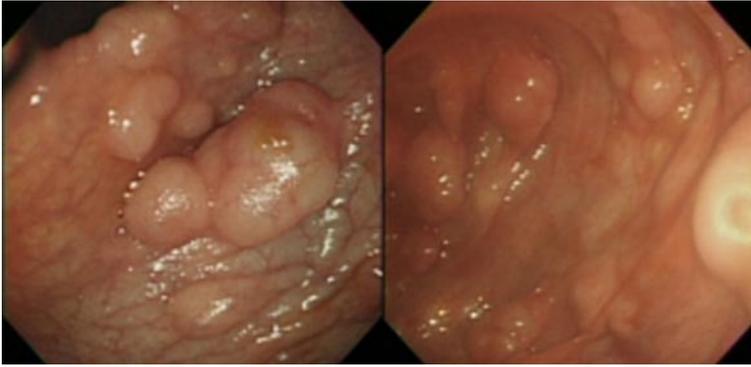

Figure 3 Intraoperative colonoscopy showed numerous soft polypoid masses with normal overlying mucosa located between the ascending colon and middle part of transverse colon.

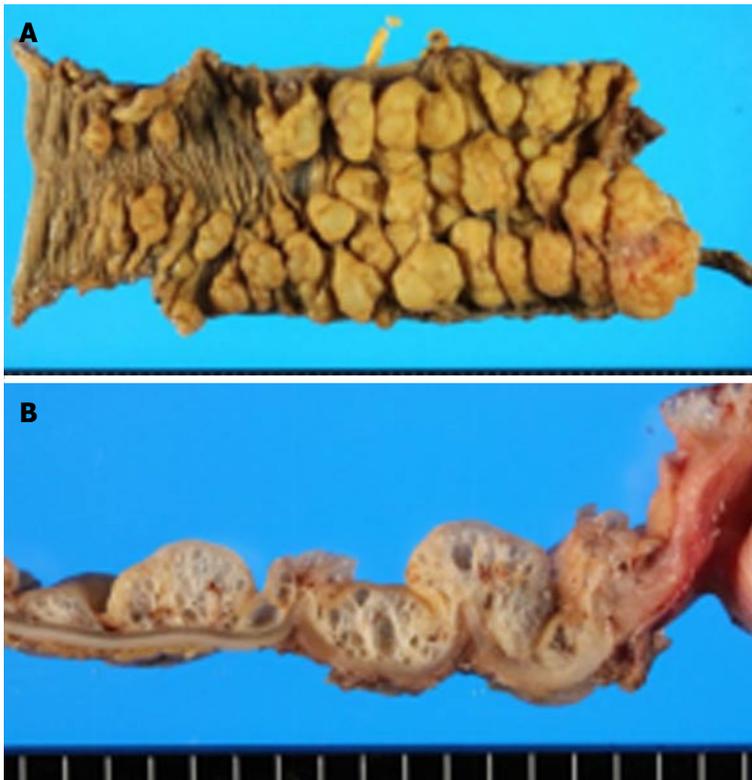

Figure 4 The resected specimen revealed polypoid lesions with normal mucosa and cystic structures (A), submucosal cysts had a spongy consistency (B).

masses with normal overlying mucosa (Figure 3). A right hemicolectomy was performed because other polyposis diseases or intussusception relapse could not be ruled out, and to help make a final pathological diagnosis. A gross examination showed that the mucosa of the resected colon appeared normal with no evidence of ulceration or ulcer-related lesions, but instead a number of soft, yellowish cystic masses (Figures 4). A histological examination of sections of the colonic wall revealed large cysts in the submucosal layer (Figure 5A). The cysts were empty, but were surrounded by a distinct fibrous wall and were lined by macrophages that frequently coalesced to form multinucleated giant cells (Figure 5B). Based on these findings, the patient was diagnosed with pneumatosis cystoides intestinalis. The postoperative course was uneventful and the patient was discharged on postoperative day 9. No recurrence was noted on radiographic imaging performed on postoperative 14 mo.

DISCUSSION

Classically, PI can be subdivided into 2 distinct groups: primary PI, representing 15% of cases, and secondary PI, representing 85% of cases^[5]. Secondary PI, where the gas accumulates as linear collections and reflects a pathological condition, has been attributed to endoscopic procedures, immunological disturbances, bowel mucosal disruptions, and intra-abdominal pathologies. In contrast to secondary PI, primary PI is characterized by intramural gas that is cystic and benign in nature and does not always require urgent laparotomy^[6]. Although PI may occur in association with acquired immunodeficiency^[7], transplant status^[8], cancer treatment^[9,10], scleroderma^[11], cystic fibrosis^[12], systemic lupus^[13], inflammatory bowel disease^[2], intestinal ischemia^[14], colitis^[15], or trauma^[16], the exact etiology of both primary and secondary PI remains unknown.

There is currently no consensus on the appropriate

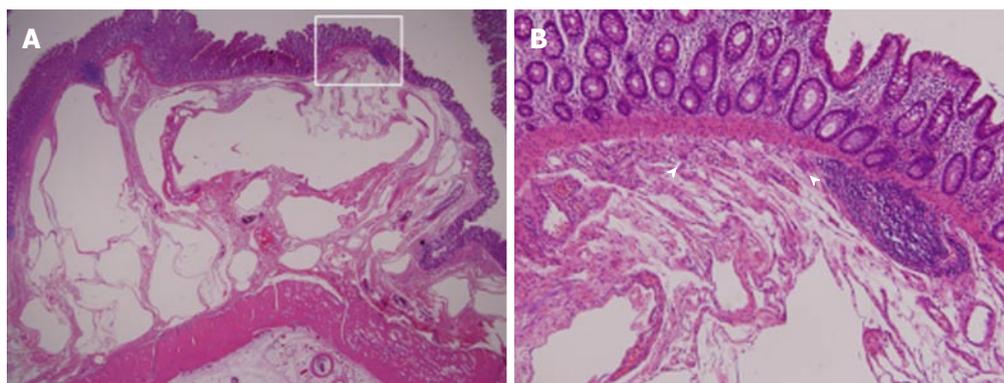

Figure 5 Histopathological examination revealed cystic air-filled spaces within the submucosa, which were partially lined by clusters of foreign-body macrophages (arrow heads) (hematoxylin-eosin stain; A: × 40, B: × 400).

NR: Not referred; PVG: Portal venous gas; A/C: Ascending colon; D/C: Descending colon; T/C: Transverse colon; CS: Colonoscopy; BE: Barium enema; CML: Chronic myelogenous leukemia; MPGN: Membranoproliferative glomerulonephritis.

management of PI, although many mechanical, bacterial, and pulmonary hypotheses have been proposed regarding PI etiopathogenesis, and its management can be challenging for surgeons^[17]. Many studies have investigated the use of risk factors as predictors of a compromised bowel and the probable need for surgery, such as patient age and the presence of hypotension, peritonitis, renal failure, or serum lactate levels^[18]. Other studies have attempted to create algorithms for PI management that, while helpful, are also tedious and may be difficult to apply clinically in circumstances where the patient requires rapid evaluation^[19]. In this case, we performed urgent laparotomy because he had intestinal obstruction due to intussusception and several inflammatory symptoms.

Although the course of primary PI may be benign or may not frequently result in a need for urgent surgery, laparotomy should be considered in cases with intestinal obstruction due to intussusception. To our knowledge, 9 reported cases, including the present case, had intussusception associated with primary PI (Table 1)^[20-27]. The mean patient age was 19.0 ± 16.0 years (range 0-48 years), which is younger than has been reported previously^[19]. It is notable that more than

44% of these patients received an immunosuppressive drug, and few patients appeared to have intestinal ischemia. All patients had the intussusception in the colon, particularly on its right side. Five out of 9 patients had co-morbidities, most of which required an immunosuppressive drug. With the exception of the article placed as reference number 22, no other articles referred to the presence of portal venous gas, which often indicates ischemic bowel disease. Only 2 cases experienced successful reduction of the intussusception with barium enema^[22,23], although long-term outcomes were not reported. Among the 4 cases with initial successful reduction of the intussusception by colonoscopy or barium enema, all of these patients eventually needed surgery: One case had persistent abdominal pain after solution of intussusception; in one case, the intussusception could not be completely resolved; one case had bowel obstruction; and for one case the indication of surgery was not clearly stated. For the present case, we performed an urgent laparotomy because of bowel obstruction with intussusception of the ascending colon. Right hemicolectomy for this case was performed because of the possibility of there being another polyposis disease present and because relapse

of the intussusception could not be ruled out.

In conclusion, although primary PI often represents a benign condition that should not be considered as an argument for surgery, emergent laparotomy should be considered for cases with intussusception, obstruction, and unsuccessful resolution of intussusception by colonoscopy or barium enema.

COMMENTS

Case characteristics

A 20-year-old man presented our hospital with a 3-d history of intermittent lower abdominal pain.

Clinical diagnosis

The authors performed an urgent laparotomy under the diagnosis of acute abdomen with obstructing intussusception.

Differential diagnosis

A right hemicolectomy was performed because other polyposis diseases or intussusception relapse could not be ruled out.

Laboratory diagnosis

All serum levels tested were within the normal range, with the exception of serum total bilirubin (1.5 mg/dL; normal range, 0.3-1.2 mg/dL). White blood cells (WBCs) (21000/ μ L), hemoglobin concentration (17.1 g/dL), and the C-reactive protein concentration (0.5 mg/dL) were also elevated.

Imaging diagnosis

Computed tomography revealed intussusception of the ascending colon with air within the wall.

Pathological diagnosis

A gross examination showed that the mucosa of the resected colon appeared normal with no evidence of ulceration or ulcer-related lesions, but instead a number of soft, yellowish cystic masses, suggesting that to be pneumatosis cystoides intestinalis.

Treatment

A right hemicolectomy was performed because other polyposis diseases or intussusception relapse could not be ruled out, and to help make a final pathological diagnosis.

Related reports

To our knowledge, 9 reported cases, including the present case, had intussusception associated with primary pneumatosis cystoides intestinalis.

Experiences and lessons

Although primary pneumatosis intestinalis (PI) often represents a benign condition that should not be considered as an argument for surgery, emergent laparotomy should be considered for cases with intussusception, obstruction, and unsuccessful resolution of intussusception by colonoscopy or barium enema.

Peer-review

This is an interesting article summarising a case of PI and intussusception with a review of the cases in the literature.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Eelco de Bree, MD, PhD, Associate Professor, Department of Surgical Oncology, University Hospital, 71110 Heraklion, Greece

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Lymph node metastasis informs prognosis and is a key factor in deciding further management, particularly adjuvant chemotherapy. It is core to all contemporary staging systems, including the widely used tumor

node metastasis staging system. Patients with node-negative disease have 5-year survival rates of 70%-80%, implying a significant minority of patients with occult lymph node metastases will succumb to disease recurrence. Enhanced staging techniques may help to identify this subset of patients, who might benefit from further treatment. Obtaining adequate numbers of lymph nodes is essential for accurate staging. Lymph node yields are affected by numerous factors, many inherent to the patient and the tumour, but others related to surgical and histopathological practice. Good lymph node recovery relies on close collaboration between surgeon and pathologist. The optimal extent of surgical resection remains a subject of debate. Extended lymphadenectomy, extra-mesenteric lymph node dissection, high arterial ligation and complete mesocolic excision are amongst the surgical techniques with plausible oncological bases, but which are not supported by the highest levels of evidence. With further development and refinement, intra-operative lymphatic mapping and sentinel lymph node biopsy may provide a guide to the optimum extent of lymphadenectomy, but in its present form, it is beset by false negatives, skip lesions and failures to identify a sentinel node. Once resected, histopathological assessment of the surgical specimen can be improved by thorough dissection techniques, step-sectioning of tissue blocks and immunohistochemistry. More recently, molecular methods have been employed. In this review, we consider the numerous factors that affect lymph node yields, including the impact of the surgical and histopathological techniques. Potential future strategies, including the use of evolving technologies, are also discussed.

Core tip: The number of lymph nodes in surgical resection specimens is influenced by numerous factors. Good practice by surgeons and pathologists is essential to maximize lymph node yields, but there are non-modifiable factors related to patient and tumour. Extended lymphadenectomy, extra-mesenteric lymph node dissection, high arterial ligation and complete mesocolic excision, all increase lymph node yields, but a definite benefit in prognosis is not proven and the optimal extent of surgical resection remains contentious. Conversely, further development in sentinel lymph node biopsy techniques could allow selective lymphadenectomy, whilst providing appropriate information to guide adjuvant therapy.

INTRODUCTION

Lymph node metastasis (LNM) informs prognosis and is a key factor in deciding further management, particularly adjuvant chemotherapy. As such, lymph node metastasis has had a role in colorectal cancer staging from the earliest classification systems. Its importance in prognosis has been borne out by successive classification systems and is reflected in all contemporary staging systems, in particular the widely used tumor node metastasis (TNM) staging system, developed and maintained by the Union for International Cancer Control and American Joint Committee on Cancer (AJCC).

Patients with node-negative disease have 5-year survival rates of 70%-80% in contrast to 30%-60% in those with node-positive disease. Survival is improved in the latter group by adjuvant chemotherapy. The 20%-30% disease recurrence in apparently completely excised tumours without lymph node metastases is thought to be due to occult lymph node disease. If this subset could be identified by better lymph node staging, they might also benefit from adjuvant chemotherapy.

There are several prognostic factors other than lymph node disease status that also identify patients who might benefit from adjuvant treatment. These include venous invasion, peri-neural invasion, tumour perforation, serosal involvement and incomplete resection^[1,2]. However, lymph node assessment remains a mainstay of deciding adjuvant chemotherapy. To achieve accurate staging, surgeons and pathologists must exercise due diligence in their respective practices. Most authorities recommend examination of a minimum of 12 lymph nodes, although the evidence base for this is weak. Behind this apparently simple number are numerous complex issues, many without

clear solutions. In this review, we consider the factors that affect lymph node yields including the influence of surgical and histopathological techniques. Evolving concepts and technologies that are not in widespread use, such as sentinel lymph node evaluation, are also discussed.

FACTORS INFLUENCING LYMPH NODE ASSESSMENT

In order to identify and maximise the diagnostic information from lymph nodes within a specimen, it is important to understand the factors that influence the lymph node harvest (LNH). This relates to a range of different factors: The pathologist, the surgeon and factors inherent to the patient and tumour. While tumour and patient characteristics cannot be changed, the pathologist can employ various techniques to maximise both the LNH and gain additional diagnostic information from enhanced study of the lymph node. The surgeon can modify the surgical procedure to excise more tissue or use ancillary techniques to aid selection and examination of lymph nodes by the pathologist.

ROLE OF THE HISTOPATHOLOGIST

Contemporary lymph node staging

There are several tumour staging systems, of which the TNM staging system is the most widely used internationally. It seems self-evident that lymph node metastasis indicates the presence of tumour cells within a lymph node. However, precise definition of different types of burden is crucial. Metastatic disease is often sub-classified into isolated tumour cells (ITCs, < 0.2 mm), micrometastases (defined as > 0.2 mm but < 2 mm) and macrometastases (\geq 2 mm). More recently, the concept of molecular positivity has been introduced. The classification of nodal disease (N-stage) under the current 7th edition of the TNM staging system (TNM7) is summarised in Table 1.

A universally agreed definition of what constitutes lymph node metastasis is important for communication between all parties involved in treating, diagnosing and researching colorectal cancer. It facilitates uniformity for the purposes of entry to clinical trials, subsequent applicability of the ensuing results and interpretation of historical trends. Any criteria should be objective, reproducible, evidence-based and met with broad agreement. However, significant changes to the criteria in successive editions of TNM have been criticised for lacking some of the above qualities.

Detailed analysis of the changes wrought by the two most recent TNM editions is presented elsewhere^[3-5]. The main changes are summarised diagrammatically in Figure 1, but a few points warrant discussion. In the 6th edition (TNM6)^[6] of the TNM staging system, isolated tumour cells became classed as N0 for the purposes of grouping tumours into AJCC stage I to IV, in contrast to N1 in the 5th edition (TNM5)^[7]. Secondly, extra-mural

Table 1 Nodal staging in the 7th edition of the tumor node metastasis staging system

N Stage	Description
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N0 (i-)	No regional lymph node metastases histologically, negative IHC
N0 (i+)	Isolated tumour cells, identified by H&E and/or IHC
N0 (mol-)	No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
N0 (mol+)	Positive molecular findings (RT-PCR), but no regional lymph node metastases detected by histology or IHC
N1mi	Micrometastases
N1	Metastasis in 1-3 regional lymph nodes
N1a	Metastasis in 1 regional lymph node
N1b	Metastasis in 2-3 regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2b	N2b Metastasis in seven or more regional lymph nodes
N2a	N2a Metastasis in 4-6 regional lymph nodes

IHC: Immunohistochemistry. RT-PCR: Reverse transcription-polymerase chain reaction.

deposits are difficult to classify. In a study of 69 tumour deposits, step sections were performed on what were initially diagnosed as tumour deposits. A significant proportion were found to represent other patterns of tumour spread^[8]. The “3 mm rule” stipulated in TNM5 was not based on published data, but had the advantage of being objective and reproducible^[9], in contrast to the assessment of “contour” introduced in the 6th edition (TNM6)^[10]. The “contour rule” was dropped in the 7th edition (TNM7), but explicit criteria were not provided to replace it. Left to the discretion of the pathologist, classification of extra-mural tumour is fraught with inter-observer variability^[11]. Unsurprisingly, there has been stage migration as a result of these changes, making it difficult to compare historical data. Data from the Surveillance, Epidemiology and End Results population-based registries showed that 10% of colorectal cancer cases had “tumour deposits”, of which 30%-40% occurred without concomitant lymph node metastases. Compared to TNM6, this represented up-staging of 2.5% of colon and 3.3% of rectal cases to N1c, a significant stage migration from stage I to stage III^[12]. There have also been misgivings over the use of TNM7 following neoadjuvant treatment, where patchy tumour regression may give the false appearance of lymph node metastasis or discontinuous tumour deposit. Finally, the changes in definition tend to reduce lymph node counts^[13], a concern where LNH is being used as a marker of “quality”. It is hoped that the 8th edition, due to be published this year, will resolve some of these issues.

Dissection

In many pathology laboratories, macroscopic examination and dissection of colorectal cancer specimens is

delegated to trainee pathologists, sometimes with limited experience and expertise. These large resection specimens tend to be left to the end of the “cut-up” session when time may be limited. Even in experienced hands, the detection of minute lymph nodes in mesenteric fat by palpation and dissection is painstaking and time-consuming. Marked variation in the assessment of colorectal cancer in the pathology laboratory, particularly in lymph node yields, is not a new issue^[14,15], but there is now more awareness of the crucial role of dissection. Results from staff pathologists^[16] and non-pathologist dissectors^[17-19] may be superior, but it is likely that a major factor is not the expertise of the operator, but rather the time devoted to searching for lymph nodes. de Burtet *et al.*^[20] studied LNH in gastrointestinal tumour resection specimens. Twenty minutes was allocated to an initial lymph node search, followed by an extra 5 and 10 min, which increased yields by 12% and 20% respectively. Twenty additional minutes added a mean of 6 lymph nodes, albeit with a diminishing rate of lymph node discovery. The United Kingdom Royal College of Pathologists’ Guidelines on Staffing and Workload allocates 8 points for cutting-up a colorectal resection, corresponding to an anticipated time spent of 31-50 min^[21]. This would appear to underestimate the time required for a thorough job if de Burtet *et al.*^[20] findings are correct. Often little thought is given to the ergonomics around cut-up. To optimise lymph node yields, we recommend that large specimens should be dealt with first when the operator is still fresh.

Handling

Current practice in handling of lymph nodes is not uniform. The United Kingdom Royal College of Pathologist guidance recommends embedding each lymph node whole, if < 4 mm, and a central block through longest axis for larger nodes^[22]. It is common practice to bisect or serially slice larger lymph nodes.

Typically, a single haematoxylin and eosin stained section is cut from each lymph node block, representing only a tiny volume of the lymph node in a single axis. Cutting more sections increases detection of lymph node metastases, including up-staging of several cases^[23], but the workload implications for the laboratory and histopathologist makes routine application of this unfeasible. Similarly, identification of small deposits of tumour by immunohistochemistry increases detection, but once again, has significant cost and workload implications.

Lymphatic mapping, the process of injecting tracer at the tumour site and following lymphatic flow to identify lymph nodes, has been used to identify sentinel lymph nodes (SLN). These SLNs are then subject to more intensive histopathological scrutiny, so-called ultrastaging^[24], typically consisting of additional levels and/or immunohistochemistry and in some cases molecular techniques^[25]. The utility of SLN ultrastaging is hampered by the limitations of current

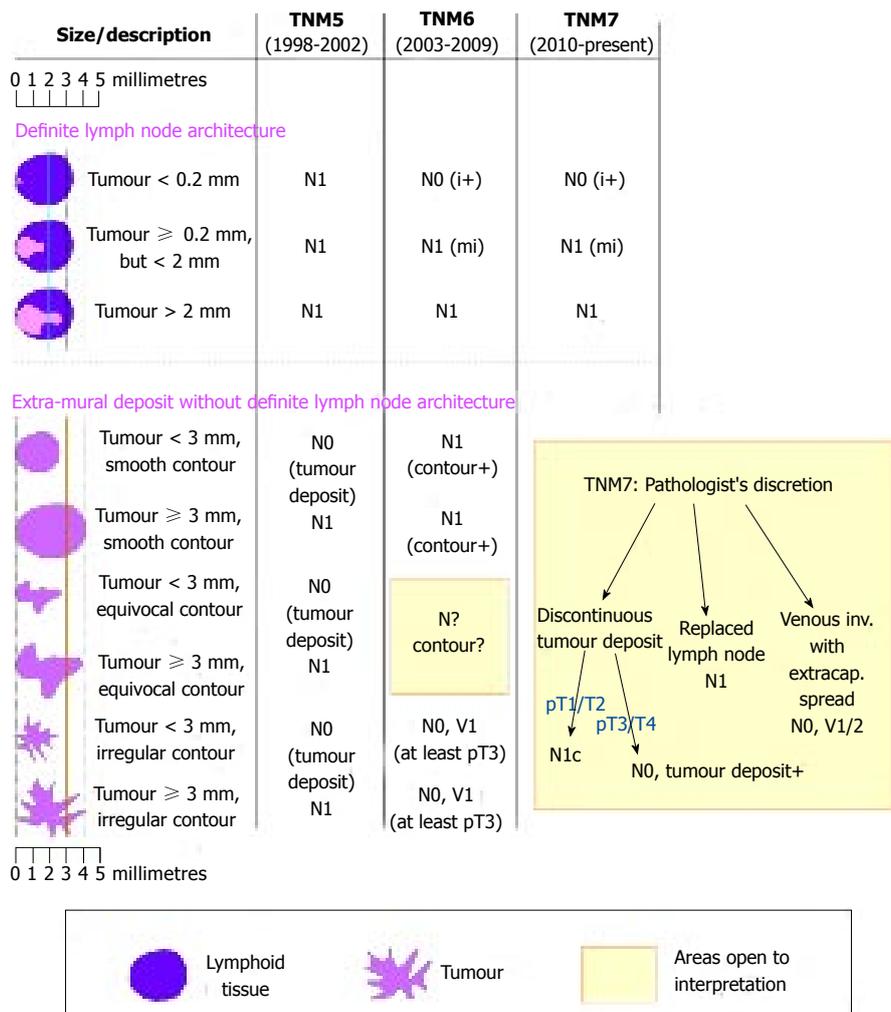

Figure 1 Changes in successive editions of the tumor node metastasis staging system. Top 3 rows: Size of deposit within definite lymph node. Under the 5th edition of the TNM staging system (TNM5)^[7], the volume of tumour cells is immaterial, but from the 6th edition (TNM6) onwards^[6], tumour burden is sub-classified by size; bottom 6 rows: Extra-mural deposits. TNM5 uses a 3 mm threshold; above this, the deposit is regarded as a lymph node metastases, below this, the deposit is regarded as a discontinuous extension of the main tumour. TNM6 relies on assessment of contour; smooth deposits are counted as nodes, whereas irregular contours are considered vascular invasion and upstaged in the T category. TNM7 leaves the decision to the judgement of pathologist with a wide range of outcomes.

SLN procedures, namely false negatives, skip lesions and failure to identify a SLN (see later section on SLN). The significance on prognosis of isolated tumour cells identified in this way is also contentious^[25] and is discussed in the later section on the size of tumour deposits.

Several other ancillary techniques have been employed to aid the LNH. Modified lymphatic mapping can be achieved by injection of India ink at the time of surgery^[26,27] and, similarly, *ex vivo* intra-arterial injection of methylene blue can accentuate lymph nodes^[28,29]. Chemical fat clearance can be performed with a variety of chemical regimens, typically a mixture of fixatives and organic solvents, such as glacial acetic acid, xylene, acetone, and alcohol. With the fat partially removed, nodes are accentuated, facilitating manual dissection and increasing yields. The clearance techniques are not in universal usage due to the slight delay introduced in finalizing a report and safety issues related to the disposal of the volumes of hazardous chemicals generated. The entire mesentery can be embedded

without fat clearance, so-called entire residual mesenteric tissue examination, which also increases yields^[30]. There is no doubt that many of these techniques increase LNH, but there are not currently enough data to show that they result in significant up-staging^[31].

Molecular techniques

The disadvantage of conventional ultrastaging is that it still relies on examination of a tiny volume of the lymph node. Lymph nodes harvested fresh can be processed to extract nucleic acids that can be analysed using reverse transcriptase and polymerase-based technologies. Some studies have used conventional polymerase chain reaction, but loop-mediated isothermal amplification, also known as one-step nucleic acid amplification (OSNA) can be performed in less than an hour and can be used intra-operatively. The results are quantitative and should reflect mRNA copy number. Thresholds are set to give grades of molecular lymph node involvement equivalent to conventional nodal staging, typically

≥ 250 copies for micrometastases and ≥ 5000 for macrometastases, although these figures are based on work done with breast cancer cases. Typical markers including carcinoembryonic antigen, cytokeratins 19/20 and guanylyl cyclase C. OSNA can be performed on the entire node^[32-34] or half of the node in combination with conventional sections^[35]. While up-staging was described in most series, there have been discrepancies not entirely explained by tissue allocation, suggesting conventional methods, albeit with ultrastaging-type protocols may have superior sensitivity and specificity. The data on how OSNA results correlates with the performance of single section histopathological analysis is sparse, particularly when isolated tumour cells are not included as a molecular category. Application of the OSNA technique to all lymph nodes harvested is not currently feasible outside of the research setting and practically-speaking, its main role is likely to be for the purposes of analysing sentinel lymph nodes.

Sentinel lymph node biopsy

The principle of sentinel lymph node biopsy (SLNB) is well established in melanoma and breast cancer, where the aim is to avoid unnecessary and potentially morbid lymphadenectomy. Unlike these two malignancies, where lymphadenectomy is a separate procedure, lymphadenectomy in elective colorectal cancer surgery is typically performed as part of a single surgical procedure. The lymphadenectomy component carries a low, but not entirely negligible morbidity. In a review of SLNB, Cahill questions the assumption that additional surgery carries no or minimal risk, particularly if radical lymphadenectomy is performed^[36]. The effects of excising unnecessary tissue are difficult to quantify. However, if SLNB can readily and reliably determine lymph node status, permitting more conservative surgery, then reduced tissue dissection, shortened operative time and better bowel function are all desirable outcomes.

Another scenario where SLNB may be informative is in early T-stage colorectal cancers, particularly pT1 polyp cancers identified by bowel cancer screening programmes. Adequate local excision of these polyp cancers is often achieved by endoscopic resection, but there is uncertainty about whether segmental resection for lymphadenectomy is indicated, a particular dilemma in patients with significant co-morbidities. While certain tumour characteristics predict lymph node metastases^[37-40], a SLNB should provide a definitive answer. SLNB can be performed laparoscopically^[41,42] and potentially *via* other minimally invasive techniques, *e.g.*, a transcolonic approach using with natural orifice transluminal endoscopic surgery^[43].

In this context, SLNB data specific to pT1/T2 tumours is of particular relevance, but many studies are small, typically include all T-stages or, in some studies, omit T-stage data. SLNB may have less of a role in pT3/T4 tumours as they are more likely to harbour lymph node metastases and therefore less likely to benefit

from initial SLNB^[44]. Additionally, an increased rate of false negatives has also been described in pT3/pT4 tumours^[36].

Broader adoption of SLNB, however, is limited by the guarded results from existing studies. SLNB is beset by a number of problems: Failure to identify a SLN, false negatives and skip lesions^[45-47]. Skip lesions have been hypothesised to be due to blocked lymphatic flow into involved lymph nodes, but this is not entirely explained by some data. It is unclear if the poor results are explained by technical problems, sub-optimal implementation of the technique or whether the concept is fundamentally flawed because of the inherently unpredictable pattern of lymph node involvement^[36,48]. Further evaluation of these techniques is required to determine whether they should be generally adopted.

ADDITIONAL HISTOPATHOLOGICAL ASPECTS IN LYMPH NODE ASSESSMENT

The most obvious measurable parameter relating to lymph nodes is the total LNH. Sampling as many lymph nodes as possible is ideal, but the focus on absolute counts alone ignores the complex and sometimes interacting factors that influence LNH. A detailed analysis of lymph node counts is presented later in this review, but other characteristics related to lymph nodes are discussed here.

Size of tumour deposit and/or lymph node

There are two separate aspects to consider. Firstly, does lymph node size, irrespective of tumour involvement, have implications on LNH or prognosis? Secondly, if a lymph node is involved, is the size of the deposit within the lymph node significant?

Chirieac *et al.*^[49] showed that nodal size significantly predicted overall survival in patients with node-negative colorectal cancer. They also speculated that high numbers of bulky negative lymph nodes were a product of an active host immune response, which ultimately contributed to improved patient prognosis and survival.

In some studies, LNM were more likely to be found in larger lymph nodes^[50,51], perhaps because they are easily palpable and therefore preferentially sampled. In node-positive disease, the size of the lymph node (as opposed to the tumour deposit) appears to have no significance on outcome^[52,53]. These studies and several others have demonstrated that many, if not the majority, of LNM occur in lymph nodes < 5 mm^[51,54]. The relevance of this is that small LNs are harder or impossible to palpate and are therefore less likely to be sampled during pathological dissection. Secondly, it is hard to completely separate the size of the tumour deposit from the size of the lymph node as the deposit obviously cannot exceed the size of the node. According to TNM7 rules, a positive 1.9 mm lymph node will either be involved by isolated tumour cells or micrometastases, but never a macrometastases (Figure 1).

This leads to the next question: Is the size of LN tumour deposit significant? The size of the largest lymph node tumour deposit appears to be prognostic^[55], but the overall volume of lymph node tumour burden appears to be less important than the number of involved lymph nodes^[56].

There is also considerable debate about the significance of isolated tumour cells. The data shows a wide variation in the incidence of isolated tumour cells and micrometastases, ranging from 11% to 59%. Some demonstrate an adverse effect on survival^[57-60], but others show no significance^[61-64]. The discrepancy reflects the differences in study design such as method of detection, length of follow-up and whether other confounding factors were considered. As previously discussed, more thorough scrutiny of lymph nodes with ultrastaging and/or molecular methods may increase detection of tumour, but it is unclear what significance this has on prognosis as direct comparison of data difficult. A 2014 meta-analysis suggests micrometastases have an adverse prognosis whilst isolated tumour cells do not^[65], but this distinction is not always straight-forward: The size cut-off of 0.2 mm is arbitrary and other definitions in terms of total cell numbers are hard to apply consistently.

Oncological practice in the United Kingdom continues to use the TNM5 definitions of lymph node metastasis, which defines the presence of any metastatic disease as N-positive, warranting adjuvant chemotherapy. Practice in other parts of the world differs, particularly in countries that have already adopted TNM7, which classifies isolated tumour cells as N0.

Extracapsular spread

Extracapsular extension is typically associated with more aggressive and infiltrative tumours. Heide *et al*^[66] noted that extracapsular extension in rectal resections was connected with adverse local control and a higher rate of distant metastases. In another study, the survival rates and disease-free survival rates for patients with metastatic lymph nodes showing an extracapsular invasion pattern were significantly worse than cases showing no evidence of extracapsular extension^[67].

Lymphoid hyperplasia/sinus histiocytosis

LNs negative for tumour may show reactive patterns such as follicular, parafollicular hyperplasia, as well as sinus histiocytosis. These have been regarded as indicators of active host immune response and are associated with an improved prognosis and 5-year survival rate^[68]. A survival advantage has also been established in metastatic lymph nodes that also demonstrate a background of benign reactive inflammatory changes^[69]. The host-response hypothesis may also explain why patients with lower lymph node yields are generally found to have a poorer prognosis, although reactive lymph nodes are more easily identified and may result in higher LNH and more accurate staging.

Ratio of involved lymph nodes

The use of the ratio of positive nodes to total LNH was first proposed by Berger *et al*^[70] in 2005 as an additional prognostic factor. Several subsequent studies have corroborated the original findings^[71-77], although what threshold to use is not clear. The results are not entirely consistent and there may also be differences between colonic and rectal tumour^[78]. A minimum LNH is required to make the ratio valid. Conversely, large numbers of lymph nodes obtained through techniques such as fat clearing may increase the overall denominator, disproportionately reducing the ratio.

Mucin pools

LNM from tumours showing prominent mucinous differentiation may manifest as pauci-cellular mucin pools. Following neoadjuvant treatment, these may be rendered acellular. Further step levels are helpful to exclude viable tumour cells, but if no cells are found, these are regarded by most pathologists as lymph node negative^[79,80].

ROLE OF THE SURGEON

The role of the surgeon is to excise the primary tumour and an appropriate amount of mesenteric tissue with clear margins, to allow adequate staging, whilst minimising potential complications. This raises the question of how much tissue should be removed to achieve optimal oncological outcomes.

Lymphadenectomy - therapeutic or prognostic?

How much tissue to remove is guided by the interpretation of the fundamental purpose of lymphadenectomy. There are divergent views on whether it is directly therapeutic or whether it provides mainly staging and prognostication^[81]. The model espoused by Halsted at the end of the 19th century assumes sequential and step-wise spread of tumour outwards from the primary site. Radical surgery to remove all tumour not only provides staging information, but also potentially cures the tumour. In contrast, the Cady *et al*^[82] paradigm assumes systemic spread may occur early in tumour growth and that improved outcomes derive from delivery of the optimum adjuvant treatment as determined by accurate staging. The Halsted radical mastectomy has been consigned to surgical history, but it is unclear if principles gleaned from breast cancer can be extrapolated to colorectal cancer.

Indirect evidence for a therapeutic effect has been inferred from studies looking at lymph node counts. The Intergroup Trial INT-0089 showed 5-year overall survival increased from 51% to 71% for N2 disease if > 35 lymph nodes were harvested compared to < 35^[83]. Given this was N2 disease, better staging and stage migration cannot entirely explain the results which showed superior survival to that of published trials using optimal adjuvant chemotherapy, implying a curative component. Other explanations are possi-

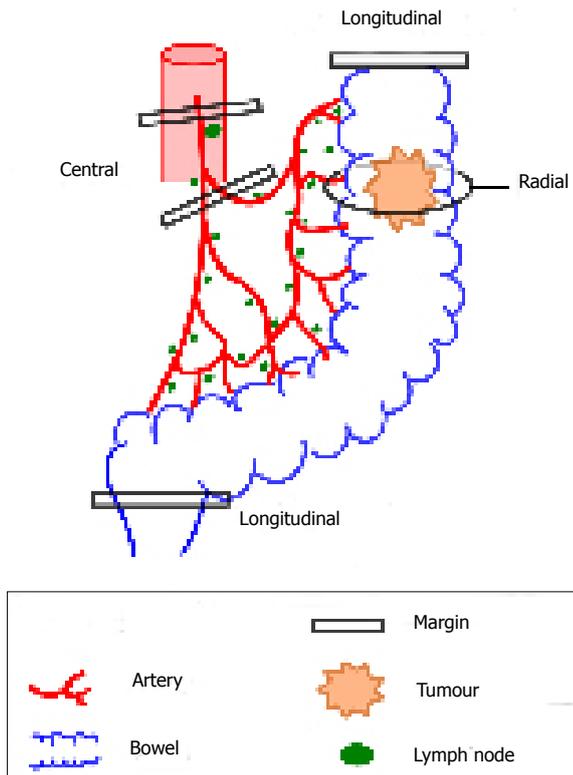

Figure 2 Anatomical extent of surgery. Schematic representation of the 3 anatomical boundaries of colorectal surgery.

ble, *e.g.*, high lymph node counts representing good host inflammatory response, but it is likely that lymphadenectomy is both prognostic and therapeutic, particularly in the rectum where total mesorectal excision (TME) achieves simultaneous local control and lymphadenectomy, with both components inherently inseparable. It is no surprise that when more mesenteric tissue is removed, LNH also increases. In theory, this leads to more accurate staging and potential therapeutic removal of involved lymph nodes. However, for many of the surgical techniques described below, the highest levels of evidence are lacking. It is therefore unclear whether the benefits of removing more tissue outweigh the increased operating time and potential morbidity associated with these procedures. A detailed review of surgical practice is beyond the scope of this review, but salient issues are considered below and readers are directed to other surgical guidelines^[84-87].

What is adequate surgery?

Margins can be thought of as extending to 3 anatomical boundaries (Figure 2). Firstly, the longitudinal margin as determined by the axial extent of the bowel excised. Secondly, the extent of mesenteric tissue excised, in a centripetal direction towards the root of the supplying artery. Thirdly, radial margins, in the broadest sense, which may include *en bloc* excision of advanced local spread, *e.g.*, the abdominal wall or adjacent organs, but also encompasses the circumferential margin, or more accurately, the non-peritonealised margin.

Frequently, these three margins cannot be manipulated independently of each other, but as a general rule, increasing the first two margins also increases lymph node yields.

Longitudinal margins

Typically, the segment of bowel containing the tumour is excised along with the mesentery delineated by its arterial supply. For colonic tumours, at least 5 cm of longitudinal clearance is advised to minimise anastomotic recurrence^[88,89]. In the rectum, 5 cm proximal and 2 cm distal appears sufficient^[90]. The Japanese Society for Cancer of the Colon and Rectum guidelines recommend at least 5 cm in the direction of lymph flow and 10 cm in opposite direction^[91]. In practice, it is the vascular supply that dictates the extent of surgery. If the tumour straddles two arterial branches, both segments should be excised. Anatomical and functional considerations may also extend resection beyond oncological requirements. For instance, in left-sided tumours, many surgeons avoid anastomoses with the sigmoid colon as it is regarded as a “high pressure” segment and also receives no contribution from the marginal artery.

The length of bowel resected may be extended in several scenarios on the basis that spread of tumour beyond normal segmental boundaries has been described, a finding partially borne out by intra-operative lymphatic mapping. Extended lymphadenectomy can be achieved by performing an extended right hemicolectomy for proximal right-sided tumours^[92,93]. Extended right hemicolectomy is also common performed for transverse colon and splenic flexure tumours, although there are no randomised, controlled trials to support this. Similarly, for left-sided tumours, one of the few randomised controlled trials in this area showed no benefit of left hemicolectomy over segmental resection^[94]. The type of surgery employed, particularly the length of specimen, has a clear influence on LNH, but without lymphatic mapping, is not clear when extended surgery should be performed.

Central margins and extra-mesenteric lymphadenectomy

Classically, colonic tumour spreads along lymphatics in the distribution of the arterial supply^[92,95,96]. Depending on their anatomical distribution, lymph nodes in the colon are described as pericolic, intermediate and apical/central/main, broadly corresponding to D1, D2 and D3 in the Japanese notation^[87]. Lymphadenectomy can be performed up to and flush with the level of the origin of the artery^[97], so-called complete vascular ligation, one of the key components of complete mesocolic excision (see below). This manoeuvre takes the apical node which is involved in about 3%-11% of tumours^[93,97,98]. In tumours of the sigmoid colon and upper rectum, high ligation of the inferior mesenteric artery has been advocated as oncologically superior. This was first promulgated by Moynihan in 1908^[99] and the debate on its value has continued for more than a

century. Despite good results in several, mainly cohort studies, other studies have shown no benefit (see systematic reviews in^[100-103]). No benefit was seen in sigmoid tumours in a multicentre randomised controlled trial^[94]. The issue, however, has not entirely been laid to rest and a randomised controlled trial of high ligation in the context of laparoscopic surgery is on-going^[104].

Routine excision or sampling of lymph nodes outside the typical lymph node basin has also been advocated. Tumours around the hepatic flexure may spread to infra-pyloric nodes^[97]. In the rectosigmoid region, the arterial supply is variable and spread to lateral (extra-mesorectal) pelvic lymph nodes may occur^[96]. One paper describes lateral pelvic node involvement in up to 18%, rising to 36% in the sub-group of Dukes' C tumours^[105]. Proponents of radical lymphadenectomy argue it is oncologically superior, both in achieving better staging but also therapeutically by removing all diseased lymph nodes. However, all of the above additions and modifications to "standard" lymphadenectomy may result in additional morbidity, particularly damage to neighbouring structures.

Depending on the anatomical site, this includes the duodenum, ureters and nerve plexuses^[106]. Vascular compromise may occur from direct vascular damage or *via* reduction in collateral flow^[107]. As extra-mesenteric and apical lymph node involvement is present only in a minority of cases, routine extended dissection represents unnecessary surgery for most patients. A selective approach has been advocated^[98], but patients with the highest rates of aberrant lymph node involvement are those with high T-stage, the same group where lymphadenectomy is least likely to be curative due to the increased risk of systemic disease. The benefit of these procedures is unproven and potential morbidity may outweigh the benefits^[108,109].

Radial margins

TME has been established as the optimal surgical technique for rectal tumours. Pioneered by Heald, introduction of the technique reduces local recurrence^[110,111]. The same anatomical and oncological principles have been extrapolated to colonic tumours, so-called complete mesocolic excision (CME)^[112]. Although a relatively new concept in the West, CME shares many features with D3 excisions that have been performed routinely in East Asia^[113,114]. It is associated with better LNHS^[115]. However, while it is supported by some compelling oncological and anatomical concepts, it encompasses many of the unproven surgical elements discussed above. The technique may prove itself in the fullness of time, but there is presently insufficient evidence to support it^[116,117]. Furthermore, the unsuccessful attempts by European surgeons to adopt D3 lymphadenectomy for gastric cancer is a salutary reminder of how challenging it is to "import" purportedly superior surgical techniques from established centres^[118].

Type of surgery

Laparoscopic and laparoscopic-assisted surgery is increasingly the default surgical approach to colorectal cancer resection. Superior peri-operative recovery and oncological equivalence has been demonstrated by several randomised controlled trials, including no significant difference in lymph node counts^[119]. Many of techniques described above can be achieved laparoscopically, *e.g.*, CME^[120-126], although randomised controlled trials are difficult to undertake. Laparoscopic CME therefore still lacks a convincing body of supportive evidence. The data on robotic surgery are promising^[127], but at present only includes a single randomised-controlled trial.

INTRA-OPERATIVE PROCEDURES

A number of procedures can be performed intra-operatively to assist in lymph node staging. As previously discussed, lymphatic mapping entails injecting a tracer at the tumour site, which travels along lymphatics and facilitates identification of lymph nodes^[24], including the sentinel lymph node. SLNs can be excised intra-operatively and for immediate results, can be subject to frozen section histological examination or OSNA^[128]. Other technologies that provide immediate intra-operative results are the subject of on-going research, *e.g.*, optical coherence tomography and real time elastography^[129].

Outside these techniques, the default histological analysis is performed on sections cut after formalin-fixation and paraffin embedding of the SLN. The results are therefore not available to influence immediate operative management. The exception is where the lymphatic mapping process identifies tracer in "aberrant" lymph node territory. The surgeon can choose to sample the abnormal lymph nodes or perform more radical lymphadenectomy. In 2 studies, *in vivo* lymphatic mapping changed the procedure in 9% and 22% of cases respectively^[129,130]. In the latter study, nodal positivity was higher in patients undergoing a change of procedure.

THE INFLUENCE OF PATIENT AND TUMOUR CHARACTERISTICS

Patient

Several patient characteristics have been identified that influence LNHS^[131]. However, factors identified in some studies are not corroborated by others. Fewer lymph nodes are generally obtained from specimens from older patients^[132-134]. Gender seems to have no effect, while low counts have an inconsistent association with obesity, as measured by body mass index^[135,136].

Tumour characteristics

Several histological characteristics of the primary

tumour have been shown to be associated with an increased risk of LNM. One meta-analysis identified 42 different factors. Only 15 were reported in 2 or more studies and not all are routinely analysed during standard reporting procedures^[137]. Factors that are easily assessed during routine histological reporting include tumour site^[133,134,138], stage^[133] and differentiation. Higher counts are seen in tumours with micro-satellite instability^[139]. While not an exhaustive list, many of these features lack reproducibility, sensitivity and/or specificity. It is therefore uncertain whether any single feature in isolation is reliable enough to influence decisions on adjuvant treatment. Neoadjuvant chemotherapy and/or radiotherapy typically reduces the numbers of nodes sampled^[133,140].

Predictive factors in submucosal (pT1) tumours are of particular interest as these are typically resected endoscopically and may require segmental resection for lymphadenectomy. Adverse factors in this group include poor tumour differentiation, depth of invasion and lymphovascular invasion^[37-40]. If sentinel lymph node biopsy techniques can be refined, this would greatly aid decision-making in this group on whether additional surgery is appropriate.

LYMPH NODE YIELDS AS A MEASURE OF QUALITY

Many of the surgical and histopathological techniques discussed are based on the presumption that increased lymph node yields invariably leads to more accurate stage. This assumption warrants critical appraisal. Many organizations such as the American Society of Clinical Oncology, the National Comprehensive Cancer Network and the United Kingdom Royal College of Pathologists have guidance stipulating a minimum lymph node yield of 12 lymph nodes per case. The choice of 12 was proposed in 1990 by the Working Party Report to the World Congress of Gastroenterology in Sydney^[141], partly supported by subsequent studies, but has a poor evidence base.

Others have suggested alternative minimum numbers depending on the T-stage of tumour^[142], with more numbers required for low T-stage disease. While it has been clearly demonstrated in numerous studies that prognosis improves with the number of lymph nodes sampled^[143-146], this association does not prove causation. Furthermore, the association of lymph node counts and survival applies even in node-negative disease^[147] which lends support to the alternative explanation that high lymph node yields are a surrogate marker of a vigorous host immune response to tumour. Conversely, low lymph node counts are associated with a worse survival and may, in itself, be an indication for adjuvant treatment. Much of the existing evidence is based on studies where LNs were harvested without recourse to special techniques and it is unclear if the same survival associations apply when additional or

special techniques "inflate" the number of lymph nodes sampled. Not all studies have demonstrated a beneficial effect of higher lymph node yields^[148]. Yet others have observed a trend of increased lymph node yields over several years, most likely reflecting better surgical and histopathological practice, but without a corresponding increase in the detection rate of LNM^[149,150]. Similarly, the use of special techniques fares no better^[151]. At the risk of repetition, we need to clearly distinguish the principle of association from causality. Increased lymph node yields show an association with survival, but do not cause it. Various techniques may increase the lymph node count, but may not change the underlying nature of the disease. It is established that lymph node yields are multifactorial, influenced by a combination of patient, tumour, surgical and pathological factors^[131,152].

Clearly, there must be minimum standards in both surgical and histopathological practice. Surgery that fails to remove enough mesentery for staging and a cursory, hurried dissection by a pathologist, sampling only a handful of lymph nodes are likely, in combination, to lead to under-staging. However, for the majority of practitioners, the message about the importance of achieving accurate lymph node staging has been heard and implemented. Audit of LNHS is good practice, but the unthinking pursuit of ever higher lymph node yields should be resisted. In particular, it is unreasonable to link lymph node yields with quality payments, particularly when it is established that many factors influencing lymph node yields are outside the control of both surgeon and pathologist.

CONCLUSION

The importance of colorectal cancer lymph node staging cannot be over-emphasised. We have discussed many of the controversies associated with this challenging area and provided guidance about the rational application of additional techniques. TNM7 has not been universally adopted internationally^[22], but publication of TNM8 is anticipated in this year. The authors anticipate that this will address some of the issues and lead to a consensus approach. The variable contribution of surgical, pathological, patient and tumour related factors means that this remains a contentious subject. This complex area continues to evolve with new developments, surgically and pathologically, providing novel methods to evaluate nodal disease.

Abstract

The role of fecal lactoferrin and calprotectin has been extensively studied in many areas of inflammatory

bowel disease (IBD) patients' management. The post-operative setting in both Crohn's disease (CD) and ulcerative colitis (UC) patients has been less investigated although few promising results come from small, cross-sectional studies. Therefore, the current post-operative management still requires endoscopy 6-12 mo after intestinal resection for CD in order to exclude endoscopic recurrence and plan the therapeutic strategy. In patients who underwent restorative proctocolectomy, endoscopy is required whenever symptoms includes the possibility of pouchitis. There is emerging evidence that fecal calprotectin and lactoferrin are useful surrogate markers of inflammation in the post-operative setting, they correlate with the presence and severity of endoscopic recurrence according to Rutgeerts' score and possibly predict the subsequent clinical recurrence and response to therapy in CD patients. Similarly, fecal markers show a good correlation with the presence of pouchitis, as confirmed by endoscopy in operated UC patients. Fecal calprotectin seems to be able to predict the short-term development of pouchitis in asymptomatic patients and to vary according to response to medical treatment. The possibility of both fecal markers to be used in the routine clinical practice for monitoring IBD patients in the post-operative setting should be confirmed in multicentric clinical trial with large sample set. An algorithm that can predict the optimal use and timing of fecal markers testing, the effective need and timing of endoscopy and the cost-effectiveness of these as a strategy of care would be of great interest.

Core tip: Inflammatory bowel diseases (IBDs) are chronic conditions, requiring life-long therapy and monitoring. Surgery is not curative and the disease

might recur after operation as post-operative recurrence in Crohn's disease patients and pouchitis in ulcerative colitis patients. In both cases, endoscopy with histology is the gold standard procedure to assess disease activity. Non-invasive markers of intestinal inflammation, such as fecal calprotectin and lactoferrin, might be useful in the post-operative management of IBD patients, in order to identify individuals requiring endoscopy, so that they can avoid unnecessary invasive investigations. This paper reviews the current knowledge on the use of fecal markers in this specific setting.

INTRODUCTION

Inflammatory bowel disease (IBD) is chronic, relapsing-remitting inflammatory conditions of the gastrointestinal tract. Both Crohn's disease (CD) and ulcerative colitis (UC) might require surgical intervention for different indications. Operated patients, both CD and UC patients, need to be followed-up regularly, because the risk of post-operative recurrence (CD patients) and of pouchitis (UC patients) is very common. However, the post-operative management is not clearly defined, in terms of needs of medications and timing of clinical, biochemical and endoscopic follow-up. Therefore, patients often undergo several invasive procedures to re-assess disease activity and exclude complications.

The role of non-invasive markers has been extensively studied in the diagnosis, management and monitoring of IBD patients. In particular, fecal markers, calprotectin (FC) and lactoferrin (FL), represent intestinal infiltration by leukocytes and correlate with the severity of endoscopic and histological intestinal inflammation^[1,2].

Calprotectin is a calcium- and zinc-binding protein of neutrophils, that is released in case of activation or apoptosis/necrosis^[3]. It displays several physiological roles in inflammatory and infectious processes and has anti-proliferative capability. The long stability of FC at room temperature (up to 7 d) is an advantage for its use in clinical practice. Lactoferrin is an iron-binding glycoprotein of neutrophils that, after degranulation, regulates their margination and diapedesis through the intestinal wall in case of inflammation^[4]. Unlike calprotectin, its stability at room temperature is guaranteed only for 2 d.

More recently, a meta-analysis confirmed the usefulness of C-reactive protein (CRP) and FC in excluding IBD in patients with symptoms of irritable bowel syndrome^[5]. Another meta-analysis showed that CRP, FC, and FL might aid in the triage of IBD patients for endoscopic evaluation when they are symptomatic^[6].

Currently, FC and FL do not replace endoscopy with histology, however this might become the future approach.

Still now, due to limited studies on the efficacies of FC and FL as non-invasive biomarkers, no consistent conclusion was made about their use in post-operative management of IBD patients. In this context, we aimed to review the efficacy of FC and FL from the available studies for use of FC and FL as non-invasive diagnostic markers of inflammation in post-operative CD and UC.

CD

CD is a chronic progressive destructive, disabling disease, clinically characterized by relapsing-remitting behavior. Even during periods of clinical remission the disease progresses, leading to structural and irreversible bowel damage in the majority of patients^[7]. In the natural history of CD, intestinal resection is often required to treat strictures, fistula, or abscesses. Historical population-based studies reported that, overall, the cumulative risk for surgery 10 years after diagnosis is around 40%-55%^[8]. There are emerging data suggesting that the early use of immune-modulators and biologics might delay disease progression and thus the timing of first surgical intervention. In an Australian population-based registry, authors observed indeed a fall in surgery rates (the one and 5 year resection rates were 13% and 23%, respectively)^[9]. Similarly, a Hungarian population based study showed that reduction of surgery rates was independently associated with early introduction of immune-modulators^[10].

Although, surgery is not curative and the disease often recurs in many cases (in the neoterminal ileum or in the ileo-colonic anastomosis), that leads to progressive loss of intestinal function and disability. Post-operative recurrence can be clinical, endoscopic, radiological or surgical. The reported incidence rates of post-operative recurrence depend on the definition used, the time of observation and the study design. Unfortunately, the available epidemiological data are heterogeneous and difficult to interpret. Buisson *et al.*^[11] summarized the data coming from randomized controlled trials; referral centers studies and population-based studies. Clinical recurrence was higher in population-based studies and referral center studies, reaching 61% at 10 years. Data about endoscopic recurrence at one year derived mainly from referral center studies (rates ranging from 48% to 93%) and randomized controlled trials (rates ranging from 35% to 85%). However, the definition of endoscopic post-operative recurrence was heterogeneous.

The established risk factors for post-operative recurrence are smoking, prior intestinal resection, fistulizing behavior, perianal disease and extensive disease (> 50 cm)^[11]. It is fundamental to identify high-risk patients and offer efficient treatment in order to maintain remission. However, the most appropriate therapeutic approach has still to be established. At present, the only universally accepted preventive measure for post-

operative recurrence is to quit smoking^[12,13].

Landmark studies by Rutgeerts *et al.*^[14,15] demonstrated that the post-operative clinical course of CD is predicted by the severity of endoscopic lesions during the first year after surgery. The presence of severe endoscopic lesions (Rutgeerts' score \geq i2) gives a high risk of early clinical relapse and complications^[14], but this can be observed already 6 mo after curative resection^[16].

As mentioned, detection of post-operative recurrence is mainly based on endoscopic appearance. Therefore, patients soon after surgery are expected to undergo endoscopy and repeat several evaluations, which timing is still need to be determined.

Fecal markers might be the most realistic alternative to ileocolonoscopy; their reliability as markers of intestinal inflammation has been proved in different settings and they are entering routine management. However, data about their use in the post-operative setting are poor.

Clinical and biochemical recurrence

The correlation between fecal markers and clinical and serological activity is controversial also in the post-operative setting.

We observed in 63 operated CD patients that levels of both FL and FC remained high after a median follow-up of 40.5 mo even in case of clinical remission, suggesting the persistence of subclinical inflammation^[17]. However, episodes of clinical flares predicted higher levels of FL. Only FL significantly correlated with CRP, showing a potential also as a maker of systemic inflammation. We investigated the correlation between FL levels and systemic inflammation in other 36 CD patients in clinical remission after ileo-colonic resection^[18], and demonstrated a significant correlation with IL-6 and CRP and an inverse correlation with albumin and serum iron. A major limitation of both studies was the absence of endoscopic evaluation to confirm endoscopic recurrence and its correlation with fecal markers.

Lamb *et al.*^[19] followed-up a small cohort of 13 CD patients for one year after surgery with regular FC and FL measurements. In case of early normalization of these biomarkers (within two months), a subsequent two-fold increase in the upper limit of FC and FL correlated with a relapse. Both markers demonstrated better performance than CRP. The authors studied also a second post-operative cohort of 104 patients in a cross-sectional study. In this study, both FC and FL correlated significantly with the Harvey Bradshaw Index (HBI) of clinical activity; in particular, severely active patients (HBI \geq 6) had higher levels of fecal markers (more than twice the upper normal limit). However, surprisingly there was no significant difference between the FC and FL values in those with endoscopic post-operative recurrence (25 patients out of 43 patients who underwent endoscopic assessment) and those without.

Yamamoto *et al.*^[20] prospectively investigated the relationship between the severity of endoscopic inflammation and fecal markers in 20 CD patients in remission during 6-12 mo after ileocolic resection. All patients underwent ileocolonoscopy at study entry and were then followed for 12 mo. Both fecal markers were significantly higher in patients (30%) who developed clinical recurrence. A cutoff value of 170 μ g/g for FC had 83% sensitivity and 93% specificity to predict a risk of clinical recurrence within 12 mo from the baseline endoscopy, while a cutoff value of 140 μ g/g for FL had a sensitivity of 67% and a specificity of 71%.

Endoscopic recurrence

The correlation of fecal markers with the presence of endoscopic recurrence should be the major endpoint in studies evaluating their role in post-operative recurrence. Orlando *et al.*^[21] observed that amongst 50 CD patients who underwent intestinal resection a FC level > 200 mg/L had 63% sensitivity and 75% specificity to diagnose endoscopic post-operative recurrence one year after the operation.

In the study performed by Yamamoto *et al.*^[20] both FC and FL correlated with the presence of endoscopic post-operative recurrence according to Rutgeerts' score. On the contrary, laboratory measurements (white blood cell count, platelet count and CRP level) did not significantly correlate with the endoscopic score.

A recent study performed in Sweden did not confirm the promising results of fecal markers in the post-operative setting proposed by the earlier studies^[22]. Authors evaluated the correlation between FC and the endoscopic findings one year after ileo-caecal resection in 30 CD patients; they observed that the median FC values did not significantly differ between patients in endoscopic remission or recurrence. However, most patients with low values were in remission and all patients with FC > 600 μ g/g had recurrence. The collection of the stool sample for FC measurement after colonoscopy might influence FC levels. This happened for only six patients, who collected the sample 1-4 wk after the endoscopy, and might not be sufficient to explain the absence of statistically significant difference between the groups of patients. Furthermore, the longitudinal part of the study, in which stool samples were delivered monthly until ileocolonoscopy, showed an important variability in FC concentrations. According to these findings, a single measurement of calprotectin might not be significant in the decision making process, and this was already demonstrated in the follow-up of patients undergoing anti-TNF treatment^[23].

Recently, results from the Post-Operative Crohn's Endoscopic Recurrence (POCER) Trial became available^[24] and data about the role of FC in monitoring and detecting post-operative recurrence were extracted^[25]. It is a prospective, randomized, controlled, multicenter trial, which evaluated a therapeutic strategy based on risk stratification of patients, with treatment step-up in case of recurrence detected at ileocolonoscopy, performed at

6 and 18 mo after surgery^[26]. This trial clarified that an active strategy based on the postoperative endoscopic monitoring, together with treatment intensification for early recurrence, is more effective (at least in the short term) than standard drug therapy alone and waiting for clinical recurrence. The surgically induced and verified remission (after resection of the macroscopically involved intestine) is an ideal starting point for the use of a noninvasive marker to monitor for recurrent inflammation. In the POCER trial FC concentration was increased markedly before surgery and decreased substantially after resection of all macroscopic diseased segments at 6 mo. Combined 6- and 18-mo FC levels correlated significantly with endoscopic recurrence, whereas CRP and CDAI did not. A cutoff of FC > 100 mg/g detected patients with endoscopic recurrence with 89% sensitivity and 58% specificity; the negative predictive value (NPV) was 91%. In this cohort, colonoscopy could be avoided in 47% of cases without endoscopic recurrence, but at the cost of missing 11% of patients with endoscopic recurrence. FC could be useful also in treatment monitoring, since it decreased in patients who underwent treatment intensification. A FC level of < 51 µg/g in patients in remission at 6 mo after surgery predicted maintenance of remission at 18 mo, with NPV 79%; sensitivity, specificity and PPV in this particular situation were less satisfying (50%, 68% and 36%, respectively), therefore the FC measurement remains of modest value in predicting long term future endoscopic recurrences.

Rapid test

Usually fecal markers are determined through the conventional ELISA method, that is effective, but time-consuming. A new rapid test for FC (FC-QPOCT) has been evaluated for the prediction of endoscopic remission in 115 CD patients^[27]. Twenty nine out of these patients were previously resected and endoscopic activity was scored according to the Rutgeerts' score. Median FC-QPOCT levels were able to discriminate between patients with and without endoscopic post-operative recurrence (98 µg/g vs 234.5 µg/g, respectively; $P = 0.012$). There was no significant difference in FC levels between the different degrees of the Rutgeerts' score. The accuracy of FC-QPOCT in predicting post-operative recurrence presented an AUC of 71.53. A 283 µg/g cut-off value had 67% sensitivity and 72% specificity (similar results were obtained with the ELISA method). However, accuracy was lower than that obtained in non-resected patients (AUC 0.933). Neither clinical activity nor serological biomarkers had a significant correlation with post-operative recurrence.

The validation of rapid fecal tests could be of further utility in the out-patient management of operated patients, avoiding the waiting time of laboratory reports.

Taken these results together, serial measurement of FC at regular intervals in the postoperative period might be the best way to predict future endoscopic behavior^[25,28].

It has been proposed that an algorithm combining FC and colonoscopy, based on the stratification of patients according to the risk of permanent bowel dysfunction, could be a cost-effective strategy to detect asymptomatic recurrence^[28]. This approach need further validation in larger, prospective trials, but might be a cost-effective strategy for the management of operated CD patients.

Results of the major studies in CD patients are reported in Table 1.

UC

The clinical course of UC may range from prolonged periods of remission to acute severe colitis requiring intensive medical treatment. Emergency colectomies are required in case of life-threatening complications of colitis in hospitalized patients unresponsive to medical treatment. Elective colectomy is indicated for refractory disease, intolerance to medical treatment and colonic neoplasia.

Surgery rates at 10 years from diagnosis are approximately 10%^[29,30], showing a decline over the years for elective colectomies (probably due to immunomodulators)^[31]; in contrast, emergent colectomy rates remain stable. Extensive colitis at diagnosis is proposed as a risk factor for colectomy in several studies across different cohorts of patients^[29,30].

Proctocolectomy with ileal pouch-anal anastomosis (IPAA) is the procedure of choice for most patients with UC requiring colectomy. Pouchitis is a non-specific inflammation of the ileal reservoir and the most common complication of IPAA in patients with UC^[32,33]. The incidence of a first episode of pouchitis depends on the duration of follow up, occurring in up to 45% of patients 10 years after surgery^[34,35]. Pouchitis recurs in more than 50% patients and up to 10% of patients develop chronic pouchitis; refractory pouchitis is rare^[33]. Increased bowel movements, urgency, and abdominal pain in patients with IPAA may be caused by different inflammatory conditions (pouchitis, cuffitis, or CD) or non-inflammatory conditions (irritable pouch syndrome). The diagnosis of pouchitis requires therefore endoscopic confirmation with mucosal biopsies^[36,37]. The Pouchitis Disease Activity Index (PDAI) was developed to standardize diagnostic criteria and assess the severity of pouchitis, combining symptoms, endoscopy and histology^[36]; a total PDAI score ≥ 7 is diagnostic for pouchitis. Patients with suspected pouchitis need endoscopy for a proper diagnosis. The use of fecal markers for the detection of pouch inflammation might avoid the repetition of such invasive investigation^[38].

The literature on fecal markers in the post-operative setting in UC patients is quite scarce. Furthermore, the majority of studies was conducted on small samples of patients and have a cross-sectional design, which do not permit to clarify the evolution over time of the disease and the consensual behavior of the fecal markers. However, these studies form the basis of evidence that FC and FL are useful as inflammatory markers also in

Table 1 Studies evaluating fecal calprotectin and lactoferrin in operated Crohn's disease patients

Ref.	FC/FL	Method	No. of patients	Aim	Best cut-off	Sens %	Spec %	Main findings
Scarpa <i>et al</i> ^[17]	FC and FL	ELISA	63 (22 endoscopy)	Role as marker of intestinal inflammation after ileocolonic resection	/	/	/	High FC and FL levels at long-term follow-up after resection even in case of clinical remission Correlation between FL and CRP Higher levels of FL in case of clinical recurrence
Ruffolo <i>et al</i> ^[18]	FL	ELISA (IBD-scan)	36	Correlation with systemic inflammation and prognostic value in terms of need of surgery for recurrence	/	/	/	FL as expression of subclinical intestinal inflammation (through IL6-CRP cascade)
Lamb <i>et al</i> ^[19]	FC and FL	ELISA (PhiCal) ELISA (IBD-Scan)	13 (prospective cohort) 104 (cross-sectional cohort; 43 endoscopy)	Evaluation of the course of FL and FC after ileocaecal resection. Identification of postoperative recurrence; Correlation between FC and FL	/	/	/	Prospective cohort: Normalization of fecal markers by 2 mo after surgery in uncomplicated patients Cross-sectional cohort: Significant correlation between FC and FL Significant correlation of fecal markers with HBI No significant difference between the FC and FL values in those with endoscopic recurrence and those without
Yamamoto <i>et al</i> ^[20]	FC and FL	ELISA (Cell Science) and Colloidal Gold Agglutination reagent (Auto Lf-Plus, respectively)	20	Evaluation of the relationship between endoscopic activity and FC/FL Assessment of Fc and FL predictive value for future clinical recurrence	FC 170 mg/g FL 140 mg/g (for prediction of clinical relapse)	83 67	93 71	Significant correlation between FC and FL Correlation with endoscopic activity Ability to predict clinical post-operative recurrence
Orlando <i>et al</i> ^[21]	FC	ELISA	50 (39 endoscopy)	Evaluation of the one year postsurgical endoscopic recurrence	200 mg/L	63	75	FC > 200 mg can be an indication to colonoscopy in patients with negative ultrasound in order to detect early recurrence
Lasson <i>et al</i> ^[22]	FC	ELISA (Buhlmann)	30	Correlation of FC with the endoscopic findings one year after ileocaecal resection Evaluation of the variation of FC in individual patients during 6 mo prior to the ileocolonoscopy	/	/	/	No difference in the concentrations of FC between patients in endoscopic remission and patients with recurrence one year after ileocaecal resection Significant variability of FC concentrations over time
Wright <i>et al</i> ^[25]	FC	ELISA (fCAL, Buhlmann)	135 (319 fecal samples)	To assess whether monitoring FC can substitute endoscopy and be used as surrogate marker of recurrent post-operative disease	100 µg/g	89	58	FC correlated with the presence of recurrent disease at endoscopy and with endoscopic severity FC has sufficient sensitivity and negative predictive values to monitor for recurrence FC can be used to monitor response to treatment after detection of recurrence FC has better diagnostic performance than CRP and clinical index of activity
Lobatón <i>et al</i> ^[27]	FC	ELISA (Buhlmann) FC-QPOCT (Quantum Blue)	115 (29 resected)	To evaluate the performance of a new rapid test for FC in predicting endoscopic remission (in both operated and non-operated CD patients)	283 µg/g	67	72	Significant correlation between ELISA and rapid test FC was able to discriminate between the presence or absence of endoscopic recurrence, but not distinguish different levels of severity

CD: Crohn's disease; CRP: C-reactive protein; ELISA: Enzyme-linked immunoassay; FC: Fecal calprotectin; FL: Fecal lactoferrin; HBI: Harvey Bradshaw Index; Sens: Sensitivity; Spec: Specificity.

the post-operative setting.

In 24 patients with ileo-anal pouch (both UC patients and with familial adenomatous polyposis) FC showed a strong association with pouchitis ($P = 0.0002$), and correlated with the severity of inflammation detected at endoscopy and histology in the 9 patients having pouchitis^[39]. A cut-off of 92.5 $\mu\text{g/g}$ feces in 54 patients who underwent restorative proctocolectomy (46 UC patients and 8 with familial adenomatous polyposis coli) reached 90% sensitivity and 76.5% specificity in diagnosing pouchitis^[40]. No difference was found in symptom scores of patients with FC concentrations above or below 50 $\mu\text{g/g}$ ($P = 0.155$), confirming that the clinical presentation is aspecific.

Thirty-two patients with pediatric-onset of UC who underwent proctocolectomy with IPAA were enrolled in a cross-sectional study to assess whether FC was related to pouchitis^[41]. Patients with recurrent pouchitis had significantly higher FC levels ($832 \pm 422 \mu\text{g/g}$) followed by those with a single episode ($290 \pm 131 \mu\text{g/g}$) and those with no history of pouchitis ($71 \pm 50 \mu\text{g/g}$) ($P = 0.019$). FC levels correlated also with the amount of neutrophilic infiltration of the distal ileum at histology. The cross-sectional design of the study and the small sample size are of course important limits of the study.

Also FL showed satisfactory results in detecting pouch inflammation (due to either pouchitis, cuffitis or CD). In 60 patients with IPAA, a cut-off of 13 $\mu\text{g/mL}$ could distinguish irritable pouch syndrome from pouchitis, cuffitis, or CD, with 97% sensitivity and 92% specificity^[42]. FL levels correlated with the PDAI score (correlation coefficient 0.73; $P < 0.001$), especially with the endoscopic subscore. Although the cut-off level of 13 $\mu\text{g/mL}$ showed the best combination of specificity and sensitivity, authors recommended a cutoff level of 7 $\mu\text{g/mL}$ to decrease the possibility of false negative results. In case of higher levels, pouch endoscopy with biopsy is necessary to distinguish among different causes of inflammation. Lim *et al.*^[43] achieved similar results in 2008, evaluating the levels of FL in 32 patients with IPAA, showing 100% sensitivity and 86% specificity in diagnosing pouchitis, according to PDAI.

We evaluated the interplay between the ileal-pouch microbiota and several inflammatory parameters in the pathogenesis of pouchitis in 32 consecutive patients^[44]. Although it was not the primary aim of the study, we observed that FL correlated with the presence of mucosal ulcers, neutrophils and monocytes infiltration and the histologic diagnosis of pouchitis, confirming the ability of the fecal marker in detecting mucosal inflammation.

Recently, Yamamoto *et al.*^[45] conducted a longitudinal study to assess the utility of sequential dosage of FC and FL for the early diagnosis and prediction of pouchitis after restorative proctocolectomy for UC. Sixty patients were followed up (with clinical and biochemical assessments) every 2 mo for one year after the ileostomy closure. In case of symptoms suggestive of pouchitis, endoscopic examination was

immediately undertaken; otherwise, asymptomatic patients performed endoscopy at one year. Between 4 and 10 mo before the diagnosis of pouchitis (10 patients, 17%), the median FC and FL levels remained low and stable. However, these levels significantly increased 2 mo before the diagnosis of pouchitis, although patients were asymptomatic. In contrast, in 50 patients without pouchitis fecal levels did not change. In particular, a cut-off value of 56 $\mu\text{g/g}$ for FC had a NPV of 100% and a diagnostic accuracy of 87% to predict pouchitis; a cut-off value of 50 $\mu\text{g/g}$ for FL had a NPV of 98% and a diagnostic accuracy of 88% to predict pouchitis. Again, there was no significant correlation between the clinical subscore of PDAI and fecal biomarkers (FC: $r = 0.230$, $P = 0.08$ and FL: $r = 0.163$, $P = 0.21$); on the contrary, both fecal markers correlated with the endoscopic and histological subscores. In patients with pouchitis who responded to antibiotics (8/10) median FC levels dropped from 106 to 34 $\mu\text{g/g}$ and FL levels from 89 to 31 $\mu\text{g/g}$; in non-responders the levels of these fecal biomarkers increased, suggesting their usefulness for evaluating the efficacy of medical treatment and possibly for the early detection of pouch inflammation without repeating endoscopy.

In summary, fecal proteins demonstrated the potential to monitor intestinal inflammation in UC patients after proctocolectomy with IPAA. The early detection of subclinical inflammation with serial measurements of fecal markers might facilitate pre-emptive treatments in asymptomatic patients. Prospective studies need to confirm the cost-effectiveness of such strategy, especially evaluating the reduction of rates of chronic pouchitis and pouch failures^[46].

Results of the major studies in UC patients are reported in Table 2.

CONCLUSION

The role of fecal markers in the post-operative management of IBD patients seems promising. Preliminary data in CD patients came from small studies, sometimes relying only on clinical activity, without endoscopic confirmation of recurrence, and produced inconsistent data. More recently, studies have revealed the potential use of fecal markers, especially FC, in the post-operative management of CD, for the diagnosis of post-operative recurrence and possibly for monitoring the response to therapy. In UC patients, studies, although heterogeneous, have more consistently showed the correlation between fecal markers and the presence of inflammation of the pouch. Furthermore, there are no data showing that the early diagnosis of post-operative recurrence in CD patients and of pouchitis in UC patients might alter the long term outcome. The evidence of the reliability of FC and FL as markers of inflammation in the post-operative setting in both CD and UC should be strengthened in larger, longitudinal, multicentric studies, addressing the aim to refine an algorithm that stratifies the use and the optimal timing of fecal markers testing

Table 2 Studies evaluating fecal calprotectin and lactoferrin in operated ulcerative colitis patients

Ref.	FC/FL	Method	No. of patients (No. of patients with inflammation of the pouch) and type of disease	Aim	Best cut-off	Sens %	Spec %	Main findings
Thomas <i>et al</i> ^[39]	FC	ELISA	24 (9) UC and familial polyposis coli	Comparison between single and 24-h stool collections in patients with and without pouchitis (endoscopic, histologic and immunohistochemical indices)	/	/	/	Mean first morning stool concentration correlated with 24-h collection Levels of FC were significantly higher in patients with pouchitis Correlation with % of mature granulocytes and activated macrophages
Johnson <i>et al</i> ^[40]	FC	ELISA (PhiCal)	54 (20) UC and familial polyposis coli	Differentiation between inflamed and noninflamed pouches Correlation with inflammation severity	92.5 µg/g	90%	76.50%	FC levels significantly higher in pouchitis (> 50 µg/g had higher endoscopic and histological scores) Correlation with endoscopic score ($r = 0.605$) and histological score ($r = 0.708$)
Pakarinen <i>et al</i> ^[41]	FC	ELISA (PhiCal)	32 (22) UC	Cross-sectional assessment of FC after proctocolectomy for pediatric onset UC	300 µg/g (for detection of recurrent pouchitis)	57%	92%	Higher levels of FC in patients with recurrent pouchitis, followed by those with a single episode and those without (832, 290, 71 µg/g respectively, $P = 0.019$) Correlation with neutrophilic infiltration and overall inflammatory activity in the distal ileum
Parsi <i>et al</i> ^[42]	FL	In-house test	60 (30) UC	Evaluate the usefulness of FL in symptomatic patients with IPAA	13 µg/mL	97%	92%	Higher levels in patients with inflammation of the pouch Not able to distinguish between pouchitis, cuffitis and CD Not able to distinguish between asymptomatic patients and those with irritable pouch syndrome Correlation with PDAI (better for endoscopic subscore)
Lim <i>et al</i> ^[43]	FL	Rapid immunochromatographic test	32 (11) Healthy controls and pouchitis patients	Diagnostic yield for pouchitis	/	100%	86%	Sensitive method for the non-invasive diagnosis of pouchitis
Scarpa <i>et al</i> ^[44]	FL	ELISA (IBD-scan)	32 UC	Evaluate the relationship between ileal-pouch microbiota and inflammatory parameters	/	/	/	Correlation with histological inflammation Correlation with mucosal ulcers, mucosal immune infiltration Inverse correlation with <i>Eubacteriaceae spp.</i> , <i>Burkholderiaceae spp</i> and <i>Moraxellaceae spp.</i> counts
Yamamoto <i>et al</i> ^[45]	FC FL	ELISA (Cell Science) and Colloidal Gold Agglutination reagent (Auto Lf-Plus, respectively)	60 (10) UC	Evaluate the significance of consecutive monitoring of fecal markers for early diagnosis and prediction of pouchitis	56 µg/g 50 µg/g	100% 90%	84% 86%	Elevation of FC and FL already 2 mo before the diagnosis of pouchitis Correlation with PDAI score (correlation with endoscopic and histological subscores, but not with the clinical subscore) Correlation with response to therapy

and the effective need of colonoscopy. This should be based on patients-tailored approach, in order to

improve the cost-effectiveness of several postoperative fecal testing and examine the ability of such a strategy to prevent both clinical relapse and subsequent surgical resections in CD patients and the early identification with prompt treatment of pouchitis in UC patients.

Abstract

Pancreatic cystic neoplasms have been increasingly recognized recently. Comprising about 16% of all resected pancreatic cystic neoplasms, serous cystic neoplasms are uncommon benign lesions that are usually asymptomatic and found incidentally. Despite overall low risk of malignancy, these pancreatic cysts still generate anxiety, leading to intensive medical investigations with considerable financial cost to health care systems. This review discusses the general background of serous cystic neoplasms, including epidemiology and clinical characteristics, and provides an updated overview of diagnostic approaches based on clinical features, relevant imaging studies and new findings that are being discovered pertaining to diagnostic evaluation. We also concisely discuss and propose management strategies for better quality of life.

Key words: Pancreatic cystic neoplasm; Serous cystic neoplasm; Diagnosis; Management strategy; Surgery

Core tip: Pancreatic cystic neoplasms (PCNs) have been more frequently recognized clinically in recent years and serous cystic neoplasms (SCNs) account for a large proportion of all PCN cases. Recent reviews have paid much attention to general aspects of PCNs and have discussed various subtypes of PCNs, but there is still a lack of comprehensive review exclusively focused on SCNs. This review attempts to provide a concise overview and outlook of pancreatic SCN and propose management strategies.

INTRODUCTION

Pancreatic cystic neoplasms (PCNs) are increasingly being recognized incidentally with widespread use of advanced imaging techniques, including computed tomography (CT), magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS). According to the most recent WHO classification^[1], PCNs comprise serous cystic neoplasms (SCNs), mucinous cystic neoplasms (MCNs), intraductal papillary mucinous neoplasms (IPMNs) and solid pseudopapillary neoplasms (SPENs). SCNs account for nearly 16% of surgically resected PCNs and > 30% of all clinically diagnosed PCNs^[2-4], hence, they have become of concern and have posed a challenge to primary care clinicians and general practitioners. Not surprisingly, SCNs harbor some already known epidemiological characteristics. SCNs largely affect women (approximately 75% of all cases), and the mean age of patients who underwent pancreatic surgery for SCNs was 56 years in Europe, 58 years in Asia and 62 years in the United States^[5,6]. SCNs tend to be larger if they occur in male patients^[4]. In contrast with other premalignant or malignant PCNs (MCNs, IPMNs and SPENs), SCNs are usually benign, and the malignant variant serous cystadenocarcinoma is rare. To date, only approximately 30 cases of serous cystadenocarcinoma are reported in the literature^[7]. Therefore, correct diagnosis is needed to avoid unnecessary surgical interventions and exclude other malignancies.

Morphologically, SCNs can be divided into four subtypes: Microcystic, macrocystic or oligocystic (< 10% of cases), mixed form (micro-macrocystic) and a solid variant form^[8]. SCNs may arise in any part of the pancreas and occasionally can spread throughout the organ. The majority of SCNs are the microcystic lesions, which occur predominantly in the body and tail of the pancreas, whereas the oligocystic lesions normally arise from the head of the pancreas^[9,10]. When multiple lesions are identified, Von Hippel-Lindau (VHL)-disease-associated pancreatic cysts should be taken into consideration^[11]. VHL disease is a genetic disease, driven by mutation of the VHL tumor suppressor gene located on chromosome 3, which leads to development of several tumors, primarily hemangioblastoma of the central nervous system, retinal hemangioblastoma, renal cell carcinoma, adrenal pheochromocytoma and pancreatic tumors, mainly represented by pancreatic endocrine tumors and cystic tumors^[12]. It is reported that SCNs are involved in 2.7%-9.5% of patients with VHL disease^[13].

Histologically, SCN cystic walls are lined with cubic flat epithelia consisting of glycogen-rich, watery-fluid-producing cells^[14] (Figure 1). The cytoplasm is

either clear or eosinophilic and the nuclei are normally centrally located, small and hyperchromatic; mitoses are not commonly found^[15]. Although some controversy still exists, it is widely accepted that SCNs originate from the centroacinar cells^[16]. They normally express cytokeratins AE1/AE3, CAM 5.2, CK7, CK8, CK18 and CK19, epithelial membrane antigen, α -inhibin, and mucin 6^[16,17].

CLINICAL PRESENTATION AND DIAGNOSIS OF SCN

According to a study led by Tseng *et al.*^[4], approximately 47% of patients with SCN were asymptomatic and diagnosed incidentally. As for symptoms, they are not specific and often attributed to mass effects or to infiltration of adjacent structures. Abdominal pain (25%), palpable mass (10%) and jaundice (7%) are the main clinical manifestations. It also has been shown that when lesions are > 4 cm, symptoms do occur more frequently if compared to lesions < 4 cm (72% vs 22%, $P < 0.001$)^[4], which is in line with several studies reported elsewhere^[18,19]. A more recent multinational study of 2622 cases of SCN revealed that patients could present with nonspecific abdominal pain (27%), pancreaticobiliary symptoms (9%), diabetes mellitus (5%), or other symptoms (4%), with the remaining patients being asymptomatic (61%)^[20].

Given that SCNs are usually benign and asymptomatic, better surveillance and management strategies for these cysts call for accurate preoperative diagnosis. CT, MRI and EUS are three most commonly used imaging techniques for revealing SCNs. A recent study stated that the accuracy of preoperative diagnosis of PCN remains low, reaching approximately 60%, and in light of the exact diagnosis by pathology, surgical resection, most of which were Whipple resections, should not have been performed in approximately 8% of patients^[21]. In another study cohort, 9% of PCN patients underwent pancreatic resection for a non-neoplastic condition^[22], which further demonstrated the difficulty in differentiation between benign and premalignant lesions and that better preoperative diagnosis is urgently needed. Pancreatic cysts are readily identified in up to 20% of MRI studies, and 3% of CT scans^[23,24]. Both CT and MRI predict the presence of malignancy in pancreatic cysts with 73%-79% accuracy^[25]. In addition to routine radiological studies, EUS has emerged as a useful tool because it provides high-resolution imaging of the pancreas through the lumen of the stomach or duodenum and helps obtain detailed information of the cystic lesions, such as wall, margins, internal structures and parenchyma^[26,27]. In a recent prospective cross-sectional study of the prevalence of incidental pancreatic cysts during routine outpatient EUS, the prevalence of incidental pancreatic cyst was 9.4% and most were < 1 cm^[28]. The accuracy of EUS to differentiate benign from malignant neoplastic tumors and from non-neoplastic

cysts remains debatable. Some studies have stated an accuracy of $> 90\%$, while others have expressed doubt, especially when there is a lack of evidence of a solid mass or invasive tumor^[29-31]. Despite this debate, another major advantage of EUS is its ability to collect fluid from cystic lesions *via* fine-needle aspiration (FNA) for cytological and biochemical analysis, such as carcinoembryonic antigen (CEA), amylase, and *KRAS* mutations^[32].

Compared to other cystic neoplasms, accurate preoperative diagnosis of SCNs seems more feasible. As mentioned before, SCNs can be divided into four subtypes: Microcystic, macrocystic or oligocystic ($< 10\%$ of cases), mixed form (micro-macrocytic) and solid variant form^[8]. VHL-disease-associated pancreatic cysts should be considered when other cystic lesions exist. A Japanese multicenter study of 172 SCNs diagnosed by resection and typical imaging findings noted highest diagnostic accuracy for microcystic SCN (85%), with lower diagnostic rates (17%-50%) for macrocystic and mixed types. CT alone is approximately 23% accurate at diagnosing SCN^[33]. Diffusion-weighted MRI has proved to be a powerful tool with 100% sensitivity and 97% specificity for differentiating mucinous cysts from SCNs^[34]. The pathognomonic central scar, which is formed by central coalescence of the septa and commonly contains foci of calcification on imaging, is present in only approximately 30% of these

cysts^[35].

On CT/MRI, microcystic SCN typically appears as an isolated, lobulated, well-marginated, multilocular lesion, comprising a cluster of multiple (usually > 6) small cysts separated by a thin septum^[26,36] (Figure 2). Each of the small cysts is usually < 2 cm^[37]. Occasionally, the "honeycomb" pattern, characterized by numerous, sub-centimeter cysts appears as a solid mass on CT (Figure 3), but has high signal intensity when T2-weighted MRI is applied^[37]. Macrocystic SCN is characterized by a limited number of cysts, usually < 6 , showing a diameter > 2 cm, or even one single cyst^[38] (Figure 4). This subtype can be seen in approximately 10% of all cases of SCN but poses difficulty for differentiating it from MCN and branch-duct (BD)-IPMN, based on the findings of CT or MRI^[39]. In addition, if a patient has a reported history of pancreatitis, pseudocyst should be considered^[40]. The mixed micro-macrocytic type is depicted as a combination of the above two types of lesions. As for the solid variant, it consists of small cysts separated by multiple, thick fibrous septa^[41]. VHL-disease-associated pancreatic cysts, which can occur in 50%-80% of the patients with VHL disease, and are occasionally misdiagnosed as macrocystic SCNs, tend to form multiple lesions and are even diffuse throughout the pancreas^[42,43].

Generally, microcystic SCNs on EUS are imaged as numerous (> 6) small ($< 1-2$ cm) fluid-filled cysts with

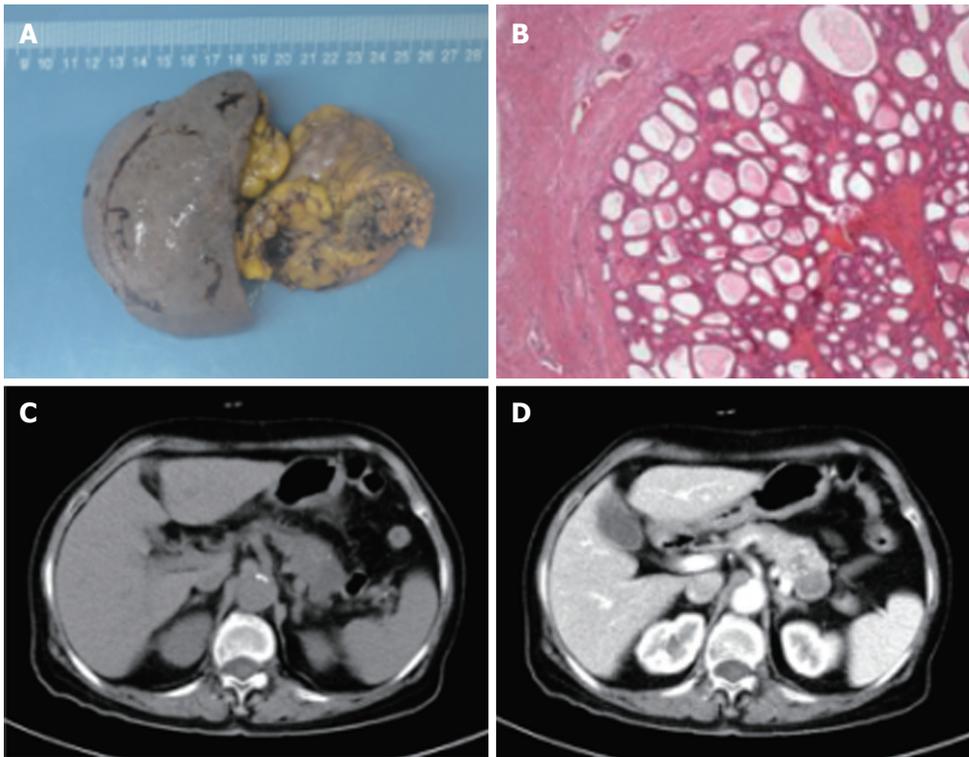

Figure 3 Solid variant microcystic serous cystic neoplasm with honeycomb characteristics. thin-walled septa and possibly calcification of the central septum^[44,45] (Figure 5). The honeycomb variants are interspersed within dense fibrous septa, with or without central fibrosis or calcification^[46,47]. The less common oligocystic SCNs usually contain larger (> 2 cm) cysts^[48]. However, the solid variant, which is defined when lesions are predominantly solid (< 10% cystic portion) and might resemble a ductal carcinoma on CT, contains numerous tiny cysts (1-2 mm) and appears as a hypoechoic mass on EUS^[49].

Management and surveillance of SCNs depend on correct preoperative diagnosis. One major concern is potential misdiagnosis of a malignancy or premalignancy as a benign SCN, which was more frequent in the past;

it was reported in seven of 28 patients in one study and in two of 49 patients in another^[50,51]. Among SCNs, macrocystic SCNs are frequently undistinguishable from MCNs and BD-IPMNs. BD-IPMNs may also present in a polycystic pattern, similar to microcystic SCNs^[52]. Typically, unlike IPMNs, SCNs are characterized by lack of communication with the main pancreatic duct. However, the absence of communication does not allow for the exclusion of IPMN, although this absence may favor the diagnosis of MCN over SCN^[53,54]. In contrast to MCNs, which usually exhibit a smooth oval shape and varied signal intensity (depending on the fluid viscosity of each lobule), macrocystic SCNs typically present with a thin wall and lobulated contours and can be

Figure 5 A microcystic pancreatic serous cystic neoplasm was discovered by endoscopic ultrasonography.

found in the head of the pancreas^[55]. A central calcified scar is virtually pathognomonic for SCNs (Figure 6), whereas peripheral calcifications are frequently observed in MCNs^[56]. Many solid variant SCNs show arterial hypervascularity on imaging studies and are frequently misdiagnosed as pancreatic neuroendocrine tumors (pNETs)^[57-59]. A recent study found that the frequency of hypervascular solid-appearing SCNs was 7.3% among surgically confirmed SCNs and unenhanced CT and MR features can help to differentiate solid variant SCNs from pNETs^[60].

Despite various potential complications of EUS-FNA, such as bleeding caused by injury of the subepithelial vascular plexus of SCNs, pancreatitis, infection, and even the seeding of malignant cells along the tract of the needle have been suggested^[61-63], EUS-FNA-related morbidity and mortality rates have remained low^[64] and the widespread use of EUS-FNA has yielded a wealth of information for cytological, chemical and molecular analysis of SCNs.

A 22- or 25-gauge needle is often used when aspirating cyst fluid during EUS-FNA. SCNs usually contain little fluid and the fluid usually contains few cellular components, and FNA cytological analysis has an unreliable sensitivity of only 30%-40%^[65]. For chemical analysis, assessment of tumor markers such as CEA, carbohydrate antigen (CA)19-9, CA15-3, CA72-4, and enzymes like amylase and lipase is often carried out, although it has proved of limited diagnostic value^[66]. Fluid from SCNs universally has low CEA levels. A level < 5 ng/mL is 95% specific for SCN, pseudocyst or pNET^[67]. However, an elevated CEA level favors a mucinous lesion, although the exact cut-off level is still in debate. It is also important to mention that the CEA threshold varies in different centers, ranging from 5 ng/mL to > 100 ng/mL^[68]. When a classic CEA cut-off level of 192 ng/mL is applied, it yields 73% sensitivity and 84% specificity for mucinous cysts^[69]. An amylase level < 250 U/L favors diagnosis of SCN over pseudocyst, with a sensitivity of 44%, specificity of 98% and overall accuracy of 65%^[68]. Other than CEA and amylase, recent studies have revealed that levels of cystic fluid

metabolites glucose and kynurenine are markedly elevated in SCNs compared to MCNs, which aids the diagnosis of SCNs^[70,71]. Although large prospective studies are warranted to validate these promising results, they shed light on a new path to seek better biomarkers. Molecular analysis of cystic fluid has gained in interest in recent years, in parallel with the advent of new techniques on sequencing. DNA analysis of KRAS mutations may help identify mucinous cysts with 54% sensitivity and 100% specificity, as demonstrated in a study containing 142 surgically resected cysts. When CEA and KRAS analysis were collectively applied, the sensitivity climbed to 83% while the specificity dropped to 85%^[72]. More interestingly, data from whole-exome sequencing of PCNs revealed that the application of a panel of five genes (*VHL*, *RNF43*, *KRAS*, *GNAS* and *CTNNB1*) allowed correct distinction of mucinous from nonmucinous cysts. All eight SCNs had intragenic mutations of *VHL* or loss of heterozygosity in or adjacent to *VHL* and did not contain mutations of the other four genes. Furthermore, point mutations of *VHL* gene were detected in cystic fluid analysis in half of the SCNs. Nevertheless, IPMNs had alterations of *RNF43*, *GNAS* or *KRAS* and never had *VHL* or *CTNNB1* mutations. MCNs always harbored *KRAS* or *RNF43* mutations but never contained *GNAS*, *CTNNB1* or *VHL* mutations^[73]. Another study stated that *GNAS* mutations were present in 10% of their cases of SCN, which was still significantly lower than in IPMNs^[74]. Thereafter, the identification of *GNAS* mutation may help discrimination of SCN from IPMN. Another mainstay of research of cystic molecular analysis gives insights into miRNAs. A panel of four miRNAs comprised miR-31-5p, miR-483-5p, miR-99a-5p and miR-375 has been developed to differentiate SCNs accurately from mucinous lesions, with 90% sensitivity and 100% specificity^[75]. While promising, these results were based on surgically archived specimens but not on cystic fluid, therefore, validation in cystic fluid samples should be addressed in future studies to fit these findings better in preoperative scenarios.

MANAGEMENT AND INTERVENTION STRATEGY FOR SCNs

As mentioned before, most SCNs follow a benign course and malignant SCNs (serous cystadenocarcinoma) are rare (< 1% of all cases). According to an investigation of 193 SCNs, along with a literature review, the clinicopathological characteristics of solid and macrocystic SCN variants are similar to those of their microcystic counterpart, and there are no deaths that are directly attributable to dissemination/malignant behavior of SCNs^[76]. It is also recommended to consider and manage SCNs as benign neoplasms initially^[77]. For this reason, correct preoperative diagnosis of SCNs could spare many unnecessary interventions and guide optimal management strategies. Currently, there

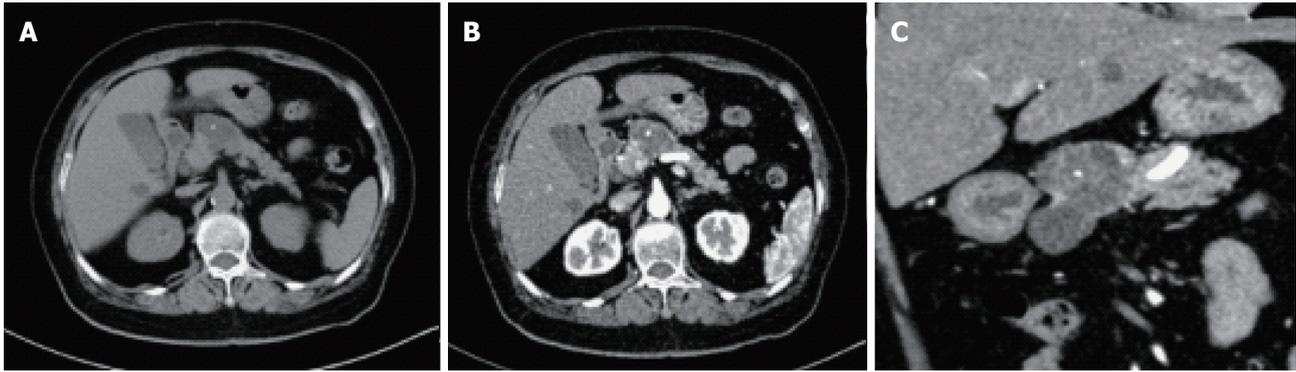

Figure 6 Central calcifications were found by computed tomography with and without enhancement (A and B), and also shown after three dimensional reconstruction (C).

is no universal consensus on the best management strategy, but it is widely accepted that not every single case should be surgically resected, regardless of how advanced surgical technology has been developed, and symptomatic, local invasive or potential malignant SCNs should be resected^[37,54,78]. It is also advised that resection should be considered for large (> 4 cm), rapidly growing SCNs, given that such SCNs are more likely to cause symptoms^[4,33]. However, it is difficult for a clinician to predict whether and when an incidentally found asymptomatic SCN will grow to cause symptoms. One older study claimed that a more rapid growth rate of approximately 1.98 cm/year was observed in cysts > 4 cm, whereas the growth rate was approximately 0.12 cm/year in cysts < 4 cm^[4]. A more recent multicenter study failed to confirm those results. In that same study, a rate of growth of 6.2% per year or a doubling time of 12 years was calculated for the nonresected SCNs, while resected SCNs grew faster (17% per year for a doubling time of 4.5 years)^[18]. In addition, there is also a paucity of knowledge about the relationship between growth rate and potential malignancy^[7]. Obviously, symptoms do occur when fast-growing SCNs are left unresected^[79]. It is tempting to conclude that initial size is neither associated with malignant transformation, nor proportionally related to developing symptoms. However, growth rate is more powerful to predict if and when the symptoms occur. Thus, the growth rate should be weighed when considering if an SCN should be subjected to surgical intervention. One multinational study stated that, in patients followed beyond 1 year ($n = 1271$), size increased in 37% (growth rate: 4 mm/year), was stable in 57%, and decreased in 6%, hence, surgical treatment should be proposed only in cases in which diagnosis remains uncertain after complete work-up^[20].

Surgery is considered curative. Despite increasing experience and advanced surgical techniques, pancreatic surgery holds a perioperative morbidity of 15%-30% and a mortality rate of 1%-2%, even in high-volume centers^[3]. The indications for surgical intervention are as follows: (1) presence of symptoms; (2) Uncertain diagnosis. MCNs and IPMNs can mimic SCNs

on radiology scans, especially macrocytic SCNs. When premalignant MCNs and IPMNs cannot be excluded, the lesions can be managed as IPMNs when the cysts are < 4 cm^[80] and are advised to be surgically removed accordingly following the International consensus in 2012 and the European consensus in 2013^[81,82]; and (3) growth rate of the neoplasm. As discussed above, large SCNs are not correlated with an increased risk of malignancy. Also, growth rate is not linked with initial size. The notion that any cyst > 4 cm or even > 5 cm be resected should be abandoned. In this regard, clinicians need to remain cautious when neoplasms grow rapidly, and make decisions on a case-by-case basis, including patient's age, comorbidity and tumor location. Large SCNs can always be closely observed first and then sent for surgery once they grow faster and cause unrelieved symptoms.

From an anatomical point of view, surgical resection of an SCN largely depends on the location of the lesion. As a result of the benign nature of SCN, as a general rule, it is recommended that pancreatic functions are protected and preserved as much as possible for better outcome and quality of life. If SCNs are localized in the pancreatic head, pylorus-preserving pancreatoduodenectomy or Begar procedure is often carried out. If SCNs are located in the body or tail of the pancreas, spleen-preserving distal pancreatectomy should be the first choice. For patients whose SCNs are located in the neck of the pancreas, central segmental pancreatectomy is an alternative procedure, preserving islet cell mass and reducing the risk of iatrogenic insulin-dependent diabetes. Enucleation is not recommended because greater morbidity (up to 35%) and associated complications such as pancreatic fistula^[83] have been reported.

As mentioned above, clinicians are encouraged to manage SCNs in a conservative manner, which means that, initially, these lesions do not require surgery but serial follow-up when radiological diagnosis is certain and symptoms are absent. However, to date, the best follow-up strategy has not been standardized. Some advocate follow-up imaging every 12 mo, while others suggest biennial surveillance^[84,85]. The European con-

sensus in 2013 suggests that asymptomatic nonresected patients should enter a follow-up program, initially repeated after 3-6 mo, and then individualized depending on growth rate^[81]. Once SCNs are resected, no further surveillance imaging is needed.

CONCLUSION AND FUTURE DIRECTIONS

Comprising about 16% of all resected PCNs, SCNs are uncommon benign lesions that are asymptomatic and found incidentally. Despite overall low risk of malignancy, the presence of these pancreatic cysts still generates anxiety, leading to extensive medical investigation with considerable financial cost to health care systems. CT and MRI alone are not powerful enough to characterize cystic pancreatic lesions fully, and more specifically, to differentiate macrocystic SCNs from MCNs. However, EUS, with or without addition of FNA, adds more diagnostic value to conventional imaging techniques. CEA, although not perfect, plays a role in differentiating pancreatic cystic lesions. New cystic fluid markers from chemical and molecular analyses are just beginning to emerge, paving a new way to future research. As for treatment and management strategy, surgery should be limited only to symptomatic SCNs and lesions that show aggressive behavior, while the majority of patients should be strictly monitored and followed up by serial imaging. Further investigations on best follow-up strategy are warranted. Patients would benefit from multidisciplinary management and receive precise medical advice once gastroenterology, surgery, pathology and radiology are all involved in individual patient care as a team. As such, patient care based on a multidisciplinary team is encouraged if applicable.

Abstract

Duodenal adenocarcinoma is a rare but aggressive malignancy. Given its rarity, previous studies have traditionally combined duodenal adenocarcinoma

(DA) with either other periampullary cancers or small bowel adenocarcinomas, limiting the available data to guide treatment decisions. Nevertheless, management primarily involves complete surgical resection when technically feasible. Surgery may require pancreaticoduodenectomy or segmental duodenal resection; either are acceptable options as long as negative margins are achievable and an adequate lymphadenectomy can be performed. Adjuvant chemotherapy and radiation are important components of multi-modality treatment for patients at high risk of recurrence. Further research would benefit from multi-institutional trials that do not combine DA with other periampullary or small bowel malignancies. The purpose of this article is to perform a comprehensive review of DA with special focus on the surgical management and principles.

Core tip: Duodenal adenocarcinoma is a rare but aggressive malignancy. Complete surgical resection is recommended when technically feasible. Pancreaticoduodenectomy or segmental duodenal resection may be employed, depending on the tumor location, and either are acceptable options as long as negative margins and adequate lymphadenectomy can be achieved. Although specific data are limited, adjuvant chemotherapy and radiation should be considered for patients at high risk of recurrence.

INTRODUCTION

Although the majority of small bowel adenocarcinomas arise in the duodenum, duodenal adenocarcinoma (DA) still represents less than 1% of all gastrointestinal cancers^[1,2]. Not surprisingly, given the rarity of the disease, there is limited data to guide treatment decisions. Early studies grouped DA with other periampullary tumors (pancreatic, ampullary, distal bile duct) when discussing their management options. However, in general, DA has a more favorable outcome. For example, compared to some other periampullary malignancies, DA is more likely to be amenable to curative resection and has more favorable long term outcomes^[3]. As a result, treatment strategies have tended to favor aggressive surgical resection. The purpose of this article is to provide a comprehensive review of the epidemiology, presentation, diagnosis, management and prognosis of DA with a special emphasis on surgical principles.

Epidemiology

Small bowel malignancies are relatively rare, accounting for only 2% of all gastrointestinal cancers in the United States^[4]. Among small bowel tumors, most malignancies arise from the ileum, followed by the duodenum and lastly the jejunum. While most tumors of the ileum are neuroendocrine in origin, adenocarcinoma is the most common duodenal cancer^[4-6]. One large population-based analysis found the duodenum to be the location of 55.7% of adenocarcinomas of the small bowel^[5]. The majority of DA arise in the second portion of the duodenum, followed by D3/D4, with cancers of the first portion of the duodenum, especially the duodenal bulb, extremely rare^[7,8].

The causative factors for DA have not been clearly identified. Dietary factors, such as increased intake of bread, pasta, sugar and red meat or reduced intake of fruits and vegetables, are risk factors for small bowel adenocarcinoma (SBA) as they are for colorectal cancer^[9]. Ingestion of alcohol, coffee and use of tobacco also seem to be risk factors^[10]. Nevertheless, the strength of these associations are small and the majority of cases of DA are not associated with any known causative agents. However, duodenal adenomas, such as those that occur in familial adenomatous polyposis (FAP) and Gardner syndrome, are associated with elevated risk of DA^[11,12]. Similarly, patients with duodenal polyps are also at increased risk^[13]. Although less investigated than in colon cancer, the adenoma-carcinoma sequence is still largely accepted in SBA as well^[14,15].

CLINICAL PRESENTATION

Since patients do not typically present until tumors have grown to sufficient size to cause symptoms, the diagnosis of DA is difficult and often delayed. When symptoms do appear they are nonspecific and include abdominal pain, nausea, vomiting, fatigue,

weakness, and weight loss. Anemia, gastrointestinal obstruction and jaundice are symptoms associated with advanced disease. Abdominal pain is the most common presenting symptom, associated with 56% of cases^[16]. As a result of these delays in diagnosis, many cases of DA are not resectable at presentation due to local and distant invasion. Less often, patients undergoing screening programs may be found to have early DA or even adenoma with dysplasia before symptoms begin^[17].

DIAGNOSIS

Imaging

Since early symptoms are typically vague, most patients initially undergo either esophagogastroduodenoscopy or cross sectional imaging. Endoscopy is the preferred diagnostic modality as it allows simultaneous visualization and biopsy. Evaluation by an experienced endoscopist is critical as examination of the entire duodenum is required. While lesions in the third or fourth portion of the duodenum can be technically challenging to view endoscopically, the use of extra-long fiber optic scopes may be helpful^[18]. Lesions in the distal duodenum may be missed on initial endoscopic evaluation, resulting in further diagnostic delays. Careful attention to proximity of pertinent structures such as the ampulla of Vater should be given. Endoscopic ultrasound may be performed simultaneously to evaluate local extension or lymphadenopathy. In addition, it may facilitate tissue diagnosis when attempts at luminal biopsy are not successful. Upper gastrointestinal series with oral contrast may facilitate precise localization, evaluate for obstruction and rule out other causes of patients' symptoms. Contrast-enhanced computed tomography is important for assessing involvement of nearby structures, determining resectability and planning surgery. In cases without a confirmed diagnosis, sensitive but non-specific radiographic features suggestive of malignancy include an exophytic or intramural mass, central necrosis and ulceration^[19]. While the role of conventional abdominal ultrasound is limited, especially for tumors < 2 cm in size, lesions appear as irregularly marginated hypoechoic masses^[20].

Pathology

Diagnosis of DA requires a thorough histopathologic examination of tissue specimens. Adenocarcinoma of gastric, pancreas, distal bile duct and ampullary origin must be ruled out. The degree of associated dysplasia should be assessed. Among extra-ampullary DA, several distinct subtypes have been described: intestinal, gastric, pancreaticobiliary and indeterminate (Table 1)^[21,22]. Interestingly, intestinal type DA has been associated with more favorable prognosis compared to other histological subtype^[22-24]. Variable expression of the classic cytokeratin markers CK7 and CK20 have made them largely unhelpful in diagnosing DA^[25,26]. However, CDX2, a sensitive marker for colorectal

Table 1 Histopathologic subtypes of duodenal adenocarcinoma

Phenotype	Histological characteristics	Histologically similar	Immunophenotype markers	Prognosis
Intestinal	Tubular/cribiforming glands lined by columnar neoplastic cells	Colonic adenocarcinoma	MUC2, CD10, CDX2	+
Gastric	Tubular/papillary proliferation with foveolar or pyloric-type differentiation	Gastric adenocarcinoma	MUC5AC, MUC6	-
Pancreaticobiliary	Simple glands of cuboidal/columnar cells with rounded pleomorphic nuclei; prominent desmoplastic stroma	Pancreatic and Extrahepatic bile duct adenocarcinoma	MUC1	-
Indeterminate	Poor differentiation	None	MUC1	-

Primary tumor (T)	Regional lymph nodes (N)		Distant metastases (M)
Tx - Primary tumor cannot be assessed	Nx - Regional lymph nodes cannot be assessed		Mx - Distant metastases not assessed
Tis - Carcinoma <i>in situ</i>	N0 - No regional node metastasis		M0 - Distant metastases not present
T1a - Tumor invades lamina propria	N1 - Metastasis in 1-3 regional nodes		M1 - Distant metastases present
T1b - Tumor invades submucosa	N2 - Metastasis in 4 or more regional nodes		
T2 - Tumor invades muscularis propria	Stage grouping		
T3 - Tumor invades into the subserosa	Stage 0	Tis	N0
	Stage I	T1-T2	N0
	Stage IIA	T3	N0
T4 - Tumor perforates visceral peritoneum; or invades pancreas/bile duct	Stage IIB	T4	N0
	Stage IIIA	Any T	N1
	Stage IIIB	Any T	N2
	Stage IV	Any T	Any N

carcinoma, is more often expressed in DA and SBA^[25,27]. Expression of Her2 in DA has been inconsistently reported in the literature^[25,28], perhaps because expression may be limited to gastric subtypes of DA^[22]. Conversely, Overman *et al.*^[25] found EGFR and VEGF expression rates of 71% and 91%, respectively, in a large series of SBA which was primarily comprised of DA.

Staging

Staging of DA is based on the 7th edition of the American Joint Committee on Cancer's TNM staging system that was published in 2010 (Table 2)^[29]. Accurate nodal staging depends on adequate lymphadenectomy at the time of surgery^[30,31].

SURGICAL MANAGEMENT

Relevant anatomy

The duodenum is the first of portion of the small intestine and functions as a conduit between the stomach and the jejunum while regulating the emptying of gastric contents and enzymatically breaking down the chyme received from the stomach. The surgical management of duodenal cancers varies by the portion of the duodenum involved, and hence the basic anatomic divisions merit review. The first segment of the duodenum is suspended by the hepatoduodenal ligament, lies intraperitoneally, begins caudal to the pylorus and extends 5 cm to the duodenal flexure.

Moving retroperitoneally, the second segment spans approximately 7.5 cm and is fixed to and curves around the head of the pancreas to travel medially at the level of L3. The transverse, or third, portion of the duodenum is 10 cm in length and lies anterior to the aorta and inferior vena cava but posterior to the superior mesenteric vein and artery. The ascending, or fourth, segment of the duodenum is approximately 2.5 cm in length and heads superior and laterally to become intraperitoneal again as it reaches the ligament of Treitz at the anatomical boundary of the duodenojejunal junction.

Surgical approach

Tumors located in the second portion of the duodenum typically require pancreaticoduodenectomy (PD) because of proximity to head of the pancreas, distal bile duct and ampulla of Vater. Conversely, tumors occurring in the first, third or fourth portion of the duodenum may be managed by either PD or segmental resection (SR). Some will argue that PD should be used for all DAs, regardless of location, to ensure wide margins and adequate regional lymphadenectomy. This opinion is based on the results of early series reporting few long-term survivors of SR^[32-39]. Still others will argue for SR of tumors in either the very proximal or very distal duodenum provided that wide margins can be achieved^[40-42] in order to avoid the morbidity of PD. Most studies that compared outcomes of two approaches found no statistically significant difference

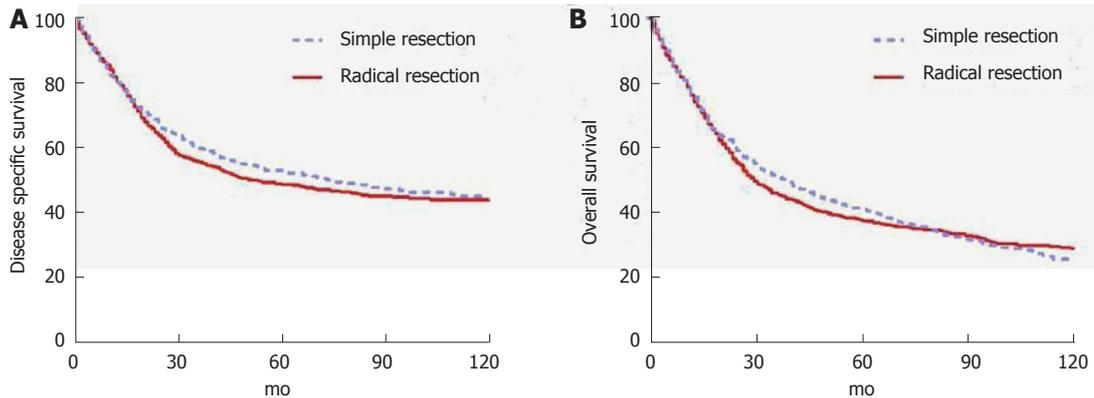

Figure 1 Outcomes of surgery for duodenal adenocarcinoma based on type of surgery. Used with permission: Cloyd *et al*^[49].

in outcomes, but were limited by small sample sizes and retrospective design^[13,42-48]. Cloyd *et al*^[49] recently utilized the surveillance, epidemiology and end results database to retrospectively compare the outcomes of radical resection (defined as a resection of the primary duodenal tumor *en bloc* with an adjacent organ, as is performed in PD) vs SR across a population-based cohort of patients with DA. In this study of 1611 patients from 1988 to 2010, radical resection was associated with a greater number of LNs excised but not improved survival (Figure 1). Although PD may be required for technical reasons in some situations, the study suggests that SR is an appropriate strategy as long as negative margins can be obtained^[49].

Regardless of the approach, an R0 resection remains the most important goal for surgery with curative attempt. Margin status directly impacts outcomes. Sohn *et al*^[35] reported the Johns Hopkins experience and showed a 5 year OS of 58% in margin negative patients vs 0% in margin positive patients. Similarly, Poultsides *et al*^[50] reviewed the Memorial Sloan Kettering Cancer Center (MSKCC) experience and found 5 year OS rates of 55% and 0% among R0 and R1 patients, respectively.

Lymphadenectomy

The importance of an adequate lymphadenectomy cannot be underscored. Sarela *et al*^[51] were among the first to report improved prognostic abilities of the N staging system with higher number of lymph nodes retrieved. In fact, a greater lymph node retrieval has independently been associated with improved survival for patients with DA^[2,31,49]. Although the American Joint Committee on Cancer has recommended a minimum pathologic evaluation of 6 lymph nodes, several authors have questioned whether this minimum number should be raised^[50,52]. Intuitively, one might expect operations that enable a better lymphadenectomy, such as a classic PD vs a pylorus-preserving PD or PD vs SR, would therefore be associated with improved survival. However, this has not been found to be the case, either in randomized controlled trials^[53] or population-based analyses^[49]. Although the reasons behind why greater

lymph node retrieval is associated with improved survival may be complex and multifactorial, it is likely primarily secondary to improved stage stratification and prognostication.

Palliative surgery

Among patients with localized DA, approximately 43%-87% will have resectable disease^[54]. Of the remainder, some will require palliation. The goals of palliative surgery for DA may include relief of gastric outlet obstruction, relief of biliary obstruction and/or pain relief. Operative interventions for gastroduodenal obstruction may include gastrojejunostomy or duodeno-jejunosomy; either may be constructed in a roux-en-y or loop fashion. Minimally invasive approaches are possible in the correct context. Surgery for biliary obstruction typically involves a roux-en-y hepatico-jejunosomy. A 13-year prospective study from the United Kingdom examining surgery for DA found that of the 178 patients included in the study, 150 underwent surgery with curative intention and 28 underwent surgery for palliation. Of those who received palliation, 15 had a gastrojejunostomy, 9 had a double bypass and 4 underwent an exploratory laparotomy without further intervention. Median survival in the palliative surgery group was 8 mo. Not surprisingly, those who undergo palliative surgery are more likely to have a larger tumor, greater degree of invasiveness, as well as regional and distant metastases^[55]. For patients who are not already undergoing surgical exploration and require palliation for enteral or biliary obstruction, endoscopically placed duodenal and biliary stents, when technically feasible, are preferable to avoid laparotomy given the limited prognosis.

Pancreas-preserving total duodenectomy

Although a comprehensive discussion is outside the scope of this review article, pancreas-preserving total duodenectomy (PPTD) has emerged as an alternative to PD or SR for patients with benign or pre-malignant conditions of the duodenum, most commonly in the setting of FAP. After total proctocolectomy, upper gastrointestinal cancers are the most common cause

of death in patients with FAP^[56]. Intense screening programs utilizing duodenoscopy with endoscopic polypectomy have proven effective in reducing the incidence of DA in this high risk population^[57]. In patients with diffuse polyposis or Spigelman stage IV disease, however, prophylactic duodenectomy may be indicated^[56,58,59]. Several techniques of PPTD have been described^[60-63] including minimally invasive options^[64]. Despite the advantages of organ preservation, short term morbidity and mortality rates remain high^[65]. It is important to note that invasive carcinoma in FAP patients should be treated similarly to sporadic DA with either PD or SR (as described above) in order to ensure adequate margins and lymphadenectomy. Pylorus-preserving PD should be avoided in patients with FAP as the residual duodenal bulb remains at risk for new polyp and carcinoma formation^[66].

ADJUVANT THERAPY

Chemotherapy

Unfortunately, little data is currently available to inform the choice of adjuvant chemotherapy following complete surgical resection. The ESPAC-3 trial was a phase 3, multi-institutional, randomized controlled trial comparing observation vs adjuvant fluorouracil vs adjuvant gemcitabine in patients with periampullary cancers (ampullary, bile duct, duodenal or other) who underwent PD with R0 or R1 resection status. Although median survival was not significantly different between the observation and adjuvant therapy groups in the primary analysis (35 mo vs 43 mo), adjuvant chemotherapy was associated with improved OS after multivariable regression (HR = 0.75, 95%CI: 0.57-0.98)^[67]. Importantly, periampullary DA comprised a small subset of this study's population and extra-ampullary DA was not included.

Given its rarity, most therapeutic studies have traditionally combined DA with either other periampullary cancers or small bowel adenocarcinomas. For this reason, chemotherapeutic regimens are not standardized, but increasingly DA is being treated similar to colorectal adenocarcinoma with oxaliplatin-based chemotherapy. Given the tendency of this disease to recur systemically, the role of adjuvant chemotherapy warrants further investigation. Current practice at many centers is to treat patients with high risk features (*e.g.*, nodal metastasis) with oxaliplatin-based chemotherapy^[50].

Definitive, or palliative, chemotherapy should be offered to all eligible patients with metastatic or

unresectable disease. A phase II prospective trial studied 30 patients with metastatic or unresectable small bowel or ampullary adenocarcinoma who received capecitabine and oxaliplatin and noted a 50% overall response rate, 10% complete response. Median time to progression was 11 mo with median overall survival 20 mo^[68,69]. Patients should also be considered for clinical trials as appropriate.

Chemoradiation

The role of adjuvant radiotherapy in the treatment of DA is not well defined. No studies have demonstrated an effect on OS with the use of chemoradiotherapy (CRT). One small study of 14 patients from Johns Hopkins with node-positive DA treated with PD and adjuvant CRT (median dose of 50 Gy, concurrent 5-FU) resulted in improved local control compared with surgery alone (93% vs 67%)^[70]. Similarly, a retrospective study of 32 patients from Duke University Medical Center was able to show modest improvement in local control (70% vs 49%) with adjuvant CRT^[71]. Unfortunately, neither study showed that adjuvant chemoradiation contributed to improved overall survival: 5-year survival 44% vs 43%^[70] and 44% vs 57%^[71], respectively. Other retrospective series have shown similar results with improvements in locoregional control but not OS^[72]. Nevertheless, this approach targeting improved locoregional control may make CRT particularly useful in patients with lymph node metastases. In a study of 122 patients at a single institution who underwent curative resection for DA, adjuvant CRT in patients with a higher prevalence of regional lymph node metastases was associated with a similar overall survival to that of a group of patients with limited or no nodal metastases who did not receive adjuvant therapy^[50].

OUTCOMES

Short term

Surgery for DA can be associated with significant morbidity and mortality. Poultsides *et al*^[50] in their contemporary series of PD at MSKCC, reported a postoperative morbidity rate of 35% and 30-d mortality rate of 2.4%. Solaini *et al*^[48] published a postoperative complication rate of 40% and in-hospital mortality rate of 3.3% for all patients undergoing surgery for DA. In these studies, postoperative pancreatic fistulae (POPF) developed following PD in 14.0% and 10.6% of patients, respectively^[48,50]. The impact of the type of resection on postoperative outcomes is controversial. Some have suggested that SR is associated with

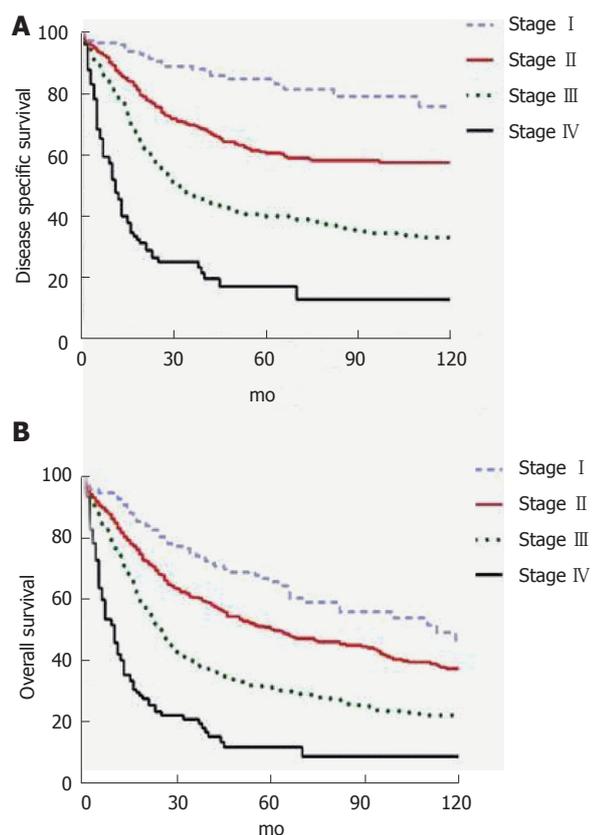

Figure 2 Stage-based disease free (A) and overall (B) survival for patients undergoing surgery for duodenal cancer based on seer data. Used with permission: Cloyd *et al.*^[49].

improved outcomes as it avoids the opportunity for POPF. Tocchi *et al.*^[13] reviewed their series of 47 patients undergoing surgery for DA and found SR to be associated with less postoperative morbidity, mortality and length of hospital stay. Bakaeen *et al.*^[44] found similar complication rates but shorter LOS in the patients undergoing SR. Other studies have failed to find an effect of surgery type on complication rates^[43,48]. The occurrence of a postoperative complication may be associated with worse long term survival^[73].

Long term

DA represents an aggressive cancer but in patients with resectable disease, long term outcomes are better than with other periampullary malignancies. In a retrospective study of 122 patients who underwent PD for DA over a 22 year period at MSKCC, ten-year OS was 41%^[50]. A prospective cohort study of 150 patients from six United Kingdom hepatopancreaticobiliary centers undergoing curative intent surgery for DA from 2000-2013 found 1-, 3- and 5-year OS rates of 83.9%, 66.7% and 51.2%, respectively. Median disease-free survival was 53 mo^[48]. A recent population-based study suggested worse outcomes with 5-year OS rates of 65.9%, 50.4%, 31.4%, and 11.9% for Stage I, II, III and IV, respectively (Figure 2)^[49]. Patients with metastatic or unresectable disease have median survival that ranges from 2-8 mo^[68,69,74,75].

Prognostic factors

Factors associated with worse outcome in DA include patient age, distant metastasis, lymph node metastasis, lymph node ratio, number of lymph nodes harvested, high tumor grade, tumor (T) stage, margin status, lymphovascular or perineural invasion, and overall cancer stage (Table 3). Lymph node metastasis remains one of the most important prognostic determinants^[41,43,44,49-51,74,76-78]. In the largest single institution series of 122 patients who underwent PD for DA, the presence of lymph node metastases was the only independent predictor of decreased survival in multivariate analysis. Five-year survival for node negative (N0) patients was 68% compared to 17% in patients with N2 disease^[50]. Another study calculated 3-year survival for node negative patients to be 87.5% compared to only 21% in patients with nodal disease^[74]. LNR, the ratio of positive LNs to number of LNs excised, may be even a more accurate predictor of prognosis^[2,31,49].

CONCLUSION

Duodenal adenocarcinoma is a rare but aggressive malignancy. Because of the nonspecific symptoms it presents with and the difficulty in confirming a diagnosis, patients may often present with advanced disease. Nonetheless, aggressive surgical resection, when possible, affords the best chance at survival. The decision of whether to perform pancreaticoduodenectomy vs segmental resection depends on the location of the primary tumor as both are acceptable options as long as negative margins can be safely obtained. Lymph node positivity is one of the most important prognostic indicators and a wide lymphadenectomy should be routinely performed. Although data are limited guiding adjuvant therapy options, oxaliplatin-based chemotherapy is typically offered to high risk patients, such as those with positive lymph nodes. In some series, adjuvant radiation is associated with improved local control but no difference in overall survival. Previous research on DA has been limited by small sample sizes and single institutional design. Further research would benefit from multi-institutional trials that do not combined DA with other periampullary or small bowel malignancies.

Abstract

Intra-abdominal adhesions following abdominal surgery represent a major unsolved problem. They are the first cause of small bowel obstruction. Diagnosis is based on clinical evaluation, water-soluble contrast follow-through and computed tomography scan. For patients presenting no signs of strangulation, peritonitis or severe intestinal impairment there is good evidence to support non-operative management. Open surgery is the preferred method for the surgical treatment of adhesive small bowel obstruction, in case of suspected strangulation or after failed conservative management, but laparoscopy is gaining widespread acceptance especially in selected group of patients. "Good" surgical technique and anti-adhesive barriers are the main current concepts of adhesion prevention. We discuss current knowledge in modern diagnosis and evolving strategies for management and prevention that are leading to stratified care for patients.

Key words: Adhesive disease; Intestinal obstruction; Diagnosis of adhesive small bowel obstruction; Non-operative management of adhesive disease; Emergency surgical treatment

Core tip: Adhesive disease is a consequence of all intra-peritoneal surgeries. We decided to carry out a systematic review about the adhesive small bowel

obstruction because it is still difficult to make differential diagnosis and to understand the right time to operate and which surgical technique to perform. Besides there is a way to prevent major adhesive disease: "Good" surgical technique and anti-adhesive barriers are the main current concepts of adhesion prevention. We discuss all current knowledge in this field.

INTRODUCTION

Adhesive disease is the most frequently encountered disorder of the small intestine; in one review of 87 studies including 110076 patients, the incidence of adhesive small bowel obstruction (ASBO) following all types of abdominal operations was 2.4%^[1].

In North America, there are more than 300000 annual hospital admissions for ASBO accounting for 850000 d of inpatient care, costing more than \$1.3 billion in medical expenditures and contributing to more than 2000 deaths annually^[2].

Dembrowski published the first data on induction of adhesions in an animal model in 1889 and in the following 120 years there have been extensive studies both *in vitro* and *in vivo*^[3].

In the past decade, limited clinical research has produced uncertainty about best practice with subsequent international variation in delivery and in outcome.

There is a diagnostic dilemma on how to distinguish between adhesive SBO and other causes, and how to distinguish between ASBO that needs emergency surgery and ASBO that can be successfully treated conservatively.

ASBO after peritoneal cavity surgery is a well-known disease entity that still harbors challenges regarding prevention, diagnosis and treatment despite general improvements in care. Good surgical technique, *e.g.*, laparoscopy, and anti-adhesive barriers at initial surgery seem to reduce ASBO but reports have conflicting results and only provide general conclusions which do not apply for each individual patient. Contrast enhanced computed tomography (CT) has improved diagnosis of ASBO in general but cannot be performed in each patient (severe vomiting, kidney failure) and fails to accurately identify adhesions as the cause. Also, predicting which treatment should be installed and success of treatment by CT is under debate. Regarding surgical treatment laparoscopy has gained popularity but also is associated with increased risk of iatrogenic complications. Particularly, identifying patients who might benefit from laparoscopic adhesiolysis and who

should not and should be treated by open surgery is a challenge.

Therefore, ASBO diagnosis, treatment and prevention are important for reducing mortality, morbidity and for socioeconomic reasons.

The aim of this review is to provide an update of the current controversies over diagnosis, non-operative/operative management and prevention of ASBO.

LITERATURE RESEARCH

We searched the Cochrane Library, MEDLINE, and EMBASE, limited to the final search date (31/03/2015) and not limited to English language publications.

We used the search terms "small bowel" or "obstruction" in combination with the terms "adhesions" or "adhesive" or "adherences".

We largely selected publications in the past five years, but did not exclude commonly referenced and highly regarded older publications.

We also searched the reference lists of articles identified by this search strategy and selected those we judged relevant.

We searched ClinicalTrials.gov (01/01/2000-31/03/2015) for current trials in ASBO.

EPIDEMIOLOGY

Intra-abdominal adhesions following abdominal surgery represent a major unsolved problem; in patients with abdominal pain, ASBO is a common cause that accounts for 4% of all emergency department admissions and 20% of emergency surgical procedures^[4].

These fibrous bands are thought to occur in up to 93% of patients undergoing abdominal surgery and can complicate future surgery considerably^[5].

Adhesion formation can result in significant morbidity, mortality and infertility in women, and adhesion-related complications are also responsible for up to 74% cases of ASBO in adults and 30% of re-admissions at 4 years after an incident intra-abdominal surgery^[6].

It is unknown whether the increase in laparoscopic intra-abdominal surgery has translated into fewer postoperative complications due to adhesions; a recent review of 11 experimental studies involving seven animal models and four human studies reported mixed results. Some reported decreased rates of adhesion formation after laparoscopy. However, there was significant heterogeneity among the human studies^[7,8].

Furthermore, some evidence suggests that this decrease in adhesion formation has not necessarily translated to a decrease in adhesion-related obstruction; in a recent randomized, multi-center trial comparing outcomes in laparoscopic vs conventional approaches in colorectal surgery for malignancy, there was no difference between the two groups in obstruction-related complications at 3-year follow-up consultations^[9].

However, in a long-term follow-up study examining the rate of hospitalization due to ASBO for patients

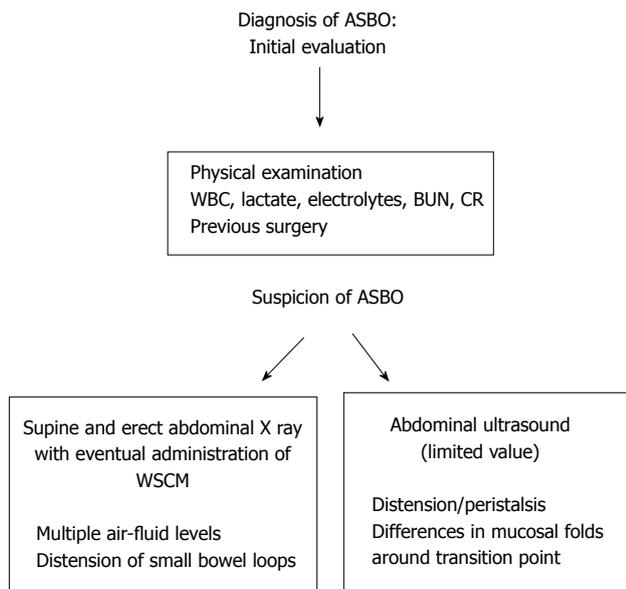

Figure 1 Adhesive small bowel obstruction diagnosis: Initial evaluation. ASBO: Adhesive small bowel obstruction; WBC: White blood cell count; BUN: Blood urea nitrogen; CR: Creatinine; WSCM: Water soluble contrast medium.

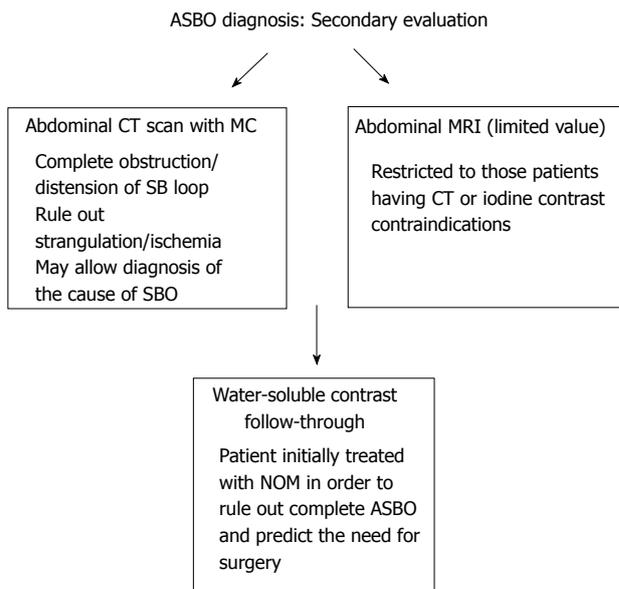

Figure 2 Adhesive small bowel obstruction diagnosis: Secondary evaluation. ASBO: Adhesive small bowel obstruction; NOM: Non operative management; CT: Computed tomography; MC: Medium contrast.

operated on due to suspected appendicitis, the laparoscopic approach resulted in significantly lower rates compared to open surgery. However, frequency of ASBO after the index surgery was low in both groups^[10].

In a recent meta-analysis the incidence of adhesive small bowel obstruction was highest in pediatric surgery (4.2%, 2.8% to 5.5%; $I^2 = 86\%$) and in lower gastrointestinal tract surgery (3.2%, 2.6% to 3.8%; $I^2 = 84\%$); the incidence was lowest after abdominal wall surgery (0.5%, 0.0% to 0.9%; $I^2 = 0\%$), upper gastrointestinal tract surgery (1.2%, 0.8% to 1.6%; $I^2 = 80\%$), and urological surgery (1.5%, 0.1% to 3.0%; $I^2 = 67\%$)^[11].

DIAGNOSIS

Preliminary assessment

The first step in the diagnostic work flow for ASBO is a detailed anamnesis and physical examination, followed by the evaluation of a complete blood count with differential especially white blood cell (WBC) count, electrolytes including blood urea nitrogen and creatinine, C-reactive protein, serum lactate, lactate dehydrogenase (LDH) and creatine kinase (CK). In patients who present with systemic signs (*e.g.*, fever, tachycardia, hypotension, altered mental status), additional laboratory investigation should include arterial blood gas and serum lactate. Although patients with ASBO generally may complain a varied assortment of symptoms, such as discontinuous abdominal pain, nausea and vomiting, associated, in the vast majority of cases, with a history of previous abdominal surgery^[11], these clinical symptoms contribute only to some extent to the diagnosis of ASBO^[12]. Unfortunately, the clinical symptoms of ASBO are even less consistent predictors in differentiating patients with bowel strangulation who

need emergency surgical intervention^[13]. Laboratory tests may be more useful to estimate the grade of systemic illness, than to confirm clinical suspicions. Actually the typical inflammatory markers, like WBC count and CPR levels, cannot discriminate between the inflammation due to ASBO and that caused by other inflammatory conditions^[14,15]. In the case of bowel ischemia due to strangulation, these markers cannot discriminate the patients who benefit from conservative treatment and those who need surgery^[16,17]. Nevertheless, when evolution to ischemia follows, serum lactate, LDH and CK may increase due to bowel hypoperfusion^[16]. However, since LDH and CK increase in any ischemic state, they are consequently quite unspecific. Instead, because serum lactate rises only at a stage when widespread bowel infarction is already well established, lactate increase is highly sensitive, but not specific, for ischemia in patients with ASBO (sensitivity 90%-100%, specificity 42%-87%), being thus a robust sign to proceed to urgent surgery^[18,19]. Recent reports indicate that, although there is no reliable clinical or laboratory marker for intestinal ischemia, an intestinal fatty acid binding protein, which is released by necrotic enterocytes, may become a useful marker for the detection of bowel ischemia^[20]. In conclusion, laboratory tests can simply indicate general disease severity and can be used to support or rule out an emergency surgical choice only in the context of agreement of a number of other clinical findings. Moreover, serum tests are clearly worthwhile in the evaluation of any patient with acute obstruction, because they may indicate needed adjustment of electrolyte abnormalities and fluid resuscitation (Figure 1).

Secondary evaluation

While ASBO may be suspected based only upon

Figure 3 Adhesive small bowel obstruction caused by single band adhesion: Computed tomography scan.

risk factors, symptoms, and physical examination, abdominal imaging is usually required to confirm the diagnosis, eventually detecting the location of obstruction and identifying complications, like ischemia, necrosis, and perforation^[21,22]. Although multiple imaging modalities are available to confirm a suspected diagnosis of ASBO, plain radiography and abdominal CT are those most suitable and useful. Thus, the preliminary assessment for all patients suspected for ASBO should include supine and erect plain abdominal radiography that can display multiple air-fluid levels with distension of small bowel together with the absence of gas in the colon^[23]. However, it must be said that the reason or site of obstruction is usually not clear on plain radiography, since a specific site between the enlarged proximal and undilated distal bowel frequently cannot be recognized with certainty. For the diagnosis of ASBO, the sensitivity, specificity, and accuracy of plain X-ray are from 79% to 83%, from 67% to 83%, and from 64% to 82%, respectively (Figure 2).

Abdominal CT scans (Figure 3), especially with administration of oral or intravenous contrast medium, perform better than plain X-ray in finding the transition point, evaluating the severity of obstruction, identifying the cause of obstruction, and recognizing complications (ischemia, necrosis, and perforation)^[24]. The sensitivity, specificity, and accuracy of CT scans for ASBO diagnosis are, respectively, from 90% to 94%, 96%, and 95%^[25]. CT has been demonstrated to be highly diagnostic in ASBO, especially in all patients with inconclusive plain X-ray^[26]. However, it should not be routinely implemented in the diagnosis-making process except when clinical history, physical examination, and plain film were not convincing for ASBO diagnosis^[27], since these are readily available, less expensive, expose the patient to less radiation, and may highlight the need for abdominal CT in some patients.

Abdominal ultrasound and magnetic resonance enterography may be useful for the diagnosis of ASBO only in selected patients and their use should be restricted to those patients having CT or iodine contrast contraindications^[28].

Although small bowel contrast studies, in general, have a limited role in the initial diagnosis of ASBO and in some circumstances, like in the presence of perforation, some of them, as those with the use of barium, are contraindicated^[24], instead those using water-soluble contrast agents (WSCA), being safer than barium in cases of perforation and peritoneal spread, are extremely valuable in patients undergoing initial non-operative conservative management in order to rule out complete ASBO and predict the need for surgery^[29]. In this sense, small bowel WSCA studies in the presence of ASBO have not only diagnostic, but especially therapeutic value^[26].

TREATMENT -

NON-OPERATIVE MANAGEMENT

Patient selection

For patients presenting with ASBO without signs of strangulation, peritonitis or severe intestinal impairment there is good evidence to support NOM.

Free intraperitoneal fluid, mesenteric edema, lack of the "small bowel feces sign" at CT-scan, history of vomiting, severe abdominal pain (VAS > 4), abdominal guarding, raised white cell count and devascularized bowel at CT-scan predict the need for emergent laparotomy^[30].

Moreover, patients with repeated ASBO episodes, many prior laparotomies for adhesions and prolonged conservative treatment should be cautiously selected to find out only those who may benefit from early surgical interventions^[30].

At present, there is no consensus about when conservative treatment should be considered unsuccessful and the patient should undergo surgery; in fact, the use of surgery to solve ASBO is controversial, as surgery induces the formation of new adhesions^[30].

Level I data have shown that NOM can be successful in up to 90% of patients without peritonitis^[31].

As a counterpart, a delay in operation for ASBO places patients at higher risk for bowel resection. A retrospective analysis showed that in patients with a ≤ 24 h wait time until surgery, only 12% experienced bowel resection and in patients with a ≥ 24 h wait time until surgery, 29% required bowel resection^[32].

Schraufnagel *et al.*^[33] showed that in their huge patient cohort, the rates of complications, resection, prolonged length of stay and death were higher in patients admitted for ASBO and operated on after a time period of ≥ 4 d.

The World Society of Emergency Surgery 2013 guidelines stated that NOM in the absence of signs of strangulation or peritonitis can be prolonged up to 72 h. After 72 h of NOM without resolution, surgery is recommended^[30].

There are no objective criteria that identify those patients who are likely to respond to conservative treatment. Less clear, in fact, is the way to predict

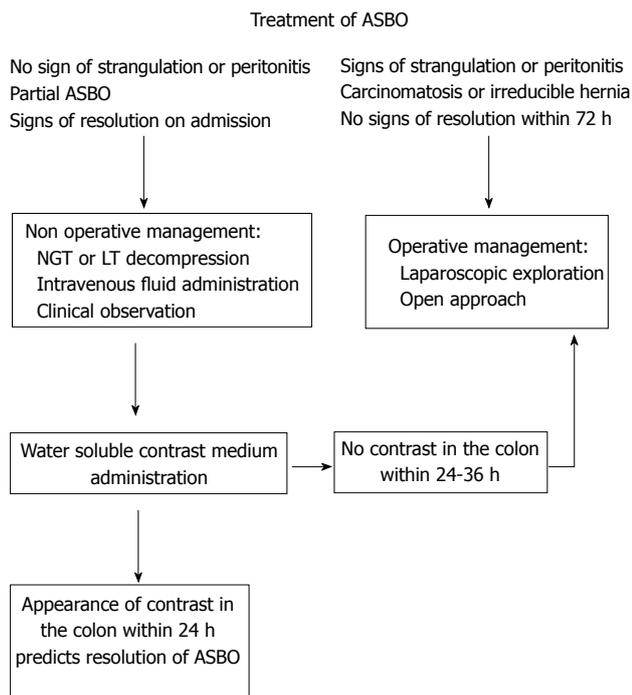

Figure 4 Adhesive small bowel obstruction treatment. ASBO: Adhesive small bowel obstruction; NGT: Naso-gastric tube; LT: Long tube.

between progression to strangulation or resolution of ASBO. Some authors suggested the following as strong predictors of NOM failure: The presence of ascites, complete ASBO (no evidence of air within the large bowel), increased serum creatine phosphokinase and ≥ 500 mL from nasogastric tube on the third NOM day^[30].

However, at any time, if there is an onset of signs of strangulation, peritonitis or severe intestinal impairment, NOM should be discontinued and surgery is recommended.

It is really difficult to predict the risk of operation among those patients with ASBO who initially underwent NOM^[30].

Tube decompression, WSCA and other treatments

Randomized clinical trials showed that there are no differences between the use of nasogastric tubes compared to the use of long tube decompression^[34].

In any case, early tube decompression is beneficial in the initial management, in addition to required attempts of fluid resuscitation and electrolyte imbalance correction. For challenging cases of ASBO, the long tube should be placed as soon as possible, more advisable by endoscopy, rather than by fluoroscopic guide^[35].

Several studies investigated the diagnostic-therapeutic role of WSCA^[36]. Gastrografin is the most commonly utilised contrast medium. It is a mixture of sodium diatrizoate and megluminediatrizoate. Its osmolarity is 2150 mOsm/L. It activates movement of water into the small bowel lumen. Gastrografin also decreases oedema of the small bowel wall and it may also enhance smooth muscle contractile activity that

can generate effective peristalsis and overcome the obstruction^[37].

The administration of WSCA proved to be effective in several randomized studies and meta-analysis. Three recent meta-analyses showed no advantages in waiting longer than 8 h after the administration of WSCA^[26] and demonstrated that the presence of contrast in the colon within 4-24 h is predictive of ASBO resolution. Moreover, for patients undergoing NOM, WSCA decreased the need for surgery and reduced the length of hospital stay^[38,39].

Oral therapy with magnesium oxide, *L. acidophilus* and simethicone may be considered to help the resolution of NOM in partial ASBO with positive results in shortening the hospital stay^[40].

Lastly hyperbaric oxygen therapy may be an option in the management of high anesthesiologic risk patients for whom surgery should be avoided^[41].

No agreement exists about the possibility to predict the recurrence risk. Factors associated with a higher risk of recurrence are age < 40 years, matted adhesion and postoperative surgical complications^[42]. Compared to traditionally conservatively treated patients, Gastrografin use does not affect either the ASBO recurrence rates or recurrences needing surgery (Figure 4)^[29].

SURGERY

Open surgery

Until recently open surgery has been the preferred method for the surgical treatment of ASBO (in case of suspected strangulation or after failed conservative management), and laparoscopy has been suggested only in highly selected group of patients (preferably in case of first episode of ASBO/or anticipated single band adhesion) using an open access technique and the left upper quadrant for entry^[30] (Figure 5).

More recently, the use of laparoscopy is gaining widespread acceptance and is becoming the preferred choice in centers with specific expertise.

A meta-analysis by Li *et al.*^[43] found that there was no statistically significant difference between open vs laparoscopic adhesiolysis in the number of intraoperative bowel injuries, wound infections, or overall mortality. Conversely there was a statistically significant difference in the incidence of overall and pulmonary complications and a considerable reduction of prolonged ileus in the laparoscopic group compared with the open group. The authors concluded that laparoscopic approach is safer than the open procedure, but only in the hands of experienced laparoscopic surgeons and in selected patients^[43].

However, no randomized controlled trial comparing open to laparoscopic adhesiolysis exists to date, and both the precise indications and specific outcomes of laparoscopic adhesiolysis for adhesive SBO remain poorly understood. The only randomized controlled trial aiming to provide level Ib evidence to assess the use of laparoscopy in the treatment of adhesive small bowel

Figure 5 Adhesive small bowel obstruction caused by single band adhesion: Open surgery.

Figure 6 Adhesive small bowel obstruction caused by single band adhesion: Laparoscopic surgery.

obstruction is currently ongoing, having the length of postoperative hospital stay as the primary endpoint and the passage of stools, commencement of enteral nutrition, 30-d mortality, complications, postoperative pain, length of sick leave, rate of ventral hernia and the recurrence of small bowel obstruction during long-term follow-up as secondary and tertiary endpoints^[44].

Laparoscopy

Laparoscopic adhesiolysis (Figure 6) for small bowel obstruction has a number of potential advantages including less postoperative pain, faster return of intestinal function, shorter hospital stay, reduced recovery time, allowing an earlier return to full activity, fewer wound complications, and decreased postoperative adhesion formation^[45].

In a recent large population-based propensity score-matched analysis involving 6762 patients^[46], laparoscopic treatment of ASBO was associated with lower rates of postoperative morbidity, including SSI, intraoperative transfusion, and overall lower resource use compared with laparotomy as well as shorter hospital stay. Laparoscopic treatment of surgical ASBO is not associated with a significant difference in operative time, rates of re-operation within 30 d, or mortality.

Further recent reports confirmed that laparoscopic surgical management of adhesive SBO is associated with quicker gastrointestinal recovery, shorter length of stay (LOS), and reduced overall complications compared to open surgery, without significant differences in operative times^[47]. Furthermore, following exclusion of bowel resections, secondary outcomes continued to favor laparoscopy.

Although laparoscopic adhesiolysis requires a specific skill set and may not be appropriate in all patients, the laparoscopic approach demonstrates a clear benefit in 30-d morbidity and mortality even after controlling for preoperative patient characteristics (lower major complications and incisional complications rate) as well as shorter postoperative LOS and shorter mean operative times. Given these findings in more than 9000

patients and consistent rates of SBO requiring surgical intervention in the United States, increasing the use of laparoscopy could be a feasible way of to decrease costs and improving outcomes in this population^[48].

Patient selection is still a controversial issue. From a recent consensus conference^[49], a panel of experts recommended that the only absolute exclusion criteria for laparoscopic adhesiolysis in SBO are those related to pneumoperitoneum (*e.g.*, hemodynamic instability or cardiopulmonary impairment); all other contraindications are relative and should be judged on a case-to-case basis, depending on the laparoscopic skills of the surgeon.

Nonetheless it is now well known that the immune response correlates with inflammatory markers associated with injury severity and, as a consequence, the magnitude of surgical interventions may influence the clinical outcomes through the production of molecular factors, ultimately inducing systemic inflammatory response and the beneficial effect of minimally invasive surgeries and of avoiding laparotomy is even more relevant in the frail patients^[50].

Laparoscopic adhesiolysis is technically challenging, given the bowel distension and the risk of iatrogenic injuries if the small bowel is not appropriately handled. Key technical steps are to avoid grasping the distended loops and handling only the mesentery or the distal collapsed bowel. It is also mandatory to fully explore the small bowel starting from the cecum and running the small bowel distal to proximal until the transition point is found and the band/transition point identified. After release of the band, the passage into distal bowel is restored and the strangulation mark on the bowel wall is visible and should be carefully inspected.

As a precaution in the absence of advanced laparoscopic skills, a low threshold for open conversion should be maintained when extensive and matted adhesions are found^[51].

Reported predictive factors for a successful laparoscopic adhesiolysis are: Number of previous laparotomies ≤ 2 , non-median previous laparotomy, appendectomy as previous surgical treatment causing adhesions,

unique band adhesion as pathogenetic mechanism of small bowel obstruction, early laparoscopic management within 24 h from the onset of symptoms, no signs of peritonitis on physical examination, and experience of the surgeon^[52].

Because of the consistent risks of inadvertent enterotomies and the subsequent significant morbidity, particularly in elderly patients and those with multiple (three or more) previous laparotomies, the lysis should be limited to the adhesions causing the mechanical obstruction or strangulation or those located at the transition point area; some authors have attempted to design a preoperative nomogram and a score to predict risk of bowel injury during adhesiolysis, and they found that the number of previous laparotomies, anatomical site of the operation, presence of bowel fistula and laparotomy *via* a pre-existing median scar were independent predictors of bowel injury^[53,54].

PREVENTION

Surgical technique

Small bowel obstruction has been the driver of research in adhesion prevention measures, barriers and agents. Recent data from cohort studies and systematic reviews point at major morbidity and socioeconomic burden from adhesiolysis at reoperation, which have broadened the focus of adhesion prevention^[55]. Applying adhesion barriers in two-stage liver surgery and cesarean section, to reduce the incidence of adhesions and adhesiolysis related complications, are examples of the change in paradigm that reducing the incidence of adhesions is clinically more meaningful than only aiming at preventing adhesive small bowel obstruction^[56]. Increasing the number of patients without any peritoneal adhesion should be the general aim of adhesion prevention.

“Good” surgical technique and anti-adhesive barriers are the main current concepts of adhesion prevention. From a recent systematic review and meta-analysis on the impact of different surgical techniques on adhesion formation it was concluded that laparoscopy and not closing the peritoneum lower the incidence of adhesions^[1].

However, the burden of adhesions in laparoscopy is still significant most likely due to the necessity to make specimen extraction incisions in addition to trocar incisions and the unavoidable peritoneal trauma by surgical dissection and the use of CO₂ pneumoperitoneum (intraperitoneal pressure and desiccation). Reduced port laparoscopy and specimen extraction *via* natural orifices may theoretically further reduce peritoneal incision related adhesion formation^[57].

Anti-adhesive barriers

Since all abdominal surgeries involve peritoneal trauma and potential healing with adhesion formation, additional measures are needed to reduce the incidence of adhesions and related clinical manifestations. These measures consist of systemic pharmacological agents,

intraperitoneal pharmaceuticals or adhesion barriers^[58]. Most clinical experience is with intraperitoneal adhesion barriers, applied at the end of surgery with the aim to separate injured peritoneal and serosal surfaces until complete adhesion free healing has occurred. Efficacy of anti-adhesion barriers in open surgery has been well established for reducing the incidence of adhesion formation^[59]. For one type of barrier (Hyaluronate-carboxymethylcellulose, HA-CMC, Seprafilm, Sanofi, Paris, France) the reduction of incidence of adhesive small bowel obstruction after colorectal surgery has also been established (RR = 0.49, 95%CI: 0.28-0.88) without patient harm^[59,60]. Oxidized regenerated cellulose (Interceed, Ethicon, West Somerville, NJ, United States) reduces the incidence of adhesion formation following fertility surgery (RR = 0.51, 95%CI: 0.31-0.86), but the impact on small bowel obstruction after gynecological surgery has not been studied^[59,61]. Drawback of both products is the difficulty to use in laparoscopic surgery, underlining the need to develop gel, spray or fluid barriers that are easy to apply *via* a trocar.

In the Prevention of Postoperative Abdominal Adhesions (P.O.P.A) study, authors randomized 91 patients to have 2000 cc of icodextrin 4% and 90% to have the traditional treatment. The authors noted no significant difference in the incidence of small bowel leakage or anastomotic breakdown; operative times, blood losses, incidence of small bowel resections, return of bowel function, LOS, early and late morbidity and mortality were comparable. After a mean follow-up of 41.4 mo, there have been 2 cases of ASBO recurrence in the icodextrin group and 10 cases in the control group ($P < 0.05$)^[61].

Consistent safety and efficacy evidence has not led to routine application of barriers in open or laparoscopic surgery. Reasons might be the lack of awareness, the question if the “effect size” is large enough for routine application or the belief that adhesion formation even may benefit the patients, *e.g.*, reinforcing intestinal anastomosis or walling off peritoneal infection. However, the most used argument against routine use is the doubt regarding cost-effectiveness of adhesion barriers. The direct hospital costs in the United States in 2005 for adhesive small bowel obstruction alone was estimated at \$3.45 billion. Costs associated with the treatment of an adhesive SBO are estimated to be \$3000 per episode with conservative treatment and \$9000 with operative treatment. The additional costs incurred by operative treatment are partially due to complications of adhesiolysis. The incidence of bowel injuries during adhesiolysis for SBO is estimated to be between 6% and 20%. Inadvertent enterotomy due to adhesiolysis in elective surgery is associated with a mean increase in costs of \$38000^[58,61,62].

In a model, counted for in-hospital costs and savings resulting from adhesive SBO based on United Kingdom price data from 2007, Wilson showed that a low priced barrier at about \$160 with 25% efficacy in preventing SBO would result in healthcare savings. Another

concept with a \$360 priced barrier, would result in a net investment on the long-term unless a higher efficacy of 60% could be achieved. In this model treatment costs for small bowel obstruction were substantially lower than more recent cost calculations. Recent direct healthcare costs associated with treatment of major types of adhesion related complications (small bowel obstruction, adhesiolysis complications and secondary female infertility) within the first 5 years after surgery are \$2350 following open surgery and \$970 after laparoscopy. Application of an anti-adhesion barrier could save between \$678-1030 following open surgery and between \$268-413 following laparoscopic surgery on the direct healthcare costs related to treatment of adhesion related complications (data not published). Benefits from reduction in SBO were \$103 in open surgery and \$32 in laparoscopic surgery, using a high (\$360) priced product and only taken into account reoperations for adhesive small bowel obstruction. From these cost modeling it seems that even routine use of anti-adhesion barriers is cost-effective in both open and laparoscopic surgery^[62-64].

CONCLUSION

Unfortunately, there are not yet devices able to totally prevent the intraperitoneal adhesion formation after abdominal surgery; only the use of correct surgical technique and the avoidance of traumatic intraperitoneal organ maneuvers may help to reduce postoperative adhesion incidence.

Abstract

In the setting of Hemorrhoidal Disease treatment, the

option of conventional hemorrhoidectomy is highly effective, but it is still associated with postoperative pain and discomfort. For this reason, technical alternatives have been developed in order to reduce complications and to provide better postoperative recovery. To accomplish this aim, non-excisional techniques such as stapled hemorrhoidectomy and Doppler-guided hemorrhoidal ligation have been introduced into clinical practice with high expectations. The aim of this article is to revise the literature about transanal hemorrhoidal dearterialization technique in the treatment of hemorrhoidal disease, looking into its evolution, results and possible benefits over other modalities of surgical treatment. The literature review showed that Doppler-guided hemorrhoidal dearterialization is a safe and effective method to treat grades II to IV hemorrhoidal disease. Outcomes in patients presenting prolapse are satisfactory and the association of anopexy is an important aspect of this operation. Anal physiology disturbances are rarely observed and mainly transitory. This technique is an excellent option for every patient, especially in those with previous anal surgeries and in patients with previous alterations of fecal continence, when an additional procedure might represent a risk of definitive incontinence.

Key words: Doppler-guided hemorrhoidal dearterialization; Hemorrhoids; Transanal hemorrhoidal dearterialization

Core tip: Management of hemorrhoidal disease is a tough task. First of all, because there are some technical alternatives that should be adequately indicated to different patients; secondly, because patients desire a good alternative associated with low morbidity, good long-term results and less postoperative pain. In this setting, the transanal hemorrhoidal dearterialization

(THD) technique is considered a safe and effective choice for internal hemorrhoids of grades II to IV. The present paper reviews technical aspects and literature results of THD in comparison to other operative techniques.

Doppler-guided hemorrhoidal dearterialization/transanal hemorrhoidal dearterialization: Technical evolution and outcomes after 20 years. *World J Gastrointest Surg* 2016; 8(3): 232-237 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/232.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.232>

INTRODUCTION

For over 60 years, since the description of hemorrhoidectomy by Milligan and Morgan *et al.*^[1] and Ferguson *et al.*^[2], conventional hemorrhoidectomy (CH) has been the standard treatment for grades III and IV hemorrhoids. It is also indicated for grade II hemorrhoids refractory to conservative methods (such as rubber band ligation or infrared coagulation) or to those that have recurred. However, CH is still associated with postoperative pain and discomfort. Thus, technical alternatives to manage hemorrhoidal disease have been sought, in order to reduce complications and to provide better postoperative recovery, especially less pain.

In this scenario, stapled hemorrhoidectomy (SH) and Doppler-guided hemorrhoidal ligation have been introduced in our practice since the 90's^[3,4]. Whether called Doppler-guided hemorrhoidal artery ligation (DG-HAL) or transanal hemorrhoidal dearterialization (THD), it is a technique for the treatment of internal hemorrhoids and it was first described by Morinaga *et al.*^[3] in 1995. Few studies have addressed the technique until after the year 2000, with a lot of papers since then.

The aim of this article was to revise the literature about this technique in the treatment of hemorrhoidal disease, looking into its evolution, results and possible benefits over other modalities of surgical treatment.

A literature search was performed in PubMed, looking for "THD", "transanal hemorrhoidal dearterialization", "DG-HAL" and "Doppler guided hemorrhoidal artery ligation". References from the selected articles were also reviewed in order to find additional studies in the subject.

TECHNICAL ASPECTS

Before Morinaga's work for the surgical treatment of hemorrhoids with Doppler-guided ligation, Jaspersen *et al.*^[5] described the successful use of Doppler-guided location of hemorrhoidal vessels for phenol injection for treatment of 1st grade hemorrhoids.

Hemorrhoidal vessels are usually found in the mucosa within 2 cm up from the anorectal junction^[6]

and this is the place where the sutures should be made in this technique (the Dearterialization itself). In the case anopexy is also to be made, this is the position where the first ligation should be made, before the running suture for the anopexy is continued distally.

Different devices were developed to accomplish the location of vessels by Doppler signal as well as to permit the ligation at the same time. Morinaga *et al.*^[3] used a device called the Moricorn to find Doppler signal 2 cm above the dentate line and then ligate arterioles at this point. Afterwards, other proctoscopes were developed and nowadays most studies use THD (THD S.p.A. Correggio, Italy), DG-HAL/DG-RAR (Agency for Medical Innovations GmbH (AMI), Feldkirch, Osterreich, Austria) or HAL-Doppler (AMI Dufour MedicalTM, Maurepas, France).

There does not seem to exist any difference in results according to the type of device used, since they operate in the same way despite the different appearance of each one.

Table 1 refers to difference in rates of success and recurrence for each technique used for the treatment of hemorrhoidal disease: conventional, stapled and dearterialization.

INITIAL RESULTS WITH THD/HAL

When we look at the studies published in the first 12 years following Morinaga's publication, only ligation was performed (without anopexy). It was only in 2007 when a modification of the technique was made, with additional anopexy for patients with prolapse^[7]. Morinaga *et al.*^[3] reported this first series with 112 patients, obtaining satisfactory results in 78% of patients with prolapse, as well as resolution of pain in 96% of patients and of bleeding in 95%.

After 6 years, Sohn *et al.*^[8] published another series of patients treated with hemorrhoidal ligation in 2001. Sixty patients were submitted to a procedure (THD) based on the principles described by Morinaga, and the authors achieved complete success in 92% of patients with prolapse, 88% of those with bleeding and 71% of those with pain. Early postoperative pain, precluding normal activities, was reported in only 8% of patients.

Giordano *et al.*^[9] published the first systematic review concerning THD/DG-HAL in 2009, analyzing 17 papers from 1995 to 2008. In all articles revised no anopexy was performed. The rate of recurrent prolapse varied between 0% and 37%. In the study where this recurrence rate of 37% was found, most patients were lost to follow up, which might have interfered in the results^[10]. The overall rate of prolapse, according to the review, was 9%. Regarding recurrent anal bleeding, the rates ranged between 0% and 21% in those 17 studies, with most papers reporting rates around 4% to 10%. The overall rate of recurrent bleeding, also according with this systematic review, is 7.8%. Early post-operative pain was reported in 18% of patients in

Table 1 Rates of success, post-operative pain and long-term recurrence after different techniques for treatment of hemorrhoidal disease

Technique	Symptom control	Post-operative pain	Recurrence
Conventional hemorrhoidectomy	95%	70%-75%	5%
Stapled hemorrhoidectomy	85%-90%	5%-20%	2%-24%
THD/DG-HAL	80%-95%	2%-20%	8%-10%
THD/DG-HAL + Anopexy	85%-95%	6%-50%	8%

THD: Transanal hemorrhoidal dearterialization; DG-HAL: Doppler-guided hemorrhoidal artery ligation.

the review.

ADDITIONAL ANOPEXY

In 2007, Dal Monte *et al*^[7] were the first to describe a modification of THD/HAL, adding anopexy of the cushions where prolapse was found. They included patients with hemorrhoidal disease grades II to IV, and anopexy was performed in a group of patients with disease grades III and IV. They compared the latter with patients not submitted to anopexy and there was a tendency of worse prolapse relapse without anopexy, although not statistically significant.

Technical aspects of anopexy consist of extending the suture in a continuous manner after the first figure-of-eight stitch, involving mucosa more superficially than the first stitch, until above the pectinate line. The exact point where the suture is to be ended is identified with an audible Doppler signal before the sutures are done. The rationale of this modification was to treat prolapse at the same procedure.

Infantino *et al*^[11] published a multicentric study showing results of the modified technique, treating grades II and III hemorrhoids. Their recurrence rate was 14.3% and patient satisfaction after 15 mo was 87%. Other 4 papers in 2009 and 2010 showed prolapse recurrence in 5%-17%^[12-15].

Several articles on THD/DGHAL with anopexy were published, and the reported prolapse recurrence rates ranged between 3% and 21% and satisfaction rates of 84% to 96%, with follow ups of until 3 to 37 mo^[12-14,16-24]. Scheyer *et al*^[25] reported good results with Dearterialization and anopexy, but in their conclusion results were not good when prolapse was not the main complaint. In one of the most recent papers on the matter, Ratto *et al*^[26] reported a recurrence of prolapse in only 6.3% and a satisfaction rate of 90% after a 11 mo follow up. In this series, 13% of patients suffered pain or tenesmus after surgery.

THD/HAL IN THE TREATMENT OF GRADE IV HEMORRHOIDAL DISEASE

Results of this treatment in patients with high-grade disease (grade IV) seem to be satisfactory in terms of

prolapse resolution.

Two series were published involving only patients with grade IV disease. In both studies anopexy was performed in addition of hemorrhoidal ligation. Giordano *et al*^[19] found an incidence of pain in 70% of patients in the first postoperative day, tenesmus in 10%, but a recurrence of prolapse of only 3% after a follow up of almost 3 years. Faucheron *et al*^[22] reported postoperative pain in only 6% of patients, tenesmus in 1% and recurrence of prolapse in 9% after 34-mo follow up.

COMPARATIVE STUDIES WITH SH

Ramírez *et al*^[27] were the first to publish a randomized trial comparing THD and PPH in 2005. Several other studies compared both techniques from 2009 until 2014. Festen *et al*^[28] published a series comparing 18 patients submitted to stapled hemorrhoidopexy and 23 patients submitted to THD. After a very short follow up of only 3 wk, THD patients had less pain in the first week, with similar results after 3 wk. Symptoms resolution was also similar between groups^[28].

Three studies found that THD patients had an earlier return to normal activities^[29-31]. Tsang *et al*^[31] found similar complication rates and similar satisfaction rates but follow up after procedures was very different (8 mo after THD and 36 mo after SH). Verre *et al*^[32] published a prospective randomized trial in 2013, with 7.9% bleeding rate after SH and none after THD. Postoperative pain was lower in THD group although not statistically significant.

Lucarelli *et al*^[33] reported a randomized trial with long-term follow up, where recurrent prolapse was the primary outcome, after a follow up of 40-43 mo. The technique performed in their study was THD with anopexy vs stapled hemorrhoidopexy. The last follow up was done through a telephone interview, with reports of prolapse recurrence in 25% of patients in the THD group vs 8.2% ($P = 0.021$) in the SH group. In spite of that, patient satisfaction was 73% in THD group vs 86.9% in the SH group. One might argue about detecting recurrence of prolapse by phone interviews, when one study by Ratto *et al*^[13] showed that patients misreported skin tags for prolapse, after a physical examination took place.

As in the study by Infantino *et al*^[34], Lucarelli *et al*^[33] did not find significant difference in levels of post-operative pain. Other studies have found lower pain levels after THD when compared to stapled hemorrhoidopexy^[30,31,35] while in some it was a trend in the group submitted to THD but did not reach statistical significance^[28,29,32].

Giordano *et al*^[29] compared THD vs SH for grades II and III, and reported a recurrence of symptoms recurrence of 14% vs 13%, while satisfaction was also similar between groups (89% vs 87%), respectively. THD technique comprised also anopexy in this study. There were no reports of fecal incontinence in both

groups.

A systematic review included 3 trials comparing these techniques, with a total of 150 patients concluded that both techniques were effective, but THD patients had less immediate postoperative pain^[36].

COMPARISON WITH CH

In our literature search, three studies were found comparing Dearterialization and CH.

In a non-blind randomized study, Elmér *et al.*^[37] compared 20 patients in each group. Although patients presented less postoperative pain after THD, symptoms were effectively controlled in both groups after long-term follow-up.

Bursics *et al.*^[38] randomized 60 patients in 2 groups and also showed similar results after 12 mo of follow up. THD group had an earlier return to normal activities ($P < 0.0005$) and less post-operative pain ($P < 0.005$). Another randomized trial was published recently, with a follow up of 24 mo, showing no difference between groups in terms of postoperative pain in the first month after surgery or regarding resumption of normal activities. Patient satisfaction in the end of follow up was also similar between THD and CH ($P > 0.05$)^[39].

Denoya *et al.*^[40] published the article with the longest follow up, 3 years. Forty patients were randomized in each group, and they also found similar results regarding resolution of symptoms and patient satisfaction.

RESULTS REGARDING ANAL PHYSIOLOGY

According to Walega *et al.*^[41], resting and squeeze pressures following DG-RAR were lower 3 mo after surgery comparing to pre-operative measures ($P < 0.05$) and this result was maintained after 12 mo after surgery.

In their comparative article, Giordano *et al.*^[29], found no complaint of incontinence after THD or SH. Only 2 patients in the SH group ($n = 24$) complained of transient urgency. Tsang *et al.*^[31] described 1 case of incontinence in SH group ($n = 37$) and none in THD group ($P = 0.111$).

In the systematic review by Giordano *et al.*^[9] the overall incontinence rate after THD was 0.4%.

IMPORTANT CONSIDERATIONS

Morinaga *et al.*^[3] described Doppler arterial hemorrhoidal ligation in 1995 as a novel treatment for hemorrhoids. This technique has become more popular and, nowadays, it is used worldwide. It is based on the premise that arterial ligation would lead to a lesser pressure on the vessels on the anal canal, thus relieving the symptoms as bleeding and prolapse. Initial articles reporting this technique showed satisfactory results.

On 2007 Dal Monte *et al.*^[7] were the first to publish a modification on the described technique, including anopexy in order to better treat prolapse for 3rd and 4th grade hemorrhoids. With this, treatment of prolapse associated with 3rd and 4th grade hemorrhoids was guaranteed and recurrence rates were better.

One of the main advantages of the THD/DG-HAL is the low morbidity rate. After CH pain can be an important distress for the patient, influencing return to normal activities. Postoperative pain seems to be lower after THD when compared to CH, as seen in comparative studies^[37,38,40]. In a systematic review concerning THD, 18.5% of patients suffered from pain in the first operative day^[9]. Although this review points out that published data on THD was low quality, thus low significance/power, many studies evaluating this technique showed good results in short-term follow-up, with immediate postoperative bleeding occurring in 0%-8% and recurrence of 3%-20%.

Some works show a high recurrence rate related to grade III or IV hemorrhoids^[10,42,43], but those studies were done before the anopexy was associated with the arterial ligation. The study with the longest follow up showed a trend to higher recurrence rate for grade III hemorrhoids compared to grade II after 5 years, but the difference was not statistically significant^[42]. Two studies involving patients only with grade IV hemorrhoidal disease showed a recurrence of 3%-9% after a follow up of almost 3 years.

SH was first described by Longo^[4] in 1998 and is also a non-excisional technique for the treatment of hemorrhoidal disease. As THD, the goal is to treat hemorrhoids without the risk of sphincter impairment and to reduce postoperative pain. However, serious complications after SH, such as major bleeding, rectovaginal fistulas and perianal sepsis, have been described^[44]. One study prospectively comparing SH and THD for grades II and III hemorrhoidal disease showed no difference regarding recurrent symptoms or patients' satisfaction with their results^[29].

Regarding anal physiology, it seems reasonable to believe that hemorrhoidal dearterialization may contribute with only minor disruption of continence, since there is no risk of anal sphincter damage. On the other hand, the technique affects hemorrhoidal cushions in the anal canal, which play a role in anal continence as well. At the same time, all techniques interfere with the cushions, since it is the goal of the treatment. Maybe due to the fact that THD is a non-excisional technique, the impact after surgery might be reduced compared to excisional techniques.

Incontinence is rarely described, and when it happens it is transitory. More important is the complaint of tenesmus after THD surgery, which is rather common, in about 10% of patients, but also transitory. In a study by Ratto *et al.*^[13], tenesmus was reported by 24% of patients but symptoms disappeared 10 d following surgery. Even though alterations in resting

and squeeze anal pressures might be seen in anorectal manometry after THD, there is no evidence of risk of incontinence with this procedure^[41].

In conclusion, Doppler-guided hemorrhoidal dearterialization is a safe and effective method to treat grades II to IV hemorrhoidal disease. Outcomes in patients presenting prolapse are satisfactory and the association of anopexy has become an important aspect of this operation, contributing to a higher success rate. Anal physiology disturbances are rarely observed and are transitory. This technique is an excellent option for every patient, especially in those with previous anal surgeries and in patients with previous alterations of fecal continence, when an additional procedure might represent a risk of definitive incontinence.

Abstract

AIM: To compare the results after revision of primary vertical banded gastroplasty (Re-VBG) and conversion to sleeve gastrectomy (cSG) or gastric bypass (cRYGB).

METHODS: In this retrospective single-center study, all patients with a failed VBG who underwent revisional surgery were included. Medical charts were reviewed and additional postal questionnaires were sent to update follow-up. Weight loss, postoperative complications and long-term outcome were assessed.

RESULTS: A total 152 patients were included in this study, of which 21 underwent Re-VBG, 16 underwent cSG and 115 patients underwent cRYGB. Sixteen patients necessitated a second revisional procedure. No patients were lost-to-follow-up. Two patients deceased during the follow-up period, 23 patients did not return the questionnaire. Main reasons for revision were dysphagia/vomiting, weight regain and insufficient weight loss. Excess weight loss (%EWL) after Re-VBG, cSG and cRYGB was, respectively, 45%, 57% and 72%. Eighteen patients (11.8%) reported postoperative complications and 27% reported long-term complaints.

CONCLUSION: In terms of additional weight loss, postoperative complaints and reintervention rate, Roux-en-Y gastric bypass seems feasible as a revision for a failed VBG.

Key words: Vertical banded gastroplasty; Conversion; Revision; Gastric bypass; Sleeve gastrectomy; Additional weight loss

Core tip: This study assesses the long-term outcome after revision of a failed vertical banded gastroplasty (VBG). This manuscript compares three types of revision: revision of the primary VBG, conversion to sleeve gastrectomy and conversion to Roux-en-Y gastric bypass. The main finding in this study is that in terms of additional weight loss, postoperative complaints and reintervention rate, Roux-en-Y gastric bypass seems feasible as a revision for a failed VBG.

Long-term results after revisions of failed primary vertical banded gastroplasty. *World J Gastrointest Surg* 2016; 8(3): 238-245 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/238.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.238>

INTRODUCTION

Obesity is a growing global problem, associated with morbidity, health care costs and even an increased mortality rate^[1]. For the treatment of obesity, bariatric surgery is very effective in achieving significantly more long-term weight loss and an improved lifestyle compared with conventional therapy^[2,3]. In 2011, over 340000 bariatric procedures were performed worldwide. Among those procedures, around 2300 procedures were a vertical banded gastroplasty (VBG), first described by Mason *et al*^[4] and later altered by MacLean *et al*^[5] and Buchwald *et al*^[6]. Aim of this procedure was to establish a restriction on food intake with a small stomach pouch, without compromising passage of food through the entire gastro-intestinal tract and thereby avoiding malabsorption of nutrients and medication^[7]. This procedure has shown in earlier reports to have good short-term results in terms of weight loss and reduction in comorbidities^[8-11]. However, there are many studies reporting on the poor long-term results after VBG, showing a tendency for weight regain and other complications resulting in a high revision rate^[12-14]. Various options are available for revisional surgery after VBG, such as revision of the VBG (Re-VBG), conversion to sleeve gastrectomy (cSG) and conversion to Roux-en-Y gastric bypass (cRYGB), in which Re-VBG appears to have the poorest outcome and cRYGB has the best short- and long-term results^[15-19]. However, data on the comparison between the revisional options remains scarce.

Although VBG had been abandoned some years

ago in the Netherlands, still a number of patients can be expected to return with complaints after VBG. In the current series, all three mentioned options for revision have been performed. The aim of this study is to compare the outcome after these revisional procedures.

MATERIALS AND METHODS

Methods

This is a single-center retrospective study. A total of 392 patients underwent primary VBG, between January 1998 and December 2008. Since 2009, VBG was not performed anymore. Only patients undergoing primary VBG at the current center were included to reduce heterogeneity. Medical charts as well as additional postal questionnaires were reviewed. Included parameters were patient's characteristics, operative details of primary and secondary procedures, evolution of weight and comorbidities following both operations, findings at additional imaging, reason for revision, short-term complications and long-term complaints after revisional surgery. The postal questionnaire contained questions on weight and comorbidities, on complaints dysphagia, vitamin deficiencies and incisional hernia. In case of insufficient weight loss, weight regain or complaints and without participation the follow-up program, the patient was invited to the outpatients department. In case of non-response, patients received a phone call and when there was no response at all, the data of the latest visit at the outpatient clinic were used as final outcome.

Excess weight was defined as the difference between the weight before surgery and the highest healthy weight, which is at a body mass index (BMI) of 25 kg/m². Total excess weight loss (%EWL) was defined as a percentage of the amount of excess weight lost after surgery, as described by Deitel *et al*^[20]. The weight before the primary VBG was used as baseline value to calculate %EWL.

Weight loss was categorized according to the criteria described by Reinhold *et al*^[21]. These criteria consider a bariatric procedure successful when an %EWL of at least 50% is achieved. Furthermore, change in BMI and % total body weight loss (TBWL) was calculated. The evolution of any present comorbidities was categorized in stable, improved (reduced amount of medication used and/or a lower setting of a Continuous Positive Airway Pressure-device), resolved (no treatment), worse and *de novo*.

Treatment

Before primary VBG, all patients underwent assessment at our outpatient clinic by a surgeon, a psychologist and a dietitian to consider whether or not they were qualified for a bariatric procedure according to the standard IFSO guidelines for bariatric surgery. There was no specific algorithm for choosing the operative technique if they were approved for a bariatric procedure. There was a tendency for the option of a gastric bypass in case of more comorbidities, otherwise a VBG was chosen at

Table 1 Baseline characteristics (*n* = 152)

	Re-VBG <i>n</i> = 21 (13.8%) Mean ± SD	cSG <i>n</i> = 16 (10.5%) Mean ± SD	cRYGB <i>n</i> = 115 (75.7%) Mean ± SD	<i>P</i> value

Interval between VBG and revision (mo)	12.3 ± 10.7	30.7 ± 26.5	47.8 ± 34.8	< 0.001
Average %EWL after VBG (%)	61.7 ± 27.0	38.7 ± 22.9	43.5 ± 25.0	0.007

Re-VBG: Revision of the vertical banded gastroplasty; cSG: Conversion to sleeve gastrectomy; cRYGB: Conversion to Roux-en-Y gastric bypass; VBG: Vertical banded gastroplasty; %EWL: Percentage of excess weight loss.

the time. All patients underwent Mason-MacLean VBG, a standard VBG first described by Mason *et al*^[4] with transection of the vertical staple line as described by MacLean *et al*^[5].

Follow-up for these patients consisted of one year guidance by a psychologist, dietician and surgeon. Thereafter, a GP continued care unless weight loss problems or complaints were an issue. In such case patients underwent an analysis by all three disciplines and/or by means of a stomach X-ray and/or a gastroscopy. If considered eligible for revision the options were a re-VBG, cSG or cRYGB.

The Re-VBG technique meant in essence one of the 2 following adjustments. If the pouch was too large, a reshaping of the pouch was performed. The other option was an adjustment of the primarily placed band at the end of the gastric pouch.

A cSG meant a division of the lower part of the stomach 6cm from the pylorus up to the transgastric window to remove the gastric fundus and part of the corpus and antrum^[22]. All sleeve gastrectomies were performed using a 34-Fr intraluminal boogie and stapled by use of the Endo GIATM (Covidien, New Haven, CT, United States).

A cRYGB started with identification of the polytetrafluoroethylene (PTFE) band. Then the stomach was transected horizontally at the proximal side of the band. The band was removed in most cases. The pouch was

resized with use of the endoscopic stapler up to the angle of His. Then, an end-to-side gastro-jejunostomy was constructed by a linear stapler and closed using PolysorbTM sutures before 2009 and V-LocTM sutures after 2009 (Covidien, Mansfield, MA, United States). The alimentary limb, measuring 150-180 cm, was pulled up in an antecolic position. Finally, a side-to-side jejun-jejunostomy was constructed, also using a linear stapler and closing the defect again with either PolysorbTM or V-locTM sutures. Mostly, the procedure was finished by closing the mesenteric defects.

Statistical analysis

All data were collected retrospectively. Management and analysis as performed by using SPSS version 22, for Windows (SPSS Inc, Chicago, IL). Quantitative data are denoted as mean ± SD, whereas rates of complications and evolution on comorbidities are presented as a percentage. The student *t* test, linear regression analysis and logistic regression analysis were used to determine any significance of the observed differences among subgroups. Statistical significance was identified when the *P* value was less than 0.05. An odds ratio (OR) was provided when applicable and considered significant when OR (95%CI) ≠ 1. Summative figures and tables were used when necessary.

No ethical approval was required for this study.

RESULTS

Three hundred and ninety-two patients who underwent primary VBG were identified. According to the medical charts and questionnaires a total of 152 revisional procedures (38.7%) were performed between April 1999 and June 2014, of which six patients underwent revision in another hospital. Necessary data of these patients was retrieved. Furthermore, these six patients did complete the postal questionnaire, so they were included in the analysis, together with the rest of the study population. Baseline characteristics are shown in Table 1.

The initial 392 patients showed an average %EWL of 51.2% ± 27.4% and 54% of all known comorbidities were either improved or resolved. The resolved comorbidities were not taken into account in the current study. The patients necessitating revision showed a lower %EWL of 45.4% ± 25.8%, compared to those not necessitating revision (54.9% ± 27.7%, *P* = 0.001). At last follow-up, 58.4% (*n* = 229) of the total of 392 patients reported long-term complaints, which in 152 patients led to a revisional procedure.

Eighty-two point two percent of the current study population was female. Follow-up of patients necessitating second revision was taken into account until second revision. A total of 127 patients (83.6%) successfully completed last follow-up by either returning the postal questionnaire or answering the questions on the phone. This resulted in a mean follow-up after

Table 2 Complaints before revision (*n* = 152)

	Re-VBG <i>n</i> = 21 (<i>n</i>)	cSG <i>n</i> = 16 (<i>n</i>)	cRYGB <i>n</i> = 115 (<i>n</i>)	Total (%)	<i>P</i> value

Excessive weight loss	0	0	1	0.7	1.000

Re-VBG: Revision of the vertical banded gastroplasty; cSG: Conversion to sleeve gastrectomy; cRYGB: Conversion to Roux-en-Y gastric bypass; GERD: Gastro esophageal reflux disease.

revisional surgery of 56.5 ± 37.9 mo. In total, 25 patients did not return the postal questionnaire and could not be reached despite repeated attempts. Of these 25 patients, two patients deceased during follow-up due to a cause unrelated to bariatric surgery. Of these patients, the unreturned questionnaires were considered as missing data and the data of last known follow-up was used as final outcome so patients could be included in the analysis.

Reasons for revision

Complaints leading to revisional surgery are shown in Table 2. Six patients have had their revisional procedure in another center and therefore the complaints remained unknown. A possible surgically technical cause for failure of the VBG was found in 54.2% of all patients in this study.

Additional tests, in this study a stomach X-ray and/or a gastroscopy, were performed for additional analysis when necessary. The three main technical problems in this study population were a wide outlet, allowing faster passage of food through the pouch (17.1%), pouch dilatation (15.8%) and outlet stenosis (9.9%). Other technical reasons for failure were band erosion (5.3%), band luxation (displacement of the PTFE-band from its original position) (2.0%), staple line dehiscence resulting in a fistula (2.7%), pouch rotation (0.7%) and band dehiscence (0.7%).

Intra- and post-operative complications

126 procedures (82.9%) were performed laparoscopically, 15 procedures (9.9%) had a primary open approach and 11 (7.2%) procedures were converted from a laparoscopic to an open approach. One conversion was due to an intra-operative gastro-intestinal perforation which could not be managed laparoscopically, the other procedures were converted because of an unacceptable laparoscopic overview due to extensive intra-abdominal adhesions. Only 2 intra-

operative complications (1.4%) occurred during surgery, both being an iatrogenic gastro-intestinal perforation.

Complications in the 30-d postoperative period were seen in a combined total of 18 patients (11.8%). No complications were seen after revision of the primary VBG (0/21). After cSG, three complications were objectified (3/16 = 18.8%): One pneumonia, one patient suffering from persistent vomiting after surgery causing dehydration. No evident cause was found for the persistent vomiting. The third patient had an ileus. In the group of patients who underwent cRYGB, 15 complications were registered (15/115 = 13.0%). Reoperation was necessary in two out of three patients with bleeding and in all patients with anastomotic leakage (*n* = 3). All leakages were found at the gastro-jejunoanastomosis. Other complications included intra-abdominal abscesses (*n* = 3), wound infection (*n* = 2), pneumonia (*n* = 1), urinary tract infection (*n* = 1), ileus (*n* = 1) and deep venous thrombosis (*n* = 1). The intra-abdominal abscesses all necessitated re-admission to the hospital for intravenous antibiotic treatment combined with either CT- or ultrasound-guided drainage. In total, eight patients were admitted for appropriate treatment of the complication, three patients did not necessitate readmission and seven complications occurred during primary admission. No significant difference was found in the total number of complications between the groups.

Weight loss and evolution of comorbidities

When not including the follow-up after any secondary revisional procedure, the mean total %EWL at last follow-up after primary revisional surgery was $66.4\% \pm 25.8\%$. In terms of change in BMI, this meant an average reduction of 12.5 ± 5.6 kg/m². Mean TBWL was $28.1\% \pm 11.2\%$. When including the 16 patients that underwent a second revisional procedure, %EWL was $68.2\% \pm 26.4\%$. Change in BMI was 12.7 ± 5.4 kg/m² and TBWL was $28.7\% \pm 11.1\%$.

At baseline, a total of 82 comorbidities were found amongst 56 patients. The separate improvement/resolution percentages for the three different procedures were 71.4%, 77.8% and 67.8% for respectively Re-VBG, cSG and cRYGB when considering each comorbidity as a separate entity. Figure 1 shows the improvement/resolution rates divided between the three groups. Table 3 shows the results after primary revisional surgery, stratified for each procedure.

Long-term complaints

At last follow-up after revisional surgery, 41 patients (27.0%) reported complaints, which in 16 cases necessitated a second revisional procedure. All long-term complaints are displayed in Table 4. In one patient after Re-VBG, complaints were caused by band erosion.

Subgroups based on reason for revision

of the total weight loss, the evolution of comorbidities and potentially also the early postoperative course, additional analysis was performed. Patients undergoing revision for either weight regain or insufficient weight loss (WR/IWL) were compared to the other reasons given earlier in this manuscript. Results are shown in Table 5.

Second revisional procedures

A total number of 16 patients underwent a second revisional procedure. 10 patients underwent conversion from a revised VBG to RYGB, five patients had their sleeve converted to RYGB. One patient necessitated revision due to persistent vomiting after RYGB. Additional analysis showed a stenosis of the gastro-jejunosotomy. The most common reasons for second revision were weight regain (43.7%) and DVFI (31.3%). Other reasons were insufficient weight loss (18.7%)

and band erosion (6.3%).

DISCUSSION

The absolute number of performed bariatric procedures is still increasing and therefore the number of revisional procedures can be expected to rise as well. Combined with the known poor long-term outcome after VBG, this fact strengthens the belief that more revisional procedures of failed VBG can be expected in the future. This study is the first to report on the comparison

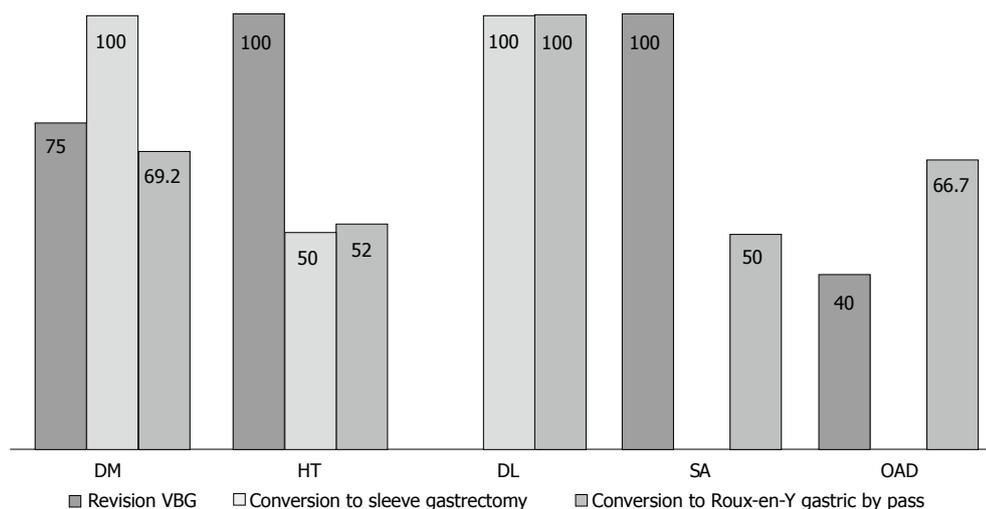

Figure 1 Improvement/resolution rates comorbidities. DM: Type 2 diabetes mellitus; HT: Hypertension; DL: Dyslipidemia; SA: Sleep apnea; OAD: Osteo-articular disease; VBG: Vertical banded gastroplasty.

between Re-VBG, cSG and cRYGB after failed primary VBG.

The revision rate of VBG was almost 39% (152 patients out of a total of 392 primary VBGs). The average %EWL after failed VBG was $45.4\% \pm 25.8\%$ at last follow-up before revision. Patients who underwent Re-VBG had a noticeable better %EWL after VBG at baseline. This can be explained by the much shorter average interval of only 12 mo between the VBG and the revision, making follow-up too short to start noticing weight regain, a common reason for revision^[17].

The main reasons for revision overall were similar to many other studies assessing either the long-term follow-up after VBG or the results after revision of the failed VBG^[12,15,17,19,23]. However, there is a difference in the type of complaints leading to the different revisional procedures in this study. Furthermore, the number of procedures differed between the groups in this study. These facts can be explained by various reasons. First of all, the indication for Re-VBG was limited (mainly band-related problems). In the early years, when a patient had complaints of DVFI, a Re-VBG was performed, especially when the DVFI was caused by band erosion. As more reports became available over the years, showing that cRYGB is a better revisional option than Re-VBG, that latter procedure was abandoned at an early stage and cRYGB has proven to be a better option and has been for quite some years, explaining the low number of VBGs^[15,16,18]. The last Re-VBG was performed in 2006. The second group, representing the cSGs, appears to have a more similar pattern of reasons for revision as seen in the cRYGB group, compared to the Re-VBG group. The size of the cSG group however is small, mainly due to early abandonment of this procedure, because there are very limited reports on the outcome of cSG over the last years and the larger experience with cRYGB, which had already proven to be a reliable procedure^[16,17,22]. The last cSG after VBG was performed in January 2010. Since then, all revisional

procedures after failed VBG were cRYGB.

The results in this study show that, although no early postoperative complications were seen in this group and the improvement/resolution rate of comorbidities is comparable with the other groups, Re-VBG is not the preferred revisional procedure after failed primary VBG. The reasons are a low total %EWL, high long-term complication rate and a high revision rate at long-term follow-up. Considering %EWL, this study actually showed an average decrease after Re-VBG, resulting in patients regaining nearly 15% of their initial excess weight. This result may be biased by the already available experience that cRYGB appeared superior to Re-VBG and the limited indication for Re-VBG^[18].

The second group in this study was the cSGs. The long-term results after cSG are acceptable, with a significant better additional excess weight loss compared to Re-VBG and an improvement/resolution rate of comorbidities comparable with cRYGB. Although cSG appears to give a lower chance on postoperative complications compared to cRYGB, a significant higher long-term complication rate compared to cRYGB and a high second revision rate are showing the limits of this revisional procedure after failed primary VBG.

Although cSG appears to be superior compared to Re-VBG, this study confirms that cRYGB seems to be the best option of these three procedures. At last follow-up, patients showed an average %EWL of almost 72%, improvement or even resolution of comorbidities in 92.8% patients familiar with one or more obesity-related comorbidities. Furthermore, the chance of developing long-term complications after cRYGB is lower compared to the other two revisional procedures. In contrast of these good results, we noticed a high postoperative complication rate of 13.0% after cRYGB. However, this rate is comparable with many previously published results showing postoperative complication rates of 6.5%–25%^[15,23–25]. In terms of %EWL, these results are comparable with previously reported data

after both revisional RYGB for failed VBG as well as after primary RYGB^[24-27]. The current good results may be affected by the used alimentary limb length of 150-180 cm, on the other hand, this seems unlikely, since previous studies have shown that a limb length of 150 cm did not produce a better %EWL compared to a limb length of 75-100 cm^[28,29].

Considering the subgroup analysis performed to differentiate between weight loss related complaints and other complaints, an expected significant difference was found in terms of %EWL. Furthermore, a difference was found in the number of different revisional procedures between the two groups, which can be explained by the earlier reported difference in reason for revision between procedures. This may also explain the difference in operative time, since a Re-VBG takes a significant shorter time than a cRYGB. After revisional surgery, no significant differences were found in terms of %EWL, postoperative complications and number of long-term complications and number of performed 2nd revisional procedures.

The reported high revision rate and previously published unfavorable results underline the limits of this old restrictive procedure^[12,13]. These rates also strengthen the expectation that a number of patients will necessitate revision in the future, since VBG is currently still performed as a primary procedure^[6]. Although revisional surgery seems feasible, the high number of complications after revision should be taken into account.

These results should be interpreted with caution due to a number of limitations in this study. First of all, the unequal distribution of groups, mainly due to a bias caused by the center's greater experience with cRYGB, thereby explaining the small number of Re-VBGs and cSGs. Furthermore, the retrospective design limits the reliability of the reported outcome. Since not all patients responded to our question to update the last known follow-up, a number of long-term complaints might have been missed, as well as potential revisional procedures performed in other hospitals. Not only the distribution between groups is unequal, also total time of follow-up is unequal, since Re-VBGs were performed only in the early and cRYGBs are still performed nowadays. The mean follow-up appears to be similar, but it should be kept in mind that Re-VBG showed a higher second revision rate as opposed to cSG and cRYGB and follow-up of the primary revision was taken into account until second revision. Keeping these limitations in mind, this study still suggests that Roux-en-Y gastric bypass is the superior choice for revisional surgery after failed primary VBG due to a good long-term %EWL, a high improvement rate of comorbidities, a low long-term complication rate and a low percentage of necessitated second revisional procedures.

In conclusion, in terms of additional weight loss, number of postoperative complaints and necessitation of a second revision, the Roux-en-Y gastric bypass seems feasible as a revision for a failed. Furthermore, the high

number of complications after VBG and complications due to revisional procedures underline that VBG should be excluded as a primary option in bariatric surgery and other restrictive should be considered instead.

COMMENTS

Background

Vertical banded gastroplasty (VBG) was a popular restrictive bariatric procedure however, has been abandoned due to a high long-term complications rate in many cases leading to the necessitation of revisional surgery. As a number of these revisions can be expected, this study reports and compares the results after revision of the primary VBG (Re-VBG), conversion to sleeve gastrectomy (cSG) and conversion to Roux-en-Y gastric bypass (cRYGB). As the number of patients with a bariatric procedure rises annually, the number of failed procedures will rise as well, some necessitating surgical treatment (by either revision or conversion). It is good to know what can be expected in both the short term and the long term when it comes to complications, weight loss and other complaints.

Research frontiers

Research on the conversion or revision of failed VBG is limited to mainly results after conversion to Roux-en-Y gastric bypass. These articles show decent results, suggesting that Roux-en-Y gastric is a feasible option as revision of a failed VBG. Results on the comparison of different conversions after failed VBG are limited.

Innovations and breakthroughs

The current article is, by the authors' knowledge, the first to compare different surgical options as treatment of failed VBG.

Applications

When confronted with failed VBG, either due to insufficient weight loss, weight regain or (other) physical complaints, conversion to Roux-en-Y gastric bypass appears to be more feasible compared to revision of the VBG or cSG.

Terminology

Re-VBG: Revision of a primary VBG; cSG: Conversion to sleeve gastrectomy; cRYGB: Conversion to Roux-en-Y gastric bypass.

Peer-review

The paper is acceptable and very interesting.

Abstract

AIM: To investigate changes over time in, and effects of sealing technology on, milk test results following pancreatotomy.

METHODS: From April 2008 to October 2013, 66 pancreatic resections were performed at the Iwakuni Clinical Center. The milk test has been routinely conducted at the institute whenever possible during pancreatotomy. The milk test comprises the following procedure: A nasogastric tube is inserted until the third portion of the duodenum, followed by injection of 100 mL of milk through the tube. If a chyle leak is present, the patient tests positive in this milk test based on the observation of a white milky discharge. Positive milk test rates, leakage sites, and chylous ascites incidence were examined. LigaSure™ (LS; Covidien, Dublin, Ireland), a vessel-sealing device, is routinely used in pancreatotomy. Positive milk test rates before and after use of LS, as well as drain discharge volume at the 2nd and 3rd postoperative days, were compared retrospectively. Finally, positive milk test rates and chylous ascites incidence were compared with the results of a previous report.

RESULTS: Fifty-nine milk tests were conducted during pancreatectomy. The positive milk test rate for all pancreatectomy cases was 13.6% (8 of 59 cases). One case developed postoperative chylous ascites (2.1% among the pancreatoduodenectomy cases and 1.7% among all pancreatectomies). Positive rates by procedure were 12.8% for pancreatoduodenectomy and 22.2% for distal pancreatectomy. Positive rates by disease were 17.9% for pancreatic and 5.9% for biliary diseases. When comparing results from before and after use of LS, positive milk test rates in pancreatoduodenectomy were 13.0% before and 12.5% after, while those in distal pancreatectomy were 33.3% and 0%. Drainage volume tended to decrease when LS was used on the 3rd postoperative day (volumes were 424 ± 303 mL before LS and 285 ± 185 mL after, $P = 0.056$). Both chylous ascites incidence and positive milk test rates decreased slightly compared with those rates from the previous study.

CONCLUSION: Positive milk test rates and chylous ascites incidence decreased over time. Sealing technology may thus play an important role in preventing postoperative chylous ascites.

Core tip: Chylous ascites is sometimes a severe complication of pancreatectomy. We previously reported that the milk test could serve to prevent chylous ascites following surgery. In this study, changes over time in milk test results, and effects of new energy devices on the test results, were investigated. Compared with the first report results, positive milk test rates and chylous ascites incidence were found to have decreased slightly. Use of the new energy devices also tended to result in decreased drainage volume. These findings suggest that the vessel-sealing technology could play an important role in preventing postoperative chylous ascites.

Aoki H, Utsumi M, Sui K, Kanaya N, Kunitomo T, Takeuchi H, Takakura N, Shiozaki S, Matsukawa H. Changes over time in milk test results following pancreatectomy. *World J Gastrointest Surg* 2016; 8(3): 246-251 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/246.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.246>

INTRODUCTION

Chylous ascites is a condition defined by the secretion of milky white fluid with high triglyceride content. Generally, it occurs due to traumatic injury or obstruction of the lymphatic system. Although it is a rare condition, there are multiple causes, such as neoplasm,

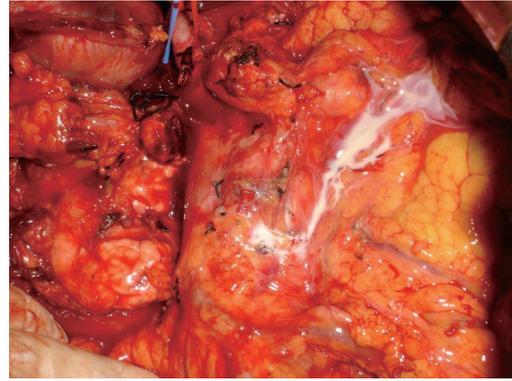

Figure 1 Milk test positive case.

inflammation, infection, surgery, trauma, and so on^[1]. As for postoperative causes, pancreatic surgery is a major cause of chylous ascites^[2-6]. According to reports, rates of chylous ascites incidence after pancreatoduodenectomy ranged from 1.8% to 13%. The cisterna chyli lies anteriorly of the first and second lumbar vertebrae, on the same plane as the pancreas. Injury to the cisterna chyli or its tributaries can occur during pancreatic resection. We experienced several cases of chylous ascites after pancreatectomy, and the condition is often associated with prolonged hospitalization. These are the reasons why we started studying the milk test in 2004 for its potential as a treatment to prevent the development of chylous ascites following pancreatic resection^[5].

On the other hand, remarkable advances have been witnessed in surgical energy technology. Such surgical energy devices as the vessel-sealing system represent a new hemostatic technology based on the combination of pressure and bipolar electrical energy that leads to the denaturation of collagen and elastin in the vessel walls and fusion of these into a hemostatic seal. Besides hemostatic ability, the new surgical energy devices might be used to block lymphatic flow. In terms of technical issues, we cannot ignore the effects of such new surgical energy technologies.

The aim of this study is to investigate changes over time in milk test results following pancreatectomy and the effects of vessel-sealing devices on milk test results.

MATERIALS AND METHODS

From April 2008 to October 2013, 66 pancreatic resections were performed at the Iwakuni Clinical Center, Iwakuni, Japan. Starting in 2004, the milk test has been routinely conducted whenever possible during pancreatectomy. Briefly, the milk test is conducted in the following way: A nasogastric tube is inserted until the third portion of the duodenum, followed by injection of 100 mL of milk through the tube. If a chyle leak is present, the patient tests positive in this milk test based on the observation of a white milky discharge (Figure 1). Seven cases were excluded: 2 laparoscopic surgeries,

DP (<i>n</i> = 9)	2 (22.2%)	7

PD: Pancreatoduodenectomy; DP: Distal pancreatectomy.

as well as 2 emergency and 3 unexpected pancreatic resections. The milk test was used in 59 of these 66 cases [47 pancreatoduodenectomy (PD); 2 total pancreatectomy (TP); 9 distal pancreatectomy (DP); 1 middle pancreatectomy]. Final diagnoses were 21 cases of pancreatic cancer, 12 intraductal papillary mucinous neoplasm, 9 bile duct cancer, 7 ampulla of Vater cancer, 2 each of chronic pancreatitis, gallbladder cancer, and duodenal cancer, and 1 each of metastatic pancreatic cancer and endocrine tumor.

Positive milk test rates, leakage sites, and chylous ascites incidence were examined. Since May 2011 in the Iwakuni Clinical Center, a vessel-sealing system (LigaSure small jaw instrument) is routinely used in pancreatectomy. Positive milk test rates before and after introduction of LigaSure (LS) as well as drain discharge volume were compared retrospectively. Finally, positive milk test rates and chylous ascites incidence were compared with the results of our previous report (conducted from 2004 to 2008)^[5].

Variables were compared using χ^2 test or Student's *t* test. JMP 9 statistical software (SAS Institute, Cary, NC, United States) was used for all analyses. *P* < 0.05 was considered statistically significant. This study was reviewed and approved by the Iwakuni Clinical Center Institutional Review Board.

RESULTS

Positive milk test rate among all pancreatectomy cases was 13.6% (8 of 59 cases). Leakage sites were as follows: Superior mesenteric artery: 4 cases; superior mesenteric vein: 2; left renal vein: 1; paraaorta: 1; and mesentery: 1. One case had two leakage sites. Six of 8 cases presented with leakage sites around superior mesenteric vessels (Table 1). One case demonstrated postoperative chylous ascites. Incidence of chylous

Table 3 Positive rate of milk test by diseases

Disease	Positive	Negative

Pancreatic disease with PD (<i>n</i> = 30)	4 (13.3%)	26

PD: Pancreatoduodenectomy.

ascites was 2.1% among the PD cases and 1.7% among all pancreatectomies. This case was milk test positive and treated with a conservative method using octreotide.

Positive rates by procedure were 12.8% for PD and 22.2% for DP (Table 2). No significant differences in positive rates were observed between the different procedures. Positive rates by diseases were 17.9% in pancreatic diseases and 5.9% in biliary diseases. When limited to PD patients in pancreatic diseases, the positive rate reached 13.3%. The positive rates were higher in pancreatic diseases, but this difference did not reach the level of statistical significance (Table 3).

When comparing figures before and after the introduction of LS, positive milk test rates for PD and TP were 13.0% before and 12.5% after, and for DP 33.3% and 0%. There was no statistical significance (Figure 2). As for drain discharge volume, the two groups were compared on the 2nd and 3rd postoperative days (POD) on average. Drain discharge volumes for the 2nd POD cases were 454 ± 237 mL (mean ± SD) before introduction of LS and 383 ± 279 mL after; for the 3rd POD cases, the volumes were 424 ± 303 mL and 285 ± 185 mL, respectively (Figure 3). Although no statistical differences were evident, a tendency for decreased drainage volume was observed when using LS on the 3rd POD cases (*P* = 0.056).

Incidences of chylous ascites were 2.9% in the previous study's period (2004-2008) among all pancreatectomy^[5] cases and 1.7% in this study. Positive milk test rates were 22.1% in the previous study^[5] and 13.6% in this study (Figure 4). Both rates represented a slight decrease compared with the first report, but this difference did not reach the level of statistical significance.

DISCUSSION

Postoperative chylous ascites is a relatively rare condition, but once it occurs the disorder can cause hyponutrition and prolonged hospitalization.

Positive milk test rates by procedure were higher for DP than for PD, but this difference was not significant. In our previous report, the incidences were nearly the same. Some authors report lower rates of chylous ascites in DP^[3], but others do not^[6]. This result might be due to the difference in disease incidence itself, but this aspect is not yet fully understood. According to the positive milk test rates, chylous ascites might

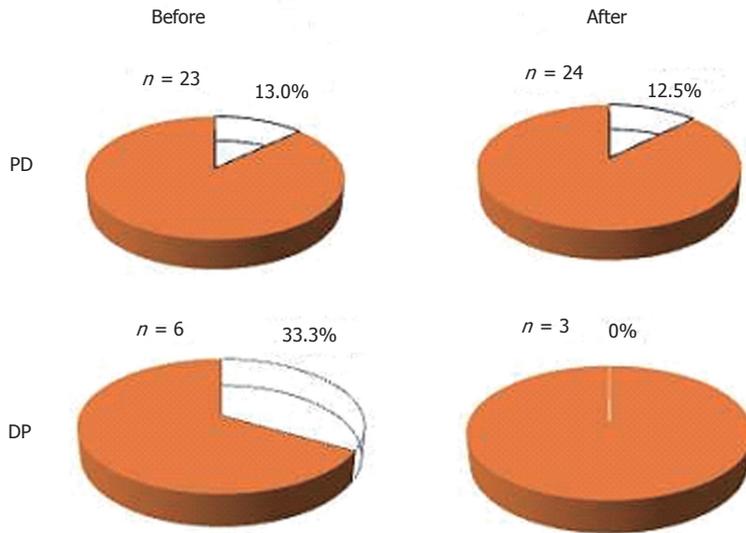

Figure 2 Comparison of milk test positivity: Before and after induction of sealing device. PD: Pancreatoduodenectomy; DP: Distal pancreatectomy.

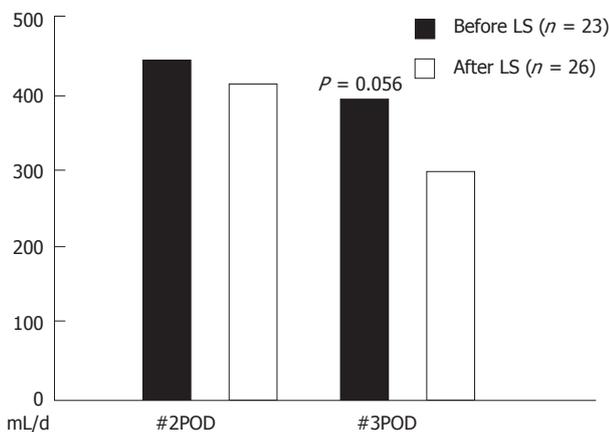

Figure 3 Drain discharge of pancreatoduodenectomy and total pancreatectomy.

occur at least equally in DP. Positive milk test rates by disease were higher in pancreatic than in biliary disease. The existence of concomitant pancreatitis with pancreatic disease might have played a role in this result. In one study, van der Gaag *et al.*^[4] reported that chronic pancreatitis is one of the risk factors for the development of postoperative chylous ascites. Kuboki *et al.*^[6] reported manipulation of the paraaortic area, retroperitoneal invasion, and early enteral feeding to be independent risk factors associated with chylous ascites. The first two of these three factors may have had something to do with the operative procedure itself. As for early enteral feeding, Malik *et al.*^[2] also alerted the medical community about the risk for chyle leak in this treatment. Careful observation of drain discharge is thus necessary before allowing such patients to begin meal intake after pancreatectomy.

The management algorithm used to treat chylous ascites integrates repeat palliative paracentesis, dietary measures, total parenteral nutrition therapy, peritoneovenous shunting, and surgical closure of the lympho-

peritoneal fistula. Somatostatin therapy should be attempted with or without total parenteral nutrition early in the course of treatment of chylous ascites before any invasive steps are taken^[7]. In addition, Kawasaki *et al.*^[8] reported effectiveness of lymphangiography not only for diagnosis but also for treatment of postoperative chylothorax and chylous ascites. In our experience, albeit somewhat limited, none of the cases required surgical treatment for postoperative chylous ascites. Chylous ascites should thus be treated by surgical procedure at the time of the initial operation. We emphasized the importance of steady ligation in our previous report. But now, new surgical energy technologies are gradually replacing that technique.

New surgical energy devices—such as the harmonic scalpel or vessel-sealing system—are reported to be useful in reducing drain discharge in colonic surgery^[9] and in axillary lymphadenectomy^[10], respectively. Nakayama *et al.*^[11] reported the utility of an ultrasonic scalpel in sealing the thoracic duct based on use of a pig model. The burst pressure after sealing by this ultrasonic scalpel was 188–203 mmHg, which is far above the pressure at which lymph vessels are occluded.

The question is what type of surgical energy device should we use to prevent chylous ascites? Seehofer *et al.*^[12] performed a comparison among a new surgical tissue management system that combines ultrasonic vibration and tissue dissection with bipolar coagulation [thunderbeat (TB)], a conventional ultrasonic scissor [Harmonic Ace (HA)], and a bipolar vessel clamp (LS), in terms of safety and efficacy. The burst pressure of the TB technique in the larger-artery category (5–7 mm) was superior to that of the HA technology. The dissection speed of the TB was significantly faster than that of the LS. Although seal width was influenced by the width of the jaw, LS had the widest seal width and the fewest gas pockets. This means that histologically LS is superior in terms of seal reliability and prevention

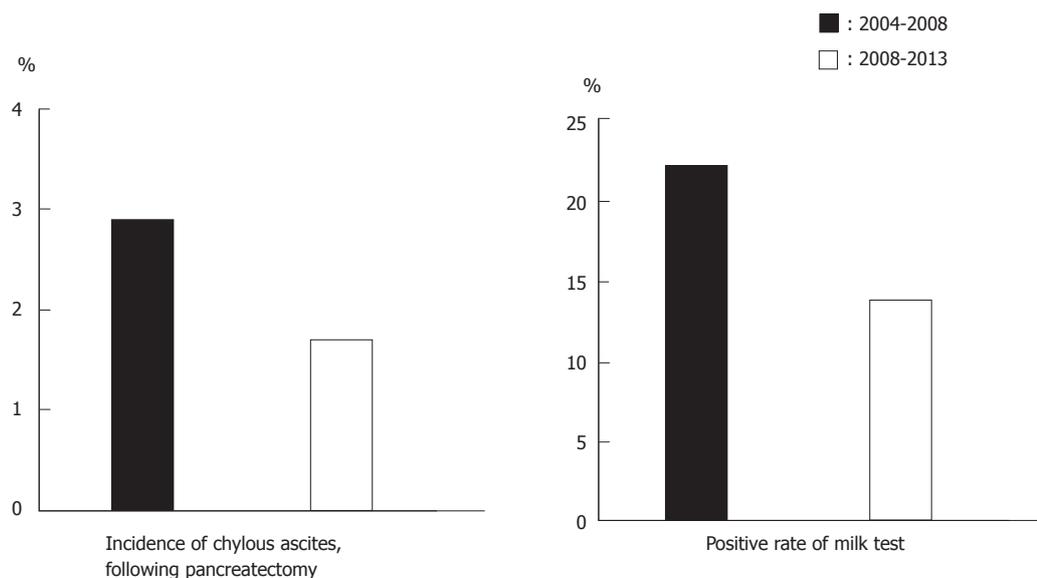

Figure 4 Changes over time in incidence of chylous ascites and milk test positivity.

of thermal injury. Janssen^[13] conducted a systematic search for randomized controlled trials that compared the effectiveness and costs of vessel-sealing devices with those of other electrothermal or ultrasonic devices in abdominal surgical procedures. The researchers involved in the study concluded that vessel-sealing devices may be considered safe and that their use may reduce costs due to reduced blood loss and shorter operating time in some abdominal surgical procedures compared to mono- or bipolar electrothermal devices. Though thermal injury is an issue that needs to be resolved, surgical energy devices can be used as another contributing factor for prevention of chylous ascites.

In our study, although there was no significant difference, both chylous ascites incidence and positive milk test rates decreased over time. The reasons for that are partly because we are more knowledgeable about chylous ascites and because of the technical advances made especially in surgical energy devices. Although we could not prove our results definitively, we think it is a matter of more numbers of cases. We therefore started planning in November 2013 a randomized prospective milk test study. In this study, we will investigate the utility of the milk test and chyle leak sites more comprehensively. We plan for the next study to include comparisons of different surgical energy devices.

In conclusion, positive milk test rates were higher in DP and pancreatic disease. Both chylous ascites incidence and positive milk test rates decreased over time. Based on the study results, surgical energy devices should be used as another contributing factor for the prevention of chylous ascites. Further investigation is needed to confirm the utility of the milk test.

COMMENTS

Background

Postoperative chylous ascites is a rare condition, but once it occurs the disorder can cause hyponutrition and prolonged hospitalization. Although chylous ascites after pancreatectomy has recently become an issue in the field of abdominal surgery, methods for prevention of chylous ascites are not well established. The authors therefore investigated the milk test as a method to resolve this condition starting in 2004. In their previous study, use of the milk test contributed to a decrease in incidence of chylous ascites. In this study, they looked at changes over time in milk test results. In addition, they assessed the effects of energy devices, which first appeared during the study period and now cannot be ignored in cases of abdominal surgery.

Research frontiers

The authors believe that the milk test is a useful method for detecting lymphorrhea during surgery. But to truly prove its utility, a prospective study is necessary. The authors therefore initiated a prospective randomized study in 2013.

Innovations and breakthroughs

To date, many papers have been published about chylous ascites, but most of them are focused on its pathogenesis or treatment. There is no study about prevention, especially in the case of pancreatectomy. The authors emphasize that postoperative chylous ascites should and can be prevented during surgery. The results of this study also suggest that new energy devices may play an important role in decreasing drain discharge.

Applications

A benefit to the milk test is that milk is easy to obtain and inexpensive. When the milk test is used, there is no need for special drugs or instruments. In addition, no complications accompany use of the milk test.

Peer-review

Reviewers mentioned that our paper provided interesting methodology and results. They stated that they are looking forward to the new study results.

Abstract

AIM: To provide an update on the aetiology, pathogenesis, diagnosis, staging and management of rectal squamous cell carcinoma (SCC).

METHODS: A systematic review was conducted according to the preferred reporting items for Systematic Reviews and Meta-Analyses guidelines. A comprehensive search of Ovid MEDLINE was performed with the reference list of selected articles reviewed to ensure all relevant publications were captured. The search strategy was limited to the English language, spanning from 1946 to 2015. A qualitative analysis was undertaken examining patient demographics, clinical presentation, diagnosis, staging, treatment and outcome. The quantitative analysis was limited to data extracted on treatment and outcomes including radiological, clinical and pathological complete response where available. The narrative and quantitative review were synthesised in concert.

RESULTS: The search identified 487 articles in total with 79 included in the qualitative review. The quantitative analysis involved 63 articles, consisting of 43 case reports and 20 case series with a total of 142 individual cases. The underlying pathogenesis of rectal SCC while unclear, continues to be defined, with increasing evidence of a metaplasia-dysplasia-carcinoma sequence and a possible role for human papilloma virus in this progression. The presentation is similar to rectal adenocarcinoma, with a diagnosis confirmed by endoscopic biopsy. Many presumed rectal SCC's are in fact an extension of an anal SCC, and cytokeratin markers are a useful adjunct in this distinction. Staging is most accurately reflected by the tumour-node-metastasis classification for rectal adenocarcinoma. It involves examining locoregional disease by way of magnetic resonance imaging and/or endorectal ultrasound, with systemic spread excluded by way of computed tomography. Positron emission tomography is integral in the workup to exclude an external site

of primary SCC with metastasis to the rectum. While the optimal treatment remains as yet undefined, recent studies have demonstrated a global shift away from surgery towards definitive chemoradiotherapy as primary treatment. Pooled overall survival was calculated to be 86% in patients managed with chemoradiation compared with 48% for those treated traditionally with surgery. Furthermore, local recurrence and metastatic rates were 25% *vs* 10% and 30% *vs* 13% for the chemoradiation *vs* conventional treatment cohorts.

CONCLUSION: The changing paradigm in the treatment of rectal SCC holds great promise for improved outcomes in this rare disease.

Core tip: Primary squamous cell carcinoma (SCC) of the rectum is a rare entity with a historically poor prognosis. This systematic review provides an in depth summary of the current body of knowledge surrounding the aetiology, pathogenesis, diagnosis, staging and prognosis of this disease. Given the current paradigm shift in the first line treatment of rectal SCC away from traditional surgical management towards definitive chemoradiotherapy, the evidence supporting this change is examined.

Guerra GR, Kong CH, Warriar SK, Lynch AC, Heriot AG, Ngan SY. Primary squamous cell carcinoma of the rectum: An update and implications for treatment. *World J Gastrointest Surg* 2016; 8(3): 252-265 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/252.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.252>

INTRODUCTION

Rectal squamous cell carcinoma (SCC) is a rare malignancy of the gastrointestinal (GI) tract. Due to the low incidence of this cancer and subsequent lack of literature, the underlying pathogenesis and risk factors are yet to be clearly defined. Furthermore, there is significant heterogeneity in the treatment regimens utilised, with the optimal management yet to be clarified. Nonetheless, certain patterns do emerge on reviewing all published cases by way of a systematic review, to determine where our future research should be directed in order to improve upon treatment and facilitate best patient outcomes.

MATERIALS AND METHODS

A systematic literature review was conducted according to the preferred reporting items for Systematic Reviews

and Meta-Analyses guidelines. A comprehensive search of Ovid Medline was performed with the abstracts screened to determine relevant articles, following which the full texts were obtained. A directed manual review of all embedded references was undertaken of the selected articles to ensure all studies published on primary SCC of the rectum were identified.

The search strategy was based on a combination of medical subject heading terms (carcinoma, squamous cell; rectum) and text words (SCC and rectum), spanning from 1946 to May 2015. The search was limited to English language with the most recent search performed on 8th May 2015.

Inclusion and exclusion criteria

The definition of rectal SCC as stipulated by Williams *et al*⁽¹⁾ which requires three exclusion criteria to be met (detailed in "diagnosis" below) was used to identify relevant studies. Consequently, studies reporting rectal SCC arising in the presence of a fistula, from an anal or gynaecological origin, a distant site *via* metastasis, or where the pathology was mixed (*e.g.*, adenosquamous) were excluded. Additionally, studies where the lesion was premalignant (*e.g.*, metaplasia or SCC *in situ*), of colonic rather than rectal origin or where the data was inadequate were excluded from the quantitative analysis.

Data extraction

Data extracted included the names of the authors, date of publication, demographic information and clinical presentation. Location of the lesion and treatment detailing the primary modality, the use of pre- and/or post-operative modalities and the type of operation where present was also noted. Other collated information included patient outcomes in the form of local recurrence, metastasis, and survival, as well as the length of follow up. Radiological, clinical and pathological complete response (CR) was also recorded where available.

RESULTS

The database and bibliography search identified 487 articles in total. After screening the articles for inclusion and exclusion criteria, 79 were included in the qualitative review and 63 in the quantitative analysis as detailed in Figure 1. This included 43 case reports and 20 case series with a total of 142 individual cases reported. Given the inherent bias in case reports and the inconsistency with reporting important prognostic variables including stage and pathological grade, an in depth individual patient data meta-analysis was not performed.

DISCUSSION

Background

Epidemiology: Rectal SCC is a rare disease with the current literature consisting primarily of case reports, case series and one large population based study.

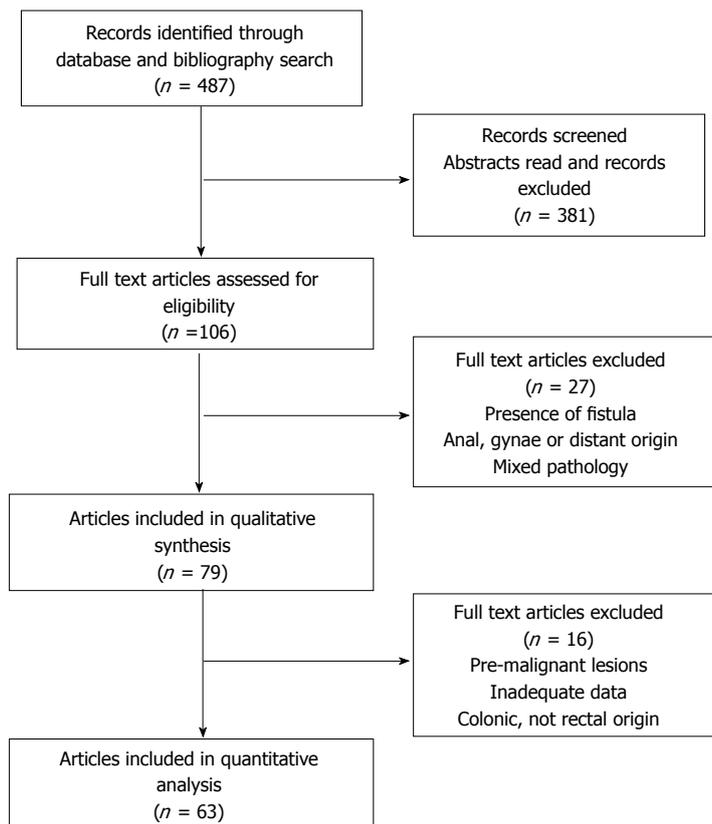

Figure 1 Preferred reporting items for Systematic Reviews and Meta-Analyses flow diagram.

While SCC can occur throughout the GI tract, it most commonly affects the upper aerodigestive tract down to the oesophagogastric junction, and the anal canal. SCC of the rectum however is much less common accounting for 0.3% of all histological subtypes^[2]. While pure SCC is the most frequent histology, cases with a mixed histologic pattern, generally adenosquamous, have been described^[3]. While other rectal cancer subtypes including neuroendocrine, lymphoma and gastrointestinal stromal tumours occur infrequently, rectal SCC remains the most rare with the exception of sarcoma^[2].

Schmidtman^[4] reported the first case of SCC of the colon in 1919, with Raiford^[5] publishing on the first case of rectal SCC in 1933. While SCC can be diagnosed throughout the colorectum, the most common site of predilection is the rectum (93.4%), followed by the right colon (3.4%)^[2]. The true incidence of rectal SCC can be most accurately drawn from the large population based study from the National Cancer Institute (NCI), which estimated it at 1.9 per million population in the year 2000, or 3 per 1000 colorectal cancers. This study also identified a significant rise in the incidence of rectal SCC between 1992 and 2000, estimating it at 5.9% per year. Extrapolating from this figure, the current incidence may be as high as 3.5 per million population^[2].

While strong epidemiological evidence on rectal SCC is absent, patient demographics and risk factors can be gauged from the published retrospective reviews and population study. Patients diagnosed with SCC of the rectum have ranged in age from 39 to 93 years

old, with an average age of 63 years. Female gender predominates, accounting for 57.4% vs 42.6% of cases in the NCI study. Patients most frequently present with early stage localised (stage I/II, 52.8%) or regional (stage III, 29.3%) disease and there is no apparent ethnic or geographic predisposition^[2].

Despite a lack of firm risk factors with a causal link to the development of rectal SCC, loose associations have been identified. The strongest association evident in the literature is that of proctitis, generally secondary to ulcerative colitis. There have been multiple case reports of rectal SCC in this setting, one of which compared the incidence with that of the general population to demonstrate a markedly increased risk in ulcerative colitis patients^[6-15]. Of significance, there has also been a report of rectal SCC in the setting of active Crohn's disease of the rectum^[16], and in the setting of chronic prolapse^[17]. Drawing upon this association with inflammation, the literature also contains three reports of parasitic infections with colorectal SCC, in the form of Schistosomiasis in two cases, and Amoebiasis in one, however, their significance is unclear^[1,18,19].

Other postulated risk factors have included a past history of radiotherapy for other pelvic malignancies, which has been noted in several case reports^[20-23]. Additionally, colorectal adenocarcinoma, both synchronous and metachronous has been identified in patients with SCC of the rectum^[3,24-27]. For colonic SCC, asbestos exposure and colonic duplication have also been associated, but this has not been the case for SCC of rectal origin.

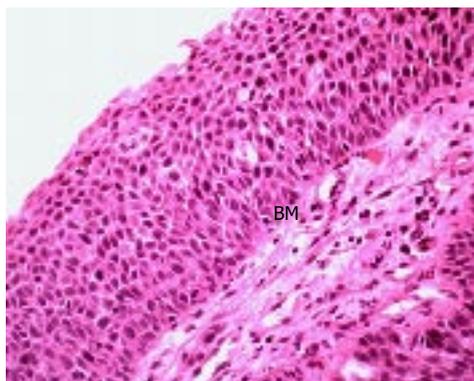

Figure 2 Haematoxylin and eosin stain of rectal squamous cell carcinoma *in situ*. This demonstrates architectural distortion, marked nuclear hyperchromatism and pleomorphism, along with full thickness basal layer expansion and no surface maturation. There is no evidence of invasion through the basement membrane (BM) (Image courtesy of Associate Professor Ken Opeskin, Department of Pathology, St Vincent's Hospital, Melbourne).

Given the strong association of human papilloma virus (HPV) with anal SCC, several studies have investigated its role in rectal SCC. This has produced variable results, with as many studies identifying HPV 16 in colorectal SCC specimens^[12,17,28,29], as those that have failed^[3,16,18]. Given this limited evidence, HPV infection as a risk factor for rectal SCC remains to be proven.

Pathogenesis: Despite reports of rectal SCC since the early 20th century, it's underlying aetiology remains unclear. While multiple theories have been postulated over this time period, its pathogenesis continues to be unravelled by assimilating the current body of evidence.

The theory of chronic inflammation leading to squamous metaplasia and subsequent carcinoma is one of the most prominent. This idea draws upon the fact that irritation and inflammation can lead to a change in the epithelial lining. This is termed metaplasia and is known to occur in the GI tract in response to exposure to various stressors^[30]. Metaplasia is the reversible change of one adult cell type into another and represents an adaptive substitution of stress-sensitive cells by a cell type better able to withstand that particular insult^[31]. The postulated inciting cause for the chronic inflammation leading to metaplasia has included the risk factors mentioned above of ulcerative colitis^[6,32], radiotherapy^[14,20-23] and infection^[18].

Adding support to this theory is firstly the description of squamous metaplasia in the colorectum in numerous instances. This has included sporadically^[33-36], in the regenerating epithelium of chronic ulcerative colitis^[15,32], in a rat by instillation of a chronic irritant (H₂O₂) and in a mouse secondary to chronic rectal prolapse^[37,38]. Secondly and of most significance, is the demonstration of an adjacent histological sequence in the rectum, from squamous metaplasia through dysplasia to carcinoma *in situ* (Figure 2) and invasive squamous carcinoma (Figure 3)^[6,7,12,15,24,35].

Drawing further upon this theory is the idea of

pluripotent mucosal stem cells capable of multidirectional differentiation, first postulated in the 1950's^[17,39-41]. Further work by Nahas *et al*^[16] in 2007 was based on the fact that keratin profiles vary amongst epithelia but remain constant in neoplastic transformation. They demonstrated that rectal SCC and adenocarcinoma stain for cytokeratin CAM5.2, unlike SCC of the anal margin, suggesting a common cell of origin for both rectal cancer subtypes. This lends support to an idea that the mucosal lining of the rectum contains a common pluripotent endodermal stem cell, which under certain conditions (inflammation and epithelial damage) can undergo squamous differentiation to better protect the rectum from the inciting cause. This is visualised as an area of metaplasia, which can subsequently undergo dysplasia and carcinomatous change if the inciting cause is not removed.

HPV has been postulated as a possible factor in inciting the dysplastic change of the squamous metaplasia. However, while there is a strong association between HPV and SCC of multiple sites including the anus, head/neck and cervix, the role in SCC of the rectum has not currently been established. There are more than 100 subtypes of HPV, with the most frequently encountered oncogenic forms being HPV 16 and 18. There are only a limited number of studies that have examined for HPV in rectal SCC, and they have utilised varying techniques for detection with discordant results. Audeau *et al*^[18] used immunohistochemistry to examine 20 squamous lesions (squamous metaplasia, SCC, adenosquamous carcinoma), without evidence of HPV 6, 11, 16 or 18. Frizelle *et al*^[3] and Nahas *et al*^[16] used an *in situ* hybridisation technique on 6 and 5 rectal SCC specimens respectively, again without evidence of HPV deoxyribonucleic acid (DNA). However, studies by Sotlar *et al*^[28] (1 rectal SCC), Kong *et al*^[12] (2 rectal SCC, 1 rectal SCC *in situ*), Matsuda *et al*^[29] (1 rectal SCC) and Jaworski *et al*^[17] (2 rectal SCC *in situ*), all identified HPV 16 in 7 rectal squamous lesions when utilising the PCR method, which is regarded as the gold standard. This may indicate that the sensitivity of the test employed in the detection of HPV has previously masked its presence.

The case presented by Sotlar *et al*^[28] is also of particular interest, given that it reported the findings of adjacent squamous metaplasia, dysplasia, and carcinoma in sequence, with HPV 16 identified in all three components and the surrounding non-tumour affected rectal mucosa. This mirrors the pre-neoplastic to neoplastic progression well documented in HPV driven anogenital cancers. Furthermore, they identified transcriptional activity of the HPV E6/7 oncogenes critical to HPV's role in carcinogenesis. This may suggest that there are two possible pathways to the pathogenesis of colorectal SCC, HPV driven and non-HPV driven. However, while there is currently limited evidence surrounding HPV in rectal SCC, a clear association and a role in causation remains to be

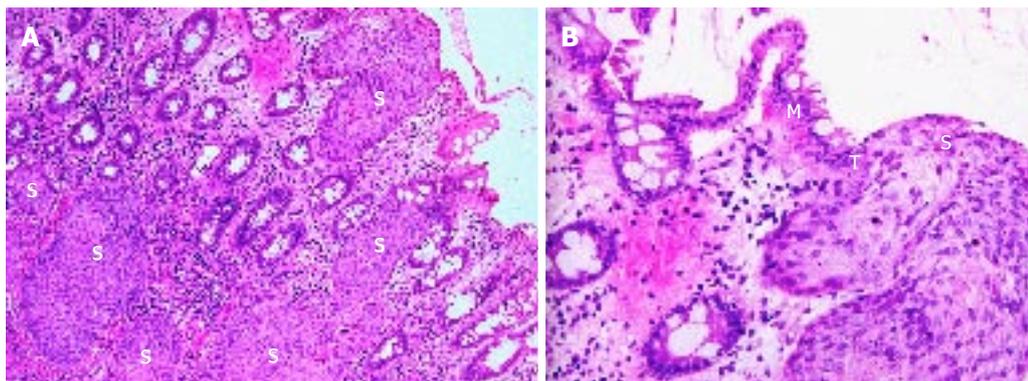

Figure 3 Haematoxylin and eosin stain of rectal squamous cell carcinoma. A: Widespread invasive squamous cell carcinoma (S) throughout the mucosa and submucosa of the rectal wall; B: Demonstration of the clear transition (T) between normal rectal mucosa (M) and invasive squamous cell carcinoma (S).

proven.

Patients with HIV have a higher incidence of HPV infection than the general population and additionally, HIV infection increases susceptibility to virally promoted cancers including Burkitt's lymphoma (Epstein barr virus), Kaposi's sarcoma (human herpes virus 8) and anogenital carcinoma (HPV). Consequently, it could be inferred that the cell mediated immune deficiency associated with HIV would predispose to rectal SCC. However, this is not borne out on review of the literature, with only two case reports of rectal SCC in the setting of HIV infection^[29,42].

Another postulated aetiology, has arisen from the finding of squamous differentiation within colorectal adenomas. Williams *et al*^[1] found this to be present in 3 of 750 adenomas, with a separate villous adenoma containing both invasive squamous and adenocarcinoma. Others have reported squamous metaplasia in adenomatous polyps^[43-46] in addition to a further case of SCC in a villous adenoma^[47]. These findings may again represent the squamous differentiation of a basal colonic cell, with changes inciting development of the adenoma also possibly leading to the metaplastic change.

Diagnosis and staging

Clinical presentation and diagnosis: The pattern of presentation for patients with rectal SCC is similar to those with adenocarcinoma of the rectum. The most frequently reported symptom is per rectal bleeding, followed less commonly by altered bowel habit (constipation, diarrhoea, tenesmus), pain and weight loss^[48]. The duration of symptoms can be variable, but most patients report a symptom history of weeks to months^[49,50].

Many presumed rectal SCCs are in fact an extension of an anal or gynaecological carcinoma, and consequently vigilance in diagnosis is important. Certain exclusion criteria stipulated by Williams *et al*^[1] in 1979, remain relevant for a diagnosis of primary rectal SCC to be established: (1) metastasis to the rectum from SCC of another organ; (2) squamous-lined fistula tract involving the affected region of rectum; and (3) SCC of

anal or gynaecological origin extending into the rectum.

With the above in mind, a detailed history and physical examination should be undertaken, with particular attention to the gynaecological system and anal canal. This often necessitates an examination under anaesthesia of both systems in addition to endoscopy.

The definitive diagnosis of rectal SCC is confirmed by performing a complete colonoscopy with biopsies of any abnormalities. Demonstration of the discontinuity of a lesion from the anal squamous mucosa is of great importance. Rectal SCC has been reported to have a varied endoscopic appearance dependent on the stage of disease. This can range from a small mucosal polyp (Figure 4), plaque or ulceration through to a large obstructing mass (Figure 5)^[51]. Pre-malignant lesions in the form of squamous metaplasia have also been identified by way of narrow band imaging (NBI) in addition to rectal SCC^[32,52]. One report identified an appearance of dark brown dots similar to the intraepithelial papillary capillary loops (IPCL) which herald squamous epithelium in the oesophagus using NBI^[32]. There are classification systems utilising the appearance of IPCL in the oesophagus in order to identify and differentiate squamous lesions along the spectrum towards invasive carcinoma^[53]. Given the possible aetiological sequence of metaplasia through to invasive carcinoma, NBI may find a role in the detection and treatment of pre-malignant lesions for those at high risk, in particular ulcerative colitis patients.

Histologically, if the diagnosis remains unclear, immunohistochemistry can aid in the characterisation of the lesion. This is particularly useful in cases of poorly differentiated tumours where the morphology and architecture provide little clue to the origin. Cytokeratins AE1/AE3, CK 5/6 (34BE12 stains CK5) and p63 stain for cells of squamous origin, assisting in the differentiation from a rectal adenocarcinoma. Cytokeratin CAM5.2 aids in the differentiation of rectal from anal, characteristically staining for rectal squamous cell or adenocarcinoma but not anal SCC. This is particularly useful for squamous carcinomas of the lower rectum^[16].

Squamous cell carcinoma associated antigen is

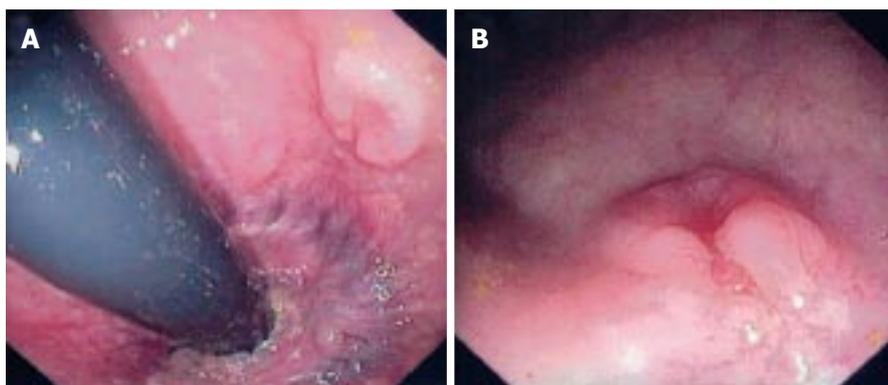

Figure 4 Endoscopic appearance of an early rectal squamous cell carcinoma. Rectal SCC presenting as a flat polypoid lesion with a central ulcerated depression in the distal rectum, 6 cm from the anal verge. A: Endoscopic retroflexed view; B: Endoscopic end-on view. SCC: Squamous cell carcinoma.

a serum tumour marker expressed by epidermoid tumours, including squamous carcinomas of the anal canal. Despite studies demonstrating weak evidence it may relate to nodal or relapsed disease in anal SCC, its use in diagnosis and follow-up remains controversial^[54-56]. With very limited data in the setting of rectal SCC, there is currently no clear utility for SCCAg in the diagnosis or management of these patients^[57].

Staging: Accurate staging of rectal SCC is of critical importance, in the same way that it dictates prognosis and management in anal SCC and rectal adenocarcinoma. In the literature, various staging systems have been translated into use for rectal SCC, most commonly the tumour-node-metastasis (TNM) system for rectal adenocarcinoma^[18,49,58-62] or the TNM system for anal SCC^[16,63,64]. While arguments can be made for the use of either staging system, the AJCC staging for rectal carcinoma is likely to have the greatest relevance. Firstly, the tumour stage focuses on the importance of the level of invasion through the rectal wall rather than the maximal dimension of the carcinoma. Secondly, nodal involvement is likely to follow the lymphatic drainage to the mesorectum and higher echelons, in preference to the alternative routes often involved in anal carcinoma such as the inguinal basins.

Staging involves evaluation of the primary tumour, and assessment for regional and metastatic disease. For loco-regional evaluation, as with rectal adenocarcinoma, magnetic resonance imaging (MRI) pelvis and endo-rectal ultrasound (ERUS) both have a role^[65]. A preference for either modality is often dependent on the experience with each technique at individual institutions. In terms of utility, ERUS has advantage in determining the depth of tumour invasion, particularly with differentiating T1/2 lesions. For delineation of more advanced T3/4 tumours and to determine local nodal involvement, pelvic MRI provides improved definition^[65,66]. Recently, there has been growing interest in the use of MRI diffusion weighted imaging (DWI) as a functional modality to assess treatment response in the staging of rectal adenocarcinoma^[67]. With the current shift towards definitive chemoradiotherapy in the treatment of rectal SCC, MRI is likely to find an increasingly useful role, not only for structural pre-treatment staging, but more importantly to determine the functional response of the tumour post-treatment in order to guide the need for operative intervention (Figure 6).

Computed tomography (CT) chest, abdomen and pelvis should be undertaken routinely in order to exclude metastatic disease. Increasingly, Fluorodeoxyglucose -

positron emission tomography fused with simultaneous CT and more recently MRI imaging, is also finding a role in the staging of rectal SCC. Firstly, it allows exclusion of a non-rectal primary SCC that has metastasised to the rectum. Secondly it defines the extent of the primary and nodal disease. Thirdly, it has utility similar to MRI DWI imaging, in assessing the functional response of the tumour by comparing pre and post-treatment scans (Figure 7)^[65,68].

Treatment

The treatment of rectal SCC has traditionally involved surgery, in some cases preceded or followed by adjuvant radiotherapy or chemotherapy (Table 1)^[16,69]. However, in the last decade, there has been increasing interest in the response of rectal SCC to definitive chemoradiotherapy, with very encouraging results (Table 2).

Surgery: Surgery has historically been adopted from the treatment of rectal adenocarcinoma with the operative technique, dependent upon the stage and

location of the tumour. Local excision either trans-anal or endoscopic, has been advocated for selected cases, with several publications reporting short-term survival without recurrence in the setting of trans-anal excision followed by chemoradiotherapy^[12,16,48,70,71]. This included a T3 lesion and another with positive distal and radial margins, suggesting the chemoradiation may have played an important role in reducing local recurrence^[16,70]. With the evolution of endoscopic techniques, in particular endoscopic mucosal resection and submucosal dissection in the treatment of early rectal cancers^[72], these procedures may have a role in managing rectal SCC. Generally, the option of local excision would be limited to low risk T1 lesions, characterised as being well differentiated, without lymphovascular involvement, nodal or metastatic disease.

For most rectal SCC's, anterior resection (AR) or abdominoperineal resection (APR) has classically been performed. The choice and extent of the operation is dependent upon the tumour location and depth of invasion, occasionally requiring exenteration, with

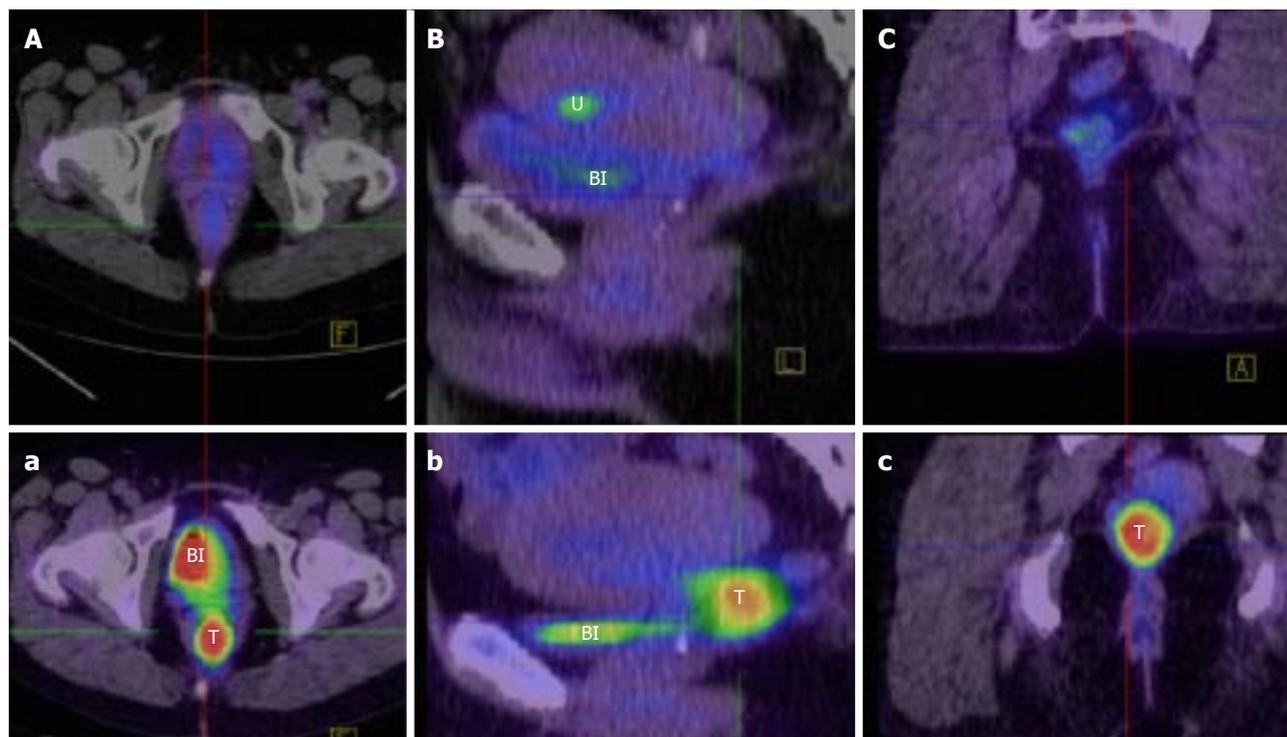

Figure 7 Positron emission tomography/computed tomography appearance of rectal squamous cell carcinoma. Pre (a, b, c) and post (A, B, C) treatment fused FDG-PET/CT imaging in axial (A, a), sagittal (B, b) and coronal (C, c) planes of a rectal SCC (T), demonstrating a complete metabolic response. [FDG is also visibly concentrated anteriorly in the bladder (BI) in images a, B, b, and in the endometrium (U) in image B (menstruation)]. FDG: Fluorodeoxyglucose; CT: Computed tomography; PET: Positron emission tomography; SCC: Squamous cell carcinoma.

removal of involved pelvic structures. On review of the literature, APR was performed much more frequently than AR prior to the year 2000, with an equal split in the frequency of both procedures following the turn of the century (Table 1). This is likely to reflect both the change towards sphincter preservation and avoidance of a permanent stoma in operations for rectal cancer over previous decades, in addition to a down-staging effect of chemoradiation, which is now commonplace. While the incidence of APR and a definitive stoma has been falling, in a similar manner to rectal adenocarcinoma, most patients with a low rectal SCC will require a temporary covering ileostomy given the greater risk of anastomotic leak. Furthermore, for those patients presenting with an obstructing tumour, the use of a defunctioning stoma is an attractive option, providing time to appropriately stage the patient and consider the optimal treatment, including definitive chemoradiotherapy.

Chemoradiotherapy: Following the validation of Nigro's protocol in multiple randomised controlled trials, it has now become the accepted standard treatment for anal SCC. Surgery, previously the preferred management, has subsequently been relegated to a salvage role^[73,74]. In light of this development, a trend of treating rectal SCC in the same manner has emerged.

On review of the literature, which spans from 1933 to the present, it is difficult to compare the treatment of rectal SCC, given the lack of a standardised staging system and treatment protocol. Nonetheless, an

increasing trend in the use of chemoradiation either as definitive treatment or in conjunction with surgery is emerging. There have been several prospective studies evaluating the role of chemoradiation as the primary therapy. The earlier cohorts demonstrated suboptimal outcomes, without a change in mortality or avoidance of surgery^[25,75]. However, with improvements in chemotherapy, radiotherapy and the accuracy of determining stage and response, a multitude of recent studies utilising an anal SCC based treatment regimen have reported promising results (Table 2)^[3,16,49,57,61,63,69].

The 3 most recent case series all published in 2015, comprise 22 patients treated with definitive chemoradiotherapy. Of this grouped cohort, a CR was identified by clinical examination and/or imaging in 14 of the 22 patients^[59,63,76]. The remaining 8 patients who demonstrated either progression of disease, a partial response or discordance between clinical and radiological findings, underwent a salvage operation. Of this group, 5 were noted to have a complete pathological response, equating to 19 of the 22 patients demonstrating a CR. Median follow up was 25 mo, with three patients suffering a recurrence, two of whom underwent a salvage operation, and one who received radiotherapy given the recurrence was outside the original field of treatment. Of these three, one succumbed to their disease at 14 mo post salvage surgery. One patient with an initial partial response and subsequent salvage operation developed metastatic disease without local relapse. The remaining 20 patients

are alive without evidence of disease^[59,63,76].

Expanding from the above findings, when all cases reported in the literature are examined, it is obvious that patients undergoing definitive chemoradiotherapy have a far superior survival then what has been historically recorded (Table 1 compared with Table 2). The overall survival for the chemoradiation group was 86% compared with 48% for conventional treatment. Likewise, the local recurrence and metastatic rates

were respectively 25% vs 10% and 30% vs 13% for the chemoradiation vs conventional treatment cohorts. These differences are likely due to a combination of factors, including improvements in imaging, tumour staging and perioperative workup and patient care over time. Furthermore, there are significant limitations in the analysis and interpretation of these results, related to the inherent heterogeneity of case reports and the inconsistency in recording important prognostic variables

including stage and grade. Despite these limitations, the treatment itself almost certainly accounts for a significant component of the dramatically improved local control and survival.

As with rectal and anal cancer, one of the most pertinent issues with definitive chemoradiation, is determining treatment response, which currently can only be confirmed on histopathology^[73,77]. In the studies to date on rectal SCC, response to chemoradiotherapy has been assessed variably, from 6-8 wk up to 6 mo after the conclusion of treatment. This generally involves a combination of a clinical assessment, by way of a repeat EUA/proctoscopy + biopsy, and an imaging assessment in the form of MRI ± PET/CT ± ERUS^[49,58,60,61]. For patients with a complete clinical and radiological response, follow up and surveillance is performed at regular intervals with reducing frequency out to five years, generally 3 monthly for the first two years, and 6 monthly out to five years. While this is certainly labour and resource intensive with consequent costs, the improved overall and stoma free survival certainly

justifies this approach.

For those cases with clear progression of disease through chemoradiation, salvage surgery should be undertaken as the next line of treatment to ensure optimal outcomes. However, in the setting of a partial response or stable disease, the pathway is less clear. It has been suggested that a more prolonged assessment, with regular EUAs even out to 6 mo, could be required for a better evaluation of tumour response. This is in consideration of the finding that multiple patients with an eventual pathological CR had clinical and radiological findings suggestive of persistent disease in the early post chemoradiation stage^[16]. This is also in keeping with the accepted management of anal SCC, where a delayed tumour response may continue for 6 mo after the completion of chemoradiation^[63]. In the grouped chemoradiation cohort (Table 2), a CR on pathology was identified in 57% of patients, suggesting that time may have played a role in assessing clinical and radiological response. As with rectal and anal cancer, this is likely to remain a contentious area until a more effective means

of determining response is available^[78].

Despite the encouraging results of chemoradiotherapy, currently a set treatment protocol is yet to be established. It appears that 5FU based chemotherapy combined with high dose external beam radiotherapy may be efficacious. However, while these trends are grossly evident from the literature, there is a need for further research in order to determine the most effective regimen to optimise patient outcomes.

It is unlikely that a randomised trial comparing surgery and chemoradiotherapy will ever be conducted for this rare cancer. Given the current knowledge base, it may be reasonable to suggest that primary treatment should be chemoradiotherapy, with surgery reserved as a salvage option. The suggested regimen would be a total dose of 50.4 to 54 Gy external beam radiation in 1.8 Gy per fraction, given concurrently with 5FU and mitomycin C.

Future options: Over recent years, there has been an increasing use of molecular targeted therapies in solid and haematological malignancies^[79]. Furthermore, immunotherapy in the form of tumour vaccines, adoptive T cell therapy and immune checkpoint inhibitors has become a major focus for research in the treatment of cancer, with translated clinical success in specific tumour types^[80]. While there is currently no literature on these modalities in rectal SCC, the early results in other tumours holds promise for a possible role in future treatment, particularly in the cohort of patients with persistent, recurrent or metastatic rectal SCC.

Prognosis

The most important predictor of survival in all cancers is the stage of disease. This is based upon three factors; the size of the primary tumour and depth of invasion (T stage); the location and number of lymph nodes involved (N stage); and the presence or absence of metastasis (M stage). Rectal SCC follows the same route of lymphatic spread for involvement of lymph nodes as rectal adenocarcinoma. Additionally, it has a similar pattern of metastasis with the liver, lung and bones most commonly affected^[66].

While the majority of patients with rectal SCC present with locoregional disease (stage I-III, 82.1%), they are associated with a poorer overall survival when compared stage for stage with adenocarcinoma. From review of the population study by the NCI, the overall 5-year survival for rectal SCC was found to be 48.9% compared with 62.1% for adenocarcinoma. When localised, the 5 years OS was 73.7% (91.8% - adenocarcinoma), with 31.3% (65.8%) for regional and 20.8% (8.8%) for metastatic^[2]. While the above figures and those from older studies report a poor prognosis for patients with rectal SCC, recent studies employing a new treatment paradigm, demonstrate a significantly improved overall survival. The possibility of further

advances in treatment as this disease is better defined, gives hope for improved patient outcomes.

While SCC of the rectum is a rare entity, there is an increasing body of evidence that is improving our understanding of its underlying aetiology. Despite the literature lacking uniformity in the staging and management of rectal SCC, it is hard to ignore the impressive improvements in overall survival and sphincter preservation by way of chemoradiotherapy as the primary modality of treatment. This holds much promise for the future, and certainly lays the foundation for further investigation into determining the optimal treatment regimen.

COMMENTS

Background

A summary of the current body of knowledge surrounding the pathogenesis, presentation, diagnosis, staging and management of rectal squamous cell carcinoma (SCC), with a focus on the changing treatment paradigm and consequent improved patient outcomes.

Research frontiers

While the underlying pathogenesis of rectal SCC is yet to be fully defined, a possible role for human papilloma virus presents an avenue for future investigation. Furthermore, the identification of pre-malignant lesions in the development of rectal SCC raises the possibility of surveillance in high risk patients. The use of magnetic resonance imaging (MRI) and positron emission tomography (PET) has an emerging role not only in diagnosis and staging, but also importantly as a functional modality to determine response to chemoradiotherapy. This role has arisen from the recent shift in the primary treatment of rectal SCC to chemoradiotherapy, accompanied by a dramatic improvement in overall survival.

Innovations and breakthroughs

Assimilation of the current body of evidence lends support to the presence of pre-malignant lesions and a metaplasia-dysplasia-carcinoma sequence in the development of rectal SCC. Staging for rectal SCC fits more appropriately with the tumour-node-metastasis (TNM) criteria for rectal adenocarcinoma than anal SCC. MRI and PET are finding an increasing role in diagnosis, staging and assessment of response to treatment in rectal SCC. Chemoradiotherapy offers improved patient outcomes without the associated morbidity of surgery. Improved markers of complete response will assist in determining the need for salvage treatment in this patient cohort.

Applications

Consideration should be given to screening for premalignant lesions in high risk individuals. Uniform staging utilising the current TNM criteria for rectal adenocarcinoma should be encouraged. PET and MRI should be incorporated into the evaluation of patients, pre and post treatment. Definitive chemoradiotherapy offers improved patient outcomes without the associated morbidity of surgery. While treatment must be individualised and based on patient and tumour factors, chemoradiation should form the basis of primary management.

Terminology

Complete response refers to the resolution of tumour following treatment with chemoradiotherapy. While radiological investigations and clinical examination can act as surrogate markers, a true complete response can currently only be determined post resection and pathological examination.

Peer-review

The review article described the background, diagnosis and staging, treatment,

and prognosis of primary SCC of the rectum. The whole article is well written and characterized.

Abstract

AIM: To review the current data about the success

rates of fibrin sealant use in pilonidal disease.

METHODS: Fibrin sealant can be used for different purposes in pilonidal sinus treatment, such as filling in the sinus tracts, covering the open wound after excision and lay-open treatment, or obliterating the subcutaneous dead space before skin closure. We searched Pubmed, Google-Scholar, Ebsco-Host, clinicaltrials, and Cochrane databases and found nine studies eligible for analysis; these studies included a total of 217 patients (84% male, mean age 24.2 ± 7.8).

RESULTS: In cases where fibrin sealant was used to obliterate the subcutaneous dead space, there was no reduction in wound complication rates (9.8% vs 14.6%, $P = 0.48$). In cases where sealant was used to cover the laid-open area, the wound healing time and patient comfort were reported better than in previous studies (mean 17 d, 88% satisfaction). When fibrin sealant was used to fill the sinus tracts, the recurrence rate was around 20%, despite the highly selected grouping of patients.

CONCLUSION: Consequently, using fibrin sealant to decrease the risk of seroma formation was determined to be an ineffective course of action. It was not advisable to fill the sinus tracts with fibrin sealant because it was not superior to other cost-effective and minimally invasive treatments. New comparative studies can be conducted to confirm the results of sealant use in covering the laid-open area.

Key words: Pilonidal disease; Fibrin sealant; Evidence base medicine; Systematic review

Core tip: Fibrin sealant use in pilonidal disease treatment may involve filling in the sinus tracts, covering the laid-open area after excision, or obliterating the subcutaneous dead space before skin closure. This systematic review demonstrates that when the fibrin

sealant was used to obliterate the subcutaneous dead space, there was no reduction in wound complications. It was unadvisable to fill the sinus tracts because it was not superior to the other more cost-effective treatments with a 20% recurrence rate. More studies are necessary for sealant use in covering the laid-open area, which has promising results, predicting shorter wound healing time and increased patient satisfaction.

Kayaalp C, Ertugrul I, Tolan K, Sumer F. Fibrin sealant use in pilonidal sinus: Systematic review. *World J Gastrointest Surg* 2016; 8(3): 266-273 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/266.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.266>

INTRODUCTION

Pilonidal sinus is a benign disease seen more commonly in young males and negatively alters the quality of life. Its prevalence was reported as 26 cases per 100000 people^[1]. The mainstay of pilonidal sinus treatment begins with the surgical excision of the sinus tracts, which is followed by either primary closure after excision or laying open the wound for secondary healing; these are the most commonly preferred surgical methods. However, these traditional techniques prolong the recovery period, cause a delay in returning to daily life, and ultimately interrupt the educational or professional lives of these young and active patients.

Fibrin sealant may be used for different purposes in pilonidal sinus surgery. Filling the sinus tracts with the fibrin sealant instead of surgically removing the sinus tracts has been described in the literature as a minimally invasive technique. Additionally, the open surface of the surgical area may be covered with the fibrin seal in the lay-open technique. A third option requires that the potential dead space that is formed after the total excision and primary closure of the defect may be obliterated by the fibrin sealant. All these methods are used in order to accelerate the recovery period, to decrease morbidity, and to enable a quick return to work. Our aim in this review was to collect all accessible data in the literature on the treatment of pilonidal disease with fibrin sealant and to make a prediction about the promising treatments.

MATERIALS AND METHODS

The databanks of www.ncbi.nlm.nih.gov/pubmed, www.cochrane.org, scholar.google.com and web.a.ebscohost.com were last searched on the 3rd of June, 2015, using the key words [(pilonidal*) and (glue* OR sealant*)]. All varieties of researches, including congressional summaries describing the patient data about the treatment, were analyzed. Two reviewers (IE & CK) determined the selection of the searched articles on www.ncbi.nlm.nih.gov/pubmed and www.cochrane.org

by the key words in all fields. Some studies were excluded due to the nature of their content (editorial letters, reviews, duplicated studies). Later, a search to scholar.google.com and web.a.ebscohost.com were done by the key words in titles of the studies. Lastly, www.clinicaltrials.gov was also searched. We performed an additional reference cross check as well.

As we were scanning the literature for the pilonidal sinus treatment modalities using fibrin glue, publications concerning the use of fibrin glue to fill the tracts without excision, publications concerning covering the defect following surgical excision and publications concerning filling the cavity with fibrin glue before primary closure were all included in this analysis. Treatments of pilonidal sinuses outside of the sacrococcygeal area (interdigital, umbilical, penile, vulvar) were excluded.

We used no limitations to the patient and journal features. All patients were accepted for analysis if there were enough data. There was no restraint with regard to article language, country, or journal. In cases of disagreement during analysis, a consensus of the two researcher authors was necessary for the acceptance of the studies. Data for affiliation, number of patients, age, gender, history of prior pilonidal surgery, method of application, complications, recurrence, time to heal, length of follow-up period, success, clinical findings, inclusion and exclusion criteria, body mass index, intra-operative and postoperative complications, duration of surgery, postoperative pain, postoperative hospital stay, time off work, and overall satisfaction were analyzed.

Data were organized into tables, and column sums were done including percentages, means \pm standard deviations, or the ranges. If the studies reported the median and range, the mean and standard deviation were estimated by Hozo *et al.*^[2] method. Percentages were preferred for the dichotomous parameters and means for the continuous parameters^[3]. The Chi-square test or the Fisher exact test (if expected values were less than 5) and Student's *t* test were used. (SPSS 17.0). $P < 0.05$ was accepted as statistically significant.

RESULTS

A total of nine publications were found that detailed the use of fibrin sealant in pilonidal sinus treatment^[4-12] (Figure 1). These publications included 217 patients that were treated between June 2001 and December 2013 (Table 1). Eighty-four percent of the patients were male, and their mean age was 24.2 ± 7.8 (ranged 12-70). One of the studies was conducted within a pediatric age group; the mean age for participants in this study was 14.5 and their mean body weight was 73 kg^[12]. The inclusion criteria and the surgical techniques used in these studies constituted sufficient heterogeneity (Tables 2 and 3). The studies were gathered into three subgroups depending on the application technique of the fibrin glue (Table 3). Fibrin sealant was used to obliterate the dead space before wound closure in three studies^[4,8,9]. In two other studies, it was used to cover

filled with the fibrin sealant without performing any surgery, which was intended to constitute a definitive treatment^[5,10-12]. Thirty-nine percent of all these interventions were performed under local anesthesia. An average of 3.8 mL (ranged 1-6 mL) of fibrin glue was used; drains were used in only 7.3% of these cases (Table 4).

In three studies, fibrin sealant was applied in order to obliterate the subcutaneous dead space^[4,8,9]. There were no recurrences in any of these cases after a mean follow-up period of 15.2 mo (Table 5). However, wound-related complications were observed in 16.4% of the patients. In one study, the authors declared that postoperative purulent drainage after fibrin sealant application was more frequent in cases requiring recurrent surgeries^[4]. In another study, the amount of drainage decreased within the fibrin sealant group, but instances of wound complications did not decrease significantly^[8]. In another study, fibrin sealant was replaced with a subcutaneous drain; there were no wound-related complications within the no-drain fibrin sealant group^[9]. In the studies with control groups^[8,9],

it was observed that use of the fibrin sealant did not decrease wound complication rates (control groups 9.8% vs sealant groups 14.6%; $P = 0.48$) (Figure 2).

Fibrin sealant was used in two studies in order to shorten the wound's healing period and to mitigate the negative effects associated with an open wound following surgical excision^[6,7] (Table 6). Healing periods for these patients were around 17 d and the morbidity rate was only 6%, which mainly involved early detachment of the fibrin sealant. When the fibrin sealant detached from the wound, either a new sealant was applied to the wound^[7], or it was left open for secondary intention^[6]. Work-off time of those patients was reported to be lower than expected (5.3 + 2.1 d)^[7]. In this group of patients, there were no recurrences reported and the patient satisfaction rate was reported to be 88% (Table 6).

Simply filling the pilonidal sinus tracts with fibrin sealant after curettage was used in four studies conducted with 113 patients as a minimally invasive treatment modality. Work-off time was generally less than 7 d, and the morbidity rates were generally

reported to be less than 1% (Table 7). The success rate for this group of patients was about 80%, after a mean follow up of 21.7 mo. In other words, the recurrence rates were around 20% (Figure 3).

DISCUSSION

The fibrin sealant is composed of two ingredients; human fibrinogen and bovine thrombin. When the two of these are combined, the thrombin converts the fibrinogen into fibrin in less than a minute. This 3 dimensional fibrin plug is used as a haemostatic or a sealing agent. Fibrin was first used as a local haemostatic material in Germany about 100 years ago^[13]. In the 1940s, it was used to repair the peripheral nerves^[14] and to keep skin grafts in place^[15]. Although it has been used commercially in Europe since 1972, it was not approved by the FDA for use in the United States^[16] until around 1998. Nowadays, fibrin sealant has been approved by the FDA for the following uses; hemostasis in surgical interventions, sealing of the colon during colostomy closure, and fixation of skin grafts given to burn patients^[16,17]. The other uses for fibrin sealants that fall outside of the FDA indications include prevention of seroma formation, fixation of mesh, and fistula tract closure^[16].

Recently, there has been a tendency to use minimally invasive surgical techniques in the treatment of pilonidal sinus, as with other surgically-treated diseases^[18]. Ideal treatment of pilonidal sinus should be conducted in outpatient settings under local anesthesia, have less postoperative pain, fast recovery, high success rates, and low costs^[18]. Fibrin sealant can be used for three purposes; (1) to obliterate the dead space under a closed wound; (2) to cover an open wound; (3) for primary treatment of sinus tracts in which they are filled with the sealant.

Obliterating the dead space under the wound

Seroma formation is a commonly observed complication following primary closure or flap closure of a wound. The collection of seroma leads to dehiscence of the wound, prolongation of the healing period, necessitates increased wound dressing changes, and causes a decrease in the patient's overall comfort and satisfaction. Deep sutures or use of drains are the most common techniques for closing the dead space, which prevents seroma formation. However, deep sutures increase pain and invert the natal cleft, which is ought to be flattened. The presence of the drains detracts from patient comfort, increases the workload associated with wound care, and raises the risk of infection. It is suspected that the use of the fibrin sealant may decrease seroma formation and decrease the need for the use of drains. But this analysis did not reveal that the fibrin sealant is effective in decreasing wound complications. Similar seroma problems were reported in mastectomy and axilla dissection cases, and many studies have been conducted with the fibrin sealant as a method of seroma prevention^[19]. Studies on fibrin sealant use in breast cancer surgery laid the groundwork for the use of fibrin sealant in treatment of pilonidal sinus patients. But the evidence-based medicine showed that the fibrin sealant did not influence the incidence of seromas, wound infections, overall complications, and the length of hospital stays for patients undergoing breast cancer surgery^[19]. The fibrin sealant's inability to prevent

seroma formation can be explained by its tendency to liquefy as it dissolves, and that it causes a tissue reaction^[20]. With the help of this analysis and similar studies conducted in mastectomy patients, we can conclude that the use of the fibrin sealant to obliterate the subcutaneous dead space is not very effective in preventing wound complications. Additionally, it has been observed that the use of the fibrin sealant leads to higher rates of subcutaneous fluid accumulation than treatment with drains^[9].

Covering the open wound by fibrin sealant

To this aim, the fibrin sealant can be used to decrease pain, dressing changes, and healing period. Nevertheless, a control group is needed to confirm that fibrin sealant does indeed achieve these desired ends. The absence of a control group in these studies^[6,7] makes it difficult to objectively evaluate the effectiveness of this technique. Without any comparative studies having been conducted, this technique cannot be proposed as an acceptable application.

Filling the sinus tracts with fibrin sealant

Fibrin sealant may be used as a sole treatment modality in pilonidal sinus treatment. Filling the sinus tracts with fibrin sealant without any other surgery has the advantages of less pain, shorter recovery period and a rapid return to daily life, and fewer dressing changes. Although it is generally recommended that this procedure be performed under local anesthesia, two thirds of all the reported cases were, surprisingly, performed under general anesthesia (Tables 3 and 4). Since even surgical excisions of the pilonidal sinus and flap procedures are performed under local anesthesia^[21], the use of the general anesthesia for a mere tract debridement and fibrin sealant application may be supererogatory. According to us, general or regional anesthesia should be used under special circumstances (pediatric patients, jitters, history of adverse reactions to local anesthesia, etc.). In this meta-analysis, an 80%

success rate for filling sinus tracts with fibrin sealant is pleasing. However, this result should be approached with caution. In one study, there was a 39% rate of non-responders^[10]. Another study included sinuses only with one orifice and cases without any purulent drainage (may be asymptomatic)^[11]. There was no study that was conducted with a sufficient number of symptomatic patients. Additionally, there was no information about the effect of repetitive applications of the sealant on this success rate. The results of single applications were also unknown. Conditions requiring repeated applications were not identified. Similar analyses were performed previously for phenol application in pilonidal disease; a success rate of 70% in single application and a success rate of 86.7% in repetitive applications were reported^[22,23]. Even if the 80% success rate is to be accepted as accurate, it nevertheless does not constitute an advantage over phenol application. Furthermore, fibrin sealant is much more expensive than phenol. In cases where repeated sealant applications are necessary, the use of phenol may offer an advantage due to the higher cost of fibrin. We may comfortably claim that the treatment of pilonidal tracts with fibrin sealant is not definitively superior to other minimally invasive methods. Additionally, the higher cost of fibrin sealant does not justify its routine use in filling sinus tracts as a primary treatment modality.

A review was published in 2012 about the fibrin sealant use in pilonidal sinus^[24]. In this review, which analyzed only 5 publications with a total number of 85 patients, researchers declared that adjuvant fibrin sealant in the treatment of pilonidal sinus was a promising technique, and they justified more research about it^[24]. In the last four years, new studies have been conducted; our systematic review analyzed 9 publications, which included 217 patients altogether. Analyzing more patients than the previously published review provided us to make some specific comments.

However, it is obvious that more studies are still necessary for clear comments.

The limitations of our study were (1) a low number of randomized controlled trials; (2) heterogeneity of the studies involved; and (3) a lack of subgroup analysis for special groups (pediatric cases, recurrent cases, etc.). Because of these constraints, we used descriptive statistics in general, and sometimes meta-analysis. Despite these limitations, some results of this analysis are able to justify certain conclusions. In our opinion, the use of fibrin sealant in preventing subcutaneous seroma formation is not advantageous. The use of the fibrin sealant in order to fill the sinus tracts is also not advised, as its success rate was not greater than that of more cost-effective minimally invasive methods. New studies must be conducted regarding fibrin sealant use in covering wounds after excision and lay-open.

COMMENTS

Background

Fibrin sealant may be used for different purposes in pilonidal sinus surgery. All the methods are used in order to accelerate the recovery period, to decrease morbidity, and to enable a quick return to work. The aim in this review was to collect all accessible data in the literature on the treatment of pilonidal disease with fibrin sealant and to make a prediction about the promising treatments.

Research frontiers

Fibrin was first used as a local haemostatic material in Germany about 100 years ago. In the 1940s, it was used to repair the peripheral nerves and to keep skin grafts in place. Although it has been used commercially in Europe since 1972, it was not approved by the Food and Drug Administration for use in the United States until around 1998.

Innovations and breakthroughs

Recently, there has been a tendency to use minimally invasive surgical techniques in the treatment of pilonidal sinus, as with other surgically-treated diseases. Ideal treatment of pilonidal sinus should be conducted in outpatient settings under local anesthesia, have less postoperative pain, fast recovery, high success rates, and low costs. Retrieved manuscripts concerning the utility of fibrin sealant in pilonidal disease were reviewed by the authors, and the data were extracted using a standardized collection tool.

Applications

This review suggests that fibrin sealant can be used for three purposes; (1) to obliterate the dead space under a closed wound; (2) to cover an open wound; (3) for primary treatment of sinus tracts in which they are filled with the sealant.

Terminology

The fibrin sealant is composed of two ingredients; human fibrinogen and bovine thrombin. When the two of these are combined, the thrombin converts the fibrinogen into fibrin in less than a minute. This 3 dimensional fibrin plug is used as a haemostatic or a sealing agent.

Peer-review

In this systematic review, the authors have presented a thorough and critical analysis of the utility of fibrin sealant for the treatment of pilonidal disease as a minimally invasive method.

Abstract

AIM: To perform a systematic review and meta-analysis on post-operative complications after surgery for Crohn's disease (CD) comparing biological with no therapy.

METHODS: PubMed, Medline and Embase databases were searched to identify studies comparing post-operative outcomes in CD patients receiving biological therapy and those who did not. A meta-analysis with a random-effects model was used to calculate pooled odds ratios (OR) and confidence intervals (CI) for each outcome measure of interest.

RESULTS: A total of 14 studies were included for meta-analysis, comprising a total of 5425 patients with CD 1024 (biological treatment, 4401 control group). After biological therapy there was an increased risk of total infectious complications (OR = 1.52; 95%CI: 1.14-2.03, 8 studies) and wound infection (OR = 1.73; 95%CI: 1.12-2.67; $P = 0.01$, 7 studies). There was no increased risk for other complications including anastomotic leak (OR = 1.19; 95%CI: 0.82-1.71; $P = 0.26$), abdominal sepsis (OR = 1.22; 95%CI: 0.87-1.72; $P = 0.25$) and re-operation (OR = 1.12; 95%CI: 0.81-1.54; $P = 0.46$) in patients receiving biological therapy.

CONCLUSION: Pre-operative use of anti-TNF- α therapy may increase risk of post-operative infectious complications after surgery for CD and in particular wound related infections.

Key words: Crohn's; Post-operative complications; Biological; Anti-tumor necrosis factor- α ; Monoclonal antibody; Infliximab; Adulimimab

Core tip: Pre-operative use of anti-tumor necrosis

factor alpha (TNF- α) therapy increases risks of post-operative infectious complications after surgery for Crohn's disease, particularly wound sepsis. Surgery should be planned carefully and ideally performed after appropriate cessation of anti-TNF- α therapy to mitigate increased post-operative risks.

Post-operative abdominal complications in Crohn's disease in the biological era: Systematic review and meta-analysis. *World J Gastrointest Surg* 2016; 8(3): 274-283 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i3/274.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i3.274>

INTRODUCTION

The introduction of biological therapy for gastrointestinal Crohn's disease (CD) has been a significant landmark in non-operative management of this chronic relapsing condition. The central role of the cytokine tumor necrosis factor- α (TNF α) in persistence of mucosal inflammation underlies the marked efficacy of monoclonal antibodies such as Infliximab and Adalimumab^[1,2]. Multiple randomised clinical trials including ACCENT and CHARM have shown high clinical response (35%-50%) and maintenance rates for both infliximab and adalimumab in modest to severe CD. Eight-weekly infusion regimes appear to be most effective for patients with an initial response to the induction dose of monoclonal agent. Long term use of such agents is supported up to three years and is extremely effective as a steroid-sparing therapy^[1-3]. Currently monoclonal antibodies are being utilised earlier in the treatment algorithm for moderate to severe inflammatory disease, in addition to more complex intra-abdominal fistulating disease in an attempt to achieve mucosal healing and remission. However, a significant proportion of patients do not achieve mucosal healing and eventually arrive at surgical intervention after step-up therapy (10%-20% per year of use of infliximab)^[4,5]. Other indications for surgery include intolerance of therapy due to complications. Thus, surgical intervention is required in up to 50% of patients with CD within 10 years of diagnosis^[6]. There are concerns as to operative intervention within the context of such potent immunosuppression due to the nature of biological therapy.

Current data reveals a contradictory picture of the adverse effects of pre-operative use of anti-TNF- α agents and postoperative complications following bowel resection. Several studies indicate an increase in septic complications; whether it be abdominal sepsis or superficial wound infections^[7,8]. Other studies report no adverse impact of monoclonal antibodies on post-operative outcome^[9-11]. It would be beneficial to subject study findings in a comprehensive meta-analytical framework to identify any associations. Several meta-analyses have been performed previously and have

examined total or major postoperative complications after abdominal surgery in treatment and control groups^[12-14]. In contrast, our analysis aims to study specific septic complications in the CD patient receiving anti-TNF α therapy to investigate postoperative risk in greater detail.

MATERIALS AND METHODS

Search strategy

PRISMA statement guidelines were followed for conducting and reporting meta-analysis data. We searched Medline and Embase from inception to May 2015 using the search terms "infliximab" or "immunosuppressant" or "monoclonal antibody" or "Humira" or "Adalimumab" or "Remicade" and "Crohn's disease" or "Crohn disease" and "complications" or "outcomes" or "postoperative" or "morbidity". The identical terms were used again in PubMed. The search encompassed titles, abstracts, subject headings and registry words. Articles were limited to those published in the English language, animal studies excluded and duplicates were removed.

Study selection

Studies identified from the differing searches were amalgamated and titles and abstracts were scrutinised to include relevant material only. Full text versions were obtained of eligible articles and were reviewed by both authors (PW and HP) to ensure that appropriate data was selected for analysis. Discrepancies between the authors were resolved by discussion of the particular manuscript. Studies were only included in the analysis if patients had intestinal resection with anastomosis for CD and had been administered infliximab within 90 d preceding abdominal surgery. Postoperative complication rate (30-90 d) including anastomotic leak was a compulsory outcome measure. Studies without the aforementioned data were excluded. Studies on indeterminate colitis, ulcerative colitis (UC) or ileoanal pouch were excluded.

Data extraction

Data were interrogated by both authors (PW and HP) and salient patient, disease and surgery-related factors were noted. The number of patients in the treatment (pre-operative anti-TNF administration) and control group (no use of pre-operative anti-TNF agent) were noted and compared for the outcomes of interest. Both groups comprised of patients with CD. Studies on mixed groups of patients with CD and UC were only included if data pertinent to CD could be extracted with a separation of patients on IFX and those on other therapy. Other conditions such as neoplasia and ileoanal pouch procedures were excluded. An attempt was made to establish severity of CD by noting the presence of pre- or intra- operative abscess and use of steroids pre-operatively. The overall postoperative complication rate was analysed as well as superficial and intra-abdominal sepsis occurrence. Mortality, re-operative and stoma rates were noted if reported and duration of follow-up

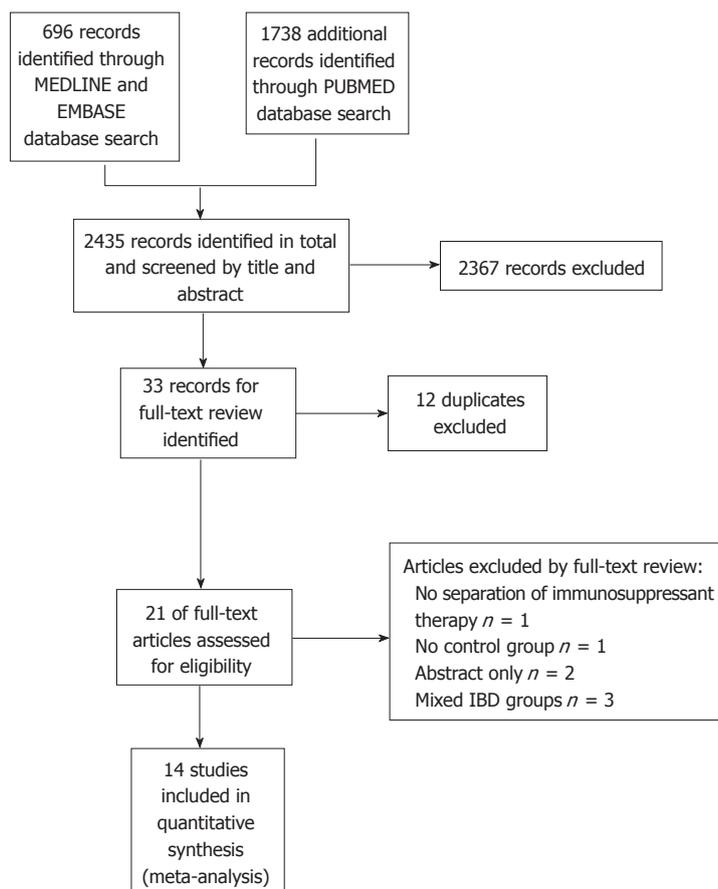

Figure 1 Preferred reporting items for systematic reviews and meta-analyses reporting diagram. IBD: Inflammatory bowel disease.

was recorded. Any intestinal resection with anastomosis and/or strictureplasty was included in analysis.

Risk of bias

The Newcastle-Ottawa score for case-control studies was used to assess the quality of included studies. A maximum of 9 stars was attainable. Publication bias was assessed by funnel plot for each outcome measure. Analysis was repeated without outlier high risk studies as required to reduce bias.

Statistical analysis

Extracted data were entered onto a Microsoft Excel spreadsheet (MS Office 2010, Microsoft, WA, United States) by the lead author (HP) with verification from the co-author (PW). All statistical analyses were performed on Rev Man 5.3 (<http://tech.cochrane.org/revman>; 2014) and SPSS (version 20; IBM). The groups were compared for pre-operative characteristics using χ^2 test without Yates correction and unpaired *t* test for dichotomous and continuous variables respectively. A *P* value of < 0.05 was considered significant.

Outcome measures for meta-analysis were chosen to test the null hypothesis of equivalent post-operative complications in both groups. Primary outcome measures comprised of total infectious complications, abdominal sepsis and anastomotic leak. Secondary outcome measures were wound sepsis, re-operation and mortality rate.

Dichotomous variables were analysed with the Mantel-Haenszel statistical method and random effects model. This particular model was chosen as it does not assume homogeneity between studies in terms of methodology or clinical characteristics and thus allows a more conservative analysis than the fixed effects model. Certain outcome measures were not reported by all studies and hence, the total number of patients in treatment and control groups was variable. No outcome measures were expressed as continuous variables.

Odds ratio, 95%CI, Forest and funnel plots were generated by Rev Man software. Study heterogeneity was assessed by τ^2 and χ^2 testing with a quantitative measure of heterogeneity provided by the I^2 measure. An I^2 value of greater than 50% was considered evidence of substantial heterogeneity.

RESULTS

Search results

The search strategy identified a total of 2434 articles from Medline, Embase and Pubmed databases after application of English language and Human filters. Title and abstract screen eliminated 2367 articles with 33 remaining for analysis. Duplicates were removed at this stage as results from the 3 databases were amalgamated at this point. This left 21 articles for full text review. A total of 14 studies were relevant for meta-analysis after perusal of all 21 articles by both

authors. (Figure 1; PRISMA reporting diagram)^[7-11,15-23].

Study and patient characteristics

The characteristics of the 14 included studies are summarised in Table 1. There was no overlap of study population between included studies. All studies were retrospective case control type including two that reported formal case control matching^[15,18]. A total of 5425 patients with CD were included in the analysis of which 1024 received anti-TNF α agents (treatment group) and 4401 received non-biological therapy (control group). All treatment cases had received anti-TNF agents within the preceding 12 wk before surgery. Infliximab was the only biologic agent used in 8/14 studies (57%). Patients in the remaining 6 studies received either Infliximab, Adalimumab

or another biological agent. Mono or combination therapy with corticosteroids and/or immunomodulators (thiopurines) was used in the majority of the control group. Unsurprisingly, there was a significant difference between steroid use in the treatment and control groups ($P = 0.0012$, χ^2 test). There was no difference between the two groups in terms of age ($P = 0.135$, unpaired t test) and gender distribution ($P = 0.456$, χ^2 test). A subset of patients was eligible for assessment of difference in age as some studies reported age as mean and others as median. Thus, the mean was used and 3 studies could be analysed with no significant difference identified ($n = 629$ in total, unpaired t test $P = 0.135$). There was no difference between the two groups in terms of pre-operative abscess ($P = 0.344$, χ^2 test) or stoma creation during the procedure ($P = 0.66$, χ^2 test).

Outcome measures

Primary and secondary outcome measures from each study are summarised in Table 2.

Total infectious complications

8 out of 14 studies^[7-11,15,18-21] reported total infectious complications and entered 567 treatment cases and 1291 controls for analysis. Total infectious complications were reported in 4 out of 8 and were derived in 4 studies^[7,10,18,21] by summation of reported site-specific complications. A total of 165 complications were reported in the treatment group as compared to 252 in the control group. There was an increased risk of total infectious complications in the treatment group (OR = 1.52; 95%CI: 1.14-2.03) that reached statistical significance ($Z = 2.87$; $P = 0.005$) (see Figure 2.

Total infectious complications: Study event rate Forest plot). There was a low risk of heterogeneity amongst analysed studies as indicated by the I^2 index (23%) and Tau^2 variable (0.04; Rev Man 5.3). The Cochran Q test revealed some heterogeneity but not to a significant extent ($\chi^2 = 9.06$, $df = 7$; $P = 0.25$).

Postoperative abdominal sepsis

Abdominal sepsis was reported in nine out of fourteen studies^[7-9,10,15,18,19,22,23] and comprised all abdominal septic complications including anastomotic leak, abscess and/or fistula. Septic outcomes were reported in 7 studies and derived in two studies^[9,15]. A total of 60 complications (60/697) were reported in the treatment group and 148 (148/3291) in the control. There was a trend towards increased postoperative abdominal sepsis

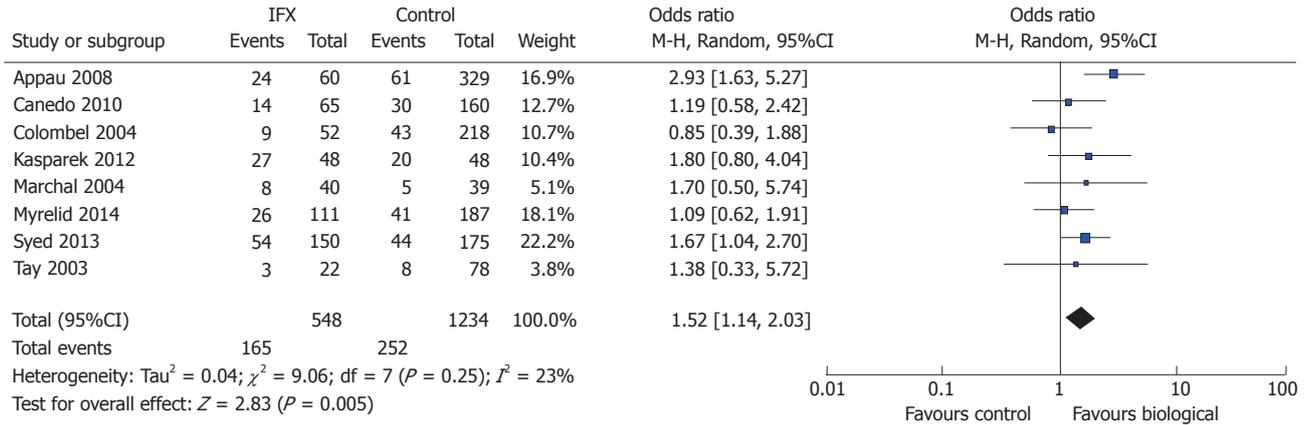

Figure 2 Total infectious complications: Study event rates and forest plot. Forest plot showing significantly higher total infective complications in patients receiving biological therapy - note confidence interval does not overlap one.

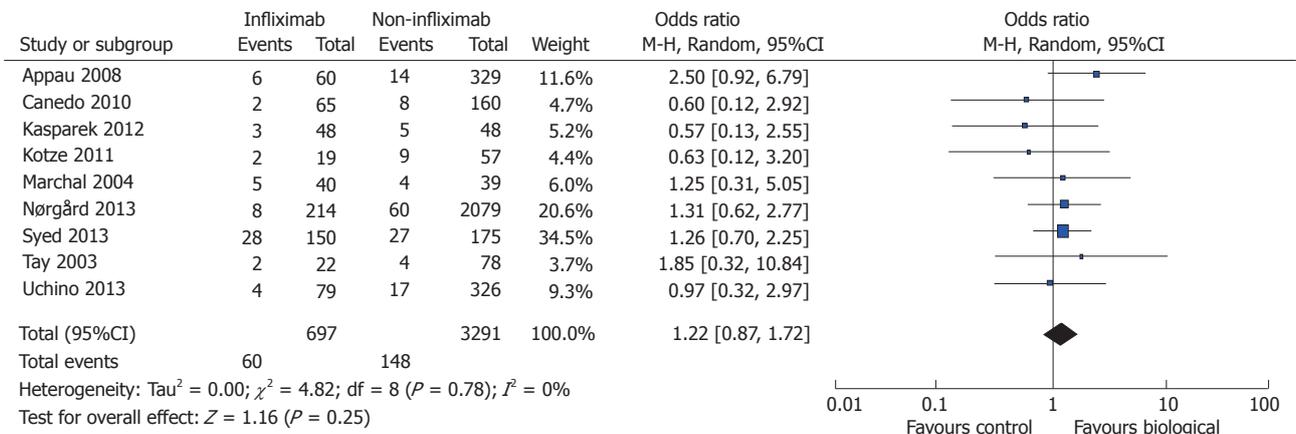

Figure 3 Postoperative abdominal sepsis: Study event rates and forest plot.

in the treatment group (OR = 1.22; 95%CI: 0.87-1.72; $P = 0.25$). (see Figure 3. Postoperative abdominal sepsis: study event rates and forest plot) Heterogeneity amongst studies was minimal with I^2 index of 0% and Tau^2 variable of zero again. Cochran Q test supported lack of heterogeneity with a P value of 0.78.

Anastomotic leak

A total of eleven studies reported on anastomotic leak rates in the two study groups which enabled 812 cases and 3356 controls to be entered for analysis^[7-10,15-21]. There were 43 and 166 anastomotic complications reported in the case and control group respectively. There was a trend towards increased rate of anastomotic leak in the case/treatment group (OR = 1.19; 95%CI: 0.82-1.71; $P = 0.26$) (see Figure 4. Anastomotic leak: Study event rates and forest plot). Minimal heterogeneity was noted in the group ($I^2 = 0\%$; $\text{Tau}^2 = 0$) as further confirmed by a low Cochran Q score ($Q = 6.16$; $P = 0.72$).

Wound infection

A total of seven studies reported data on postoperative wound infection in 461 cases and 1151 controls^[7,8,10,15,16,18,22]. There were 51 and 96 wound

complications reported in the case and control group respectively. There was a trend towards increased rate of wound sepsis in the treatment group (OR = 1.29; 95%CI: 0.62-2.68; $P = 0.49$) (see Figure 5. Wound infection: study event rates and forest plot). Substantial heterogeneity existed in the analysed studies with an I^2 value of 50% and Tau^2 value of 0.42. The Cochran Q test also revealed significant heterogeneity ($P = 0.06$). An outlier study^[22] was identified on the funnel plot and exclusion from meta-analysis revealed an increased risk of postoperative wound infection in the treatment group (OR = 1.73; 95%CI: 1.12-2.67; $P = 0.01$) (see Figure 6. Wound infection: Funnel plot with outlier and Figure 7. Wound infection: Modified study event rates and forest plot). Heterogeneity also became minimal with the second analysis ($\text{Tau}^2 = 0$; $I^2 = 0\%$).

Re-operation and mortality rates

The rate of re-operation was not reported widely and only six studies were eligible for analysis^[7-10,15,21]. Thus, a total of 648 cases and 2978 controls were analysed with a predictable low re-operation rate (67 vs 240). There was a potential trend for increased re-operation in the treatment group (OR = 1.12; 95%CI: 0.81-1.54; $P = 0.54$) with a minimal element of heterogeneity (Tau^2

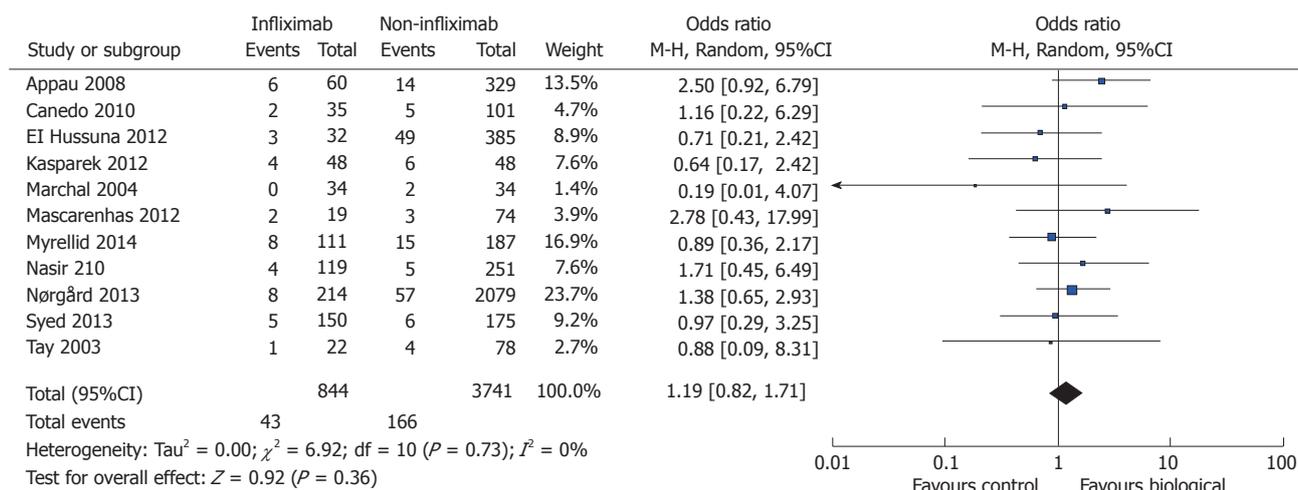

Figure 4 Anastomotic leak: Study event rates and forest plot.

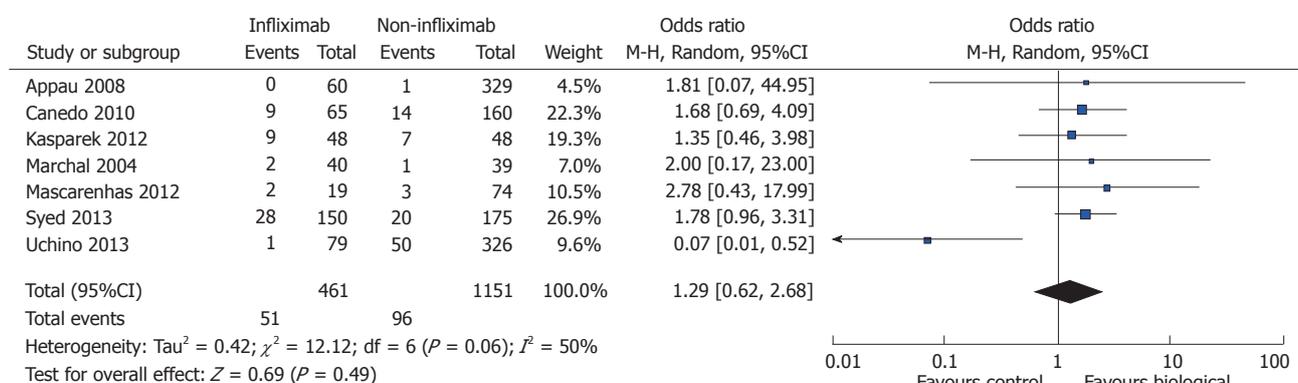

Figure 5 Wound infection: Study event rates and forest plot. Lone outlier study (Uchino 2013) visible on forest plot.

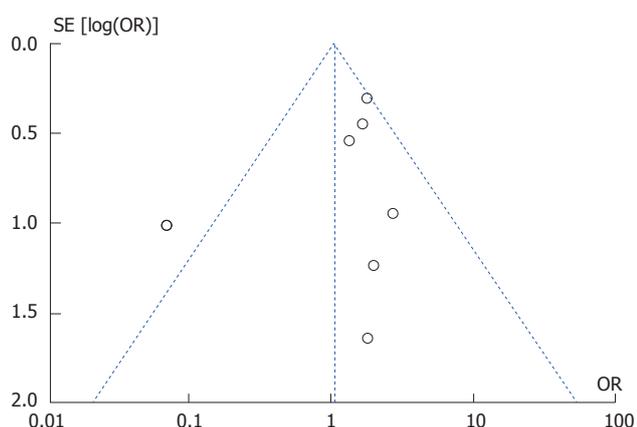

Figure 6 Wound infection: Funnel plot with outlier. A single statistical outlier visible outside the funnel plot suggestive of possible publication bias.

= 0.00; $I^2 = 0\%$; Cochran $Q = 4.65$) (see Figure 8. Re-operation: Study event rates and forest plot).

Thirty-day mortality rates were reported in ten out of 14 studies and were low as expected from sample size (ranging from 0 to 3 actual events per study). There was only one large-scale study and thus further statistical analysis was not attempted^[9].

DISCUSSION

Surgery for abdominal CD presents unique challenges to the surgeon and gastroenterologist. There are substantial risk factors pertaining to patient physiology, operative anatomy and co-existing medication. Anti-TNF agents have shown remarkable therapeutic efficacy in CD but concerns over increased rate of opportunistic infections and re-activation of latent TB remain^[24,25]. Our meta-analysis demonstrates an increased risk of total infectious complications after abdominal surgery in patients receiving anti-TNF α therapy. Furthermore, after adjusting for publication bias a significant increase in wound sepsis was also identified. There was no increase in risk of intra-abdominal outcomes of anastomotic leak or abdominal sepsis for the same patient group. Re-operation rate was also not increased in the treatment group receiving anti-TNF α agents. Mortality rate was not compared between treatment and control groups as event numbers were too small for meaningful statistical analysis.

We defined total infectious complications to include abdominal, wound, urinary and respiratory sepsis and data was available in 8 out of 14 studies for analysis.

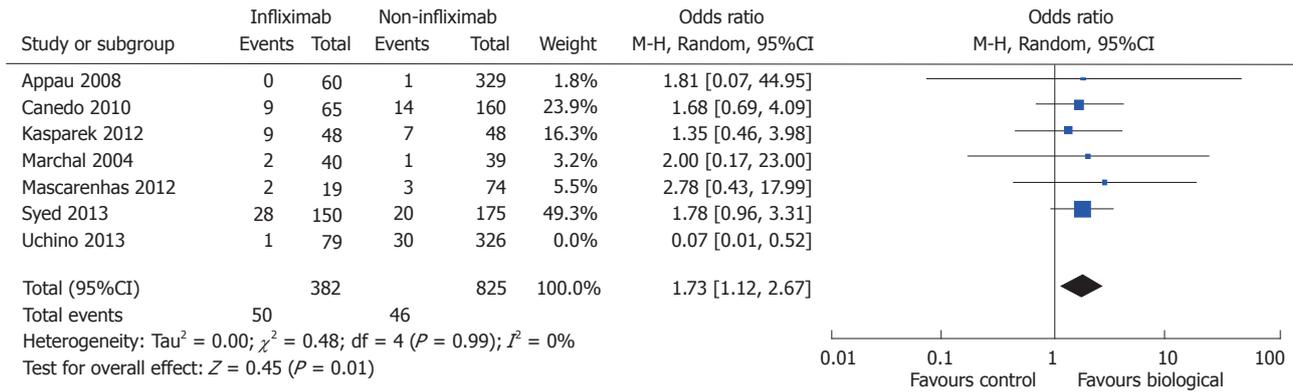

Figure 7 Wound infection: Modified study event rates and forest plot.

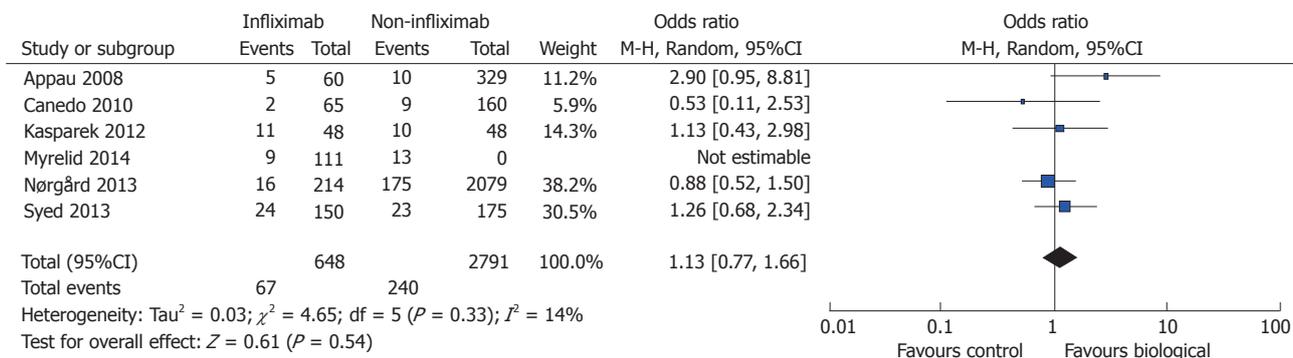

Figure 8 Re-operation: Study event rates and forest plot.

Half of the included studies reported on the full spectrum of septic complications as described previously and data was derived in the remainder. There was some minor heterogeneity noted, which may be expected with such data given variability between studies in the criteria used to define infections arising from surgical wounds, or the urinary and respiratory tracts. Use of derivative data may also lead to a degree of inaccuracy as multiple septic complications could have occurred in the same patient and as a consequence result in over or underestimation of the true absolute event rate. Reassuringly, in spite of such confounders heterogeneity was slight with no major outliers seen on funnel plot.

The outcome measures of anastomotic leak, abdominal sepsis and wound infection were analysed separately in an attempt to define the relative contribution of each outcome to the increased risk for total infectious complications. A tendency was noted towards increased complications with biological therapy for anastomotic leak and abdominal sepsis though this was not significant for either measure. In addition, heterogeneity was minimal for both analyses. The more objective nature of abdominal sepsis and anastomotic leak in terms of diagnosis and data recording may explain homogeneity in the meta-analysis. Thus, the demonstrated increase in total infectious complications in the anti-TNF α group may be inferred to be “non-abdominal” in origin. A significant increase in wound infection rates were noted in patients treated with anti-

TNF α agents.

Prior meta-analyses have revealed similar findings^[12,14,26,27] apart from one analysis with equivalent outcomes across both groups^[13]. An increased risk was found for major postoperative infection in 4 out of 5 meta-analyses that addressed this issue^[12,14,26,27]. The meta-analysis that showed no difference between treatment and control groups divided postoperative complications into major and minor categories^[13]. Postoperative sepsis was allocated to either category depending on type and thus it is difficult to extrapolate the true risk of sepsis in this analysis. Our meta-analysis differs from previous efforts in that we concentrated solely on infectious postoperative complications. Analyses were also conducted separately for site specific sepsis. This was performed to assess the excess burden of each outcome in patients on anti-TNF α therapy and has not been performed previously. It is also noted that heterogeneity was markedly reduced in our analysis as compared to previous efforts and could reflect more stringent inclusion criteria.

There are several limitations to our meta-analysis. Firstly, the severity of CD is likely to be disparate between the treatment and control groups. Anti-TNF α therapy is usually prescribed for disease that is refractory to steroids and/or immunomodulators. Thus, patients would be expected to possess a greater risk for postoperative complications as operative pathology may be more complex. We attempted to analyse this by

comparing the presence of preoperative abscess or use of stoma as part of the operative procedure between the treatment and control groups. There was no significant difference identified in either of these parameters and that could indicate a degree of equivalence in disease severity between the treatment groups. However, it seems more likely that these parameters may not be sensitive enough to differentiate usefully between either group. A more objective comparison of CD severity between groups could be performed using quantitative measures such as the Crohn's Disease Activity Index (or Harvey-Bradshaw index). Unfortunately, no attempts at comparative disease severity stratification were performed within the included studies.

Patients in the control group received differing medications which again suggests that disease severity is not consistent across the control group. As previously mentioned postoperative complications are not defined or diagnosed in a standardised manner across the included studies. Thus, there may be over- or under- representation of the true extent of particular postoperative complications.

A significant limitation of this meta-analysis relates to the retrospective nature of all the included studies and the fact that only two studies attempted to match case and control groups albeit in a limited fashion^[15,18]. This accurately reflects the existing literature and randomised controlled trials to address this issue are not feasible or ethical, so data is likely to be restricted to cohort studies in the future.

In conclusion, our meta-analysis may provide further support to the hypothesis of an increase in postoperative infectious complications in patients receiving anti-TNF α therapy. Our results are similar to other analyses on this subject and we have attempted to extract the specific infectious complications that are increased in this group of patients. A significant increase in both total infectious complications and wound infection rates in patients receiving anti-TNF α therapy were identified.

Our meta-analysis does not support the use of a protective stoma in patients receiving anti-TNF α therapy as a single risk factor, as there was no increase in abdominal sepsis, leak or re-operation rate. Our recommendation is to consider operative risk for patients with CD on an individual basis, incorporating recognised risk factors such as steroid use, hypoalbuminaemia, presence of fistula or abscess, in addition to preoperative anti-TNF α therapy alone. Furthermore, it seems sensible to attempt to mitigate risk of postoperative infection by planning surgery after cessation of anti-TNF α therapy where possible.

COMMENTS

Background

Current data reveals a contradictory picture of the adverse effects of pre-operative use of anti-TNF α agents and postoperative complications following bowel resection. It would be valuable to perform a comprehensive meta-analysis to identify any associations. The authors' analysis aims to study specific septic

complications in the Crohn's disease patient receiving anti-tumor necrosis factor alpha (TNF- α) therapy to investigate postoperative risk in greater detail.

Research frontiers

Not applicable as this is a meta-analysis from synthesised data from previous original studies.

Innovations and breakthroughs

Their meta-analysis demonstrates an increased risk of total infectious complications after abdominal surgery in patients receiving anti-TNF α therapy. This is the first meta-analysis to show a site-specific increase in septic complications, in particular wound sepsis.

Applications

The authors recommend risk assessment on an individual basis for patients with Crohn's disease taking into account use of anti-TNF α therapy in combination with other known risk factors for post-operative septic complications. Discontinuation of anti-TNF α should be considered 6-8 wk prior to planned surgery.

Terminology

Anti-TNF α therapy: Anti-tumour necrosis factor alpha therapies are mostly monoclonal antibodies to tumour necrosis factor, a chemokine which is implicated in the abnormal inflammatory response associated with active inflammatory bowel disease. CD: Crohn's disease; UC: Ulcerative colitis; Fistulating disease: Enterocutaneous or inflammatory mass with entero-entero fistulae and/or fistula-ano.

Peer-review

This is a well-written review about the role of the pre-operative use of anti-TNF α therapy that may increase risk of post-operative infectious complications after surgery for CD and in particular wound related infections.

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Ai-Wen Wu, MD, PhD, Professor, Department of Gastrointestinal Surgery, Key Laboratory of Carcinogenesis and Translational Research, Ministry of Education, Peking University Cancer Hospital and Institute, Beijing 100142, China

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (World J Gastrointest Surg, WJGS, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Abstract

Due to the overwhelming burden of colorectal cancer (CRC), great effort has been placed on identifying genetic mutations that contribute to disease development and progression. One of the most studied polymorphisms that could potentially increase susceptibility to CRC involves the nucleotide-binding and oligomerization-domain containing 2 (*NOD2*) gene. There is growing evidence that the biological activity of *NOD2* is far greater than previously thought and a link with intestinal microbiota and mucosal immunity is increasingly sought after. In fact, microbial composition may be an important contributor not only to inflammatory bowel diseases (IBD) but also to CRC. Recent studies have showed that deficient *NOD2* function confers a communicable risk of colitis and CRC. Despite the evidence from experimental models, population-based studies that tried to link certain *NOD2* polymorphisms and an increase in CRC risk have been described as conflicting. Significant geographic discrepancies in the frequency of such polymorphisms and different interpretations of the results may have limited the conclusions of those studies. Since being first associated to IBD and CRC, our understanding of the role of this gene has come a long way, and it is tempting to postulate that it may contribute to identify individuals with susceptible genetic background that may benefit from early CRC screening programs or in predicting response to current therapeutic tools. The aim of this review is to clarify the status quo of *NOD2* mutations as genetic risk factors to chronic inflammation and ultimately to CRC. The use of *NOD2* as a predictor of certain phenotypic characteristics of the disease will be analyzed as well.

Core tip: Recently, data from animal models showed that nucleotide-binding and oligomerization-domain containing 2 (*NOD2*) deficiency leads to dysbiosis and to an increased risk of colitis and colitis-associated colorectal cancer (CRC). Furthermore, it is now known that this receptor has a much more expanded role than previously thought. Concerning population-based studies, and despite initial inconsistencies, recent data points to an important role for *NOD2* mutations in CRC susceptibility. Identifying carriers of such polymorphisms may allow them to be included in stricter CRC surveillance programs. A link between *NOD2* mutation carriage and response to different chemotherapy regimens is also a promising field of research.

INTRODUCTION

Despite several advances in the diagnosis and treatment of colorectal cancer (CRC), it continues to be one of the most significant causes of morbidity and cancer-related deaths^[1]. Apart from familial syndromes that account for 5%-10% of CRC cases^[2], this disease is considered to have a multifactorial etiology and therefore predicting individual risk has been problematic, as there are many genetic polymorphisms with probably modest individual effect^[3]. Due to its proven role as a genetic predisposing factor for chronic inflammation, most notably in Crohn's disease (CD)^[4], nucleotide-binding and oligomerization-domain containing 2 (*NOD2*) mutations have been suggested to have a similar role in CRC. This assumption derives from the fact that several gastrointestinal cancers are strongly linked to chronic inflammatory conditions. The risk for malignancy may even increase according to the degree of underlying inflammation, as is the case for long-standing ulcerative colitis^[5] and *Helicobacter pylori* (*H. pylori*)-induced chronic gastritis. One plausible hypothesis is that pro-inflammatory stimulus may lead to continuous cell proliferation, angiogenesis and eventually DNA damage^[6]. If the association between chronic inflammation and cancer is based on solid experimental and epidemiological data, what remains to be fully understood is how do *NOD2* mutations lead to chronic inflammation?

The *NOD2* protein plays an important role in innate immunity by recognizing bacterial lipopolysaccharides and activating the nuclear factor-kappaB. The mutant alleles for *NOD2* gene are thought to cause loss of function - deficient recognition, impaired clearance and proliferation of bacterial pathogens that lead to increased pro-inflammatory cytokines and subsequently to chronic inflammation^[7]. Recently, the role of *NOD2* has been analyzed under a different light, as it seems to take a central place in the intricate balance between protection

of the intestinal mucosa under physiological settings and the production of pro-inflammatory cytokines in chronic inflammatory conditions. Any shift, either gain or loss of function for *NOD2*, elicits a disturbance in the immune system that may lead to inflammation^[8].

Another promising approach to understanding the pathogenesis of these diseases is the modulation of intestinal microbiota. Formerly considered a passive element in the homeostasis of the intestinal mucosa, the microbiota is nowadays considered as essential for epithelial differentiation and in maintaining a protective environment^[9]. To that end, commensal bacteria and *NOD2* interact in a feedback-like mechanism - *NOD2* keeps bacterial proliferation in a steady, controlled state and the microbiota intervene in controlling *NOD2* expression^[10]. Animal models with high risk genotype for colitis and CRC show less severe or even absent inflammation and fewer cases of adenomas if raised in selected bacterial or germ-free conditions^[11], suggesting that changes in microbial species affect colitis and CRC development.

From 2004 to 2010, several population-based studies tried to find an increased risk for CRC in *NOD2* polymorphism carriers. The most studied mutations have been two missense mutations - R702W (rs2066844 C/T) and G908R (rs2066845 C/G), and a frameshift mutation - 3020insC (rs2066847 insC). The frequency of these polymorphisms differs greatly between populations, being much less common in Asian cohorts^[12]. Even among Caucasian populations, there is significant genetic heterogeneity that may have limited the findings of such studies. Furthermore, the source of controls and the type of methodology used are also potential bias. Another relevant finding is that individual polymorphisms may increase the risk of CRC only in selected groups (*e.g.*, German individuals under 45-year-old carrying R702W polymorphism^[13]). These promising studies may ultimately lead to identifying individuals with susceptible genetic background, other than those with well-known familial syndromes, therefore benefitting from early diagnostic screening.

In order to find recent publications (2004 to present) on *NOD2* mutations and CRC susceptibility, an extensive literature search was performed using PubMed and MEDLINE. The key search terms used were *NOD2*/caspase recruitment domain 15 (CARD15) mutations, CRC genetics, microbiota, mucosal immunity and chronic inflammation, either alone or in combination. All articles identified were English-language, full-text papers. We also searched the reference lists of identified articles for further relevant papers.

THE EXPANDING *NOD2* ROLE

In order to protect the epithelium of the gastrointestinal tract, the largest surface in our body exposed to external environment, a number of obstacles within the mucosa are disposed to prevent the spread of pathogenic organisms. Besides mechanical barriers

such as the mucus layers, the innate immune system is probably the first mechanism to act against deleterious microorganisms, and once triggered it becomes activated within minutes^[14]. This almost immediate response is due to pathogen recognition receptors (PRRs). One of the most prominent families of PRR includes Nod-like receptors (NLRs) that recognize bacterial wall component peptidoglycan. Certainly the most researched member of this family is *NOD2*, expressed in dendritic cells, leukocytes and epithelial cells of the gastrointestinal tract, especially after inflammatory stimuli^[15]. Paneth cells are secretory epithelial cells found in small bowel crypts that express significant levels of *NOD2*. The structural features of NLRs include a central nucleotide-binding oligomerization domain, a variable N-terminal protein-protein interaction domain, defined by the CARD, and a C-terminal leucine-rich repeat that senses pathogen-associated molecular patterns^[8]. After activation, recruitment of a serine threonine kinase called RIP2 occurs, which leads to the enrollment of the NF- κ B signaling pathway, leading to the transcription of immune response genes^[16].

Along with this traditional role, *NOD2* plays a part in the induction of autophagy as well. This process leads to the destruction of damaged proteins and organelles which has paramount importance not only in recycling biomolecules but also in eliciting anti-microbial properties^[17]. Growing evidence has shown that *NOD2* may be also a relevant player in CD4⁺ T cell function and in generating a Th1 response. This leads to the production of IFN- γ by T cells. In addition to detecting bacterial pathogens, *NOD2* has shown a different role in host defense. According to *in vitro* studies, *NOD2*-deficient animals showed an increased susceptibility to several viral infections^[18]. The response to certain parasite infections may be compromised as well, due to a reduced production of IFN- γ ^[16,19]. In *NOD2*^{-/-} animals, through stimulation of Th1-associated cytokines, an increase in mucosal permeability and low-grade chronic inflammation occurs^[20].

The aforementioned evidence places *NOD2* in the center of the immune system, quite distant from its first described role as a "simple" pathogen sensor. But the essential question remains: How do *NOD2* mutations predispose to CD and do they have a role in cancer development?

Although our understanding of these complex interactions has improved in recent years, we still have no solid evidence to prove that polymorphisms in *NOD2* actually lead to the production of a stable protein. Currently, there are at least two possible ways in which *NOD2* mutations can lead to chronic inflammation and CD. The first is related with the basic function of *NOD2* as a positive regulator for innate response. We can assume that if there is no efficient *NOD2* activation during early phases of pathogen exposure, bacteria will proliferate and ultimately lead to chronic inflammation. An alternative explanation involves the deficient activation of *NOD2* as well, but in a later stage, during an ongoing inflammatory

process. A continuous stimulus of pro-inflammatory pathways will take place, triggering toll-like receptors (TLR) (*NOD2* is a negative regulator of TLR signaling) and favoring Th1 response and the release of cytokines. Animal models have shown that *NOD2* has a paramount importance in the bactericidal activity of ileal crypts and the regulation of ileal microbiota. This allows us to hypothesize that ileal CD caused by *NOD2* mutations is due to the dysfunction of Paneth cells^[8,10,21]. This diverse function of *NOD2* may explain the heterogeneity of CD^[16].

In what concerns CRC, there are several factors that could explain its link to *NOD2* mutations. It is a well-known fact that the risk for CRC increases with duration and severity of the inflammatory process, while it decreases when anti-inflammatory drugs such as mesalazine and immunomodulators such as azathioprine are used in ulcerative colitis, consistent with a causative role for inflammation in colon carcinogenesis. The chemopreventive activity of aspirin and other nonsteroidal anti-inflammatory drugs in CRC supports this concept as well.

If these mutations play a consistent part in the pathogenesis of inflammatory bowel diseases (IBD), most notably in CD, then the hypothesis that such mutations are potential risk factors for cancer may have solid grounds. The study by Couturier-Maillard^[9] shed some light in the role of *NOD2* in colitis-associated cancer: *NOD2*^{-/-} mice showed increased tumor load in the distal colon than wild-type animals. Furthermore, this risk was shown to be transmittable if both animals were cohoused. An acceptable rationale to explain these findings may involve an unbalance between pro- and anti-inflammatory cytokines and lead to the loss of autophagy and apoptosis stimuli. This could eventually lead to increased risk of infection, chronic inflammation and cancer^[22].

The most promising body of evidence that supports the role of *NOD2* in colorectal carcinogenesis involves its capacity to shape a protective assembly of gut bacterial communities. The deregulation of intestinal microbiota seems to be the essential element in the complex interaction between *NOD2* mutations and CRC.

LINKING MICROBIOTA TO MUCOSAL IMMUNITY AND CRC

Recently, a significant effort has been made to identify the components and the role of intestinal microbiota in colonic health and homeostasis. The microbiota has been increasingly recognized as a major player in normal metabolic and physiologic processes. This community of 10¹³-10¹⁴ microorganisms represents a perfect example of symbiotic relationship. It exerts several essential functions like the synthesis of essential compounds for the normal growth of colonic mucosa, regulation of its lymphoid tissue and synthesis of amino acids that inhibit the growth of pathogenic microorganisms. The latter is

of paramount importance, as a delicate equilibrium has to be achieved between commensal bacterial load and the innate immune system. The commensal bacteria must be contained in their capacity to proliferate and should be maintained in adequate amounts. Conversely, any change in the composition of luminal bacterial flora may favor the production of toxins and metabolites associated with carcinogenesis and induce dysregulation of the immune response, allowing pathogenic agents to replicate, therefore promoting and sustaining inflammation and carcinogenesis^[23]. A well balanced gut microbiota leads to healthy colocytes through the production of important compounds and the correct modulation of the immune system. It is now believed that *NOD2* mutations may result in altered host-microbial interactions in the intestinal mucosa.

COMPOSITION OF THE MICROBIOTA

It is known that the human intestine is sterile in utero, but progressively over 36000 bacterial species colonize the gastrointestinal tract and develop a symbiotic relation with their host. The human distal intestinal microbiota includes two predominant phyla, the Firmicutes and Bacteroidetes, with less significant contributions from Proteobacteria and Actinobacteria, and minor contributions from Fusobacteria, Verrucomicrobia, and Cyanobacteria^[24]. The production of propionate and butyrate from the degradation of indigestible polysaccharides is one of its main roles. Despite being outnumbered by other species, Actinobacteria, Proteobacteria (including *Escherichia coli*) and Verrucomicrobia, showed potential to influence health outcomes^[25]. A significant effort is being made to characterize the diverse genetic material of these numerous microorganisms (also known as microbiome). Ultimately, the goal is to understand the link between variations in the composition of these communities and common diseases, such as IBD and CRC. The hypothesis formulated by several investigators lies on the ability of these variations of the microbiota to cause a breakdown of the balance between bacterial communities and the epithelial barrier may lead to chronic inflammation. It is thought that some species may not be able to maintain a quiet state of protective immunity in dysbiotic conditions. For example, *Bacteroides thetaiotaomicron* was found to be not only a commensal but also an opportunistic microorganism in predisposed individuals^[26].

A special attention has been devoted to factors that may influence the composition of the microbiota. Aging, place of birth and mode of delivery are quite relevant determinants. Antibiotics are also important and modifiable factors, especially with larger antimicrobial spectrums, as their effect on the microbiota varies from drastic to only temporary. After the end of the antibiotic treatment, certain species may recover in about a month while others may not recover at all, most often in children^[27]. Besides antibiotics, different dietary habits may modify significantly the microbiota as well. Quite interestingly, even a short-term increase in fat

and carbohydrate consumption may influence not only the relative abundance of each bacterial species, but also the functionality of the microbiota^[28]. Obesity has also been proposed as a major factor in this equation, as it may alter the composition of the microbiota and increase its metabolic potential to harvest energy from the host diet. The capacity of the microbiota to confer host traits was revealed by studies where fecal content was transplanted from obese mice into lean germ-free recipients. The recipients showed significant weight gain and increased adiposity^[29]. This surprising discovery opened the door for further investigation on genetic and microbiota manipulation and its ability to cause disease in animal models. Another interesting concept was revealed by Couturier-Maillard *et al.*^[9]. The absence of *NOD2* confers a transmissible risk for colitis and CRC, even to immunocompetent hosts. In other words, after sharing the same environment with *NOD2*^{-/-} mice, wild-type animals treated with dextran sodium sulfate revealed an increased risk for colitis, probably due to an altered commensal flora acquired from knockout mice. This dysbiotic microbiota is then passed to the next generation. Growing evidence now shows us that the risk for colitis and CRC is influenced by specific members of the commensal microbiota. In fact, in *IL10*-deficient mice treated with colon-specific carcinogen azoxymethane (AOM) showed high levels of mucosal inflammation and adenoma development when raised in conventional conditions, but when *Bacteroides vulgatus* is the only commensal, the carcinogenicity of AOM is somewhat attenuated. Even more surprising is the fact that these mice show almost no inflammation or adenomas if created in a germ-free environment^[11]. This is consistent with the notion that treating *NOD2*-deficient mice with broad spectrum antibiotics may mitigate its disease risk^[9]. In the opposite direction, a recent study suggests that antibiotics promote inflammation through translocation of commensal colonic bacteria and it is suggested that this may explain the association between increasing antibiotic use and the growing incidence of inflammatory disorders^[30].

The importance of *NOD2* as a regulator of microbiota and consequently as a risk factor for injury of the colonic mucosa was reinforced by studies using reciprocal fecal microbiota transplantation. Such interventions led to profound changes in the microbiota. The end result was that *NOD2*-deficient mice that received fecal transplantation from wild-type animals showed decreased mucosal injury and inflammation. On the contrary, there was an increased risk of colonic disease in wild-type hosts that received dysbiotic fecal microbiota from *NOD2*-deficient mice^[9]. A crucial role in this equilibrium is played by Paneth cells, specialized secretory epithelial cells of the small intestinal crypts that express *NOD2* at high levels. Recent studies demonstrated that *NOD2*-deficient mice had a significant rise in the amount of commensal bacteria in the terminal ileum, probably due to impaired cryptal activity^[31]. This is a potential mechanism by which *NOD2* mutations may disturb intestinal homeostasis and

lead to CD and colitis-associated CRC. But the intestinal microbiota role in this equilibrium is not passive at all. On the contrary, it is now known that it plays a part in controlling the expression of *NOD2* as well.

The influence of *NOD2* in microbial communities and its consequences on disease risk have solid basis. But how exactly does an altered microbiota lead to colonic inflammation? One possible explanation is the production of bioproducts with anticancer properties by the metabolic machinery of the microbiota. Butyrate and other small-chain fatty acids are nutrients formed by the fermentation of indigestible carbohydrate and are known to have an interesting paradoxical activity. In colon carcinoma cells, it leads to apoptosis, inhibits cell proliferation and angiogenesis, therefore showing a protective effect. On the other hand, in normal colonic cells it shows opposite effects as it prevents apoptosis^[32]. Another potential role for the microbiota and especially for butyrate is maintaining inhibition of the histone deacetylase, therefore maintaining histones in an acetylated state, thus facilitating the transcription of anti-oncogenes^[33]. This is an objective of anticancer drugs such as Vorinostat, an approved agent for the treatment of cutaneous T cell lymphoma. Detrimental influences are provided by the accumulation of toxic compounds in the gut that can exert a mutagenic action. Poli-heterocyclic amines, deoxycholic acid and calibactin are examples of compounds directly or indirectly produced by commensal bacteria that harbor potential to damage colonocytes' DNA^[34]. This conflicting evidence supports the idea that the role of the microbiota shouldn't be considered univocal, but rather be regarded as a complex set of influences that may have a protective or deleterious effect on mucosal immunity, depending on its specific components. It is reasonable to postulate that the same bacterial agents will elicit different effects according to each individual genetic background and environmental exposure.

CASE-CONTROL STUDIES ON *NOD2* POLYMORPHISMS

Conflicting

This is a common word found in the introduction of most studies on *NOD2* mutations as a risk factor for CRC. However, for an adequate analysis of the published results, several factors should be taken into consideration.

First, the most studied polymorphisms of *NOD2* have significantly different prevalence in different populations. Three of the most common polymorphisms were not found in 342 patients included in a Malaysian study^[12]. On the contrary, in a Danish study that included more than 40000 individuals, about 13% were carriers of at least one of the polymorphisms^[35]. An obvious conclusion is that we should analyze these results according to the geographic region where they were conducted. Even in European studies, where these polymorphisms are thought to be more common, the number of carriers

is often low. For example, in a study from Finland, there was only one homozygote for the R702W mutation in a universe of 1400 subjects^[36]. Achieving solid conclusions with such low numbers is extremely difficult. Another limiting aspect that may hinder the conclusions of such studies is the source of controls. The results differ according to the source of controls. According to a meta-analysis that included 30 case-control studies about *NOD2* polymorphisms and cancer risk^[37], there was only an increased risk in the subgroup with hospital-based controls, while no significant risk was observed in population-based studies. A factor worth looking at as well is that the great majority of studies about *NOD2* polymorphisms described so far analyzed only DNA extracted from nonneoplastic tissue (searching only germline mutations). For a complete understanding of the role of these mutations in the pathogenesis of CRC, an investigation of the neoplastic tissue should be undertaken as well (somatic mutations). To our knowledge, there is only one study that tried to determine if these mutations were of germline or somatic nature^[38]. A total genotypic agreement between blood and neoplastic samples was observed, therefore suggesting that CRC susceptibility associated with these variants is linked to germline mutations, apparently without the participation of somatic mutations.

Most studies addressing *NOD2* polymorphisms and CRC are essentially linkage studies concerning a specific country or region. Nowadays, genome-wide association studies (GWAS) have a significant impact on medical research. As they search for differences in allele frequencies or genotypes in a large number of patients, through the identification of thousands of single-nucleotide polymorphisms, GWAS have stronger statistical power than linkage studies. However, as it was already mentioned, the frequency of *NOD2* polymorphisms shows a significant geographic variability. As GWAS often recur to samples from a quite diverse set of countries, the effect of these polymorphisms in a certain population may go unnoticed.

When analyzing the results from these studies, it is important to consider each polymorphism separately as well. It seems plausible to admit that each polymorphism will have different effects on *NOD2* function and therefore its effect on cancer risk will probably be different as well. The most studied polymorphisms are two missense mutations - rs2066845 C/G (G908R) and rs2066844 C/T (R702W), and one frameshift mutation - rs2066847 insC (3020insC). For the first missense mutation, G908R, results are equivocal (Table 1). Case-control studies failed to identify an increased susceptibility to CRC for G908R mutation carriers in German, Portuguese and Hungarian populations^[13,38,39]. On the other hand, a Greek study was able to find an association between this mutation and CRC susceptibility^[40]. In what concerns meta-analysis, the results are conflicting. In the meta-analysis by Tian *et al.*^[41], there is evidence for an increased risk, but more recently, in 2014, a new meta-analysis showed no association between CRC and the G908R mutation^[37]. For the last of the missense mutations,

R702W, there is strong evidence for an important role in CRC susceptibility. Several population-based studies and two meta-analyses revealed a significantly increased prevalence of this mutation in CRC patients (Table 1). For the frameshift mutation 3020insC, most studies support a relevant role for an increased risk of disease (Table 1)^[40,42]. Both meta-analysis published on this subject revealed that carrying the 3020insC mutation was associated with a higher risk for CRC development^[37,41].

If our objective is to assess the risk for CRC in *NOD2* polymorphism carriers, we should analyze the combined effect of the three main mutations. Several studies tried to determine if there was an increased risk for an individual carrying at least one of these polymorphisms. According to at least three population-based studies^[13,38,40], there was evidence of an increased CRC risk if one or more of the described polymorphisms were identified.

Besides searching for a potential role for *NOD2* mutations and a hypothetic increased susceptibility for CRC, several groups searched for genotype-phenotype correlations in these patients. One of the main concerns for investigators and clinicians working in the field of CRC are young patients suffering from this disease. Finding a marker of increased risk that could identify patients under 50 that should enter an early surveillance program is obviously a sought-after goal. In a German cohort of patients under 50, a significant association between *NOD2* mutations and CRC susceptibility was described^[13]. In a Portuguese study^[38], the R702W variant was associated with an increased risk for CRC only in female patients under 60. In the opposite direction, the groundbreaking work by Kurzawski *et al.*^[42], the first group that tried to find a correlation between these polymorphisms and CRC, revealed a bigger propensity of 3020insC mutation carriers to develop CRC at a later age. An association with certain phenotypic characteristics was researched as well. Tumor location

and size, vascular or lymphatic invasion, differentiation and distance to margins in resected specimens showed no relation with the presence of *NOD2* polymorphisms in most studies^[38,39,43]. This lack of genotype-phenotype agreement may be due to the genetic heterogeneity of the disease or it can be explained by the small number of mutation carriers diagnosed with CRC, therefore limiting the ability to reach such a conclusion. Only a Greek study was able to show a relevant association between tumor stage (TNM classification) and the occurrence of these mutations^[40].

Currently, new therapies for cancer are designed for a specific set of patients that are expected to respond, according to certain clinical and biological features. For example, Cetuximab is only prescribed to patients with advanced CRC and no mutation in the *KRAS* gene (wild type at codons 12 and 13 of *KRAS*). For *NOD2* mutations, a potential role for predicting response to treatment was researched as well. In 2014, Omrane *et al.*^[44] described an association between CRC patients carrying 3020insC polymorphism and the need for neoadjuvant chemotherapy. The presence of this polymorphism was able to predict failure of neoadjuvant chemotherapy. Conversely, the presence of 3020insC mutation was predictive of successful adjuvant chemotherapy^[44]. Despite the relatively small size of the sample, this may be a promising role for *NOD2* mutations, needing confirmation by large-scale studies.

Routine detection of *NOD2* mutations is still not being offered in the management of CRC patients. However, there is a new simple and cost-effective tool for the genetic screening of CRC^[45]. Besides well-known mutations in *MLH1*, *MSH2* and *MSH6* genes, the DNA microarray assay also searches the 3020insC polymorphisms in the *NOD2* gene. This may be a useful tool in clinical practice in CRC screening programs.

Due to the already described conflicting nature of the results from studies on *NOD2* mutations and CRC risk,

two meta-analyses on this subject were conducted (Table 2)^[37,41]. The first was published in 2010 and remains, to our knowledge, the only meta-analysis that studied *NOD2* mutations and CRC exclusively. A total of 85 papers were screened, but only 8 were considered appropriate to be included (all from Caucasian populations), totaling 3524 CRC cases and 2364 controls (Table 2). The most significant risk for CRC was found in patients carrying the G908R mutation (5 studies; OR = 1.98; 95%CI: 1.14-3.44). Increased risk was also found for the R702W mutation (5 studies; OR = 1.59; 95%CI: 1.09-2.32) and the missense mutation 3020insC (7 studies; OR = 1.44; 95%CI: 1.13-1.84). For an individual carrying at least one of these high-risk alleles, there is also an increased probability of developing CRC (5 studies; OR = 1.58; 95%CI: 1.03-2.42). The most recent meta-analysis on this subject studied the effect of *NOD2* mutations in the susceptibility for several types of cancer (melanoma, breast cancer, non-Hodgkin lymphoma and different gastrointestinal tumors). A total of 30 articles were included, 11 of which exclusively with CRC patients, published from 2004 to 2010. The results were similar to the ones described by Tian *et al*^[41], as it was demonstrated that both R702W and 3020insC were risk factors for CRC (Table 2). The only discrepancy was the effect of carrying G908R polymorphism. This allele was found to contribute to the overall risk of cancer, but not specifically to CRC. The studies included in this meta-analysis showed no obvious heterogeneity ($I^2 < 50\%$). Excluding any of the included studies would not change significantly the outcome, therefore suggesting that these results are statistically robust^[41].

***NOD2* MUTATIONS AND OTHER MALIGNANT AND NON-MALIGNANT CONDITIONS**

Since the publication in 2001 by Ogura *et al*^[41] of the first study about *NOD2* mutations and increased susceptibility

to CD, several investigators tried to understand the intricate mechanism behind this association and to find a link between these polymorphisms and other inflammatory and malignant conditions.

In fact, a role for *NOD2* mutations has been postulated for several malignant diseases other than CRC. In common digestive tract tumors, a significant number of published studies have addressed this putative relation. The 3020insC missense mutation was shown to be a risk factor for intestinal type gastric cancer in a Portuguese population^[46]. The same was demonstrated by an Italian study for the R702W and 1007fs polymorphisms^[47]. According to the meta-analysis by Liu *et al*^[37], there was an increased risk for gastric cancer for carriers of the G908R and 3020insC mutations, but the same was not observed for the R702W polymorphism. In a recent population-based Chinese study, an increased risk for gastric cancer was found for individuals carrying the rs718226 AG or GG genotype. Interestingly, this single-nucleotide polymorphism revealed significant joint effects with *H. pylori* in dysplasia and gastric cancer risk. On the contrary, both the rs2111235 C allele and the rs7205423 G allele showed a protective effect, as they were associated with a decreased risk of progression to dysplasia and gastric cancer in *H. pylori*-infected subjects^[48].

In what concerns pancreatic cancer, there was no evidence of increased risk neither in the familial nor the sporadic form of the disease^[37,49]. The same meta-analysis revealed an increased risk for MALT lymphoma, breast, lung and laryngeal cancer for the carriers of the 3020insC mutation. On the other hand, none of the *NOD2* mutations were found to be risk factors for melanoma or non-Hodgkin lymphoma^[37].

These discrepancies found between different studies may be attributed to a variety of factors, especially those that influence the expression of these polymorphisms, as well as differences in sample size, geographic variation or genotyping methods^[22].

The effect of *NOD2* as a risk factor for disease is best established in CD. After an etiologic role was consolidated for these mutations in CD, further investigation was undertaken to find out if these mutations influenced the behavior, prognosis and response to treatment as well. The presence of one mutation increased the risk for structuring or penetrating disease by 8% and this effect was largely increased if two *NOD2* mutations were present (41% risk increase)^[38]. An Australian study revealed as well that carriers have a more aggressive disease, needing more frequent and more precocious surgery^[50]. A recent European multicenter cohort study recently revealed that *NOD2* mutations and early use of immunomodulatory drugs are the most relevant predictors of the course of disease^[51].

It was speculated as well that certain disease phenotypes and their response to treatment could be influenced by *NOD2* mutations. The development of perianal fistulas is thought to depend on the proliferation of luminal bacteria. As such a possible connection between *NOD2*, a regulator of host response to microbial agents, and perianal fistulas was evaluated in recent literature. These fistulas showed significantly worse response to antibiotics in *NOD2* mutation carriers^[52], probably due to impaired recognition of intestinal bacteria and a decreased ability to mount an effective innate immune response. This kind of studies emphasizes the importance of gene mapping and corresponding phenotypic correlations in order to predict disease severity and optimize treatment strategies.

CONCLUSION

In the last fifteen years, the proposed role of *NOD2* and its mutations in disease has grown significantly. From only a susceptibility gene to an important predictor of prognosis and response to treatment in CD, these mutations have been postulated as a risk factor in several conditions such as mycobacterial infections, common gastroenterological disorders and malignant diseases like gastric and colorectal cancer. The expanding role of this receptor as a major coordinator of several inflammatory pathways and a modulator of microbiota is increasingly accepted, mainly due to evidence arising from *NOD2*-deficient animal models. In fact, it was shown that losing *NOD2* activity leads to more severe colitis and higher propensity to adenomas and CRC. It seems likely that *NOD2* may be the key element of the intricate puzzle that links the disturbance of mucosal immune defense, dysbiotic bacterial communities and conditions such as CD and colitis-associated CRC.

Furthermore, *NOD2* polymorphisms such as 3020insC and R702W seem to increase susceptibility to CRC. The search of these mutations is still not offered routinely in clinical practice. However, the identification of its carriers would allow such patients to be included in a more intense CRC surveillance program, contributing to early diagnosis of a disease that carries such a heavy burden. Predicting response to different chemotherapy regimens

according to the presence of *NOD2* polymorphisms could become a useful tool for clinicians. More large-scale studies should be conducted to confirm this association. The development of new therapeutic targets based on research about *NOD2* protein function and interactions could ultimately lead to a tailored approach to the treatment of CRC.

Abstract

The stomach is the sixth most common cause of cancer

worldwide. Surgery is an important component of the multi-modality treatment of the gastric cancer. The extent of lymphadenectomy has been a controversial issue in the surgical management of gastric cancer. The East-Asian surgeons believe that quality-controlled extended lymphadenectomy resulting in better loco-regional control leads to survival benefit in the gastric cancer; contrary to that, many western surgeons believe that extended lymphadenectomy adds to only postoperative morbidity and mortality without significantly enhancing the overall survival. We present a comprehensive review of the lymphadenectomy in the gastric cancer based on the previously published randomized controlled trials.

Key words: Gastric neoplasms; Lymphadenectomy; Gastrectomy; Survival; Disease recurrence

Core tip: The only potentially curative option for the gastric cancer is surgery which may promise complete resection. Presently, D2 lymphadenectomy is the standard of care in an operable gastric cancer. Routine excision of spleen and pancreatic tail should not be undertaken as it increases the postoperative morbidity without adding significantly to overall survival.

Garg PK, Jakhetiya A, Sharma J, Ray MD, Pandey D. Lymphadenectomy in gastric cancer: Contentious issues. *World J Gastrointest Surg* 2016; 8(4): 294-300 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i4/294.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i4.294>

INTRODUCTION

As per GLOBOCAN 2012 data, the stomach is the sixth most common cause of cancer worldwide with an age-standardized incidence and mortality of 12.1/100000 and 8.9/100000 population^[1]. Though the multimodality

management of the gastric cancer has gradually become the standard of care, surgery continues to be at the forefront of it^[2]. Needless to say, complete surgical excision is the only potentially curable treatment available for an operable non-metastatic gastric cancer. In the last three decades, there has been a considerable debate related to the extent of lymphadenectomy in gastric cancer surgery at various surgical forums. The East Asian surgeons believe that the quality-controlled extended lymphadenectomy results in better locoregional control and leads to survival benefit in the gastric cancer; on the contrary, many western surgeons believe that the extended lymphadenectomy only adds to postoperative morbidity and mortality without significantly enhancing the overall survival. The present mini-review is an attempt to address this contentious surgical issue based on the information available from the published randomized controlled trials in this area.

Classification of lymphnode stations and types of lymphadenectomy

The lymph nodes stations of the stomach are categorized anatomically and identified numerically by the Japanese Gastric Cancer Association (JGCA) as published in the Japanese classification of gastric carcinoma: 3rd edition in 2011^[3]. Table 1 displays the various lymph nodes stations and their anatomical definitions. Previously, in its description of 2nd edition of Japanese classification of gastric carcinoma, JGCA classified regional lymph nodes into three groups based on the location of primary gastric tumor^[4]. These three groups of lymph node basins were used to describe the extent of lymph nodes dissection in a gastrectomy: D0 dissection - no dissection or incomplete dissection of the group 1 nodes; D1 - dissection of all the group 1 nodes; D2 - dissection of all the group 1 and group 2 nodes; and D3 - dissection of all the group 1, 2 and 3 nodes. This needs to be understood that each lymph nodal station would carry a different meaning for a particular primary tumor location - suprapyloric (station 5) falls under group 1 for an antral primary tumor while it would come under group 3 for proximal third gastric cancer. As expected, this classification was perceived to be quite complicated in the surgical fraternity, especially among western surgeons; and rightly so, it failed to garner widespread acceptance^[5]. In order to bring uniformity in the extent of lymphadenectomy, JGCA remarkably simplified the definition of lymphadenectomy in its recent classification^[6]. The lymph node stations 1-12 and 14v have been categorized as regional gastric lymph nodes while metastasis to any other node station classified as M1. The Japanese Gastric Cancer Guidelines 2010 (version 3) state that the extent of systematic lymphadenectomy is defined according to the type of gastrectomy indicated with the D level criteria.

For a total gastrectomy - D0 lymphadenectomy includes anything less than D1; D1 includes dissection of level 1 to 7; D1 + includes D1 lymph nodal dissection and stations 8a, 9 and 11p; D2 incorporates D1 lymph nodal dissection and stations 8a, 9, 10, 11p, 11d and

12a. For tumors involving the distal esophagus, D1+ includes dissection of 110 while D2 includes dissection of 19, 20 and 111. For a distal gastrectomy - D0 lymphadenectomy includes anything less than D1; D1 includes dissection of level 1, 3, 4sb, 4d, 5, 6 and 7; D1 + includes D1 lymph nodal dissection and stations 8a and 9; D2 incorporates D1 lymph nodal dissection and stations 8a, 9, 11p, and 12a.

RATIONAL AND EXTENT OF LYMPHADENECTOMY

The key point of debate related to the extent of lymphadenectomy has been to balance the oncological benefit vis-à-vis postoperative morbidity and mortality^[7,8]. The oncological scenarios where survival is thought to be increased by the extended lymphadenectomy are few; moreover, there is paucity of level I evidence confirming the survival benefit^[8]. There is a widely held view among the western surgeons that malignant lymph nodes are indicators and not governors of survival^[9,10]. Contrary to this view, Japanese surgeons have demonstrated that better loco-regional control through quality-controlled radical resections with extensive lymphadenectomy, leads to improvement in survival by preventing the loco-regional recurrences and thereby reducing the distant metastasis. There have been a few randomized controlled trials (RCTs), published in the last two decades, which compared various extents of lymphadenectomy in the gastric cancer surgery to assess the associated postoperative morbidity and mortality, and their impact on survival (Table 2).

D1 vs D2 lymphadenectomy

The contentious issue of the extent of lymphadenectomy was a real dividing line between the Japanese surgeons and western surgeons in the 1990s. There are three published RCTs which have compared the D1 and D2 lymphadenectomy in the gastric cancer surgery.

The landmark Dutch trial was conducted by Dutch Gastric Cancer Group from August 1989 till July 1993^[11]. They randomized 711 patients into two groups: One group had D1 dissection while the other group had D2 dissection. The D1 dissection included clearance of 1st tier lymph nodal echelons (stations 1-6) while D2 dissection incorporated additional clearance of 2nd tier lymph nodal echelons (stations 7-11). Distal pancreatectomy with splenectomy was done in all patients who had a D2 dissection in order to achieve adequate lymphadenectomy, while it was done selectively in a D1 dissection, when they were involved by the tumor. The eligibility criterion of the patients for inclusion in the trial was the presence of histologically confirmed gastric cancer without evidence of distant metastasis. The quality control was undertaken with the histopathological confirmation of lymph nodes and their number at a particular station. They coined two terms: "Contamination" and "non-compliance" to describe violation of the protocol. The "contamination"

Table 1 Anatomical definition of lymph node stations

Lymph node station	Label	Anatomical description
1	Right paracardial	Right paracardial LNs, including those along the first branch of the ascending limb of the left gastric artery
2	Left paracardial	Left paracardial LNs including those along the esophagocardiac branch of the left subphrenic artery
3	Lesser curvature	3a: Along the branches of the left gastric artery 3b: Along the 2 nd branch and distal part of the right gastric artery
4	Left gastric curvature	4sa: Left greater curvature LNs along the short gastric arteries (perigastric area) 4sb: Left greater curvature LNs along the left gastroepiploic artery (perigastric area)
	Right greater curvature	4d: Rt. greater curvature LNs along the 2 nd branch and distal part of the right gastroepiploic artery
5	Suprapyloric	Along the 1 st branch and proximal part of the right gastric artery
6	Infrapyloric	Along the first branch and proximal part of the right gastroepiploic artery down to the confluence of the right gastroepiploic vein and the anterior superior pancreaticoduodenal vein
7	Left gastric artery	Along the trunk of left gastric artery between its root and the origin of its ascending branch
8	Common hepatic artery	8a: Anterosuperior LNs along the common hepatic artery 8p: Posterior LNs along the common hepatic artery
9	Celiac	Along the coeliac artery
10	Splenic hilum	Lymph nodes in the splenic hilum including those adjacent to the splenic artery distal to the pancreatic tail, and those on the roots of the short gastric arteries and those along the left gastroepiploic artery proximal to its 1 st gastric branch
11	Splenic artery	11p: Proximal splenic artery LNs from its origin to halfway between its origin and the pancreatic tail end 11d: Distal splenic artery LNs from halfway between its origin and the pancreatic tail end to the end of the pancreatic tail
12	Hepatoduodenal ligament	12a: Hepatoduodenal ligament LNs along the proper hepatic artery, in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas 12b: Hepatoduodenal ligament LNs along the bile duct, in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas 12p: Hepatoduodenal ligament LNs along the portal vein in the caudal half between the confluence of the right and left hepatic ducts and the upper border of the pancreas
13	Posterior pancreatic head	On the posterior surface of the pancreatic head cranial to the duodenal papilla
14v	Superior mesenteric vein	Along the superior mesenteric vein
15	Middle colic vessels	Along the middle colic vessels
16	Para-aortic	16a1: Paraaortic lymph nodes in the diaphragmatic aortic hiatus 16a2: Paraaortic lymph nodes between the upper margin of the origin of the celiac artery and the lower border of the left renal vein 16b1: Paraaortic lymph nodes between the lower border of the left renal vein and the upper border of the origin of the inferior mesenteric artery 16b2: Paraaortic lymph nodes between the upper border of the origin of the inferior mesenteric artery and the aortic bifurcation
17	Anterior surface of pancreatic head	On the anterior surface of the pancreatic head beneath the pancreatic sheath
18	Inferior border of the pancreatic body	Along the inferior border of the pancreatic body
19	Infradiaphragmatic	Infradiaphragmatic, predominantly along the subphrenic artery
20	Paraesophageal, esophageal hiatus	In the diaphragmatic esophageal hiatus
110	Paraesophageal, lower thoracic	In the lower thorax
111	Supradiaphragmatic	Supradiaphragmatic lymph nodes separate from the esophagus
112	Posterior mediastinal	Posterior mediastinal lymph nodes separate from the esophagus and the esophageal hiatus

LNs: Lymph nodes.

was considered when a surgeon dissected two or more lymph node stations which should not have been dissected; the "non-compliance" was considered when a surgeon did not dissect two or more lymph node stations which should, otherwise, have been dissected. It was thought that a high contamination in D1 dissection and a high noncompliance in D2 dissection would blur the distinction between operative procedures in the two groups and it would affect the conclusions. They reported a significantly high postoperative morbidity (43% vs 4%, $P < 0.001$) and mortality (10% vs 4%, $P < 0.004$) in the D2 dissection group as compared to the other group. Moreover, they reported no difference in 5-year survival

in between the two groups (34% in D1 vs 33% in D2). Based on these results, they concluded that their data did not support routine D2 lymphadenectomy in gastric cancer patients. However, this trial drew a lot of criticism in view of a number of flaws. The participating surgeons had no previous experience of D2 lymphadenectomy; they were trained with the help of videotapes and booklets. There were a number of centres which were low volume centres for gastric resection, performing only a few in a year. The non compliance was very high in the D2 lymphadenectomy group, to the tune of 51%. The 11-year follow-up data of this trial (published in 2004) indicated similar survival in between the two groups

Table 2 Previously published randomized clinical trials addressing the extent of lymphadenectomy in gastric cancer

Ref.	Study period	Study groups	Median follow-up	Result	Conclusion
Cuschieri <i>et al</i> ^[14]	1986-1993	D1 = 200, D2 = 200	6.5 yr, overall	5-yr OS in D1 vs D2 - 35% vs 33%, (HR = 1.10, 95%CI: 0.87-1.39)	Classical Japanese D2 resection offers no survival advantage over D1 surgery
Songun <i>et al</i> ^[13]	1989-1993	D1 = 380, D2 = 331	15.2 yr, overall	5-yr OS D1 vs D2 - 21% vs 29%, (log-rank $P = 0.34$), subgroup analysis of patients without pancreatico-splenectomy, 15-yr OS in D1 vs D2 = 22% vs 35% (HR = 1.34, 95%CI: 1.09-1.65; log-rank $P = 0.006$)	Spleen preserving D2 resection should be recommended as the standard surgical approach to resectable gastric cancer
Degiuli <i>et al</i> ^[17]	1998-2006	D1 = 133, D2 = 134	6.7 yr, overall	5-yr OS in two arms D1 vs D2 - 66.5% vs 64.2%, (difference -2.3, 95%CI: -14.0 to 9.3; $P = 0.695$), 5-yr disease-specific survival in pathological tumour pT2-4 in two arms D1 vs D2 - 38% vs 59%; $P = 0.055$	No difference in overall 5-yr survival between D1 and D2 resection; D2 lymphadenectomy may be a better choice in patients with advanced disease and lymph node metastases
Wu <i>et al</i> ^[19]	1993-1999	D1 = 110, D3 = 111	94.5 mo, for survivors	5-yr OS in D1 vs D3 - 53.6% vs 59.5% difference between groups 5.9% (95%CI: -7.3 to 19.1), log-rank $P = 0.041$)	D3 dissection offers a survival benefit for patients with gastric cancer compared with D1 dissection
Sasako <i>et al</i> ^[21]	1995-2001	D2 = 260, D2 + PAND = 263	5.6 yr for D2 lymphadenectomy alone and 5.7 yr for D2 lymphadenectomy plus PAND 94.5 mo, for survivors	5-yr overall survival rate for D2 vs D2 + PAND -69.2% vs 70.3% HR for death 1.03 (95%CI: 0.77-1.37; $P = 0.85$)	No survival benefit with D2 lymphadenectomy plus PAND in curable gastric cancer as compared with D2 lymphadenectomy alone
Yonemura <i>et al</i> ^[22]	1995-2002	D2 = 135, D2 + PAND = 134	NS	5-yr overall survival rate for D2 vs D2 + PAND -52.6% vs 55.0% ($\chi^2 = 0.064$; $P = 0.801$)	Prophylactic D4 dissection is not recommended for patients with potentially curable advanced gastric cancer
Kulig <i>et al</i> ^[20]	1999-2003	D2 = 141, D2 + PAND = 134	Results awaited	Results awaited	Results awaited

D1: D1 lymphadenectomy; D2: D2 lymphadenectomy; OS: Overall survival; HR: Hazard ratio; PAND: Para-aortic node dissection.

(30% for D1 vs 35% for D2, $P = 0.53$); risk of relapse in two groups was also shown to be similar (78% for D1 vs 65% for D2, $P = 0.43$)^[12]. The 15-year survival data for the Dutch trial (published in 2010), however, swayed the evidence towards the D2 dissection; gastric-cancer-related deaths were significantly higher in the D1 group compared with the D2 group (HR = 0.74 for D2 vs D1, 95%CI: 0.59-0.93, $P = 0.01$), whereas death due to other causes was not different between the two groups (HR = 1.22 for D2 vs D1, 0.95-1.58, $P = 0.12$). Loco-regional recurrences were higher in D1 group compared to D2 group (40.7%, 155/380 vs 21.8%, 83/330). The 15-year overall survival for patients who had curative resections was 21% (95%CI: 17-26) for D1 and 29% (98 of 331, 24-34) for D2 (log-rank P value, 0.34); however, the difference in survival (25% for D1 vs 35% for D2, log-rank P value 0.08) in two groups became more evident if the postoperative deaths in two groups were excluded (4% in D1 and 10% in D2). Subgroup analysis showed that pancreatectomy and splenectomy, which were routinely done in D2 group as per the protocol, significantly lowered the overall survival. These findings led the authors to recommend spleen preserving D2 dissection in the patients with resectable gastric cancer^[13].

Another landmark trial published in 1999 was MRC trial conducted by Cuschieri *et al*^[14]. This was a large multicentric trial (patients recruited by 32 surgeons) which randomized 400 patients into two arms: 200 patients in one arm underwent D1 dissection which was defined as removal of lymph nodes within 3.0 cm of the tumor while another 200 patients in other arm had D2 dissection which incorporated additional removal of omental bursa, the hepatoduodenal and retroduodenal nodes (antral lesions), and the splenic artery/splenic hilar nodes and retropancreatic nodes by distal hemipancreatectomy for middle and upper third lesions. The authors reported that D2 lymphadenectomy was associated with significantly higher postoperative complications (D2 vs D1, 46% vs 28%, $P < 0.001$); the postoperative mortality was also significantly higher in the D2 group (13%) than in the D1 group (6.5%; $P = 0.04$)^[15]. The authors showed that the 5-year survival rates were 35% for D1 resection and 33% for D2 resection and there was no statistically significant difference in overall 5-year survival between these two arms (HR = 1.10, 95%CI: 0.87-1.39, where HR > 1 implies a survival benefit to D1 surgery) after a median follow-up of 6.5 years. Gastric cancer-specific survival was also similar in the D1 and D2 groups (HR = 1.05,

95%CI: 0.79-1.39) as was recurrence-free survival (HR = 1.03, 95%CI: 0.82-1.29). Based the findings of the trial, the authors suggested that the classical Japanese D2 resection offered no survival advantage over D1 resection. However, they did not refute the possibility that the D2 resection without pancreatoco-splenectomy might be better than standard the D1 resection as there was a significant survival disadvantage in the group undergoing splenectomy with distal pancreatectomy ($P = 0.01$). This fact may also be responsible for confounding the results as 57% of the D2 group underwent distal pancreatectomy and splenectomy vs 4% in the D1 group. Though the D2 lymphadenectomy included more extensive lymph nodes dissection than the D1, there was a little difference in the median number of nodes examined with a mean of 13 in the D1 group vs 17 nodes in the D2 group.

The Italian gastric cancer study group (IGCSG) conducted another trial to compare the D1 and D2 lymphadenectomy in the gastric cancer^[16,17]. The previous trials, MRC and Dutch trial, reported higher postoperative morbidity and mortality in the D2 lymphadenectomy. In order to address the safety concerns and survival benefits of D2 lymphadenectomy, IGCSG initiated multicentric RCT in 1998; they randomized 267 patients into two arms - D1 and D2 lymphadenectomy. The promising part of the trial was its strict quality controlled surgery - only those surgeons who had participated in their previous trial were asked to participate in the present trial in order to avoid bias related to surgical inexperience in D2 gastrectomy technique. However, the trial still had high contamination (17.3%) and non-compliance (33.6%) among the operated patients. In their initial publication of short term results of trial, the authors reported that the overall morbidity rate following D1 and D2 dissections was comparable (12.0% vs 17.9%, P value 0.178) as per intention to treat analysis; there was also no difference in the 30-d postoperative mortality rates (D1 vs D2, 3.0% vs 2.2%, $P = 0.72$). They concluded that the postoperative complications following D2 lymphadenectomy are not as high as they have been reported in previous randomized western trials in the specialized centers, and it should be considered a safe option for the radical management of gastric cancer in Western patients in an appropriate setting^[17]. The authors published their long term results in 2014^[16]. The median follow-up was 8.8 (range 4.5-13.1) years for surviving patients and 2.4 (0.2-11.9) years for those who died, and was not different in the two treatment arms. The overall 5-year survival was similar in two groups (D1 vs D2, 66.5% vs 64.2%, P value = 0.69). Subgroup analyses showed a 5-year disease-specific survival benefit for patients with pathological tumour 1 (pT1) disease in the D1 as compared to D2 (98% vs 83 %, $P = 0.015$), and for patients with pT2-4 status and positive lymph nodes in the D2 as compared to D1 (59% vs 38%, $P = 0.055$). The authors concluded that D2 lymphadenectomy might be a better choice in patients with advanced disease (pT2-4) and lymph node metastases. Though the overall 5-year survival

rate of approximately 65% in the whole patient cohort is impressive, it seems to be related to the unexpectedly high proportion (33%) of patients with pT category 1 tumors, who have a good prognosis and probably would not benefit from a D2 procedure^[18]. The Italian study contributes to the view that D2 lymphadenectomy can be performed safely and adequately, producing 5-year survival results that help to close the gap between survival results reported from Asia and those from Europe.

D1 vs D3 lymphadenectomy

Wu *et al.*^[19] reported a randomized controlled trial of nodal dissection for patients with the gastric cancer from Taiwan; they randomly allocated 221 patients with the advanced gastric cancer at the Taipei Veterans General Hospital, Taiwan, to either D1 lymphadenectomy or D3 lymphadenectomy during the study period 1993-1999. At a median follow-up of 94.5 mo, the authors reported that the 5-year overall survival was 59.5% (95%CI: 50.3-68.7) for the D3 group and 53.6% (95%CI: 44.2-63.0) for the D1 group (difference between groups 5.9%, 95%CI: -7.3 to 19.1, log-rank $P = 0.041$) as per the intention to treat analysis. Among patients who had R0 resection, D3 dissection group had fewer disease recurrences than D1 (42% vs 52%), though it did not attain statistical significance (P value = 0.117, χ^2 test). However, among this R0 resection group, D3 group had significantly higher 5-year overall survival than D1 group (61.1%, 95%CI: 51.9-70.3 vs 54.2%, 95%CI: 44.8-63.6; difference between groups 6.9%, 95%CI: -6.3-20.7, log-rank $P = 0.026$). The authors concluded that D3 nodal dissection performed by well trained and experienced surgeons offers survival advantage compared with D1 in gastric cancer. This trial had its own limitations. The preoperative work up of the patients was not stringent as sizeable number of patients ($n = 114$, 34%) met exclusion criteria. More troublesome is those 64 patients who were found to have not met the protocol after randomization in view of early cancer, oesophageal invasion, or positive resection margin following histopathological examination. This highlights the growing role of high resolution computed tomography and endoscopic ultrasonography for accurate disease staging. The authors did not mention anatomical mapping of late nodal recurrences; this detailed anatomic information would have highlighted whether extensive lymphadenectomy helped avoiding the nodal recurrence in the dissected lymph node basins.

D2 vs extended D2 lymphadenectomy

Three published RCTs have addressed this issue of D2 vs extended D2 (including Paraaortic lymph node dissection). Significant postoperative morbidity and mortality following extensive lymphadenectomy has always been a matter of grave concern especially among the western surgeons. In order to address the safety concerns of extensive D2 dissection, Polish Gastric Cancer Study Group published the interim analysis of their multicentre, randomized clinical trial which was

initiated to evaluate the possible benefits of extended D2 (D2+) lymphadenectomy after potentially curative resection of gastric cancer^[20]. They defined standard D2 lymphadenectomy according to the JGCA classification; D2+ lymphadenectomy included additional removal of para-aortic nodes. They randomized 275 patients into two groups: 141 to standard D2 and 134 to D2+ lymphadenectomy. The overall morbidity rates were comparable in two groups: D2 and D2+ (27.7%, 95%CI 20.3-35.1 vs 21.6%, 95%CI: 13.7-29.5, P value = 0.248). The postoperative mortality rates were also similar in two groups (D2 vs D2+, 4.9% vs 2.2%, P value = 0.376). They concluded that the interim safety analysis suggested similar surgical outcome in two groups. Long term survival data from the POLAND trial is still awaited.

Though the POLAND trial established the safety of extended D2 dissection, the JCOG 9501 trial failed to establish oncological benefit of D2 extended dissection^[21]. The JCOG 9501 trial addressed the surgical issue if addition of para-aortic nodal dissection (PAND) to D2 lymphadenectomy for stage T2, T3, or T4 tumors improves survival. They conducted a multi-centric (24 hospitals in Japan) randomized controlled trial to compare D2 lymphadenectomy alone with D2 lymphadenectomy plus PAND in patients undergoing gastrectomy for curable gastric cancer. They randomized 523 patients with curable stage T2b, T3, or T4 gastric cancer to D2 lymphadenectomy alone ($n = 263$ patients) or to D2 lymphadenectomy plus PAND ($n = 260$ patients). No adjuvant treatment was prescribed to any patient following surgery. The rates of surgery-related complications (anastomotic leakage, pancreatic fistula, abdominal abscess, pneumonia) in two groups were similar (D2 vs D2+, 20.9% vs 28.1%, P value = 0.07), Death rates from any cause within 30 d after surgery in two groups were also similar. There was also no difference in 5-year overall survival rate in two groups (D2 vs D2+, 69.2% vs 70.3%, HR = 1.03, $P = 0.85$). There were no significant differences in recurrence-free survival between the two groups (HR for recurrence 1.08, $P = 0.56$). The authors concluded that D2 lymphadenectomy plus PAND does not improve the survival rate in curable gastric cancer in comparison to D2 lymphadenectomy alone.

The third RCT was conducted by the East Asia Surgical Oncology (EASO) group to evaluate the survival benefit of para-aortic dissection in addition to the D2 lymphadenectomy in potentially curable gastric adenocarcinoma^[22]. They randomized 269 patients into two groups 135 patients were allocated to the D2 group and 134 to the D2 + para-aortic lymphadenectomy (D2+, also designated as D4 by the authors) group. There was no statistically significant difference in survival between the two groups (52.6% for D2 vs 55.0% for D2+, $\chi^2 = 0.064$; $P = 0.80$). The authors concluded that prophylactic para-aortic dissection is not recommended for patients with potentially curable advanced gastric

cancer. It is worth mentioning here that out of 12 patients who had pathologically positive station 16 nodes, three of them survived for more than 5 years (median survival 2.8 years).

What do we learn from these trials?

Though the MRC^[15] and Dutch trial^[11] suggested that D2 dissection is associated with significantly higher postoperative morbidity in terms of anastomotic leakage, pancreatic leakage, reoperation rates, wound infection and pulmonary complications, it seems that higher postoperative risk reported with D2 dissection in these trials can be contributed largely to splenectomy and pancreatectomy and not to D2 itself. Secondly, inadequate surgical training in the D2 dissection and sub-optimal quality control would further explain the higher postoperative morbidity and mortality in earlier trials. IGCSG trial showed that D2 dissection could be performed safely without splenectomy and distal pancreatectomy, with comparable mortality and morbidity to those for D1 dissection^[17]. Splenectomy or distal pancreatectomy might be considered beneficial only when the primary tumour or metastatic lymph nodes directly invade these organs. Routine resection of spleen and pancreatic tail is no longer recommended as a necessary component of modern D2 dissection^[23].

Though the initial results of the Dutch trial and the MRC trial did not show survival benefit of D2 lymphadenectomy, 15-year follow-up data of Dutch trial clearly swayed the evidence in favour of spleen preserving D2 lymphadenectomy. This was despite the significant problem of contamination and non-compliance. This further reiterated the notion that long term follow-up is needed to document the survival benefit of good loco-regional control. It must be remembered that adjuvant treatment is not the replacement of inadequate surgery; subgroup analysis of Intergroup 116 trial showed that while adjuvant chemoradiotherapy is required after D0/1 dissection, it had no added value after D2 dissection^[24-26].

Prophylactic dissection of station 16 does not provide any significant benefit over standard D2 lymphadenectomy, though 25% 5-year survival among patients with pathologically positive para-aortic nodes in EASO group trial^[22] gives a hope for this patient cohort.

When will there be reconciliation in Eastern and Western surgeons is not the issue; the basic question remains what is the optimum lymphadenectomy for a given patient to improve survival without adding significant postoperative complications. A personalized surgical approach may be beneficial in a given patient to select D1 or D2 lymphadenectomy - a D2 lymphadenectomy may not benefit a patient with early gastric cancer and may indeed lead to increased complications; on the contrary, patients with more advanced disease may benefit from an extensive lymphadenectomy^[27].

CONCLUSION

Presently, the D2 lymphadenectomy is the standard of

care in an operable gastric cancer. Routine excision of spleen and pancreatic tail should not be undertaken as it increases the postoperative complications without adding significantly to overall survival.

Abstract

AIM: To investigate changes in intestinal *Akkermansia muciniphila* (*A. muciniphila*) and explore the mechanism underlying the therapeutic effects of Roux-en-Y gastric bypass (RYGB) surgery on type 2 diabetes in diabetic Goto-Kakizaki (GK) rats.

METHODS: Male diabetic GK rats ($n = 12$) aged 8 wk were randomly assigned to the surgery group (GK-RYGB) or sham surgery group (GK-Sham) ($n = 6$ per group), and another 6 male Wistar rats aged 8 wk served as controls (WS-Sham). In the surgery group, RYGB surgery was conducted, and a sham operation was performed in both sham groups. Fasting blood glucose (FBG) levels before and after surgery, fasting levels of serum insulin and serum glucagon-like peptide-1 (GLP-1) and levels 30 min after intragastric injection of glucose, and the amount of *A. muciniphila* in the stool were determined. Insulin and GLP-1 were measured by enzyme-linked immunosorbent assay, and *A. muciniphila* were detected by fluorescence-based quantitative polymerase chain reaction.

RESULTS: The FBG was improved, and serum GLP-1 and insulin increased significantly ($P < 0.05$) in the GK-RYGB group after surgery compared to levels before surgery and to levels in the GK-Sham group. Before surgery, the amounts of *A. muciniphila* in the GK-RYGB and GK-Sham groups were significantly lower than in the WS-Sham group ($P < 0.05$). After surgery, the amount of *A. muciniphila* in the GK-RYGB group increased markedly compared to that before surgery and to that in the GK-Sham and WS-Sham groups ($P < 0.05$). In addition, the *A.*

muciniphila amount was positively related to GLP-1 ($r = 0.86, P < 0.05$).

CONCLUSION: Our results demonstrated RYGB surgery may increase GLP-1 secretion, elevate serum insulin after intragastric injection of glucose, and improve insulin resistance in diabetic GK rats, thereby contributing to a significant reduction in blood glucose. The increased amount of *A. muciniphila* after RYGB surgery may be related to elevated GLP-1 secretion.

Key words: Roux-en-Y gastric bypass surgery; Type 2 diabetes; Glucagon-like peptide-1; Glucose-dependent insulinotropic peptide; *Akkermansia muciniphila*

Core tip: Roux-en-Y gastric bypass (RYGB) surgery can improve blood glucose with definite efficacy in obese patients with type 2 diabetes mellitus and that this effect is also long lasting. But the mechanism of RYGB is not clear. Our study demonstrated RYGB surgery may increase glucagon-like peptide-1 (GLP-1) secretion, elevate serum insulin after intragastric injection of glucose, and improve insulin resistance in diabetic Goto-Kakizaki rats, thereby contributing to a significant reduction in blood glucose. The increased amount of *Akkermansia muciniphila* after RYGB surgery may be related to elevated GLP-1 secretion.

INTRODUCTION

According to the International Diabetes Federation^[1], diabetes mellitus (DM) affected about 370 million people in 2011, and an estimated 550 million people will develop DM. Of DM patients, 90% are diagnosed with type 2 DM (T2DM)^[2]. The specific etiology of T2DM is still unclear, but it is widely accepted that T2DM develops as a result of genetic and environmental factors^[3]. Intestinal microorganisms have been regarded as environmental factors^[4] and are closely related to the occurrence and development of metabolic diseases, including DM^[5-8].

In recent years, increasing numbers of studies have reported that Roux-en-Y gastric bypass (RYGB) surgery may alter the intestinal flora. Animal experiments^[9,10] and clinical trials^[11,12] have revealed that the intestinal flora change significantly after RYGB surgery. However, a majority of studies focused on the bacterial genus, and a specific type of bacterium has never been investigated in depth. Studies in the field of internal medicine typically emphasize *Akkermansia muciniphila* (*A. muciniphila*),

and findings demonstrate that *A. muciniphila* is closely related to the occurrence and development of obesity and DM^[13-18]. In the present study, RYGB surgery was performed in diabetic Goto-Kakizaki (GK) rats, and blood glucose, glucagon-like peptide-1 (GLP-1), and the amount of *A. muciniphila* in the stool were measured before and after surgery to evaluate the association of postoperative blood glucose and GLP-1 with the amount of *A. muciniphila* and to explore the potential mechanisms underlying the therapeutic effects of RYGB surgery on T2DM.

MATERIALS AND METHODS

Animals

GK rats aged 8 wk (specific pathogen free; $n = 12$) and Wistar rats ($n = 6$) were purchased from Shanghai SLAC Laboratory Animal Co., Ltd. China. GK rats were randomly assigned to 1 of 2 groups ($n = 6$ per group): The GK-RYGB group and GK-sham group. Wistar rats served as controls (WS-Sham group). This study was approved by the Ethics Committee of the Beijing Tiantan Hospital Affiliated to Capital Medical University, and all the procedures were performed in accordance with the Guide for the Care and Use of Laboratory Animals.

Surgical procedures and postoperative treatments

Before surgery, rats were fasted for 12 h and then were intraperitoneally anesthetized with 10% chloral hydrate at 0.35 mL/100 g, followed by RYGB surgery. A 4-cm incision was made in the upper abdomen, and laparotomy was performed: First, the stomach was divided just below the gastroesophageal junction from the greater to the lesser curve, taking care to preserve the vagus nerve in this region. A gastric pouch of approximately 20% of the total stomach volume was preserved. Second, the jejunum was divided 8 cm below the ligament of Treitz, and the distal cut end was anastomosed on the anterior surface of the gastric pouch with 5-0 suture. The anastomosis was 4-6 cm in length. Third, a 1-cm enterotomy was made on the antimesenteric aspect of the jejunum 10 cm distal to the gastrojejunostomy and was anastomosed to the proximal cut end of the jejunum as an end-to-side anastomosis that was 4-6 cm in length.

Sham surgery was performed in the following manner: A midline 4-cm incision was made in the upper abdomen, and laparotomy was performed. The gastrointestinal tract was explored, straightened out, and placed back into the abdominal cavity. Food was withheld for 24 h after surgery, but animals were given *ad libitum* access to water. Beginning 2 d after surgery, fluid (10% glucose) was administered for 2 d, and normal diet was resumed at 4 d after surgery. None of the animals in the 3 groups died during the experiment.

Fasting blood glucose

Fasting blood glucose (FBG) was measured at 1 wk before surgery and at 1, 2, 3, and 4 wk after surgery.

Table 1 Fasting blood glucose in different groups before and after surgery ($\bar{x} \pm s$, mmol/L)

Time point	GK-RYGB	GK-Sham	WS-Sham
1 wk presurgery	6.98 ± 0.32 ^a	7.07 ± 0.57 ^a	4.57 ± 0.26
1 wk postsurgery	6.42 ± 0.25 ^c	6.82 ± 0.49 ^a	4.25 ± 0.23
2 wk postsurgery	6.01 ± 0.20 ^{a,c,e}	6.88 ± 0.52 ^a	4.37 ± 0.22
3 wk postsurgery	5.60 ± 0.26 ^{a,c,e}	6.93 ± 0.52 ^a	4.37 ± 0.23
4 wk postsurgery	5.72 ± 0.25 ^{a,c,e}	7.03 ± 0.52 ^a	4.50 ± 0.24

^a*P* < 0.05 vs WS-Sham group; ^c*P* < 0.05 vs GK-Sham group; ^e*P* < 0.05 vs presurgery value. GK: Goto-Kakizaki; RYGB: Roux-en-Y gastric bypass; WS: Wistar.

Rats were fasted overnight, blood was collected from the tail vein, and glucose was measured with a glucose meter (Beijing Yicheng Company) at 8:00 AM.

Serum insulin and GLP-1

Serum insulin and GLP-1 were measured 1 wk before surgery and 4 wk after surgery. Rats were fasted overnight, and blood was collected from the tail vein at fasting status and at 30 min after intragastric administration of 1 g/kg glucose. Blood was transferred into an EDTA-pretreated tube and centrifuged at 3000 rpm for 12 min at 4 °C. The serum was collected and stored at -80 °C for further analysis. Rat radioimmunoassay kits (IBL, Germany) were used for the detection of serum insulin and GLP-1 according to the manufacturer's instructions.

Homeostasis model assessment-insulin resistance

Homeostasis model assessment-insulin resistance (HOMA-IR) was measured before surgery and 4 wk after surgery as follows: HOMA-IR = fasting plasma glucose (mmol/L) × fasting insulin (pmol/L)/22.5. HOMA-IR was used to evaluate the insulin resistance.

A. muciniphila in the stool. Extraction of bacterial DNA took place as follows: Stool was collected 1 wk before and 4 wk after surgery and was stored at -80 °C. The standard Muc^T (ATCC BAA-835^T) was thawed, cultured, and then stored at 4 °C. DNA was extracted with the QIAamp bacterial genomic DNA extraction kit (Qiagen, Germany) according to the manufacturer's instructions and then was stored at -20 °C for use. Next, primers for polymerase chain reaction (PCR) were designed: On the basis of the V1 and V6 variable regions of 16S RNA of *A. muciniphila*^[17], forward and reverse primers were designed with Primer Premier 5.0 (Premier Biosoft, Palo Alto, CA, United States) and were synthesized as follows:

Forward: 5' CAGCACGTGAAGGTGGGGAC 3'

Reverse: 5' CCTTGCGGTTGGCTTCAGAT 3'

Product length: 214 bp.

Routine PCR was conducted as follows: Genomic DNA extracted from the bacteria in rat stool, and standard bacteria served as templates for routine PCR. The purity and integrity of genomic DNA were determined by 1.0% agarose gel electrophoresis. After PCR, the amplified DNA was harvested with a DNA retrieval kit (Company,

Country). The retrieved DNA of standard bacteria served as standards for fluorescence-based quantitative PCR, and a standard curve was delineated.

A 10-fold dilution series of standard DNA template and DNA template from stool bacteria were independently prepared and used for real-time quantitative PCR. Product specificity was determined according to the melt curve, and the Ct value and the standard curve were employed to calculate the amount of measured bacteria (copies per g stool).

Statistical analysis

Statistical analysis was performed with SPSS version 19.0 (Chicago, IL, United States), and data were expressed as mean ± standard deviation ($\bar{x} \pm s$). Comparisons of means among groups were done with one-way analysis of variance. A value of *P* < 0.05 was considered statistically significant. Correlations between *A. muciniphila* amount and serum GLP-1 were evaluated with Pearson correlation analyses and univariate regression analyses.

RESULTS

Blood glucose and insulin

Before surgery, FBG in GK rats was significantly higher than that in Wistar rats (*P* < 0.05). At 1 wk after surgery, FBG was reduced in the 3 groups, but a significant difference was found only in the GK-RYGB group (*P* < 0.05). FBG increased gradually in the GK-Sham group and the WS-Sham group within 2 wk after surgery. At 2, 3, and 4 wk after surgery, FBG in the GK-RYGB group was lower than that in the GK-Sham group but was still higher than in the WS-Sham group. After surgery, FBG in the GK-RYGB group was significantly different from that in the GK-Sham and WS-Sham groups (*P* < 0.05) (Table 1).

Before surgery, fasting serum insulin (FSI) values in GK rats was significantly lower than those in Wistar rats (*P* < 0.05). At 4 wk after surgery, the FSI values in the GK-RYGB group and GK-Sham group increased compared to values before surgery (*P* > 0.05). At 4 wk after surgery, the FSI at 30 min after intragastric administration of glucose in the GK-RYGB group increased significantly compared to that before surgery and was significantly higher than in the GK-Sham group but lower than in the WS-Sham group after surgery (*P* < 0.05) (Table 2).

Before surgery, HOMA-IR in GK rats was significantly higher than that in Wistar rats (*P* < 0.05), suggesting higher insulin resistance in GK rats before surgery. At 4 wk after surgery, HOMA-IR in the GK-RYGB group was significantly lower than that before surgery and that in the GK-Sham group after surgery (*P* < 0.05), indicating that RYGB surgery can improve insulin resistance in GK rats (Table 3).

GLP-1

Before surgery, fasting GLP-1 in GK rats was significantly lower than that in Wistar rats (*P* < 0.05). At 4 wk after

Table 2 Serum insulin in different groups before and after surgery ($\bar{x} \pm s$, pmol/L)

Group	Presurgery		4 wk postsurgery	
	Fasting	30 min after intragastric glucose	Fasting	30 min after intragastric glucose
GK-RYGB	15.20 ± 0.67 ^a	27.07 ± 1.07 ^a	16.05 ± 1.41 ^a	47.57 ± 4.24 ^{a,c}
GK-Sham	15.26 ± 0.76 ^a	27.49 ± 1.29 ^a	15.43 ± 0.97 ^a	27.26 ± 1.26 ^a
WS-Sham	18.54 ± 0.99	104.00 ± 4.96	19.01 ± 0.42	103.68 ± 4.85

^a $P < 0.05$ vs WS-Sham group; ^c $P < 0.05$ vs GK-Sham group. GK: Goto-Kakizaki; RYGB: Roux-en-Y gastric bypass; WS: Wistar.

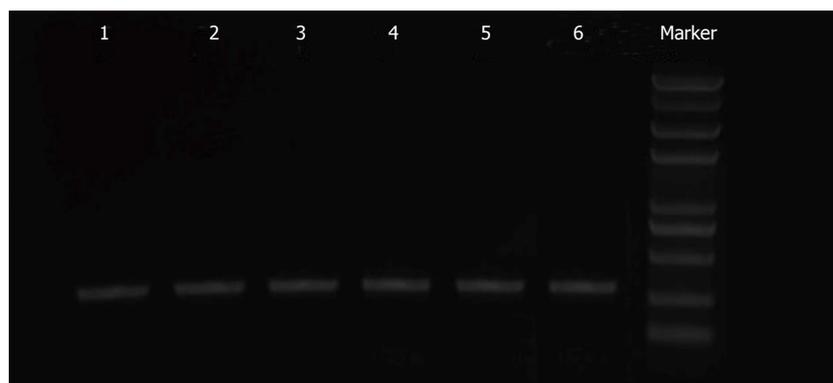

Figure 1 Electrophoresis of extracted DNA in the Goto-Kakizaki-Roux-en-Y gastric bypass surgery group.

surgery, fasting GLP-1 in the GK-RYGB surgery group was significantly higher than in the GK-Sham group ($P < 0.05$) but was comparable to that in the WS-Sham group ($P > 0.05$) (Table 4).

A. muciniphila: The extracted bacterial DNA is shown in Figure 1. The marker was a 100-bp ladder DNA marker with clear bands, suggesting that the extracted DNA was legible.

Amount of *A. muciniphila* before and after surgery in different groups

At 1 wk before surgery, the amount of *A. muciniphila* in GK rats was significantly lower than that in Wistar rats ($P < 0.05$). At 4 wk after surgery, the amount of *A. muciniphila* was 9.34 ± 0.18 copies per g stool in the GK-RYGB surgery group, which was significantly higher than that before surgery and that in the WS-Sham group and GK-Sham group ($P < 0.05$). This suggests that the amount of *A. muciniphila* in rat stool increases in GK rats after surgery (Table 5).

Correlation between intestinal *A. muciniphila* and serum GLP-1

The amount of *A. muciniphila* served as an independent variable and serum GLP-1 content as a dependent variable. A scatterplot (Figure 2) of the results showed a linear relationship between serum GLP-1 and the amount of *A. muciniphila*, and spots were found mainly within the 95%CI. Correlation analysis showed that r (the Pearson correlation coefficient) was 0.867, suggesting a significant positive correlation between serum GLP-1 and the amount of *A. muciniphila*. The amount of *A. muciniphila* was used as an independent variable and

the level of serum GLP-1 was used as a dependent variable for univariate analysis, and the results showed that $P = 0.00$.

DISCUSSION

The effectiveness of surgery in the treatment of T2DM has been widely accepted after 20 years of clinical practice, and surgery has been included in guidelines for the treatment of DM^[19,20]. Previous studies have shown that RYGB surgery can improve blood glucose with definite efficacy in obese patients with T2DM^[21-24] and that this effect is also long lasting^[14]. Moreover, this surgery may be better to mitigate T2DM-related complications compared to pharmacotherapy^[11,13,25].

Although surgery has favorable therapeutic efficacy for T2DM, the specific mechanism of action is still unclear and may be related to changes in gastrointestinal hormones^[26,27]. One of the widely studied gastrointestinal hormones is GLP-1, which, with its receptor GLP-1R, has been a focus of studies in internal medicine. To date, GLP-1 analogues (e.g., liraglutide) and GLP-1R agonists (e.g., exenatide) have been developed and used in clinical practice with favorable efficacy^[28]. Currently, published animal experiments^[26] and clinical trials^[29] have demonstrated that GLP-1 increases after RYGB surgery. In the present study, our results also showed that GLP-1 secretion increases in GK rats after RYGB surgery. GLP-1 acts mainly to increase glucose-induced insulin secretion, increase glucagon secretion, improve insulin sensitivity, promote regeneration of islet β cells, and reduce their apoptosis^[30], leading to reduction in blood glucose. In our study, the results showed that FBG remained unchanged in GK rats after RYGB surgery, but

GK-RYGB	21.01 ± 0.90 ^a	34.36 ± 1.46 ^{c,e}
GK-Sham	21.19 ± 0.53 ^a	24.98 ± 2.63 ^a
WS-Sham	29.31 ± 1.51	32.13 ± 1.52

^a*P* < 0.05 *vs* WS-Sham group; ^c*P* < 0.05 *vs* GK-Sham group; ^e*P* < 0.05 *vs* presurgery. GK: Goto-Kakizaki; RYGB: Roux-en-Y gastric bypass; WS: Wistar.

Table 5 Amount of *Akkermansia muciniphila* in different groups before and after surgery (log10 copies/g)

Group	Presurgery	4 wk postsurgery
GK-RYGB	7.85 ± 0.09 ^a	9.34 ± 0.18 ^{a,c,e}
GK-Sham	7.79 ± 0.08 ^a	7.82 ± 0.09 ^a
WS-Sham	8.51 ± 0.08	8.82 ± 0.06

^a*P* < 0.05 *vs* WS-Sham group; ^c*P* < 0.05 *vs* GK-Sham group; ^e*P* < 0.05 *vs* presurgery. GK: Goto-Kakizaki; RYGB: Roux-en-Y gastric bypass; WS: Wistar.

serum insulin increased after intragastric administration of glucose, suggesting that RYGB surgery may elevate glucose-induced insulin secretion *via* increasing GLP-1 secretion. In addition, our results revealed that HOMA-IR in GK rats after RYGB surgery was significantly lower than that before surgery and that in the GK-Sham group, indicating that RYGB surgery can improve insulin sensitivity *via* GLP-1 induction in GK rats.

The mechanism whereby RYGB increases GLP-1 secretion is still unclear. Evidence suggests that early contact of the distal small intestine with food after food intake following RYGB surgery may induce the secretion of GLP-1^[27], but studies to date have not elucidated the mechanisms whereby food induces GLP-1 secretion. Thus, the role of food in increased GLP-1 secretion still requires clarification. Tolhurst *et al.*^[31] speculated that intestinal microorganisms were closely related to GLP-1 and their metabolites (such as short-chain fatty acids) may act on the corresponding receptors on L cells to stimulate GLP-1 secretion. However, whether intestinal microorganisms induce GLP-1 secretion after RYGB surgery and the putative mechanisms of this action are still poorly understood.

Studies^[29,32] have confirmed that intestinal microor-

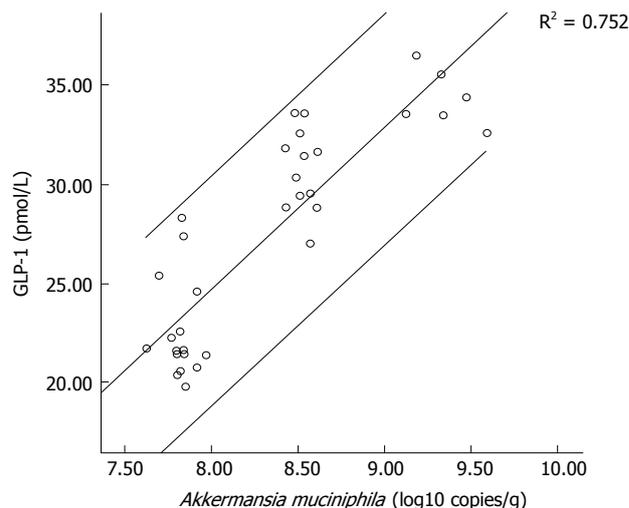

Figure 2 Scatterplot of the amount of *Akkermansia muciniphila* vs levels of glucagon-like peptide-1. GLP-1: Glucagon-like peptide-1.

ganisms may affect body weight and blood glucose. *A. muciniphila* has been a focus in current studies because apparently it can reduce body weight and improve blood glucose as well as insulin resistance^[15-18]. However, the role of *A. muciniphila* in the therapeutic effects of RYGB surgery on T2DM have never been studied. In this study, the results showed that the amount of *A. muciniphila* in the stool of GK rats was significantly lower than that in Wistar rats before surgery, suggesting that the amount of *A. muciniphila* in diabetic rats was lower than that in healthy rats. At 4 wk after RYGB surgery, the amount of *A. muciniphila* increased significantly in GK rats, suggesting that RYGB surgery can increase the intestinal amount of *A. muciniphila* in GK rats. Hansen *et al.*^[33] speculated that 2-oleoylglycerol, a metabolite produced by intestinal *A. muciniphila*, may stimulate the secretion of gastrointestinal hormones, especially GLP-1, in L cells in the distal small intestine. In the present study, correlation analysis and regression analysis confirmed that the amount of *A. muciniphila* was positively correlated with that of GLP-1. Thus, we speculate that RYGB surgery not only increases the intestinal amount of *A. muciniphila* but also elevates GLP-1.

Our findings indicate that GLP-1 increases after RYGB surgery, which then elevates serum insulin after intragastric administration of glucose and improves insulin resistance and effectively reduces blood glucose in GK rats. The increased intestinal amount of *A. muciniphila* following RYGB surgery may contribute to the elevated secretion of GLP-1 after RYGB surgery. But, the modality whereby *A. muciniphila* increases as a result of RYGB still remains undefined, nor is clear how GLP-1 increases, which needs further research in the future.

COMMENTS

Background

Type 2 diabetes mellitus (T2DM) is an endocrine and metabolic disease, which has become a significant worldwide health problem. According to the International

Diabetes Federation, T2DM has become the third most common type of non-infectious disease worldwide following cardiovascular disease and cancer. The conventional therapies include diet adjustment, exercise, self-monitoring of blood glucose and drug. But none of these therapies is adequately effective in maintaining long-term glycemic control and preventing complications. Therefore, an effective treatment for T2DM is urgently required. Of the current treatments for T2DM, Roux-en-Y gastric bypass (RYGB) surgery is considered to be an effective long-term treatment. However, the mechanisms that drive these outcomes remain incompletely understood.

Research frontiers

Recently, T2DM is characterized by altered gut microbiota, and *Akkermansia muciniphila* (*A. muciniphila*) is one of substantial gut microbiota. *A. muciniphila* which belongs to the phylum Verrucomicrobia, has been identified as a mucin-degrading bacteria that resides in the mucus layer, and it is the dominant human bacterium that abundantly colonizes this nutrient-rich environment. And its abundance inversely correlates with body weight and T2DM in mice and humans. *A. muciniphila* becomes hot gut microbiota in basic research for diabetes.

Innovations and breakthroughs

In this study, the authors used Goto-Kakizaki (GK) rats, a genetic model of T2DM, to investigate whether the RYGB surgery influenced the population of *A. muciniphila*. The authors' findings indicate that glucagon-like peptide-1 (GLP-1) increases after RYGB surgery, which then elevates serum insulin after intragastric administration of glucose and improves insulin resistance and effectively reduces blood glucose in GK rats. The increased intestinal amount of *A. muciniphila* following RYGB surgery may contribute to the elevated secretion of GLP-1 after RYGB surgery.

Applications

The authors' findings indicate that GLP-1 increases after RYGB surgery, and effectively reduces blood glucose in GK rats. The increased intestinal amount of *A. muciniphila* following RYGB surgery may contribute to the elevated secretion of GLP-1 after RYGB surgery. The authors' findings may explain the mechanism that RYGB surgery can improve blood glucose with definite efficacy in obese patients with T2DM.

Peer-review

The authors need to be congratulated for their innovative research study on relevant clinical topic. The experimental work has been scheduled and performed according to the current principles of the experimental project. The manuscript itself is concise, written in an elegant style according to all requirements of original contribution.

Abstract

AIM: To analyze the results of laparoscopic colectomy in complicated diverticular disease.

METHODS: This was a retrospective cohort study conducted at an academic teaching hospital. Data were collected from a database established earlier, which comprise of all patients who underwent laparoscopic colectomy for diverticular disease between 2000 and 2013. The series was divided into two groups that were compared: Patients with complicated disease (abscess, perforation, fistula, or stenosis) (G1) and patients undergoing surgery for recurrent diverticulitis (G2). Recurrent diverticulitis was defined as two or more episodes of diverticulitis regardless of patient age. Data regarding patient demographics, comorbidities, prior abdominal operations, history of acute diverticulitis, classification of acute diverticulitis at index admission and intra and postoperative variables were extracted. Univariate analysis was performed in both groups.

RESULTS: Two hundred and sixty patients were included: 28% (72 patients) belonged to G1 and 72% (188 patients) to G2. The mean age was 57 (27-89) years. The average number of episodes of diverticulitis before surgery was 2.1 (r 0-10); 43 patients had no

previous inflammatory pathology. There were significant differences between the two groups with respect to conversion rate and hospital stay (G1 18% *vs* G2 3.2%, $P = 0.001$; G1: 4.7 d *vs* G2 3.3 d, $P < 0.001$). The anastomotic dehiscence rate was 2.3%, with no statistical difference between the groups (G1 2.7% *vs* G2 2.1%, $P = 0.5$). There were no differences in demographic data (body mass index, American Society of Anesthesiology and previous abdominal surgery), operative time and intraoperative and postoperative complications between the groups. The mortality rate was 0.38% (1 patient), represented by a death secondary to septic shock in G2.

CONCLUSION: The results support that the laparoscopic approach in any kind of complicated diverticular disease can be performed with low morbidity and acceptable conversion rates when compared with patients undergoing laparoscopic surgery for recurrent diverticulitis.

Core tip: Several studies have shown clear benefits of the use of laparoscopic colectomy in diverticular disease. However, this approach is not well defined in patients with complicated disease. In the current study, the results support that laparoscopic surgery can be performed with acceptable results for any indication of diverticular disease.

Laparoscopic approach in complicated diverticular disease. *World J Gastrointest Surg* 2016; 8(4): 308-314 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i4/308.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i4.308>

INTRODUCTION

Traditionally, the surgical treatment of complicated diverticular disease involved the sigmoid resection and Hartmann's procedure. Over time, many authors demonstrated good results with the use of primary anastomosis with or without protective ostomy^[1-3]. Today, it is clear that the laparoscopic approach has become the gold standard for the surgical treatment of patients with recurrent diverticulitis^[4,5]. However, the application of this procedure in complicated diverticular disease remains controversial. Even more questionable is the use of the technique in patients with complicated diverticulitis on the emergency setting and the possibility of sigmoid resection in one step. The main objective of this study was to evaluate the results of the laparoscopic approach in patients with any type of complicated diverticular

disease.

MATERIALS AND METHODS

Data were collected prospectively from all patients who underwent laparoscopic sigmoid resection for diverticular disease between 2000 and 2013. Those patients with any other colorectal disease were excluded. All surgeries were performed or supervised by two surgeons with similar experience in laparoscopic surgery.

The series was divided into two groups: Patients with complicated diverticular disease (G1) and patients operated for recurrent diverticulitis without evidence of any complication (G2).

Patients with at least one of the following signs were considered to have a complicated diverticular disease: Presence of chronic abscess or severe sequelar inflammation at the time of surgery; fistula; stenosis; or free perforation with purulent or faecal peritonitis.

Demographic characteristics, previous abdominal surgeries and the number of previous episodes of diverticulitis were considered for analysis. Intraoperative variables (e.g., operative time, intraoperative complications and conversion rate) were evaluated. Finally, recovery parameters, length of hospital stay and morbidity and mortality were studied.

Conversion was considered when an unplanned incision was made or when other maneuvers beyond the extraction of the specimen were performed over the planned incision^[6].

Complications were categorized according to the classification of Dindo *et al.*^[7]. Mortality related with the procedure was considered when it occurred during hospitalization or within 30 d after surgery.

Statistical analysis

G1 to G2 were compared using univariate statistical analysis. The student's *t*-test or ANOVA were used to analyze continuous variables, whereas the χ^2 or Fisher test were used for categorical variables.

RESULTS

In a 14-year period, 260 laparoscopic sigmoid resections were performed due to diverticular disease. Seventy-two (28%) patients were included in G1 and 188 (72%) in G2.

The patients characteristics from G1 were: 31 (43%) with pericolic or pelvic abscesses; 21 (29%) with perforation; 12 (17%) with fistulae (9 colovesical and 3 colocutaneous); and 8 (11%) with stenosis.

Procedures performed in G1 were: 65 (90%) sigmoid resections with primary anastomosis; 5 (7%) sigmoid resections with primary anastomosis and protective stoma and 2 (3%) Hartmann's procedures. Fifty-two patients (72%) were operated on emergency setting without significant differences when compared with patients operated for subacute disease. In G2, sigmoid resection with primary anastomosis was performed in all cases.

Table 1 Preoperative variables *n* (%)

Examined variables	Complicated diverticular disease (G1) [<i>n</i> = 72 (28)]	Uncomplicated diverticular disease (G2) [<i>n</i> = 188 (72)]	<i>P</i> value
Sex			0.474 (N/S)

Table 2 Intraoperative variables *n* (%)

Examined variables	Complicated diverticular disease (G1) [<i>n</i> = 72 (28)]	Uncomplicated diverticular disease (G2) [<i>n</i> = 188 (72)]	<i>P</i> value
Operative time (min)	193 ± 66 (80-345)	156 ± 58 (65-400)	< 0.05
			<i>t</i> -test
Intra-operative complications	3 (4)	4 (2)	0.892 (N/S)
	2 iatrogenic colonic/rectal perforation 1 bladder injury	1 epigastric vessels lesion 2 spleen injuries 1 ureteric injury	χ^2
Conversion rate	13 (18)	6 (3)	< 0.05
			χ^2
Length of colon resected (cm)	23 ± 8 (11-4.5)	22 ± 8 (10-53)	0.531 (N/S)
			<i>t</i> -test

N/S: No statistical significance.

Demographic data were homogeneous between the groups but G2 patients presented more previous episodes of diverticulitis [G1: 1.36 ± 1.4 (0-5) vs G2: 2.42 ± 1.3 (0-10), *P* < 0.05] (Table 1).

G1 patients had longer operative time [G1: 193 ± 66 (80-345) min vs G2: 156 ± 58 (65-400) min, *P* < 0.05] and higher conversion rate [G1: 13/72 (18%) vs G2: 6/188 (3.2%), *P* < 0.05]. The reasons for conversion in G1 included: Presence of a bulky inflammatory tumor (5 cases); adhesions (3 cases); otherwise unclear anatomy (2 cases); hemorrhage (2 cases); and bladder injury (1 case). In G2, the causes of conversion were: Inability to identify anatomy (4 cases); spleen injury (1 case); and ureteric injury (1 case).

In patients with complicated diverticular disease, a sigmoid resection with primary anastomosis without protective stoma was performed in 65 cases (90%). In 5 cases of purulent perforation (7%), a sigmoid resection with primary anastomosis with protective stoma was necessary, whereas in 1 case of stenosis and other case of fecal peritonitis a Hartmann procedure was the surgery of choice. In 29 (40%) of these cases, a splenic flexure mobilization was performed. In patients with uncomplicated diverticular disease, a sigmoid resection

with primary anastomosis without protective stoma was performed in all cases (*P* < 0.05), with necessity of splenic flexure mobilization in 73 cases (39%, *P* = 0.887).

There were no differences in the rate of intraoperative complications (Table 2). In two cases of G1, an iatrogenic bowel perforation was found without necessity of conversion for its resolution. However, in one case of bladder injury, conversion was required. The intraoperative complications in G2 were: 1 epigastric vessels lesion; 2 spleen injuries; and 1 ureteric lesion. A conversion was necessary in one spleen injury and in the ureteric lesion.

Table 3 shows the variables of postoperative recovery. Patients in G1 had slower intestinal transit slower oral intake comparing with G2. For these reasons, among others, the hospital stay was longer in this group [G1: 4.7 ± 3.1 (2-15) vs G2: 3.3 ± 1.8 (1-17) d, *P* < 0.05]. The postoperative complication rate was also higher in G1 [G1: 16/72 (22%) vs G2: 23/188 (12%), *P* < 0.05], but there were no major complications in assessing differences (Grade III, IV and V) (Table 4). The mortality rate was 0.38% (1 patient), represented by a death secondary to septic shock in G2 without evidence of anastomotic fistula. There was no reason to believe that the death was related to the procedure.

Table 3 Gastrointestinal recovery

Examined variables	Complicated diverticular disease (G1) <i>n</i> : 72 (28%)	Uncomplicated diverticular disease (G2) <i>n</i> : 188 (72%)	<i>P</i> value
Intake > 1000 mL	Day 2.1 ± 2.1 (0-10)	Day 1 ± 0.8 (0.5)	< 0.05 <i>t</i> -test

DISCUSSION

Historically, the surgical management of complicated diverticular disease has consisted of laparotomy, colonic resection and end-colostomy (Hartmann's procedure). Today, controversy exists regarding the role of primary colorectal anastomosis with or without fecal diversion^[3] and the feasibility of the use of the laparoscopic approach.

Several series have demonstrated that laparoscopic sigmoid resection can be performed with acceptable morbidity and mortality for both inflammatory and neoplastic diseases^[8-10]. The laparoscopic approach demonstrated several advantages, such as smaller wounds, shorter ileus, early resumption of dietary intake and reductions in hospital stay^[11]. Furthermore, as shown by Jensen *et al.*^[12], it results in decreased costs and equivalent quality of life, making it the preferred approach in suitable patients. Laparoscopic sigmoidectomy has been shown to be safe, feasible and equivalent to open surgery for uncomplicated diverticulitis^[4,5,13]. When expertise is available, the laparoscopic approach to elective colectomy is preferred^[14].

Since the minimally invasive approach offers important benefits, laparoscopic sigmoid resection due to recurrent diverticulitis is one of the most common procedures performed in colorectal surgery.

A prospective study published by Alves *et al.*^[5] comparing open vs laparoscopic elective sigmoidectomy for uncomplicated diverticular disease found that the minimally invasive approach has a low postoperative complications rate, with a conversion rate of 15.3%, whereas the overall morbidity rate was 16%.

A recent randomized controlled trial by Klarenbeek *et al.*^[15] comparing laparoscopic vs open sigmoidectomy for diverticular disease has shown significant advantages of laparoscopic surgery, with a 27% reduction in major morbidity for patients who underwent this approach.

The present series shows favorable results in patients who underwent laparoscopic resection for uncomplicated diverticulitis and found a 3% conversion rate to open surgery, with a 12% of morbidity rate.

Currently, the operative management of complicated diverticulitis has progressed to include laparoscopic surgical techniques. In 1978, Hinchey's classification was

described to determine which patients should undergo primary anastomosis after resections and this remains the system used in the majority of the publications^[16]. As shown in a retrospective study published by Li *et al*^[17], there has been an increase in the use of nonoperative and minimally invasive strategies in treating patients with a first episode of acute diverticulitis. However, the Hartmann procedure remains the most frequently used urgent operative approach^[17]. The laparoscopic approach has demonstrated acceptable morbidity and mortality rates, although the frequency of conversion increases with the severity of adhesions and the presence of fistulas or abscesses^[18,19]. Recently, some studies have been published that include patients with complicated diverticular disease who underwent laparoscopic sigmoid resections. These studies report a conversion rate of between 11.5% and 37% and a postoperative complication rate of between 11.5% and 28%^[20-22]. In the present series no differences in global morbidity were identified between the groups.

The safety of laparoscopic management for complicated and fistulizing diverticular disease has been previously addressed^[21,23]. Despite the fact that laparoscopic resection for complicated disease would be expected to be challenging, reports have demonstrated no differences in operative time or conversion rate^[24].

Few groups have reported their experience in laparoscopic management of colovesical or colovaginal fistula^[23,25,26]. These cited studies did not identify differences in hospital stay or postoperative complications when compared to open approach. Conversion rate ranged between 7% to 25%^[27,28]. The present series included 9 patients with colovesical and 3 patients with colocutaneous fistulas. All of these patients were successfully operated by laparoscopy.

Regarding colonic stenosis, studies have reported favorable outcomes but with an increased conversion rate^[29,30]. In this series eight patients were treated successfully due to stenosis, with a conversion rate of 12.5%.

Historically, the treatment of perforated diverticulitis was performed in stages, as in Hartmann's procedure, which remains the procedure of choice in Hinchey III-IV diverticulitis and is considered the best therapeutic option by many surgeons^[31-35]. However, this technique has a low level of recommendation based on the literature evidence. Moreover, a further disadvantage of this approach is that the majority of these patients will never have a stoma reversal^[35,36].

Recently, several studies have demonstrated the benefits of laparoscopic sigmoid resection with primary anastomosis without protective stoma^[37-40].

Richter *et al*^[2] reported that colon resections with primary anastomosis could be performed with high degree of safety in 90% of patients, although the risk increases in immunosuppressed patients or in patients with kidney or liver chronic failure.

A systematic review found no significant differences in mortality rate or other complications for patients with

Hinchey III-IV who underwent Hartmann's procedure or resection with primary anastomosis^[38].

In our series, 11 Hinchey III-IV patients were treated by laparoscopic sigmoid resection without any stoma protection and only one of them was converted to open surgery. The postoperative complication rate was 10%. Neither anastomotic leaks nor mortality rate were registered.

Recently, other groups have described the use of laparoscopic peritoneal lavage (LPL) and drainage for diverticular peritonitis, with or without posterior elective surgery^[41-44]. Karoui *et al*^[45] reported that LPL in Hinchey III complicated diverticulitis is an effective and safe alternative to colon resections with primary anastomosis or protective stoma, and demonstrate that it shortens the hospital stay, avoids a stoma in the majority of patients and decreases postoperative abdominal morbidity. Rogers *et al*^[46] reported lower mortality and morbidity than those in whom resection was considered necessary. This procedure appears promising in selected patients. However, more studies comparing LPL against laparoscopic sigmoid resection with primary anastomosis should be performed before clinical recommendations can be given.

COMMENTS

Background

Diverticular disease is among the most common diseases in developed countries. It is estimated that approximately 20% of patients with diverticulosis develop diverticulitis over their lifetime. Surgical treatment can be evaluated emergently or electively, based on the stage of the disease and clinical presentation. Laparoscopic surgery is now widely accepted for the treatment of elective diverticular disease. The benefits include reduced blood loss, pain, morbidity and length of stay. Its use for complicated diverticulitis remains controversial.

Research frontiers

In the present study, the authors reported the results of seventy-two patients with complicated diverticular disease treated by laparoscopic surgery.

Innovations and breakthroughs

In literature the laparoscopic surgery is widely recommended for diverticular disease. However, this approach is not well defined in patients with complicated disease.

Applications

The study suggests that the laparoscopic approach can be applied for the patients with any kind of complicated diverticulitis.

Terminology

A diverticulum is a saclike protrusion in the colonic wall that develops as a result of herniation of the mucosa and submucosa through points of weakness in the muscular wall of the colon. Diverticulitis describes the presence of an inflammatory process associated with diverticula. Complicated diverticular disease is defined as diverticulitis with associated abscess, phlegmon, fistula, obstruction, bleeding, or perforation.

Peer-review

This paper gives an accurate description about the role that the laparoscopy may have in the treatment of complicated acute diverticulitis, which frequency is constantly increasing in our society. This paper well structured and presented, giving to the reader, the opportunity to easily understand it.

Abstract

AIM: To determine the outcome of the management of iatrogenic gastrointestinal tract perforations treated by over-the-scope clip (OTSC) placement.

METHODS: We retrospectively enrolled 20 patients (13 female and 7 male; mean age: 70.6 ± 9.8 years) in eight high-volume tertiary referral centers with upper or lower iatrogenic gastrointestinal tract perforation treated by OTSC placement. Gastrointestinal tract perforation could be with oval-shape or with round-shape. Oval-shape perforations were closed by OTSC only by suction and the round-shape by the "twin-grasper" plus suction.

RESULTS: Main perforation diameter was 10.1 ± 4.3 mm (range 3-18 mm). The technical success rate was 100% (20/20 patients) and the clinical success rate was 90% (18/20 patients). Two patients (10%) who did not have complete sealing of the defect underwent surgery. Based upon our observations we propose two types of perforation: Round-shape "type-1 perforation" and oval-shape "type-2 perforation". Eight (40%) out of the 20 patients had a type-1 perforation and 12 patients a type-2 (60%).

CONCLUSION: OTSC placement should be attempted after perforation occurring during diagnostic or therapeutic endoscopy. A failed closure attempt does not impair subsequent surgical treatment.

Key words: Over-the-scope clip; OVESCO; Perforation; Gastrointestinal tract

Core tip: The aim of this study was to determine the outcome of over-the-scope clip management of patients with iatrogenic gastrointestinal tract perforations in eight high-volume tertiary referral centers. Technical success was of 100% and clinical success of 90%. Moreover, after evaluating our results we did a classification of the iatrogenic perforation: We defined the perforation with round-shape "type-1 perforation" and the oval-shape one as "type-2 perforation".

Over-the-scope clips in the treatment of gastrointestinal tract iatrogenic perforation: A multicenter retrospective study and a classification of gastrointestinal tract perforations. *World J Gastrointest Surg* 2016; 8(4): 315-320

INTRODUCTION

Iatrogenic perforations that occur during endoscopic procedures are generally managed surgically^[1,2]. Some authors prefer a non-surgical approach in selected cases, despite the considerable risk of morbidity and mortality^[3,4]. Most cases of iatrogenic perforation occur during therapeutic endoscopic procedures, including bilio-pancreatic procedures, particularly in the context of endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) for the treatment of superficial neoplasia, but there are also descriptions of cases occurring during diagnostic upper or lower gastrointestinal (GI) endoscopy^[5-7]. The reported incidence of perforation during diagnostic endoscopy is between 0.01% and 0.6% while that during therapeutic endoscopy is between 0.6% and 5.5%. Using an over-the-scope clip (OTSC) it would be possible to close these perforations immediately during the endoscopy.

Through-the-scope (TTS) clip closure of endoscopic perforations has been described in the literature since 1997^[8,9]. However, there are limitations to closing full-thickness defects with TTS clips. The closure is confined to the mucosal and submucosal layers, with relatively low closure force, and the opening span between the jaws is restricted. A new device, the OTSC system (Ovesco Endoscopy AG, Tübingen, Germany) is designed to create full-thickness closure by using teeth arranged in the shape of a bear trap and has a simple method of application. The OTSC is made of a super-elastic, shape-memory alloy (nitinol), which takes its former, unbent shape after the clip is released, and thus exerts constant compression on the tissue between the jaws of the clip. von Renteln *et al.*^[10] showed, in a porcine model, that the OTSC clips provide a full-thickness closure of perforations.

Although the use of an OTSC has been well established during natural orifice transluminal endoscopic surgery^[11] and treatment of bleeding^[12-14] in recent years some reports have been published describing the usefulness of OTSC in closing acute iatrogenic perforations, first in animal models and then in humans^[15-17].

The aim of our study was to determine the outcome of the management of iatrogenic gastrointestinal tract perforations treated by OTSC.

MATERIALS AND METHODS

Data were retrospectively collected from eight high-volume tertiary referral endoscopy units. Data from all patients undergoing immediate or 24 h - delayed OTSC placement for acute iatrogenic perforation, during diagnostic or therapeutic endoscopy or other therapeutic maneuvers, in the period between December 2012 and January 2015 were reviewed and reported as

Table 1 Site, type of procedure being during occurred gastrointestinal perforation and type of applied over-the-scope clip

Number of patients	20 (13 F and 7 M)
Site	Esophagus (<i>n</i> = 1) Stomach (<i>n</i> = 3) Duodenum (<i>n</i> = 4) Jejunum (<i>n</i> = 2) Cecum (<i>n</i> = 1) Ascending colon (<i>n</i> = 1) Sigmoid colon (<i>n</i> = 7) Rectum (<i>n</i> = 1)
Procedure	Diagnostic colonoscopy (<i>n</i> = 7) EUS (<i>n</i> = 3) EMR (<i>n</i> = 4) ERCP (<i>n</i> = 3) ESD (<i>n</i> = 2) Tracheostomy (<i>n</i> = 1)
OTSC-type	9/t mm (<i>n</i> = 2) 10/t mm (<i>n</i> = 5) 11/a mm (<i>n</i> = 1) 11/t mm (<i>n</i> = 12)

OTSC: Over-the-scope clip; F: Female; M: Male; EUS: Endoscopic ultrasound; EMR: Endoscopic mucosal resection; ERCP: Endoscopic retrograde cholangio-pancreatography; ESD: Endoscopic submucosal dissection; a: Atraumatic teeth; t: Traumatic teeth.

mean \pm SD. All endoscopic procedures were carried out in patients who were conscious or deeply sedated with anesthesiologist support. The length of follow-up was of 3-mo.

Two different techniques were used for placing the OTSC at the site of the perforation: Only aspirating the defect inside the cap in which OTSC is mounted, or using the “twin-grasper” (Figure 1). The twin-grasper is generally used when the defect assumed a round-shape and only aspiration was used when oval-shape.

The twin-grasper, deployed through the working channel of the scope, was used to approximate the two edges of tissue, withdrawing them inside the cap, before releasing the OTSC. The twin-grasper has two independently movable lateral arms, allowing the two edges of the perforation to be grasped at two different times. The twin-grasper ensures that all layers of the gastrointestinal wall are contained in the bite, creating a full-thickness closure of the perforation. The technical success or failure of the OTSC placement was documented by contrast X-ray.

Two different OTSC clip were used in the study: With traumatic and with atraumatic teeth. Traumatic OTSC differ from the atraumatic because of the presence of a spike over the tooth, allowing a best grasping of the tissue.

RESULTS

Of the 20 patients recruited, thirteen were female and seven male. Their mean age was 70.6 ± 9.8 years. The sites of perforation were esophagus (*n* = 1), stomach (*n* = 3), duodenum (*n* = 4), jejunum (*n* = 2), cecum

Figure 1 Over-the-scope clip pre-loaded on the scope with the “twin-grasper” (from ovesco.com).

(*n* = 1), ascending colon (*n* = 1), sigmoid colon (*n* = 7) and rectum (*n* = 1). Twelve of the perforations occurred during diagnostic endoscopy [3 during endoscopic ultrasound; 7 during colonoscopy in patients with diverticular disease and 2 in a Billroth II patient with a duodenoscope during identification of the papilla of Vater during endoscopic retrograde cholangiopancreatography (ERCP)] and eight during therapeutic endoscopy (4 during endoscopic EMR, 2 during ESD, one during therapeutic ERCP and one during tracheostomy). The diameters of the OTSC used were 9 mm (*n* = 2), 10 mm (*n* = 5) and 11 mm (*n* = 13). Mean perforation diameter was 10.1 ± 4.3 mm (range 3-18 mm). Seventeen of the 20 perforations were treated by application of OTSC immediately, and 3 the day after. Most of the used OTSC clips had traumatic teeth (19 traumatic and 1 atraumatic). Results are summarized in Table 1.

In all of the 20 patients the OTSC was placed successfully (100% technical success) with the correct deployment of the OTSC clip in the site of the defect. The clinical success rate was 90% (18 of the 20 patients) (Figure 2). In two of the patients (10%) the defect was not completely sealed. The first case of unsuccessful closure was a duodenal perforation, as shown by an X-ray transit study of the upper gastrointestinal tract performed immediately after placement of the OTSC, and the patient underwent duodenocephalo-pancreatectomy on the same day because of pancreatic head neoplasia. In both failures the OTSC was applied immediately after the recognition of the perforation. The second case was a sigmoid perforation during colonoscopy; the patient underwent sigmoid laparoscopic resection the day after because developing of peritonitis and the surgical specimen showed an incompletely sealed defect. No technical difficulties were encountered by the different endoscopists in placing the clips in different sites of the gut. No adverse events or deaths were recorded after OTSC placement during 3-mo follow-up and OTSC clips were not retrieved. Eight (40%) out of the 20 patients had a round-shape perforation and 12 patients an oval-shape one (60%). In all of 8 patients with round-shape perforation the defect was closed by twin-grasper plus suction and in all of the 12 patients with oval-shape

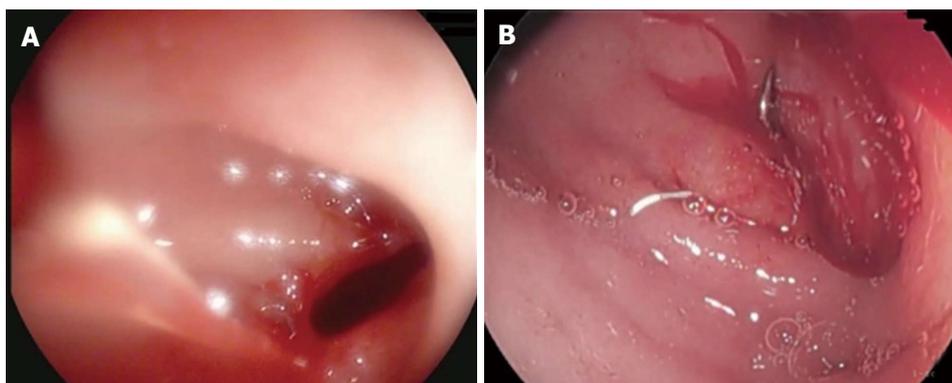

Figure 2 Duodenal type-2 perforations after endoscopic ultrasound (A) sealed by an over-the-scope clip (B).

perforation the defect was closed only by suction.

DISCUSSION

Iatrogenic perforation has always been considered a potential pitfall of diagnostic and therapeutic endoscopic maneuvers and a challenge to treat, especially before the advent of OTSC. In our series the technical success rate was 100% (20/20 patients) and the clinical success rate was 90% (18/20 patients). In two cases (10%) we did not have complete sealing of the perforation and the patients underwent surgery. Similar data were reported by Voermans *et al.*^[18] in the Clipper study, with a clinical success of 89%. Importantly, in this prospective multi-center study the mean endoscopic closure time was 5 min and 44 s ± 4 min and 15 s.

The efficacy of OTSC is based on the capacity of the clip to provide full-thickness closure of the perforation, a property well proven in some studies in animal models. At post-mortem examination executed after the OTSC placement, laparotomies revealed the full-thickness closure of the defect and peritoneum or small bowel included in the closure in some cases^[19-21].

On the analysis of our data we observed that most of the round-shape defects were closed with the aid of the "twin-grasper" and the oval-shape defect were closed by scope aspiration. On the basis of these results we can propose classification of perforations into two types: Round-shape "type-1 perforation" and oval-shape "type-2 perforation" (Figure 3). The "twin-grasper" plays an essential role in presence of large perforations for its capability to approximate the two edges of the defect

allowing a more secure grasp of the defect by the OTSC clip.

The use of suction has to be done in moderation, since excessive suction may grasp a good amount of the bowel wall and result in luminal restrictions. Excessive suction applied in the perforation area can also theoretically lead to catch of anatomical structures from outside of the bowel wall and involve them into the clipping site. The reason is the relatively low control of the tissue invagination process into the cap and the frequent limitation in visualization during suction. The suction should be used with caution in the colon, which has a relatively thin wall.

The role of OTSC in the management of endoscopic iatrogenic perforation has been discussed also in some case reports and small series. A case of spontaneous iatrogenic perforations sealed by OTSC clip have been described^[22]. Changela *et al.*^[23] recently described three cases of endoscopic perforation successfully treated by OTSC.

In 2010 Parodi *et al.*^[24] demonstrated the usefulness of the OTSC in a small series of patients with GI perforations up to 20 mm. One of the 10 treated cases was solved completely by placing two additional covered stent. More than one OTSC clip can be placed in presence of an iatrogenic perforation. A Japanese group published recently the possibility to apply as many as three OTSC clips in a series of 23 treated patients for bleeding, fistula and perforation of which 4 mucosal defect were observed during ESD^[25]. Moreover, a recent systematic review performed by Weiland *et al.*^[26] based on a small case series because of the lack of randomized and clinical trials in this field, showed OTSC clip placement to be a safe and effective method in the closure of GI tract defects, as perforations and acute anastomotic leak.

Gubler *et al.*^[27] in a series of 14 patients treated by OTSC clip placement for acute iatrogenic perforations of the GI tract demonstrated closure of the GI defects is possible in the presence of a perforation up to 30 mm diameter.

The largest study currently available in the literature about the use of OTSC in acute perforation by Haito-Chavez *et al.*^[28] including 188 patients with 48

perforations, with a median defect diameter of 7 mm. The rate of successful technical closure of the perforations was 97.5%, with an immediate clinical success of 94.9% and an overall long-term follow-up (207 d) rate of 90%; this rate was higher than that for closure of leaks (73.3%) and significantly higher than that for closure of fistulae (42.9%).

It is now established that the use of OTSC clips may reduce the rate of emergency surgery^[29] when an accidental perforation occurs and maybe considered as a mini-invasive endoscopic alternative to surgical repair. Recently, the position statement of the European Society of Gastrointestinal Endoscopy, has introduced the use of OTSC clips in GI tract acute iatrogenic perforations^[30]. However, despite the good results reported in the different published studies, OTSC clips are inappropriate in presence of delayed diagnosis by days or weeks, in individuals in whom there is significant peritoneal contamination, in long serosal tears of the colon, and perforations with endoscopic sphincterotomy where placement may result in sealing off the pancreatico-biliary orifices.

In our opinion, considering the high rates of technical and clinical success in sealing perforations of the gastrointestinal tract, OTSC placement should be performed to manage perforations occurring during diagnostic or therapeutic endoscopy or other therapeutic maneuvers, even in small endoscopic centers provided that the endoscopists' training is adequate. It allows a short stay in hospital and results in less hospital costs. Moreover, a failed attempt at OTSC deployment does not preclude subsequent surgical treatment. We suggest using the "twin-grasper" plus aspiration when a perforation type-1 occurs and only aspiration, if the endoscopist is confident with the OTSC system, in perforation type-2.

COMMENTS

Background

Gastrointestinal iatrogenic perforations are generally surgically managed. The reported incidence of perforation during diagnostic endoscopy is 0.01%-0.6%, while during therapeutic endoscopy is 0.6%-5.5%. Using an over-the-scope clip (OTSC) it is possible to close these perforations immediately.

Research frontiers

Through-the-scope (TTS) clip closure of endoscopic perforations has been described in the literature since 1997. However, there are limitations to closing full-thickness defects with TTS clips. The closure is confined to the mucosal and submucosal layers, with relatively low closure force, and the opening span between the jaws is restricted.

Innovations and breakthroughs

Iatrogenic perforation has always been considered a potential pitfall of diagnostic and therapeutic endoscopic maneuvers and a challenge to treat, especially before the advent of OTSC. In the authors' series the technical success rate was 100% (20/20 patients) and the clinical success rate was 90% (18/20 patients). Moreover, on the basis of the shape of the defect, the authors propose a classification of gastrointestinal (GI) tract perforations.

Applications

OTSC clip placement should be performed to manage perforations occurring during diagnostic or therapeutic endoscopy or other therapeutic maneuvers,

even in small endoscopic centers provided that the endoscopists' training is adequate. It allows a short stay in hospital and results in less hospital costs. Moreover, a failed attempt at OTSC deployment does not preclude subsequent surgical treatment.

Terminology

Iatrogenic perforations are defect of the entire GI wall (from mucosa to serosa) caused by diagnostic or therapeutic maneuvers.

Peer-review

The authors have performed an interesting study of 20 cases with iatrogenic gastrointestinal perforations treated by endoscopic over-the-scope-clipping with high success rate.

Abstract

AIM: To analyze the outcomes of laparoscopic ventral mesh rectopexy in the management of complete rectal prolapse (CRP) in North Indian patients with inherent bulky and redundant colon.

METHODS: The study was conducted at a tertiary health care center of North India. Between January 2010 and October 2014, 15 patients who underwent laparoscopic ventral mesh repair for CRP, were evaluated in the present study. Perioperative outcomes, improvement in bowel dysfunction or appearance of new complications were documented from the hospital records maintained prospectively.

RESULTS: Fifteen patients (9 female) with a median age of 50 years (range, 15-68) were included in the study. The median operative time was 200 min (range, 180-350 min) and the median post-operative stay was 4 d (range, 3-21 d). No operative mortality occurred. One patient with inadvertent small bowel injury required laparotomy on post-operative day 2. At a median follow-up of 22 mo (range, 4-54 mo), no prolapse recurrence was reported. No mesh-related complication was encountered. Wexner constipation score improved significantly from the preoperative value of 17 (range, 5-24) to 6 (range, 0-23) ($P < 0.001$) and the fecal incontinence severity index score from 24 (range, 0-53)

to 2 (range, 0-53) ($P = 0.007$). No *de novo* constipation or fecal incontinence was recorded during the follow-up. On personal conversation, all patients expressed satisfaction with the outcome of their treatment.

CONCLUSION: Our experience indicates that laparoscopic ventral mesh rectopexy is an effective surgical option for CRP in North Indian patients having a bulky redundant colon.

Key words: Redundant sigmoid; Constipation; Complete rectal prolapse; Ventral rectopexy; Indian population

Core tip: Laparoscopic ventral rectopexy is a new modality for surgical correction of full thickness rectal prolapse. Avoiding a circumferential mobilization of rectum and reperitonealization of the mesh decreases the complications of rectal denervation. Authors have emphasized the results of laparoscopic ventral rectopexy on bulky and redundant sigmoid which is prevalent in Indian population. Patients were studied for a median duration of 22 mo. There were a few post-operative complications which were easily managed. Marked improvement in constipation and incontinence scores were reported. No *de novo* or worsening of existing constipation was recorded in any of the patients. In this study, no recurrence was evident during the follow-up.

INTRODUCTION

Complete rectal prolapse (CRP) is defined as circumferential and full-thickness protrusion of the rectum out of the anal verge. Surgical techniques described for CRP include anterior resection, rectopexy, or combined resection-rectopexy^[1]. Recently, minimally invasive technique for prolapse surgery has gained wide acceptance because of advantages like decreased operative pain, faster recovery and early discharge^[2]. Different laparoscopic techniques described are sutureless rectopexy, proctosigmoidectomy, and mesh rectopexy. In 2004, D'Hoore *et al*^[3] reported the long-term results of laparoscopic mesh ventral rectopexy (LMVR) with equivalent success rates and improved functional outcomes. Ventral rectopexy avoids the complications related to circumferential mobilization of rectum (*de novo* constipation) and colonic resection (anastomotic leak)^[4]. Data suggest LMVR without posterior rectal mobilization as the surgical procedure of choice for rectal prolapse as well as associated pelvic

organ prolapse^[5]. North Indian population being a predominantly vegetarian one is peculiar in having very bulky sigmoid colon. This also accounts for high incidence of sigmoid volvulus in this population. The aim of our study was to analyze the results of LMVR for complete prolapse in this patient group.

MATERIALS AND METHODS

Patients

Approval was obtained from the institutional ethics committee for performing the study. Informed consent was taken from all the patients before surgery, explaining them the benefits and procedure-related complications in detail. Only patients with CRP, confirmed on clinical examination and defecography were included in the study. Between January 2010 and October 2014, 25 patients with CRP were managed surgically, out of which 15 underwent LMVR. Primary objective of the study was anatomical correction of prolapse and secondary objective was evaluation of functional outcomes.

Pre-operative assessment

All patients were examined clinically, both in lying down and squatting position. If prolapse was not evident in resting position, patients were asked to "bear down" in squatting position. Barium enema examination was done in all patients to assess colon redundancy. Preoperative flexible sigmoidoscopy/colonoscopy was done to exclude organic disease. Data gathered from the prospectively maintained records included patient age, sex, duration of symptoms, associated other pelvic organ prolapse and presence of incontinence or constipation. Any previous surgical intervention for prolapse was recorded. Fecal incontinence was assessed using fecal incontinence severity index (FISI) and constipation by Wexner scoring^[6,7]. Patients with FISI score of more than 8 were considered to be incontinent whereas constipation was defined as Wexner score of more than 5. Objective assessment of patient satisfaction level following the procedure was done using a disease specific personal questionnaire (supplementary material).

Procedure

The surgery was performed under general anesthesia with patient in steep Trendelenburg position. The surgical technique was adopted from the original description by D'Hoore *et al*^[8]. Usually 4 ports were created. Supra-umbilical port was used as camera port. The retcosigmoid junction was identified and retracted to the left. A "J shaped" peritoneal incision was given extending from the sacral promontory to the anterior peritoneal reflection distally. Right hypogastric nerve and ureter were identified and safeguarded. With combined blunt and sharp dissection, a wide plane was developed in the Rectovaginal/rectovesical space. Any posterior rectal mobilization or lateral dissection was avoided at this stage. A strip of Prolene mesh (Ethicon Endosurgery, Blue Ash, Ohio, United States), trimmed to 3 cm × 17 cm,

was prepared and inserted into the pelvic cavity. One end of mesh was fixed to the anterior surface of the distal most part of the rectum using polypropylene sutures. Similarly, it was fixed to the lateral borders of the rectum. Care was taken to avoid full thickness bite into the rectal wall in order to prevent mesh contamination. Finally, the proximal end of mesh was fixed to the sacral promontory using Tackers (Covidien, Dublin, Ireland). Proximal traction on the rectum was avoided while fixing the mesh. In females, the distal part of the mesh was also fixed to the posterior vaginal fornix allowing the correction of a vaginal vault prolapse as well. The peritoneum was then re-approximated to completely cover the mesh. This also resulted in a refashioned, shallow pouch of Douglas.

Follow-up and post-operative assessment

Anorectal function was assessed 3, 6 and 12 mo postoperatively using the FISI and Wexner constipation score. Patient examined clinically at 3 and 6 mo. At 12 mo and later follow-up was done with telephonic interview using personal questionnaire.

Statistical analysis

Statistical analysis was done by a biomedical statistician. Mann-Whitney *U*-test was applied for unpaired data and Wilcoxon signed rank test was used for the analysis of paired data (two-sided *p*-test).

RESULTS

Demographics

Fifteen patients with CRP (6 men and 9 women) with a median age of 50 years (range, 15-68 years) underwent this procedure. Two patients had recurrent prolapse following failed previous surgery (one Theirsch's procedure and one mesh posterior rectopexy). Median duration of symptoms was 10 years (range, 0.5-40 years). Median duration of follow-up was 22 mo (range, 4-54 mo).

Clinicopathologic features

Five out of 15 patients had incontinence with median FISI score 24 (range, 0-53). Four patients had constipation with median Wexner score 17 (range, 5-24). Two patients had vaginal vault prolapse. Solitary rectal ulcer with anemia was present in two patients. Redundant colon was evident in 13 out of 15 patients on contrast enema examination.

Surgical result

The surgery was performed laparoscopically in all patients. Median surgical time was 200 min (range, 180-350 min). No intra-operative blood transfusion was required. Median length of hospital stay was 4 d (range, 3-21 d). Iatrogenic bowel injury requiring re-exploration resulted in prolonged hospital stay (21 d) in one case.

Morbidity and mortality

There was no perioperative mortality. One patient with

inadvertent small bowel injury required re-exploration on second postoperative day. One patient had transient urinary retention and two had surgical site infection, which was managed conservatively. No mesh-related complication was reported.

Surgical outcomes

At median follow-up of 22 mo, Wexner score declined to 6 (range, 0-23) from the preoperative value of 17 (range, 5-24) ($P < 0.001$) and the FISI score to 2 (range, 0-53) from 24 (range, 0-53) ($P = 0.007$). Recurrent prolapse was not reported in any of our patients. On personal questionnaire, patients were satisfied with the procedure. No new-onset constipation or fecal incontinence developed in any patient.

DISCUSSION

The goal of surgery in rectal prolapse is the correction of the anatomical defect, improvement of bowel function and prevention of *de novo* functional problems. Various abdominal and perineal procedures have been described for management of rectal prolapse, with later procedures now reserved only for high-risk patients who cannot withstand major abdominal surgery^[9]. However, long-term recurrences and the rate of persistent incontinence are higher than in abdominal procedures. Abdominal approach is now considered the standard of care and is used whenever feasible^[10]. Abdominal procedures imply sutured or mesh rectopexy, colonic resection or a combined resection-rectopexy technique. Conventionally these have been done through open approach and more recently by minimally invasive means. In a randomized controlled study, laparoscopic rectopexy was found to have less operative pain, rapid recovery and shorter post-operative hospital stay. Also the surgical complications were significantly lower in comparison to open procedures^[5]. Laparoscopic approach is now considered the standard approach and is routinely recommended in all cases. Abdominal procedures involving sigmoid resection with or without rectopexy have a reported recurrence rates of 2% to 5%. This technique also carries risk of anastomotic leak and chances of incontinence following bowel resection, particularly in elderly individuals^[11].

Conventionally, mesh rectopexy involved circumferential mobilization of the rectum up to pelvic floor with mesh placed ventrally or posteriorly. Complete rectal mobilization has been associated with autonomic nerve damage and disturbed rectosigmoid motility leading to *de novo* or worsening of existing constipation^[12].

D'Hoore *et al.*^[3,8] in 2004 described "nerve-sparing ventral rectopexy" as a procedure for rectal prolapse. The uniqueness of laparoscopic ventral rectopexy lies in the fact that mobilization is restricted to anterior rectum thus leaving the autonomic innervation intact^[3,8]. Currently, this technique has gained widespread acceptance and has been proposed by many the "standard of care" for management of pelvic organ prolapse^[2,13]. The combined benefits of laparoscopic approach and ventral rectopexy have made the procedure safe and effective with minimal

post-operative functional disturbance.

Several studies have reported a recurrence rate of about 5% following LMVR. Most recurrences occur within the first 2-3 years^[2,3]. The risk of recurrence is similar to that reported for other abdominal procedures (2% to 9%)^[14]. In the present study, no recurrence was found.

Ventral mesh rectopexy has been found to be associated with lower incidence of new-onset and greater improvement in pre-existing constipation as compared to the procedures that include posterior rectal dissection. Three randomized trials have shown an improvement in constipation by avoiding lateral and posterior dissection^[15-17]. Also, studies that have included the fecal incontinence data have shown improved symptoms following the LMVR. The incidence of new-onset fecal incontinence after LMVR has also been reported to be low^[3,5,18]. The results suggest that complications following LMVR are mostly minor. Our functional results are very similar to these studies. Pre-existing constipation improved in 80% of cases and no patient developed *de novo* constipation.

Previously, rectopexy surgery was thought to cause kinking of redundant sigmoid colon over the fixed rectum, resulting in worsening of preexisting or *de novo* constipation^[19]. For this reason, resection-rectopexy was advocated for patients with redundant sigmoid. However, D'Hoore *et al.*^[3] showed that the denervation of rectum resulting from its circumferential mobilization led to most of the post-rectopexy functional problems. Similarly, redundant sigmoid was present in 13 out of 15 patients in the present study, still all patients had improved constipation scores in the follow-up and none reported a new-onset constipation.

The mesh-related complications were of concern for us initially and were explained to the patients as well. However, in the present study we found the procedure to be safe. No mesh-related complication: Infections, erosions, or perforation was documented. Covering the mesh with the peritoneum prevented small bowel adhesion. The patients were not evaluated for postoperative dyspareunia/sexual dysfunction in this study.

There is a growing consensus that rectal prolapse is a component of a multi-compartment pelvic floor dysfunction^[20,21]. Thirty-five percent of prolapse cases have concomitant urinary incontinence, and another 15% complain of significant genital prolapse^[22]. During ventral mesh rectopexy, fixing the posterior vaginal fornix to the lower most part of mesh provides additional support to the pelvic floor. This suspends the middle compartment resulting in correction of the existing or impending genital prolapse^[3,4]. A posterior rectopexy, on the other hand just supports the posterior compartment. The distal fixation of the mesh on to the pelvic floor allows repair of large rectoceaes. It also results in a shallow, suspended pouch of Douglas, thus correcting associated enterocele or sigmoidocele automatically. Sparing of the rectal autonomic nerves appears to improve the outcome of surgery for constipation. Our findings indicate an

excellent improvement in fecal incontinence scores in the follow-up.

The Indian population is predominantly vegetarian having high residue fiber as a major component of their diet. The sigmoid colon is particularly bulky and often redundant in this part of the world, which makes it prone to volvulus also. There is thus a concern whether ventral rectopexy would be as effective in the treatment of CRP in this subset of patients as an alternative of resection rectopexy. Our study is the first report of ventral rectopexy, reinforcing the safety and efficacy of this procedure in the group of patients with bulky, redundant sigmoid colon.

In conclusion, laparoscopic ventral rectopexy appears to be a safe and effective surgical option for full-thickness rectal prolapse, especially in Indian patients with bulky and redundant sigmoid colon. However, in view of small sample size short follow-up, this needs to be validated in larger study with longer follow-up. Prospective randomized trials are warranted for level I evidence.

COMMENTS

Background

Laparoscopic ventral rectopexy is a new modality for the treatment of full thickness rectal prolapse. Avoiding a circumferential mobilization of rectum and reperitonealization of the mesh decreases the complications of rectal denervation.

Research frontiers

Redundant sigmoid colon has been considered an indication of resection rectopexy in the past. The authors have emphasized the results of laparoscopic ventral rectopexy on bulky and redundant sigmoid which is prevalent in Indian population.

Innovations and breakthroughs

Patients were followed-up for a median duration of 22 mo. There were a few post-operative complications which were easily managed. Marked improvement in constipation and incontinence scores were reported. No *de novo* or worsening of existing constipation was recorded in any of the patients. In this study, no recurrence was evident during the follow-up. This was similar to other researchers who have practiced laparoscopy ventral rectopexy. The fact that this procedure was equally effective in redundant sigmoid and loaded colon among Indian population has not been reported till date.

Applications

Laparoscopic ventral rectopexy appears to be a safe and effective surgical option for complete rectal prolapse. This needs validation with a larger cohort or a randomized study in Indian population.

Terminology

CRP: Complete rectal prolapse; FIS: Fecal incontinence severity index; LMVR: Laparoscopic mesh ventral rectopexy.

Peer-review

This is an interesting paper focusing the outcomes of laparoscopic ventral mesh rectopexy in the treatment of complete rectal prolapse in North Indian population with inherent bulky and redundant colon.

Article in press: January 22, 2016
Published online: April 27, 2016**Abstract****AIM:** To prospectively perform the PERFACT procedure in supralelevator anal fistula/abscess.**METHODS:** Magnetic resonance imaging was done preoperatively in all the patients. Proximal cauterization around the internal opening, emptying regularly of fistula tracts and curettage of tracts (PERFACT) was done in all patients with supralelevator fistula or abscess. All types of anal fistula and/or abscess with supralelevator extension, whether intersphincteric or transsphincteric, were included in the study. The internal opening along with the adjacent mucosa was electrocauterized. The resulting wound was left open to heal by secondary intention so as to heal (close) the internal opening by granulation tissue. The supralelevator tract/abscess was drained and thoroughly curetted. It was regularly cleaned and kept empty in the postoperative period. The primary outcome parameter was complete fistula healing. The secondary outcome parameters were return to work and change in incontinence scores (Vaizey objective scoring system) assessed preoperatively and at 3 mo after surgery.**RESULTS:** Seventeen patients were prospectively

enrolled and followed for a median of 13 mo (range 5-21 mo). Mean age was 41.1 ± 13.4 years, M:F - 15:2. Fourteen (82.4%) had a recurrent fistula, 8 (47.1%) had an associated abscess, 14 (82.4%) had multiple tracts and 5 (29.4%) had horseshoe fistulae. Infralelevator part of fistula was intersphincteric in 4 and transsphincteric in 13 patients. Two patients were excluded. Eleven out of fifteen (73.3%) were cured and 26.7% (4/15) had a recurrence. Two patients with recurrence were reoperated on with the same procedure and one was cured. Thus, the overall healing rate was 80% (12/15). All the patients could resume normal work within 48 h of surgery. There was no deterioration in incontinence scores (Vaizey objective scoring system). This is the largest series of supralelevator fistula-in-ano (SLF) published to date.

CONCLUSION: PERFECT procedure is an effective single step sphincter saving procedure to treat SLF with minimal risk of incontinence.

Core tip: Supralelevator fistula-in-ano (SLF) and abscess are quite difficult to treat. There is no good treatment available for this dreaded disease as the risk of incontinence is quite high when operating on such fistula. PERFECT (proximal cauterization around the internal opening, emptying regularly of fistula tracts and curettage of tracts) was done in seventeen patients with SLF. The overall healing rate was 80% (12/15). All patients could resume normal work within 48 h of surgery and there was no deterioration in incontinence scores. This is the largest series of treatment of SLF published to date.

INTRODUCTION

Supralelevator abscess (SLA) constitutes up to 9% of all cryptoglandular abscesses^[1-3]. These are difficult to treat as there is no satisfactory treatment procedure available which can manage these fistulas with a high success rate and minimal risk of incontinence. Conventionally adequate drainage followed by either a primary fistulotomy or a two stage fistulotomy using a seton fistula-in-ano was recommended^[3]. There had been great enthusiasm for ligation of intersphincteric tract (LIFT) and even BioLIFT procedures, but recently the results have been disappointing^[4].

Electrocauterization of the area around the internal opening can successfully close the internal opening of a fistula-in-ano^[5]. This step along with curettage of the tracts and regularly emptying fistula tracts [proximal cauterization around the internal opening, emptying regularly of fistula tracts and curettage of tracts (PERFACT) procedure] has been shown to be effective in treating complex anal fistulas^[5]. The efficacy of this procedure to manage supralelevator fistula-in-ano (SLF) was assessed in this study.

MATERIALS AND METHODS

This was a prospective analysis of all consecutive patients with cryptoglandular SLF and SLA treated from 2012 to 2014 at the referral colorectal unit of the hospital. The clearance (approval) was given by the institutional ethics committee. Informed consent was given by all the patients.

Inclusion criteria

All types of anal fistula and/or abscess with supralelevator extension, whether intersphincteric or transsphincteric, were included.

Exclusion criteria

Patients who could not follow the postoperative schedule and protocol were excluded.

The Vaizey objective incontinence scoring was done preoperatively and at 3 mo after surgery^[6]. On a scale of 0-24, a score of 0 implied perfect continence and a score of 24 meant total incontinence.

A preoperative magnetic resonance imaging (MRI) scan was done in every case to accurately map the fistula tracts. A schematic diagram of the coronal and transverse sections was made based on the MRI (Figures 1-3).

Principle/concept

Intraoperatively, the procedure had two steps: (1) Electrocauterization around the internal opening: The superficial layer (mucosa) around the internal opening was electrocauterized to create a fresh wound (Figures 2 and 4). The resulting wound was encouraged to heal by secondary intention (granulation tissue). The aim was to permanently close (heal) the internal opening. If there was an additional supralelevator opening in the rectum, the same procedure was done for that opening as well; and (2) curettage of tracts: All the tracts were thoroughly curetted and debrided of their lining with a curette. The transsphincteric supralelevator tract/abscess was drained and curetted through the ischioanal fossa through the external opening (Figure 2). The intersphincteric supralelevator tract/abscess was curetted through the external opening already present or through a small new incision in the intersphincteric groove (Figure 2). Once the intersphincteric space was opened up, a blunt curette was introduced through the incision into this space. The curette was advanced towards the supralelevator tract/

collection, taking guidance from the MRI scan. A finger was kept in the rectum to prevent inadvertent injury to the rectal wall.

Postoperative management

Regularly emptying fistula tracts: The curetted tracts were kept clean and empty of any serous fluid so as to ensure that the tracts healed (closed) by granulation tissue. Keeping all the tracts clean was required for 4 to 8 wk (occasionally longer) until all the tracts healed fully. The cleaning was usually done twice a day.

To ensure proper cleaning of the tracts, the following steps (one or multiple depending upon the requirement and fistula characteristics) were done during surgery: (1) The external opening was widened and the scarred puckered skin (if present) was excised. The aim was

to make the external opening bigger than 1 cm x 1 cm (Figures 4 and 5). This facilitated cleaning of the tracts for a longer duration; (2) small tubes (red rubber, nasogastric or plastic) were put in the outer part of the tract to prevent premature closure of the outer part of the tract (Figure 5)^[7]. The tube was removed before every dressing and then reinserted after the dressing. There was no need to secure the tube with a suture as the tract held the tube in place and the tube did not usually come out while walking. The cleaning was done with a swab mounted on artery forceps^[7]. The schematic diagram (Figures 1-3) provided guidance regarding the direction and depth of the tracts. The tube size and diameter was gradually decreased as the deeper portion of the tracts healed. The insertion was stopped only after it was ensured that the deeper (including the

supralelevator) part of the tract had completely healed. The healing was assessed by narrowing of the tracts and non-negotiation of the swab in the upper part of the tract. Postoperative MRI was done in patients who could afford it to assess the healing (Figure 1); and (3) in cases of long multiple tracts or horseshoe tracts, multiple holes were made along the tract (Figure 5) so that all parts of the tract could be cleaned with ease.

Intraoperative procedure

A saddle block (spinal anesthesia) or general anesthesia was given. The patient was positioned in a lithotomy or prone jack-knife position. The internal opening was localized. This was facilitated by injecting saline or

povidone iodine through the external opening.

Proximal superficial cauterization (Figures 2 and 4) was carried out with electrocautery around the internal opening, cauterizing only the mucosa and superficial part of the internal sphincter. The crypt glands, the internal opening and the tissue around it were cauterized. This usually resulted in an oval cauterized area, approximately 1 cm (wide) and 2 cm (long), with an internal opening at the center of the wound (Figures 2 and 4). After cauterization, the wound was left as such and no attempt was made to close the wound or the internal opening with any suture, stapler, glue or plug.

After this, the tracts were curetted in accordance with the MRI diagram and the tract lining was scrapped out as

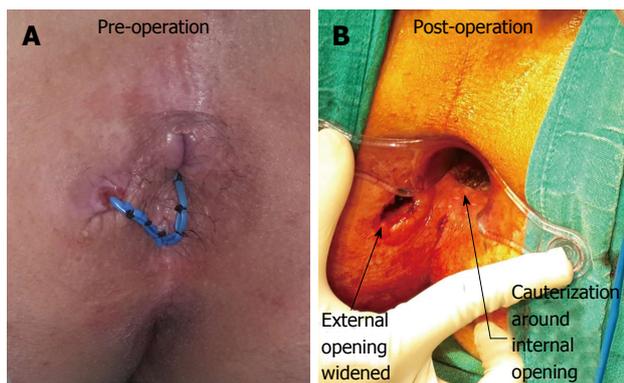

Figure 4 Cauterization around the internal opening and widening of external opening. Loose draining seton (blue color) can be seen in the preoperative (A) photograph which was inserted during the previous operation by another surgeon 3 mo before the PERFECT procedure was done. A: Preoperatively; B: Postoperatively.

much as possible with a blunt curette (Figure 2). While doing so, a finger was kept in the rectum to ensure that the curette did not accidentally perforate the rectum.

The patient was discharged on the day of operation (if done under short general anesthesia) or the first postoperative day (if done under saddle or spinal anesthesia). Antibiotics (ciprofloxacin 500 mg and ornidazole 500 mg) were prescribed twice a day for five days. The patient was instructed to resume all his/her normal activities on the same day and was encouraged to walk briskly for five kilometers every day. This helped to keep the tracts empty.

The cleaning process of the curetted tracts was done by a cotton swab mounted on artery forceps^[7]. The tube was removed before every dressing and then reinserted after the dressing (Figure 5). No povidone iodine, hydrogen peroxide or any liquid was injected in the tract during the cleaning process as this would have prevented the internal opening from closing. The cleaning was done by a trained nurse, a medical attendant or a relative. In our setting, teaching a relative was economical and easier and hence a preferred option.

The cleaning process was done two to four times a day. For the first 10 d, the patient was called to the outpatient clinic for supervised cleaning once or twice a day depending upon the complexity of the fistula. After this, the patient could do the cleaning process at home. The cleaning process was not painful, although uncomfortable at times. No sedation was required for this. The cure was defined as a complete cessation of a purulent or serous discharge and complete healing of all the tracts. Persistence of even one of the tracts was considered a failure.

The statistical methods of this study were reviewed by Pankaj Garg, MBBS, MS, Chief Colorectal Surgeon at Garg Fistula Research Institute, Panchkula, India.

RESULTS

Seventeen patients were prospectively enrolled and

followed for a median of 13 mo (3-21 mo). Mean age: 41.1 ± 13.4 years, M:F - 15:2. Fourteen (82.4%) had a recurrent fistula, 8 (47.1%) had an associated abscess, 14 (82.4%) had multiple tracts and 5 (29.4%) had horseshoe fistulae.

The infralevator part of fistula was intersphincteric in 4 (23.5%) (Figure 1) and transsphincteric in 13 (76.5%) patients (Figure 3, Table 1). All fistula were type 3 (suprasphincteric fistula) according to Park's classification^[8] and type 5 as per St James' Hospital classification^[9]. Two patients were excluded from the analysis (they could not follow the postoperative protocol). Out of 15 patients, 11 (73.3%) were cured (Figures 1 and 3) and four patients (26.7%) had a failure of treatment. All the patients with recurrence had transsphincteric supralelevator extension (Table 1). Two patients with recurrence were reoperated on with the same procedure and one was cured. Thus, the overall healing rate was 80% (12/15). The tracts, especially the supralelevator tract, did not heal in the failed treatment patients. All the patients were discharged within 24 h of the procedure and could resume normal work in 48 h. There was no deterioration in incontinence scores at 3 mo after surgery.

DISCUSSION

The study describes a novel simple method to treat supralelevator fistula with a satisfactory cure rate (80%) and minimal risk to incontinence. The morbidity was also minimal as there was no cutting of sphincter muscle and the wound was quite small. Therefore, all the patients could resume their normal work within 48 h of surgery. As per our literature search, this is the largest series of supralelevator fistula to be published.

MRI played a pivotal role in the diagnosis of supralelevator extension. Endoanal ultrasound (EUS) and MRI are recommended for recurrent or suspected supralelevator anal fistula^[10-12]. Although both these modalities are quite sensitive in detecting perianal fistulas, the specificity of MRI is better than EUS^[13]. Since ours is a referral center for anorectal fistulas, MRI is done in all our patients with perianal fistulas. The supralelevator extension was an unsuspected incidental finding in 13 (76.5%) of our patients. Twelve (92.3%) of these 13 patients had recurrent anal fistula and 11 (84.6%) had multiple tracts. These findings reaffirm the suggestion that MRI should be done in all patients with recurrent and complex anal fistula^[11-13]. MRI is perhaps the best method to assess SLA and fistula as it provides images in all three planes (axial, sagittal and coronal). The coronal view enables positioning of the abscess and the tract with respect to the levator plate and clearly shows supralelevator extension in most patients (Figures 1 and 3)^[14]. MRI is also a good modality to assess the resolution of the disease process. The photographs of preoperative and postoperative MRIs showing the resolution of the supralelevator disease process are seen in Figure 1. The postoperative MRI of all the patients could not be done due to cost constraints.

Although the route of drainage of a SLA has been

described in the past^[2,3], there is no effective method available for definitive treatment of the SLF. The standard practice is to drain a SLA abscess through the rectum when a SLA spreads upwards from an intersphincteric abscess^[15,16]. This is to avoid an iatrogenic suprasphincteric fistula if the drainage is incorrectly performed through the ischiorectal fossa. On the other hand, if a SLA is secondary to an upward extension of an ischiorectal abscess, the drainage should be performed through the ischiorectal fossa to avoid an iatrogenic extrasphincteric fistula^[2,3,8,15,17,18]. Subsequent management is opening the intersphincteric space through the rectum by dividing the internal anal sphincter (IAS) or by a staged seton procedure.

Both the internal and external anal sphincters play an important role in maintaining continence^[19-21]. Using cutting seton in high transsphincteric anal fistula can affect continence in up to 60% of patients^[19]. On the other hand, completely sparing the external anal sphincter (EAS) but dividing the IAS to open the intersphincteric space through the rectum in intersphincteric fistulas also leads to continence deficits in up to 50% of patients^[20]. Therefore, both IAS and EAS play a significant role in continence preservation^[20,21]. A recent multicenter study reported a long term incidence of major incontinence (Vaizey score > 6) in 26.8% of patients undergoing fistulotomy in low perianal fistulas^[22]. This further emphasizes the need to move towards sphincter saving procedures to treat anal fistula.

The PERFECT procedure is perhaps the first method described to treat supralevator fistula which does not involve dividing either the internal or external anal sphincter. Therefore, the continence scores did not show any deterioration in any patient postoperatively. Secondly, unlike the conventional methods^[15], this procedure aimed to cure SLA and fistula in a single step. This made it less

morbid and quite cost effective as it prevented the cost of a second admission and reoperation.

The concept behind this procedure was very simple. It aimed to close the internal opening by proximal superficial cauterization in the anal canal (Figures 2 and 4). In the postoperative period, it was ensured that the wound healed by secondary intention so that the internal opening was sealed by granulation tissue. The closure of an internal opening by natural means (granulation tissue) seems to be a good alternative to other methods of closures by primary intention, such as a plug, suture, flap, stapler or a clip^[23-25].

In the PERFECT procedure, the internal opening is not widened. If the internal opening is widened, there is a chance of stool passing through the internal opening. In this procedure, only the mucosa (superficial layer) all around the internal opening is electrocauterized so as to create a fresh raw wound which heals with granulation tissue. The internal and external sphincters are not cut. Due to this, the internal opening is not wider than it was before surgery.

The second step was curettage of the tracts. This ensured that the infected epithelium was removed and the freshened raw wound in the tracts led to the generation of the granulation tissue which facilitated the closure of the tracts. However, the serous discharge of the granulation tissue needed to be thoroughly cleaned/removed from the tracts on regular basis as otherwise the stagnant discharge would become infected, leading to a collection. The latter would not only lead to the rapid reepithelialization of the tracts, but also the collected fluid could flow into the internal opening, thereby preventing its closure.

At times, the tracts were curved and branching. Preoperative MRI, which was done in all cases, helped to accurately localize the tracts. Once this was done, it

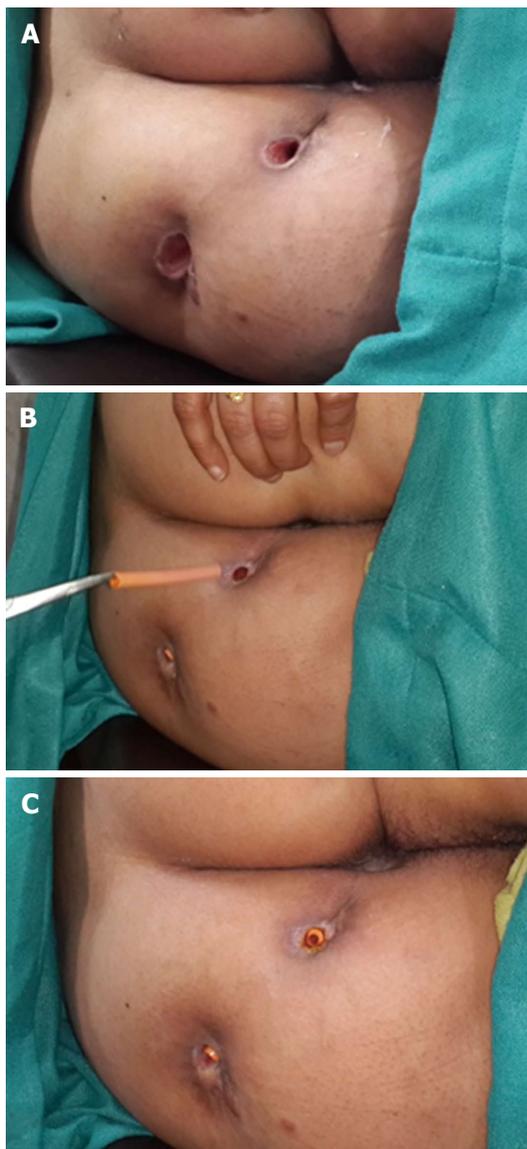

Figure 5 Widened external opening in a patient with multiple tracts (A), removal of tube to clean tracts in the office (B) and reinserted tubes in the tracts after the cleaning process (C).

helped to curette the tracts (primary tract as well as the branching secondary tracts). For this purpose, curettes of different sizes and lengths were kept handy. Cleaning the curved tracts usually did not pose much problem as the tracts were usually flexible and adapted to the shape of the curette.

The postoperative management was quite significant. It aimed to keep the tracts clean and empty and any inadequacy in this care was detrimental to the final outcome.

The cauterization of the internal opening alone was tried earlier without much success^[5]. The reason for the success of the same step in the PERFECT procedure needs explanation. Undoubtedly, the internal opening is the prime culprit in a fistula-in-ano as it allows ingress of the bacteria from the anal canal into the fistula tracts. However, once the tracts are formed and are lined by the infected epithelium, it is a mutually propagating situation.

The patent internal opening keeps the tracts infected and the infected collection in the tracts keeps the internal opening patent. Therefore, isolated attempts to close the internal opening would fail until it is accompanied by meticulous cleaning, emptying and healing of all the associated tracts. This perhaps explains the need for regular tract cleaning in the postoperative period.

The PERFECT procedure can also be done effectively in fistula cases where the internal opening cannot be localized accurately during surgery. The possible reasons of failure to identify the internal opening are twofold. Firstly, it could be due to the temporary closure of the internal opening due to debris. Secondly, it could be the closure of the collapsible fistula tract (which passes through the sphincter complex) due to the external pressure of the sphincter muscle. As per the published literature, this can happen in up to 15%-20% of cases. In the earlier published series of the PERFECT procedure, an internal opening could not be found in 15.7% (8/44) of cases^[5]. Still, this procedure was successful in 87.5% (7/8) of these patients^[5]. The MRI was done preoperatively in every case. This helped to localize the position of the tracts in the majority of cases and gave a reasonable idea where the tract is coursing towards the rectum. This information along with the examination findings during surgery (induration of the sphincter in the region of internal opening) helped to determine the most likely location of the internal opening. The superficial cauterization was done at that place. This was a safe step to do as it created only a superficial wound with no injury/damage to either of the sphincters.

The concept behind this procedure was undoubtedly simple but to achieve good results in complex anal fistulas, it required detailed analysis of the MRI scan, careful planning and mapping of the tracts (preoperatively), meticulous curettage and cleaning of all the tracts (intraoperatively) and disciplined postoperative care (postoperatively).

As discussed, the main benefit of this procedure was its ability to treat SLA/fistula in a single sitting with minimal risk to incontinence. The morbidity was also minimal as no extensive tissue cutting was done. Apart from a small superficial wound in the anal canal, the external opening was slightly widened (Figures 4 and 5). The cauterized anal wound was also small (usually about 2 cm long and 1 cm wide) (Figure 4). Due to these small wounds, the patients had little pain and were able to resume all their normal daily activities from the first postoperative day. The patients were encouraged to briskly walk 4-5 km from the first postoperative day as it facilitated keeping the tracts empty. Secondly, as both the sphincters were completely spared, the negative impact on incontinence was minimal.

The tube (mushroom catheter) has been used for drainage of perianal abscesses, both ischio-rectal abscesses^[26] and supralelevator abscesses^[15]. However, a tube has perhaps not been used in the way described in this study (to keep the outer part of the fistula tract patent). In the present procedure, a tube in the outer portion

of the fistula helped in several ways (Figure 5). First, it prevented the outer portion of the fistula tract from closing prematurely^[7]. The tube was placed until the upper inner portion of the fistula did not heal completely. Premature closure of the outer part of the tract, especially the skin, would risk accumulation of fluid which could prevent healing of the upper part^[7]. Second, unlike a loose draining seton, nothing (no seton or thread) needs to be passed through the internal opening in this technique^[7]. This helped to achieve the closure of the internal opening which would not have been possible if a draining seton had been used instead. Third, to drain supralelevator extension (with no rectal opening), a draining seton could not be used whereas a tube could be used for adequate regular drainage.

The results in fistulae with intersphincteric infralevator part (100% - 4/4) (Figure 1) were better than fistulae with transsphincteric infralevator part (72.7% - 8/11) (Figure 3). The reason for this could be that the intersphincteric space was a collapsible space. Once the abscess was adequately drained (or the fistula tract adequately curetted) and the internal opening healed by cauterization, the intersphincteric space had the tendency to collapse (close) (Figure 1).

It was observed in this series that the supralelevator component usually developed some time after the development of an infralevator anal fistula. If the infralevator anal fistula was intersphincteric, then it extended upwards in the intersphincteric plane (Figure 2). Even if the infralevator anal fistula was transsphincteric, the supralelevator extension was in the intersphincteric plane (Figure 2). Thus, the supralelevator extension was always in the intersphincteric plane. Since the supralelevator rectal opening was not present in all fistula-in-ano patients with supralelevator extension, it indicated that the supralelevator rectal opening developed later and was not as important in the pathophysiology of SLF. Mucosal papilla (granulation tissue overgrowth) was also observed at the site of the supralelevator rectal opening in four patients. Such overgrowth of granulation tissue usually occurs at the point of exudation of purulent discharge. These points indicated that the supralelevator rectal opening developed as a result of bursting the supralelevator intersphincteric abscess/collection into the rectum and this opening mainly acted as a point of drainage for the abscess/fistula. The primary source of ingress of bacteria was perhaps the opening at the dentate line. Another point in favor of this concept is that the intramural pressure during defecation in the anal canal (hence at dentate line) is quite high, whereas the intramural pressure in the rectum is comparatively low as it is a storage organ. This high pressure in the anal canal "forces" bacteria into the opening at the dentate line and this may be responsible for the persistence and propagation of the fistula and, in a few cases, development of a SLA. A small proportion of these cases then progresses to also develop a supralelevator rectal opening. Further data is needed to substantiate these observations. Unfortunately, too little

data is available on supralelevator anal fistula due to rarity of this disease and the difficulty in management it poses.

Other advantages of this procedure were the less operating time (20-30 min), the procedure was easy to perform and reproduce and no expensive gadgets were required, such as in VAAFT or an anal fistula plug^[23,25,27].

The PERFECT procedure is quite different from VAAFT. In VAAFT, the internal opening is closed by a stapler or suturing whereas in PERFECT, the mucosa (superficial layer) all around the internal opening is electrocauterized so as to create a fresh raw wound which heals with granulation tissue. The aim is to close the internal opening by secondary intention whereas in VAAFT, the aim is to close the internal opening by primary intention. Closure of tissues by primary intention put tissues under tension which increases the risk of failure. That could perhaps be the reason that the PERFECT procedure seems to be more effective than VAAFT, especially in complex and supralelevator fistulas.

This was a prospective cohort study with no control group. Undoubtedly, a control group would have added value to the study. However, a comparative study was not feasible as the prevalence of supralelevator fistula is quite low. Secondly, no other procedure in the literature has been shown to be effective in supralelevator fistula, especially in supralelevator fistula with transsphincteric component. Therefore, a comparative study could not be planned.

To conclude, the PERFECT procedure is an effective single step sphincter saving procedure to treat supralelevator anal fistula. It is associated with little morbidity and minimal risk to incontinence. Long term studies with large numbers of patients are required to substantiate the results.

COMMENTS

Background

Supralelevator fistula-in-ano (SLF) and abscess are quite difficult to treat. There is no good treatment available for this dreaded disease to date. The reason is that the risk of incontinence is quite high in operating on such fistula.

Research frontiers

SLF is extremely difficult to treat. Conventionally, drainage of the abscess is followed by either a primary fistulotomy or a two-stage fistulotomy using a seton, but these were associated with high incontinence rates. There has been great enthusiasm for ligation of intersphincteric tract and even Bio ligation of intersphincteric tract procedures, but the results have been disappointing.

Innovations and breakthroughs

This is the largest study of treatment of SLF to be published. Proximal cauterization around the internal opening, emptying regularly of fistula tracts and curettage of tracts (PERFACT) is a minimally invasive treatment in which the risk of sphincter damage is very low. This procedure was done in seventeen patients with SLF. The overall healing rate was 80% (12/15). All the patients could resume normal work within 48 h of surgery and there was no deterioration in incontinence scores.

Applications

The PERFECT procedure is a simple novel procedure with many distinct advantages. As there is no satisfactory treatment available for supralelevator fistula, this procedure provides a ray of hope to treat this dreaded disease.

Peer-review

This is a very nice study on the PERFECT procedure. The PERFECT procedure allows treating supralelevator fistula without dividing either the internal or external anal sphincter. Therefore, the continence scores showed no deterioration in any of the patients postoperatively and this procedure aimed to cure supralelevator abscess and fistula in a single step.

Abstract

AIM: To study the etiopathogenesis, management

and outcome of duodenal injury post laparoscopic cholecystectomy (LC).

METHODS: A Medline search was carried out for all articles in English, on duodenal injury post LC, using the search word duodenal injury and LC. The cross references in these articles were further searched, for potential articles on duodenal injury, which when found was studied. Inclusion criteria included, case reports, case series, and reviews. Articles even with lack of details with some of the parameters studied, were also analyzed. The study period included all the cases published till January 2015. The data extracted were demographic details, the nature and day of presentation, potential cause for duodenal injury, site of duodenal injury, investigations, management and outcome. The model (fixed or random effect) for meta analyses was selected, based on Q and I^2 statistics. STATA software was used to draw the forest plot and to compute the overall estimate and the 95%CI for the time of detection of injury and its outcome on mortality. The association between time of detection of injury and mortality was estimated using χ^2 test with Yate's correction. Based on Kaplan Meier survival curve concept, the cumulative survival probabilities at various days of injury was estimated.

RESULTS: Literature review detected 74 cases of duodenal injury, post LC. The mean age of the patients was 58 years (23-80 years) with 46% of them being males. The cause of injury was due to cautery (46%), dissection (39%) and due to retraction (14%). The injury was noted on table in 46% of the cases. The common site of injury was to the 2nd part of the duodenum with 46% above the papilla and 15% below papilla and in 31% to the 1st part of duodenum. Duodenorrhaphy (primary closure) was the predominant surgical intervention in 63% with 21% of these being carried out laparoscopically. Other procedures included, percutaneous drainage, tube duodenostomy, gastric resection, Whipple resection and pyloric exclusion. The day of detection among those who survived was a mean

of 1.6 d (including those detected on table), compared to 4.25 d in those who died. Based on the random effect model, the overall mean duration of detection of injury was 1.6 (1.0-2.2) d (95%CI). Based on the fixed effect model, the overall mortality rate from these studies was 10% (0%-25%). On application of the Kaplan Meier survival probabilities, the cumulative probability of survival was 94%, if the injury was detected on day 1 and 80% if detected on day 2. In those that were detected later, the survival probabilities dropped steeply.

CONCLUSION: Duodenal injuries are caused by thermal burns or by dissection during LC and require prompt treatment. Delay in repair could negatively influence the outcome.

Key words: Laparoscopic cholecystectomy; Duodenal injury; Duodenorrhaphy

Core tip: Inadvertent duodenal injury is a rare potentially fatal complication of laparoscopic cholecystectomy. Such injuries often go unrecognized at the time of the procedure and manifest later with significant morbidity and mortality. Literature review revealed 74 cases of duodenal injury. The injury was caused by cautery in 46%, dissection in 39% and retraction in 14% of the cases. The predominant site of injury was to the 2nd part in 61% and in 31% to 1st part. Duodenorrhaphy was the primary treatment carried out in 63% of the cases among which 21% was laparoscopically. When detected on table, 88.9% survived in contrast to 76.5% detected later. Overall mortality was 18%. The major impact of this review in clinical practice is in emphasizing the need for prompt detection of a potential duodenal injury in every patient who has unexplained postoperative course following a difficult laparoscopic cholecystectomy due to gall bladder adhesions or dissection. The change of clinical practice it should lead to is an attempt by surgeons in early detection of potential duodenal injury in such patients, which could be achieved by estimating the amylase content in subhepatic fluid collection or by upper gastrointestinal contrast studies. It also highlights the need for immediate surgical repair as any delay beyond the first postoperative day has adverse effect on outcome.

Machado NO. Duodenal injury post laparoscopic cholecystectomy: Incidence, mechanism, management and outcome. *World J Gastrointest Surg* 2016; 8(4): 335-344 Available from: URL: <http://www.wjgnet.com/1948-9366/full/v8/i4/335.htm> DOI: <http://dx.doi.org/10.4240/wjgs.v8.i4.335>

INTRODUCTION

Laparoscopic cholecystectomy (LC) is gold standard in the management of benign gall bladder disease^[1].

Unfortunately, in a small percentage of cases, it is associated with serious complications, which could be life threatening^[2-6]. These include those patients who sustain vascular or bowel injury^[2,4,6]. Among the bowel injuries, duodenal injury is extremely rare complication of LC, with a outcome that is potentially fatal^[4-26]. It is commonly unrecognized at the time of the procedure and is unfortunately diagnosed later when sepsis, peritonitis, intraperitoneal abscess or enterocutaneous fistula sets in^[2,27]. Several factors may play a role in causing these injuries, including complexity of the case and the experience of the surgeon^[5,6,15]. The incidence, mechanism of injury, diagnosis, management and outcome is described, along with the review of literature.

MATERIALS AND METHODS

Data sources

PubMed, EBSCO were searched for articles on duodenal injury during laparoscopic cholecystectomy.

Study selection

The study included articles in English literature on duodenal injury post laparoscopic cholecystectomy. The articles included case reports and case series. The references in each of these articles were further studied for additional articles on duodenal injury, post laparoscopic cholecystectomy.

The key words used as search terms were "duodenal injury", "laparoscopic cholecystectomy", "laparoscopic complications".

Data extraction

Various details were extracted from these articles. The variables studied included demographic details, presentation of symptoms and signs, day of detection of injury, investigations used to establish the diagnosis, the site of duodenal injury, possible cause, management of complication and its outcome.

Statistical analysis

The model (fixed or random effect) for meta analyses was selected, based Q and I^2 statistics. STATA software was used to draw the forest plot and to compute the overall estimate and the 95%CI for the time of detection of injury and mortality. The association between time of detection of injury and mortality was estimated using χ^2 test with Yate's correction. Based on Kaplan Meier survival curve concept, the cumulative survival probabilities at various days of injury was derived.

The PRISMA flow chart is presented in Figure 1. There were 24 studies (case report, case series) identified from the literature. None of the study was excluded. All 24 studies have been considered for both qualitative and quantitative evaluation.

RESULTS

A total of 74 cases of duodenal injuries were identified.

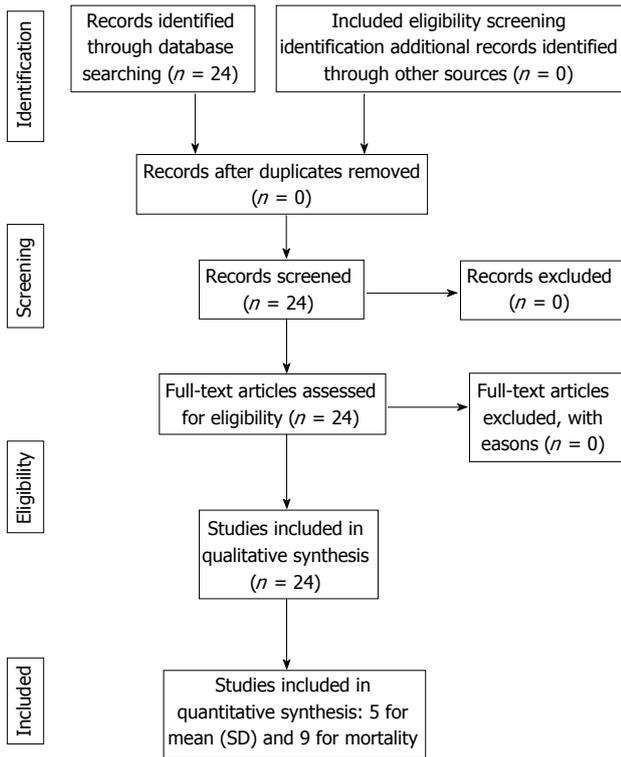

Figure 1 PRISMA flow chart.

Unfortunately details regarding the demography, presentation, investigations, management and outcome were not reported in several studies, particularly those reporting on overall complications of LC. Among the 24 cases with demography details, 11 patients (46%) were males and 13 patients (54%) were females, with a mean age of 58 years (range - 23 to 80 years) (Table 1). The mean period of detection of all the injury in the post-operative period was 1.7 d (range-immediate on table to 9th postoperative day). In 26 patients where the details of time of injury were noted, 12 (46%) of them were detected immediately on the table (day 0). Among the 28 cases where the cause of injury was reported, 13 (46%) occurred due to cautery, 11 (39%) during dissection, 4 (14%) due to retraction. There were no reported cases of injury due to veress needle or trocar insertion (Table 2). The presentation ranged from abdominal pain, nausea vomiting, abdominal tenderness, guarding, fever, peritonitis, bile drainage from the drainage tube, peritonitis, intra-abdominal abscess, sepsis and septic shock. Investigations that facilitated diagnosis included computed tomography (CT) abdomen, ultrasound with or without aspiration, estimation of amylase level in the drainage/aspirated fluid, gastrograffin study and gastroscopy and diagnostic laparoscopy (Table 1). The site of injury was reported in 13 cases of which 4 cases (31%) occurred in the 1st part, 6 cases (46%) occurred in the 2nd part above the duodenal papilla, 2 cases (15%) occurred in the 2nd part (below the papilla) and 1 case (7.6%) occurred in the 3rd part of the duodenum. Among the 30 cases where the management was reported,

19 (63%) underwent primary closure of duodenal perforation (duodenorrhaphy) among which 4 (21%) was carried out laparoscopically. The remaining procedures included percutaneous drainage in 4 cases (13.3%), tube duodenostomy (6.6%), gastric resection 2 cases (6.6%), and one each (3.3%) of Whipple resection, pyloric exclusion with gastrojejunostomy and laparoscopic endo gastrointestinal (GI) closure of perforation (Table 2). Among the 65 cases where the outcome was defined, 53 patients (82%) survived and 12 patients (18%) died (Table 2). The mean period of detection of injury in those who survived was 1.6 d (including those detected on table considered as day 0 compared to 4.25 d in those who died). However, if the ones who were detected on the table were excluded, the mean detection time for those who survived was 2.36 d compared 4.25 d for those who died.

Forest plots for duration of detection and mortality

The forest plot for time of detection of injury (in days) is presented in Figure 2. This suggests that there is no heterogeneity among studies considered in the analyses as the I^2 was about 50%. Therefore, based on the random effect model the overall mean (95%CI) duration of detection of injury is about 1.6 (1.0, 2.2) d.

The forest plot for injury related mortality is provided in Figure 3. This also suggests that there is no heterogeneity among studies, as the I^2 was about 6%. Therefore, based on the fixed effect model the overall mortality rate from these studies was 10% (0%, 25%).

Association between day of detection and mortality

Table 3 presents the mortality status according to days of detection. There were 15 patients who were detected to have injury within a day (0 or 1 d). Of them one patient died (6.7%). However, of the 13 patients who were detected to have injury after day 1, 5 of them have died (38.5%). The difference in mortality rate was significantly different suggesting that early detection was associated with lower mortality ($P < 0.05$).

Based on the Kaplan Meier survival probabilities for mortality of patients over time (days), the cumulative probability of survival was about 94%, if the injury was detected on day 1 and 80%, if the injury was detected at day 2. However, if the injuries were detected later on, then the survival probabilities dropped down steeply, especially after day 2 (Figure 4). This suggests that if the day of detection is delayed then the probability of dying is very high.

DISCUSSION

LC is the standard treatment for symptomatic cholelithiasis. Over the years, difficult LC has been conducted regularly even in patients with active inflammation, cirrhosis, adhesions and contracted fibrosed gall bladder^[1,6,28,29]. This has been possible due to the growing experience in laparoscopic surgery and advances made in

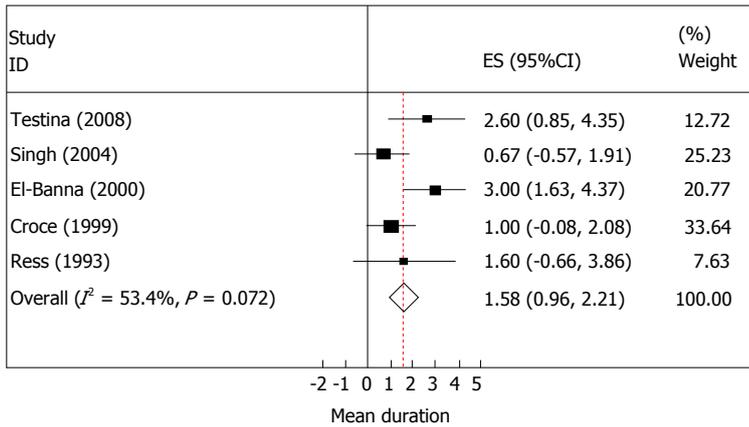

Figure 2 Forest plot of duration to detect injury (days).

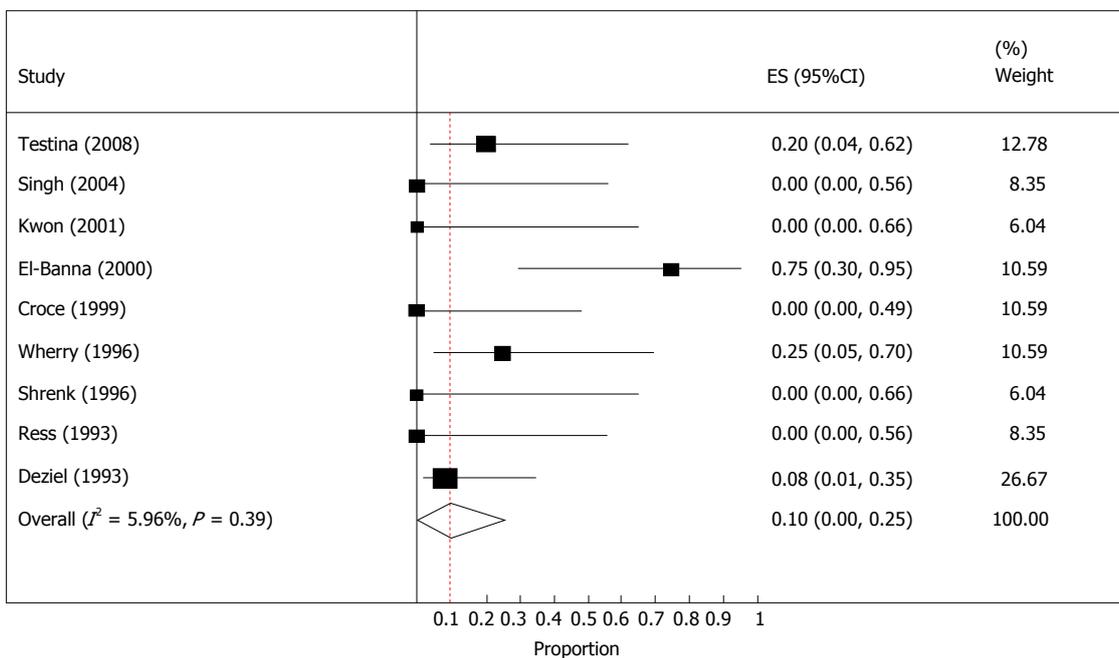

Figure 3 Forest plot of injury related mortality.

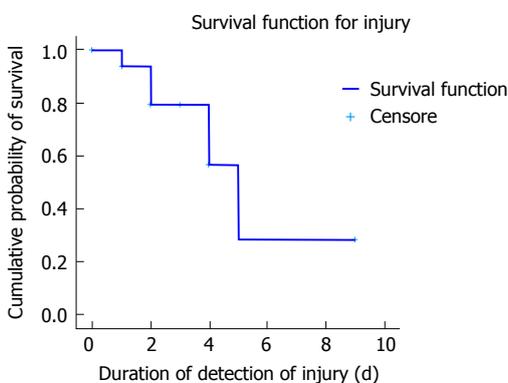

Figure 4 Survival function for injury.

instrumentation^[28,29]. Unfortunately, major complications including bowel injuries still occur, and duodenal injury among them though rare, are generally associated with significant morbidity and mortality^[4-26].

Incidence

Major complications following LC have been reported in 2% of large series among which bowel injuries occurred in 0.07%-0.9% of these cases^[15]. Among the bowel injuries, 58% occurred in small bowel, 32% in large bowel and 7% in stomach^[28]. The overall incidence of duodenal injuries is reported to be 0.04% (range 0.01%-4%)^[6]. While bile duct injury is the most common, vascular and bowel injuries are the most serious procedure related complications^[3,5,7,28-30].

Mechanism of injury

Injuries to the bowel could be related to the introduction of a Veress needle, trocar insertion, application of grasping forceps, sharp dissection with scissors and thermal contact burns or conductive burns during a laparoscopic procedure^[6,30]. In a large study of 226 bowel injuries sustained during 205969 cases of laparoscopic procedures, 50% were caused by cautery and 32% by

Veress needle or trocar insertion^[30]. In another larger study of 430 bowel injury following 329935 cases of laparoscopic procedures, small intestine injury occurred in 55.8%, followed by large intestine (38.65%)^[31]. Importantly, 66.8% of bowel injuries were diagnosed during laparoscopy or within 24 h thereafter.

Bowel injury during access

A trocar or Veress needle insertion caused 41.8% of bowel injuries and those due to coagulator or laser were in 25.6% of the cases^[31]. Bowel injuries resulting from trocar puncture is usually readily recognized and

promptly repaired^[6]. Bowel injuries related to Veress needle or trocar insertion may have declined over the years^[11]. Duodenum being anatomically retroperitoneal and away from the umbilicus (the usual site of access for pneumoperitoneum) is unlikely to sustain injury during initial step of insufflation^[25]. This is reflected in this review, were no cases of duodenal injury have been reported due to veress needle or trocar insertion.

Bowel injury during dissection

Duodenal injury is more likely to occur due to thermal injury, sustained during the use of cautery^[6,30,32]. It was

noted as a leading cause in 46% of the cases in this review. It is at risk of being overlooked in the course of surgery and may manifest itself later as a consequence of coagulation necrosis of the bowel wall^[2,5,15,31]. Bowel wall necrosis may result in delayed or walled off perforation, which may present in days or weeks^[12,15,32]. Majority of the laparoscopic duodenal injuries reported in the literature and found in our review are due to electrocautery damage, or during the dissection of difficult Calot's triangle, either due to adhesions or because of the distorted anatomy^[10,12,14,16,32]. To prevent thermal injury, the equipment should be checked regularly for defects in insulation^[4,15]. In addition, movements of

all instruments should be under direct vision by following it with camera, while the instruments are out of view^[15]. Others have suggested avoiding the use of sharp pointed suction/irrigation devices to retract the duodenum^[12]. The sharp edge of the suction device may traumatize the duodenum, when used to retract it caudally and to the left^[12]. When bowel has been grasped during manipulation, the site that is grasped is carefully inspected for any possible injury, particularly when the gut is unusually vulnerable for injury^[15]. Inadvertent bowel retraction, along with injury during the use of electrocautery is often the cause of duodenal injury^[4-6,10,14,15] (Table 2). Thermal burns can to a large

Table 3 Distribution of mortality status by days of detection of injury

extent be reduced by ensuring adequate insulation up to its tips, use of low power current, and nonuse of cautery in close proximity to the bowel. It should be rather used directly on tissues to be cauterized^[15]. One should also be aware of the capacitive coupling that occurs along the shaft of instruments, with relatively thin insulation coats^[33]. This stray energy may be responsible for otherwise unrecognized, unintentional injury during monopolar laparoscopic cauterization^[15,23,33].

The risk of complication during surgery is often reported to be related to surgeons experience; however, experienced surgeons often attempt to operate under less than ideal circumstances and in complex situations^[5,6,30]. In one of the reports, 60% of bowel injuries occurred with surgeons who were experienced and would have performed at least 100 LC^[6].

Diagnosis

Time at which bowel injury is recognized following the laparoscopic procedure is variable and is reported to range from 2 to 14 d (average 4.5 d) for small bowel injury and from 1 to 29 d (average 5.4 d) for large bowel injury^[30]. Duodenal injury may be detected on table or in the postoperative period [range 0 (on table) to 5 d] and is detected according to some report on an average on the 3rd postoperative day^[6]. However, this review noted the detection rate on an average at 1.7 d as in 46% of the cases it was detected on the table. Diagnosis of duodenal injury in postoperative period is often difficult and requires a high index of clinical suspicion, because of its rarity^[5,6,14,15,30]. Patients who had a difficult cholecystectomy due to adhesions of the gall bladder, particularly to the duodenum, are at a greater risk^[10,14,15]. The injury should be suspected in patients with unexplained cause of postoperative fever, nausea, vomiting, anorexia and abdominal distension^[5,6,12,14,15]. Pain, which may be undue and restricted initially to right hypochondrium, may later become generalized^[12,14,15]. Pain in the early stages is likely to be ignored as it is a relatively common finding after LC. However, it becomes significant, if it persists beyond 24 h and increases in intensity^[12]. Posterior wall duodenal perforation may not result in peritonitis, but may present with lumbar pain^[12].

Liver function tests may be normal or show mild elevation of bilirubin and serum amylase with normal alkaline phosphatase^[5,12,14,15]. The diagnosis however can be clinched, if the drain fluid shows high amylase levels,

in patients where drain was placed intraoperatively, because of difficult cholecystectomy^[12]. The amylase level could also be estimated by ultrasound guided aspiration of fluid of the duodenal leak^[12]. When carried out, contrast study with gastrograffin may confirm the leak^[12]. CT scan which is more sensitive than ultrasound abdomen, could reveal large collection of fluid around the duodenum or in the general peritoneal cavity, based on when the procedure is performed in the post operative period^[6]. The finding of significant amount of air and fluid in the abdomen, beyond what can be explained as a postoperative finding and the demonstration of contrast leak when performed with oral contrast^[9], are findings that are consistent with the diagnosis of duodenal injury^[12]. Obliteration of the right psoas muscle, evidenced by retroperitoneal gas, may indicate retroperitoneal duodenal leak. When in doubt, it is advisable to perform at least an early diagnostic laparoscopy, as time is of essence for a better outcome^[5,6,12,15]. Presence of bile on re-exploration, in the absence of leak from hepatic bed, cystic duct or common bile duct suggests the diagnosis of duodenal injury^[12]. Forward displacement of the duodenum by posterior mass, reflects the posterior location of the perforation^[23,25]. Unfortunately, laparoscopy may also fail in detecting a small perforation and this misdiagnosis may lead to intra abdominal or retroperitoneal collection in the lumbar region and sepsis leading to a protracted postoperative course^[12]. In the event the injury is not obvious during laparoscopy, then it would be worthwhile detecting the injury by upper GI endoscopy and demonstrating air leak around the duodenum by air insufflation.

Management of duodenal injury

The outcome of duodenal injury would depend to a large extent on the site and the time of diagnosis^[4-23]. The management could range from conservative in selected few^[8,9], to more complex surgeries in those with delayed intervention^[6,34,35]. While there are reports of successful conservative management^[8,9], most would agree on an immediate surgical intervention^[5,6,10,14,15,30]. Successful conservative management with drain has been reported in a patient with previous Billroth 11 gastrectomy^[9]. This patient had sustained a cautery induced perforation to a duodenal bulb diverticulum, rather than the duodenal wall. The site of perforation and diversion of gastric contents is reported to have attributed to the successful conservative management in this patient^[9]. Successful conservative management has also been reported in a patient where the drain that was inserted during the surgery, had inadvertently fistulated into the duodenal injury^[8]. The drain was used successfully to divert the duodenal content in postoperative period, allowing the patient to respond to conservative management^[8].

In those patients where surgical intervention is required, its nature would depend on the time of detection of injury and the site^[5,6,14,15,30]. Duodenal perforation may require meticulous search, by means of intraoperative upper GI endoscopy or duodenal mobilization by Kocher's

maneuver^[12]. When the injury is detected on table or following re-exploration shortly after LC, direct repair of duodenal injury with omental patch is feasible^[6]. This repair could be performed laparoscopically, when the duodenum is relatively healthy, defect is small and expertise is available^[11,12,16,22]. However, most recommend immediate laparotomy to assess the abdomen and secure a safe repair^[4,5-7,21]. However, delay in diagnosis beyond 48 h may lead to oedematous macerated duodenum, which will fail to hold sutures of repair, resulting in duodenal fistula^[5,6,10,14,15,30].

Site of duodenal injury is a critical factor, that influences both the outcome and approach to management^[5-7,10,14,15,30]. When injury occurs just above or below the duodenal ampulla of Vater, the biliary fluid and pancreatic juice leak will complicate matter^[5,6,10,14,15]. Resection of the damaged tissue and repair could be challenging in these cases, particularly in patients where there is a delay in diagnosis. Several approaches have been proposed in the literature, which include mucosal or serosal patches and a pedicle graft with a free vascular pedicle created from stomach, jejunum or ileal tissue; however their efficacy has not been proven^[36-38]. In general, the often practiced approach includes duodenal drainage with a decompression tube, temporary pyloric exclusion, gastrojejunostomy, feeding jejunostomy, gastric resection with external duodenal drainage with Foley or Petzer tubes^[6]; however, the outcome reported are conflicting^[34,39,40]. More aggressive approach may be warranted in the presence of larger defects and softer duodenal wall and may involve duodenojejunostomy or duodenopancreatectomy^[6,23,34]. The outcome depends to a large extent on the degree of peritonitis and sepsis, which in turn is related to the extent of delay in diagnosis^[5,6,10,14,15,29]. While the injury to descending duodenum is challenging to manage, those that occur at the duodenal bulb or superior flexure of duodenum, could be safely managed with gastric resection and duodenal stump closure^[5,6]. Majority of the patients in this review underwent duodenorrhaphy or duodenostomy. In exceptional case, a patient may undergo Whipple resection^[6]. In this review, in a solitary case, Whipple resection was carried out (Table 2). The injury was detected on the 4th postoperative day. While the need for pancreaticoduodenectomy is not clear, the gravity of the problem is reflected by the fact that the patient had a stormy postoperative period and was discharged two months later^[6].

The concerning aspect of duodenal injuries is the reported mortality in the range of 8.3%^[5] to 75%^[7]. Deziel *et al*^[5] reported an 8.3% mortality rate among 12 patients with duodenal injuries in their analysis of 77604 cases. El-Banna *et al*^[7] noted mortality in three of the four (75%) duodenal injuries. Huang *et al*^[14] reported that 4 out of 19 (21.05%) patients with duodenal injury died in their study of 39238 LC cases. Our review observed an overall mortality of 17%. It is most likely that the duodenal injuries are underreported^[6,41]. These patients are also at the risk of having significant morbidity, which

could lead to protracted hospital course^[6]. The morbidity includes intra-abdominal complications like abscess and peritonitis^[12], septicaemia, necrotising fasciitis^[6,31], pneumonia^[15], incisional hernia^[7] and lumbar abscess^[12] (Table 2). Posterior lumbar abscess may occur due to disruption of the posterior peritoneal membrane during cholecystectomy or during reoperation for duodenal repair^[12].

Duodenal injury is uncommon but is associated with significant morbidity and mortality. These are sustained during LC, usually due to thermal burn and blunt or sharp dissection. Unsatisfactory recovery post difficult LC, should raise the suspicion. Radiological imaging, analysis of the drain fluid for bile and or amylase levels and endoscopy, will facilitate the diagnosis. Early diagnostic laparoscopy is warranted when in doubt. Prompt surgical intervention, which may involve duodenal repair or resection may be required. Outcome would be significantly influenced by the delay in diagnosis.

ACKNOWLEDGMENTS

I would like to thank Professor Jeyaseelan L, Department of Statistics and Health Information, Sultan Qaboos University Hospital, Muscat, Oman for the statistical analysis and the figures.

COMMENTS

Background

Inadvertent duodenal injury is a rare but potentially fatal complication of laparoscopic cholecystectomy (LC). Such injuries often go unrecognized at the time of the procedure and manifest later with significant morbidity and mortality. In this article the literature is reviewed regarding the mechanism, presentation, investigation and management of this serious, though uncommon complication. Among the 76 cases that were detected in the literature, 46% of the injury was caused by the use of cautery and in 39% during dissection. The commonest site of injury was to the 2nd part of the duodenum and in only half of these patients, the injury was detected on table. Predominant repair was duodenorrhaphy and in 21% this was carried out laparoscopically. The mean day of detection was 1.6 d among those who survived compared to 4.25 d among those who died. Mortality of 18% was noted. This article is of importance as literature lacks adequate data on the etiopathogenesis, management and outcome of this rare, yet life threatening complication. Early detection requires high index of clinical suspicion in a patient with difficult cholecystectomy who has unexpected post operative course, raised amylase levels in fluid from the drain when placed or radiological images suggestive of subhepatic fluid collection not explained otherwise.

Research frontiers

This article reviews the literature with regards to duodenal injury post LC. Review of literature indicates the commonest cause for injury is due to cautery and blunt and sharp dissection employed during cholecystectomy. The predominant finding is, that delay in diagnosis makes simple repair with duodenorrhaphy non feasible requiring more complex surgery. In addition the poor outcome is directly related to the delay in diagnosis.

Innovations and breakthroughs

This is a review article on duodenal injury post LC and aspects of innovations and breakthroughs may not be applicable to it.

Applications

This article is of importance to surgeons who perform LC. Its applicability is in warning clinicians of this potential complication when their patient develops

postoperative abdominal pain and distension unexplained by any other cause. It then guides them in investigating these patients and managing them, while reminding them of the potential mechanism for this complication.

Peer-review

This is a good review of an uncommon condition.

THERAPEUTICS ADVANCES

- 345 Targeted therapy of gastrointestinal stromal tumours
Jakhetiya A, Garg PK, Prakash G, Sharma J, Pandey R, Pandey D

REVIEW

- 353 Implications of preoperative hypoalbuminemia in colorectal surgery
Truong A, Hanna MH, Moghadamyeghaneh Z, Stamos MJ

MINIREVIEWS

- 363 Inflammatory bowel disease surgery in the biologic era
Ferrari L, Krane MK, Fichera A
- 371 Critical appraisal of laparoscopic lavage for Hinchey III diverticulitis
Gervaz P, Ambrosetti P
- 376 Role of laparoscopic common bile duct exploration in the management of choledocholithiasis
Gupta N

ORIGINAL ARTICLE

Randomized Controlled Trial

- 382 Enhanced recovery program is safe and improves postoperative insulin resistance in gastrectomy
Fujikuni N, Tanabe K, Tokumoto N, Suzuki T, Hattori M, Misumi T, Ohdan H

SYSTEMATIC REVIEWS

- 389 Therapeutic improvement of colonic anastomotic healing under complicated conditions: A systematic review
Nerstrøm M, Krarup PM, Jorgensen LN, Ågren MS

ABOUT COVER

Editorial Board Member of *World Journal of Gastrointestinal Surgery*, Donatas Venskutonis, MD, PhD, Professor, Head of Department of General Surgery, Academy of Medicine, Lithuanian University of Health Sciences, Kaunas Clinical Hospital, Kaunas LT-47144, Lithuania

AIM AND SCOPE

World Journal of Gastrointestinal Surgery (*World J Gastrointest Surg*, *WJGS*, online ISSN 1948-9366, DOI: 10.4240) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJGS covers topics concerning micro-invasive surgery; laparoscopy; hepatic, biliary, pancreatic and splenic surgery; surgical nutrition; portal hypertension, as well as associated subjects. The current columns of *WJGS* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of gastrointestinal surgery diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJGS*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Gastrointestinal Surgery is now indexed in Emerging Sources Citation Index (Web of Science), PubMed, and PubMed Central.

Targeted therapy of gastrointestinal stromal tumours

Ashish Jakhetiya, Pankaj Kumar Garg, Gaurav Prakash, Jyoti Sharma, Rambha Pandey, Durgatosh Pandey

Ashish Jakhetiya, Pankaj Kumar Garg, Jyoti Sharma, Durgatosh Pandey, Department of Surgical Oncology, Dr BRA Institute Rotary Cancer Hospital, All India Institute of Medical Sciences, New Delhi 110029, India

Pankaj Kumar Garg, Department of Surgery, University College of Medical Sciences and Guru Teg Bahadur Hospital, University of Delhi, Delhi 110095, India

Gaurav Prakash, Clinical Hematology and Bone Marrow Transplant Unit, Department of Internal Medicine, Post-Graduate Institute of Medical Education and Research, Chandigarh 160012, India

Rambha Pandey, Department of Radiation Oncology, Dr BRA Institute Rotary Cancer Hospital, All India Institute of Medical Sciences, New Delhi 110029, India

Author contributions: Jakhetiya A and Garg PK searched the literature, analyzed the retrieved literature, and wrote the initial draft; Garg PK conceptualized the study; Pandey D, Prakash G and Sharma J provided critical inputs in literature search and analysis, and drafted the manuscript; all the authors read and approved the final draft.

Conflict-of-interest statement: There is no conflict of interest associated with any of the authors.

Abstract

Gastrointestinal stromal tumours (GISTs) are mesenchymal neoplasms originating in the gastrointestinal tract, usually in the stomach or the small intestine, and rarely elsewhere in the abdomen. The malignant potential of GISTs is variable ranging from small lesions with a benign behaviour to fatal sarcomas. The majority of the tumours stain positively for the CD-117 (KIT) and discovered on GIST-1 (DOG-1 or anoctamin 1) expression, and they are characterized by the presence of a driver kinase-activating mutation in either KIT or platelet-derived growth factor receptor α . Although surgery is the primary modality of treatment, almost half of the patients have disease recurrence following surgery, which highlights the need for an effective adjuvant therapy. Traditionally, GISTs are considered chemotherapy and radiotherapy resistant. With the advent of targeted therapy (tyrosine kinase inhibitors), there has been a paradigm shift in the management of GISTs in the last decade. We present a comprehensive review of targeted therapy in the management of GISTs.

Key words: Gastrointestinal tumors; Molecular targeted therapy; Protein kinase inhibitors; Imatinib; Survival

Core tip: Gastrointestinal stromal tumors (GISTs) are common mesenchymal tumours of the gastrointestinal tract. They are characterized by the presence of a driver kinase-activating mutation in either CD-117 or platelet-derived growth factor receptor α . Development of tyrosine kinase inhibitors has led to a paradigm shift in the management of GISTs. Surgery is the primary

modality of treatment in localized non-metastatic GISTs. Adjuvant Imatinib for three years is a preferred option for high-risk patients to lessen disease recurrence. The role of neoadjuvant Imatinib is evolving. Imatinib, Sunitinib, and Regorafenib are recommended as first, second and third-line targeted therapies, respectively, for the management of metastatic GISTs.

INTRODUCTION

Gastrointestinal stromal tumours (GISTs) are the most common mesenchymal neoplasms of the gastrointestinal tract and hypothesised to arise from the intestinal cells of Cajal^[1]. GISTs constitute 1%-3% of all malignant gastrointestinal tumours, with an annual incidence rate of 10 to 15 cases per million^[2]. Commonly, they arise from the stomach (60%-70%) and small intestine (25%-35%); other rare intestinal sites are the colorectum, oesophagus and appendix. Rarely, they can also involve extra-intestinal sites including the omentum, retroperitoneum, and mesentery (extra-intestinal GISTs)^[3]. Histologically, GISTs can be of three types: Spindle cell type (70%), epithelioid, and mixed subtype^[3]. They are diagnosed based on clinical and morphological features which are supported by immuno-histochemistry studies. CD-117 (KIT) and discovered on GIST-1 (DOG-1 or anoctamin 1) are the most sensitive and specific markers; other diagnostic markers include CD-34 (70% positivity), smooth muscle actin (20%-30% positivity), S-100 (10% positivity), and negativity for desmin (2%-4% of GISTs may be positive for desmin). About 5% of GISTs are negative for KIT expression, however many of them express DOG-1^[3-6]. Complete resection (R0) is the primary treatment in the management of localized GISTs. Traditionally, GISTs are considered chemo-resistant and radio-resistant tumors^[7]. Half of the patients have disease relapse in the first five years of surgery, and 5-year actuarial survival rate after surgery was reported as 54%^[4]. This highlights the need for effective adjuvant therapy. Imatinib, a tyrosine-kinase inhibitor (TKI) developed in 1998 for chronic myeloid leukaemia (CML), galvanized a lot of enthusiasm in the management of GISTs due to its direct inhibition of KIT and platelet-derived growth factor receptor α (PDGFRA) mutation related tyrosine kinase activity^[7]. The last 15 years witnessed remarkable progress in the field of TKIs resulting in significant improvement in the treatment outcomes in locally advanced and metastatic GISTs. The present article reviews the current status of targeted therapy of GISTs.

RATIONALE OF TARGETED THERAPY

Around 75%-80% of GISTs have KIT mutations, mainly affecting juxta-membrane domain coded by exon 11. Deletions are the most common; however insertions, substitutions and combinations can be seen. Rarely, mutations can also affect extracellular domain (exons 8 and 9) or kinase I and II domains (exons 13 and 17)^[8-10]. Approximately 20%-25% of GISTs do not have KIT mutations; around 10% of these cases have PDGFRA mutations. The remaining (10%-15%) who do not have either KIT or PDGFRA mutations are labelled as wild-type GISTs; this group forms a heterogeneous group which have mutations acting on downstream of receptor kinases^[11-13]. Ultimately mutations of KIT and PDGFRA promote cell signalling through the mitogen-activated protein kinase (MAPK) and phosphoinositide-3-kinase (PI3K) pathways^[9,10,14]. As structural similarities were detected between BCR-ABL kinase and KIT kinase, Imatinib was used in a metastatic GIST patient and it led to a dramatic response. This success led to the beginning of multiple clinical trials to establish the role of Imatinib and other TKIs in GISTs^[7,12].

ROLE OF TARGETED THERAPY IN METASTATIC GISTS

Although there has never been a randomized controlled trial (RCT) to compare targeted therapy with chemotherapy in the management of metastatic GISTs, various studies have highlighted the potential role of targeted therapy in improving survival.

Imatinib mesylate

Imatinib, a small molecule TKI with activity against BCR-ABL, KIT and PDGFRA related kinases, was the first Food and Drug Administration approved agent in metastatic GISTs. In an open label phase II trial to assess efficacy and safety of Imatinib in 147 patients with advanced GISTs, Demetri *et al.*^[13] in 2002 reported that Imatinib resulted in partial response in 53.7% and stable disease in 27.9% of patients. Therapy was well tolerated, although mild to moderate edema, diarrhea, and fatigue were common, and gastrointestinal or intra-abdominal hemorrhage occurred in approximately 5% of patients. Long-term results of this trial, published in 2008, further confirmed that nearly 50% of patients with advanced GISTs who were treated with Imatinib survived for more than 5 years. After a follow-up of up to 71 mo, there was complete response in 1.4% and partial response in 68.1%; disease remained stable in 15.6% and progressed in 11.6%. This translated into median progression free survival (PFS) of 24 mo and median overall survival (OS) of 57 mo^[15]. These results were soon validated by two phase III multi-centric RCTs which were designed to address the optimal daily dose of Imatinib. A multi-centric RCT was conducted by

EORTC Soft Tissue and Bone Sarcoma Group, the Italian Sarcoma Group, and the Australasian Gastrointestinal Trials Group to address dose dependency of response and PFS with Imatinib for metastatic GISTs^[16]. They randomized 946 patients into two groups based on daily dose of Imatinib, 400 mg either once or twice a day. At median follow-up of 760 d, higher dose Imatinib (400 mg twice a day) led to better PFS (56% vs 50%, HR = 0.82, 95%CI: 0.69-0.98, $P = 0.026$). They concluded that a dose of 400 mg twice a day leads to significantly longer PFS, as compared to once a day dosing, although both dosing achieve similar response induction. Moreover, higher dosing also resulted in a significantly higher number of treatment interruptions (64% vs 40%) or dose reductions (60% vs 16%). Relatively different results were noted by another phase III RCT, Southwest Oncology Group S0033 trial^[17]. Although the authors confirmed the effectiveness of Imatinib as a primary systemic therapy in metastatic GISTs, they concluded that higher dose (800 mg/d) does not provide any advantage over conventional dose (400 mg/d) therapy. They also reported a higher frequency of drug related toxicities among patients who received 800 mg/d Imatinib (grade 3-5 toxicities 63% vs 43%). The Gastrointestinal Stromal Tumor Meta-Analysis Group (MetaGIST) conducted a meta-analysis exploring the data of the previously published two large, randomized, cooperative-group studies which had compared two doses of Imatinib (400 mg daily vs twice daily) in 1640 patients with advanced GISTs^[18]. They reported a small (HR = 0.89; 95%CI: 0.79-1.00) but significant ($P = 0.04$) PFS advantage for the high-dose arm; however, no significant difference was observed in OS (HR = 1.00, $P = 0.97$) between the two groups. Cox regression analysis showed that higher dose therapy would potentially delay the first occurrence of disease progression and increase objective response rate in only those patients who harbor KIT exon 9 mutations. Based on these results, 400 mg daily is established as standard first line therapy; however, due consideration for higher dose (800 mg/d) may be given in patients who have KIT exon 9 mutation or have progressed on 400 mg/d of Imatinib. The subgroup analysis of these two trials also highlighted that those patients who have exon 11 mutations would respond better to Imatinib than those who have exon 9 or wild-type allele^[16-19]. Although almost all mutant subtypes are likely to have improved PFS and OS when treated with Imatinib compared to chemotherapy (historical controls), D842V mutations in PDGFRA confer resistance to Imatinib therapy; no clinical benefit has been demonstrated with Imatinib in tumours having this mutation^[18,20,21]. How long Imatinib is to be given in metastatic GISTs is the next natural question. French Sarcoma Group designed a phase III RCT to compare continuous (CONT) compared with interrupted (INT) Imatinib beyond 1 year of treatment^[22]. They randomized 58 advanced GIST patients who had either response or stable disease after one year of Imatinib therapy into two groups - 32 patients (INT arm) stopped

while 26 patients (CONT arm) continued to receive Imatinib therapy. There was a significantly higher frequency of disease progression in INT arm - 26 of 32 (81%) patients had documented disease progression patients as compared to 8 of 26 (31%) patients in the CONT group ($P = 0.0001$). Moreover, 24 of 26 patients with documented disease progression in the INT arm responded when Imatinib was reintroduced to them. This led to the conclusion that Imatinib is to be continued in advanced GISTs till evidence of disease progression or intolerance.

Other targeted agents

Sunitinib is a TKI, which inhibits KIT, PDGFRA, vascular endothelial growth factor receptors (VEGFR) 1-3 and FLT3 receptor kinase^[23]. Apart from having an inhibitory effect on oncogenic kinases, it also has antiangiogenic properties. In an initial phase I / II study, Sunitinib has shown promising clinical activity for Imatinib resistant patients^[24]. A phase III trial randomized 312 Imatinib resistant metastatic GIST patients to receive either Sunitinib or placebo; best supportive care was given in both the arms^[25]. Time to tumour progression (TTP) was four times longer in Sunitinib arm as compared to placebo (27.3 wk vs 6.4 wk, HR = 0.33, 95%CI: 0.23-0.47, $P < 0.0001$); similarly PFS was significantly better in Sunitinib arm (24.1 wk vs 6 wk, HR = 0.33, 95%CI: 0.24-0.47; $P < 0.0001$). Although relatively low but confirmed objective response rate was better in Sunitinib arm (7% vs 0%, $P = 0.006$); 16% of patients were progression free at 6 mo in Sunitinib arm vs 1% in placebo. Despite cross-over, OS was better in Sunitinib arm than placebo (HR = 0.49, 95%CI: 0.29-0.83; $P = 0.007$). Serious treatment related adverse events were 20% in Sunitinib arm and 5% in placebo arm and only 9% discontinued treatment in Sunitinib arm due to adverse events. So, Sunitinib improved TTP, PFS and OS in patients with Imatinib resistance with acceptable toxicity profile. Presently, Sunitinib is recommended as second line therapy for patients who are intolerant or have progressive disease on Imatinib. Recommended dosing schedule is 50 mg daily orally for four weeks followed by a break for 2 wk; or a continuous regimen with daily dose of 37.5 mg can also be used^[25,26].

Regorafenib is an oral multikinase inhibitor which inhibits various protein kinases, including those involved in angiogenesis (VEGFR 1-3, PDGFRB, FGFR1) and oncogenesis (KIT, RET, BRAF)^[27]. In a multicenter phase II trial, Regorafenib at a dose of 160 mg daily for 3 wk in a 4 wk cycle showed a clinical benefit rate of 79% (95%CI: 61%-91%). Median PFS was 10.0 mo^[28]. On the basis of these results, a multicentric phase III trial, GRID, was planned to evaluate the efficacy and safety of Regorafenib in metastatic GIST patients who had progressed after initial Imatinib and Sunitinib therapy. A total of 199 patients were randomized to receive Regorafenib or placebo along with best supportive care in both the arms. Disease control rate was significantly better in Regorafenib arm than in placebo arm (52.6%

vs 9.1%, $P < 0.0001$). Median PFS was 4.8 mo (interquartile range = 1.4-9.2) in Regorafenib arm and 0.9 mo (0.9-1.8) in placebo arm (HR = 0.27, 95%CI: 0.19-0.39, $P < 0.0001$). Eighty-five percent of patients crossed over from placebo to Regorafenib group, so OS was not different (HR = 0.77). Regorafenib related grade III or more toxicity was present in 61% of patients^[29]. Thereafter, Regorafenib was approved as a third line standard of care in metastatic GIST patient who have progressed or intolerant to Imatinib and Sunitinib.

Masitinib is another highly selective TKI with significant activity against GISTs. In a recent RCT it was compared with Sunitinib in advanced GIST patients after failure of Imatinib. Trial showed encouraging results in favour of Masitinib with better safety profile^[30]. Another phase III RCT (NCT01694277) is recruiting patients to evaluate the safety and efficacy of Masitinib in comparison to Sunitinib in patients with GISTs after progression with Imatinib.

ROLE OF TARGETED THERAPY IN NON-METASTATIC GISTS

Surgery is the standard of care for localized GISTs; complete excision (R0 resection), without rupturing the pseudocapsule, is the aim of surgery. Regional lymphadenectomy is usually not a part of radical surgery as lymph node metastasis is rarely present in GISTs^[31,32]. A high frequency of post-surgery disease recurrences mandates identification of high-risk group which can be exposed to adjuvant therapy. Various risk stratification systems are available to predict post-surgery disease recurrence - National Institute of Health (NIH) consensus criteria, modified NIH criteria, Armed Forces Institute of Pathology criteria, Memorial Sloan Kettering Cancer Centre prognostication criteria and prognostic contour maps^[21]. Main factors which have been identified for predicting post-surgery recurrence are mitotic rate, tumour size, and location of the tumor^[33]. Imatinib is the only recommended adjuvant targeted therapy which has been evaluated in clinical trials.

In the ACOSOG Z9000 trial, 106 patients with a high risk of recurrence (defined as tumor size > 10 cm, intra-peritoneal tumor rupture and up to four peritoneal implants) underwent curative resection and received adjuvant Imatinib for one year. After median follow-up of 7.7 years, the 1, 3 and 5-year OS rates were 99%, 97% and 83%, respectively, which compared favourably with a historical 5-year OS rate of 35%^[4].

In ACOSOG Z9001, a phase III RCT, 713 patients were randomized to adjuvant Imatinib for one year vs placebo based on tumour size more than 3 cm. The 1-year recurrence free survival (RFS) rate was 98% in Imatinib arm in comparison to 83% in placebo arm (HR = 0.33; 95%CI: 0.20-0.53; $P < 0.0001$). Retrospective analysis of the trial suggested that adjuvant therapy was more effective in high-risk patients (tumor size > 10 cm and high mitotic rate). There was no difference

in OS (HR = 0.66, 95%CI: 0.22-2.03, $P = 0.47$) due to cross-over design of the trial. Grade 3 or 4 events occurred in 30% of patients in Imatinib arm^[34]. Recently published long term results after median follow-up of 74 mo showed no significant difference in OS. They found that high mitotic rate, large tumour size and small bowel location are associated with lower RFS irrespective of tumour genotype. Imatinib therapy improved RFS in patients with KIT exon 11 deletions but not in those with exon 11 insertions or point mutations, KIT exon 9 mutations or wild type GISTs. As 400 mg/d of Imatinib therapy was prescribed in exon-9 mutation patients, this can be argued that 800 mg/d daily dose could have improved treatment outcomes based on the experience from trials conducted in metastatic GISTs. Additional studies are needed to better define the management of wild type tumours in both adjuvant and metastatic settings^[35].

In subsequent SSG XVIII/AIO phase III RCT, 400 patients were randomized based on high risk features (at least one of the following: Tumour size > 10 cm, mitotic rate > 10/50 high power field (HPF), tumor size > 5 cm and mitotic rate > 5/50 HPF, tumour rupture before or during surgery) to either 1 or 3 years of adjuvant Imatinib^[36]. Patients in 3-year arm had longer 5-year RFS compared to 1-year arm (65.6% vs 47.9%, HR = 0.46, 95%CI: 0.32-0.65, $P < 0.001$). OS was also longer in 3-year arm compared to 1-year arm (92% vs 81.7%, HR = 0.45, 95%CI: 0.22-0.89, $P = 0.02$). However, grade 3 or 4 toxicities were also higher in 3-year arm (32.8% vs 20.1%) and more patients discontinued treatment in 3-year arm (25.8% vs 12.6%) compared to 1-year arm. Based on the results of these two trials, three-year adjuvant Imatinib therapy is presently the standard of care in high-risk patients. Recently, a clinical trial (the PERSIST-5 trial, NCT00867113; ClinicalTrials.gov, 2009) examining the role of 5 years of adjuvant Imatinib in high-risk patients completed accrual; however, final results will be available after 2018.

Neoadjuvant setting is another area of interest in the management of locally advanced GISTs which are not operable upfront. In the absence of phase III trials, role of neoadjuvant therapy remains investigational. Two phase II trials have demonstrated efficacy and safety of neoadjuvant Imatinib in locally advanced GISTs^[37,38]. The dosing and duration of targeted therapy in neoadjuvant setting are currently based on the experience gathered through trials conducted in metastatic GISTs. As phase III EORTC 62005 trial designed for metastatic GISTs showed that there was no difference in overall response rate between 400 mg vs 800 mg group, this indicates that 400 mg daily dose for neoadjuvant therapy would be appropriate to downstage the tumour. As the reported median time to best response was 4 mo, this should be taken as length of neoadjuvant treatment, and it can be extended up to 6 mo^[16]. Another study suggested that neoadjuvant TKI can be given for 9 to 12 mo; however, it should not be extended beyond 12 mo because of the risk of resistance^[39]. In a pooled database

Table 1 Published randomized controlled trials of role of targeted therapy in gastrointestinal tumours

Study	Research question	Sample size	Study arms	Response rates	PFS/RFS	OS	Toxicity (Grades 3-5)	Conclusion
SWOG S0033 ^[14]	Imatinib as first line in metastatic GISTs	746	400 mg daily vs 400 mg twice daily	ORR 45% (CR 5%, PR 40%) vs 45% (CR 3%, PR 42%)	2 yr PFS 41% vs 46% (P = 0.13)	2 yr OS 76% vs 72% (HR = 0.98)	43% vs 63%	400 mg daily is initial dose and consider dose escalation with disease progression
EORTC 62005 ^[13]	Imatinib as first line in metastatic GISTs	946	400 mg daily vs 400 mg twice daily	51% vs 54%	2 yr PFS 56% vs 50% (HR = 0.82, P = 0.026)	2 yr OS 69% vs 74%	32% vs 50%, P < 0.0001	Better PFS in 400 mg twice daily with higher toxicity
Demetri <i>et al</i> ^[25]	Sunitinib as second line in metastatic GISTs	312	Sunitinib vs placebo	7% vs 0% (SD 58% vs 48%)	Median TTP 27.3 wk vs 6.4 wk (HR = 0.33, P < 0.0001)	Better in Sunitinib arm (HR = 0.49, P = 0.007)	20% vs 5%	Sunitinib is approved as a second line therapy in metastatic GISTs
GRID ^[29]	Regorafenib as third line in metastatic GISTs	199	Regorafenib vs placebo	4.5% vs 1.5% (SD 71.4% vs 33.3%)	Median PFS 4.8 mo vs 0.9 mo (HR = 0.27, P < 0.0001)	No difference, HR = 0.77	61% vs 14%	Regorafenib is approved third line therapy in metastatic GISTs
ACOSOG Z9001 ^[35]	Imatinib as adjuvant	713	1 yr (400 mg) vs placebo	Not available	1 yr RFS 98% vs 83% (HR = 0.33, P < 0.0001)	1 yr OS 99.2% vs 99.7% (HR = 0.66, P = 0.47)	30.9% in Imatinib arm	1 yr adjuvant Imatinib is effective and safe
SSG XVIII/AIO ^[36]	Imatinib as adjuvant	400	1 yr vs 3 yr	Not available	5 yr RFS 47.9% vs 65.6% (HR = 0.46, P < 0.001)	5 yr OS 81.7% vs 92% (HR = 0.45, P = 0.02)	20.1% vs 32.8%	3 yr adjuvant Imatinib improved RFS and OS

SWOG: Southwest Oncology Group; GISTs: Gastrointestinal stromal tumours; ORR: Overall response rates; CR: Complete response; PR: Partial response; SD: Stable disease; PFS: Progression free survival; RFS: Recurrence free survival; TTP: Time to tumour progression; OS: Overall survival; HR: Hazard ratio.

Table 2 Current role of targeted therapy in gastrointestinal stromal tumours

Agent	Use	Dose	Duration
Imatinib	First line in metastatic GISTs ^[13-15]	400 mg once daily (oral)	Till progression or intolerance
	Progression on 400 mg ^[13-15]	400 mg twice daily (oral)	Till progression or intolerance
	Exon 9 mutation ^[13-15]	400 mg twice daily (oral)	Till progression or intolerance
	Adjuvant in high risk cases ^[37]	400 mg daily (oral)	3 yr
Sunitinib	Neoadjuvant setting ^[29,39,40]	400 mg daily (oral)	6-12 mo
	Second line in metastatic setting ^[21,24]	50 mg once daily for 4 wk every 6 wk (oral) or 37.5 mg once daily continuously (oral)	Till disease progression or intolerance
Regorafenib	Third line in metastatic setting ^[26]	160 mg once daily for 3 wk every 4 wk (oral)	Till disease progression or intolerance

GISTs: Gastrointestinal stromal tumours.

of ten EORTC STBSG centers, 161 patients with locally advanced, non-metastatic GISTs were identified who received neoadjuvant Imatinib. R0 resection was achieved in 83% and 5-year DFS rate was 65% with median OS of 104 mo^[40]. The National Comprehensive Cancer Network guidelines recommend neoadjuvant Imatinib therapy in locally advanced GISTs to achieve R0 resection and to minimize postoperative morbidity. Imatinib can be stopped just before surgery and again restarted as soon as patients resume oral intake^[41].

Table 1 displays the published RCTs in GISTs. Table 2 displays the current role of targeted therapy in GISTs based on available evidence.

SIDE EFFECTS OF TARGETED THERAPY

Most of the side effects of Imatinib are mild and well tolerated. Anaemia (70%-80%) and leukopenia (35%-

45%) are common haematological side effects. Non-haematological toxicities include periorbital edema (60%-75%), diarrhoea (45%-55%) and fatigue (50%). Other side effects (20%-40%) are nausea, muscle cramps, leg edema, anorexia and rashes. Most patients develop tolerance for these side effects on continuous use. Therefore, patient's education about occurrence of these common side effects and advice against interrupting treatment due to these side effects is of paramount value before starting Imatinib mesylate. Previous trials have reported a higher frequency of Grade 3 or more toxicities in high dose 800 mg/d (50%-60%) compared to conventional 400 mg/d Imatinib therapy (50%-60% vs 30%-40%)^[18-20,41]. Common side-effects seen with Sunitinib therapy include fatigue (34%), diarrhoea (29%) and skin discolouration (25%); other less-common side effects are hematological toxicity (anaemia and leukopenia), hand-foot syndrome, hypertension,

and hypothyroidism^[25]. Toxicity profile of Regorafenib includes hand-foot skin reactions (56%), hypertension (49%) and diarrhoea (40%)^[29].

DRUG RESISTANCE

In GIST patients on Imatinib, resistance can be primary or secondary. Primary (intrinsic) resistance is seen in approximately 15% patients and is due to mutations such as D842V in PDGFRA and KIT exon 9, where Imatinib is not able to bind on ATP binding site of tyrosine kinase receptor^[12,25]. Secondary (acquired) resistance usually develops after 18-24 mo of treatment. A number of mechanisms have been put forward for secondary (acquired) resistance in GISTs: Occurrence of a second mutation in KIT receptor, other gene mutations, *KIT* genomic amplification and activation of an alternative receptor tyrosine kinase protein in the absence of *KIT* expression, increased serum acid glycoprotein levels and increased multidrug resistance gene expression, lower bioavailability of Imatinib during chronic therapy possibly due to up-regulation of hepatic enzymes responsible for drug clearance, and impaired drug delivery due to formation of fibrous stroma. More than 80% of patients on treatment ultimately develop secondary resistance^[16,42]. Based on the results of previous trials, the dose of Imatinib can be increased from 400 mg to 800 mg to overcome problem of resistance; however, median time of benefit with this approach is short (11.6 wk)^[16]. Like Imatinib, Sunitinib also binds to ATP binding domain of KIT and PDGFRA, but both these agents have different binding domains. Moreover, Sunitinib also has anti-angiogenesis activities and is now approved as a second-line targeted therapy in Imatinib resistant cases^[25]. However, subsequent drug resistance to Sunitinib evolves within one year due to secondary mutations. Regorafenib is approved as a third line targeted therapy in this setting^[28].

FUTURE DIRECTIONS

Although three lines of targeted therapy are present, failure to respond to Regorafenib leaves us with no further standard options. Usual strategy in this sitting is to re-challenge with previously used therapy. Further studies are needed to address this problem of TKI resistance. Various new targeted agents are under evaluation for Imatinib resistant GISTs. Masitinib, a multi-kinase inhibitor, is under evaluation as a second-line therapy in comparison to Sunitinib. Initial results are promising and a phase III RCT is recruiting patients^[30]. Ponatinib is another multi-kinase inhibitor which was studied in CML, and now its role is being evaluated for GISTs^[43-45]. Crenolanib is an inhibitor of Imatinib resistant PDGFRA kinases including D842V in GIST patients; a phase II trial has been initiated to treat this population^[46]. Inhibitors of downstream pathway kinases (PI3K and MAPK) are under evaluation^[47,48]. Heat shock protein (HSP) protects KIT oncoproteins from degradation and agents targeting

HSP 90 are under investigation for Imatinib resistant GISTs^[49]. Many new targeted agents are under evaluation to overcome the Imatinib resistance; further research will clear the air regarding their clinical application.

CONCLUSION

Application of Imatinib revolutionized the management of GISTs, and soon after its introduction, it became the standard of care in metastatic GISTs due to its promising activity in improving PFS and OS. Use of Imatinib in adjuvant setting leads to decreased postoperative recurrences and improved survival, though presently, it is only recommended for high-risk cases. Role of Imatinib in neoadjuvant settings is increasingly being explored to escalate resection rates in locally advanced GISTs. Drug resistance is a major concern with TKIs. Intense molecular research is underway to identify other pathways of drug resistance and to develop newer targeted agents.

Abstract

Serum albumin has traditionally been used as a quantitative measure of a patient's nutritional status because of its availability and low cost. While malnutrition has a clear definition within both the American

and European Societies for Parenteral and Enteral Nutrition clinical guidelines, individual surgeons often determine nutritional status anecdotally. Preoperative albumin level has been shown to be the best predictor of mortality after colorectal cancer surgery. Specifically in colorectal surgical patients, hypoalbuminemia significantly increases the length of hospital stay, rates of surgical site infections, enterocutaneous fistula risk, and deep vein thrombosis formation. The delay of surgical procedures to allow for preoperative correction of albumin levels in hypoalbuminemic patients has been shown to improve the morbidity and mortality in patients with severe nutritional risk. The importance of preoperative albumin levels and the patient's chronic inflammatory state on the postoperative morbidity and mortality has led to the development of a variety of surgical scoring systems to predict outcomes efficiently. This review attempts to provide a systematic overview of albumin and its role and implications in colorectal surgery.

Core tip: Although albumin remains a flawed marker of nutrition, it offers clear prognostic value in predicting patient outcomes after colorectal surgery. Hypoalbuminemia significantly influences the length of hospital stay, rates of surgical site infections, enterocutaneous fistula risk, and deep vein thrombosis formation. Despite the fact that hypoalbuminemia is classically defined < 3.0 g/dL, clinical judgment must account for albumin levels ≤ 3.4 g/dL as even modest hypoalbuminemia can affect outcomes. The subjective global assessment, modified Glasgow Prognostic Score, and Colorectal preoperative Surgical Score scoring systems provide convenient and valuable prognostic information that may help in the

counseling and risk adjustment of patients undergoing colorectal surgery.

INTRODUCTION

Albumin is a single polypeptide responsible for five main functions: (1) maintenance of colloid osmotic pressure; (2) binding and transport of solutes; (3) free radical scavenging; (4) platelet function inhibition and antithrombotic effect; and (5) beneficial effects on vascular permeability in the setting of shock and sepsis^[1]. Albumin is a major source of sulfhydryl groups, which sequester both leukotoxin and nitric oxide, limiting vascular permeability and dilation respectively. Serum albumin has traditionally been used as a quantitative measure of a patient's nutritional status because of its ready availability and low cost. The reliability of albumin as an assessment of malnutrition is controversial because hypoalbuminemia is an acute phase reactant and is affected by systemic inflammation^[2]. The increased demand for specific amino acids for acute phase protein synthesis degrades available body protein, including albumin^[3-5]. Therefore, nutritional status is often determined anecdotally by individual care providers based on their own clinical experience and judgment in clinical practice. In this review, we cover in-depth the clinical indications and implications of serum albumin levels in the setting of colorectal surgery. We investigate the correlation between albumin and postoperative complications, inflammatory bowel disease (IBD) treatment, nutritional response, and new prognostic models.

LITERATURE RESEARCH

We performed a systematic literature review through an electronic search of MEDLINE from PubMed and the Cochrane Library until May 2015. We used the following search terms and associations: Albumin, hypoalbuminemia, serum protein, nutrition, malnutrition, colorectal surgery, gastrointestinal (GI) surgery, complications, and mortality. Articles were assessed in a tiered fashion. We first screened the titles, assessed abstracts for relevance, then analyzed the entire text of the papers. Only papers in the English language were included. After removing duplicates, 379 total records were found, 339 of which were in English. Thirty-five articles remained after screening and their full texts were analyzed. We completed our search by visiting the bibliographies of relevant articles.

HYPOALBUMINEMIA IN SURGICAL PATIENTS

In the early 1950's, hypoalbuminemia was noted to negatively influence postoperative recovery^[6,7]. This finding was followed by work from Harvey who reported that a low serum albumin was the best indicator of concurrent sepsis^[8]. A high incidence of malnutrition in the hospital setting was only first described in 1974 by Banh^[9] and Butterworth^[10]. Contemporary data currently shows that malnutrition has a prevalence of 30% to 50% in hospitalized patients, and is one of the most important patient outcome determinants, affecting length of hospitalization, cost, morbidity, and ultimately mortality^[11,12]. Most notably, hypoalbuminemia is associated with poor tissue healing, decreased collagen synthesis, and granuloma formation in surgical wounds, ultimately delaying wound healing^[13-17]. Serum albumin levels have traditionally been used as a biochemical marker of individual nutritional status prior to surgery. It is regarded as an accurate preoperative prognostic indicator in a variety of surgical procedures including cardiac^[18], trauma^[19], and general surgery^[6,20-22]. This was perhaps best illustrated in a large-scale non-randomized retrospective study using the National Veteran's Affairs Surgical Database of 54215 patients from 44 tertiary care centers by Gibbs *et al.*^[23] on major non-cardiac surgeries. Thirty-day morbidity and mortality were measured by C-index (C) where a value of 0.0-0.5 indicates any association between variables are likely due to chance, and C of 0.5-1.0 indicates a strong predictive value or correlation^[24]. Univariate analysis revealed that albumin < 3.5 g/dL was the strongest preoperative predictor of both 30-d morbidity (C = 0.68) and mortality (C = 0.78), just ahead of American Society of Anesthesiology class. Furthermore, multivariate analysis showed that albumin levels were the strongest predictor of both morbidity [odds ratio (OR) = 0.68; 95%CI: 0.56-0.60] and mortality (OR = 0.44; 95%CI: 0.41-0.48). Albumin levels also independently predicted complication rates of systemic sepsis, acute renal failure, coma, failure to wean from ventilation, and bleeding/transfusions amongst 16 other complications (C = 0.78, 0.76, 0.76, 0.75, 0.72 respectively; all *P* < 0.001). Additionally, analysis of preoperative albumin and major post operative complications in 2003 by Kudsk *et al.*^[25] identified clinical hypoalbuminemia as an independent determinant of hospital stay, serious postoperative complications (albumin < 4.25 g/dL), and mortality (albumin < 3.25 g/dL).

On the other hand, an ongoing debate continues to exist regarding the value of albumin as a clinical marker of malnutrition. There is no clear consensus amongst healthcare professionals about the definition of malnutrition. Suggested markers include albumin and prealbumin, which are widely used today, and transferrin and retinol binding protein, which are newer evolving

nutritional markers^[9]. Recent studies have attempted to dispel several myths regarding malnutrition. Albumin and prealbumin have historically been touted as indicators of nutritional risk in the hospital setting, however early literature was based off subjective data and the underlying assumption that albumin and prealbumin accurately reflected nutritional status^[26-28]. Golden previously showed that kwashiorkor was caused by lack of antioxidants, not dietary proteins^[29] and in a small study by Carlson *et al.*^[30] of 10 military burn patients, no correlation was found between nitrogen balance and albumin level, further dispelling serum protein beliefs. A retrospective study of all nutrition consults within 2 years totaling 528 patients suggested that patients' underlying acute or chronic conditions, not nourishment, was responsible for the changes in perioperative albumin^[8]. Despite this mounting evidence, consensus exists that although albumin may be a poor marker of nutrition, hypoalbuminemia offers clear prognostic value in predicting surgical outcomes^[26,31].

HYPOALBUMINEMIA AND COLORECTAL SURGERY

Despite the growing fund of research surrounding albumin status in general surgery patients, colorectal surgery maintains a unique relationship with nutritional status and albumin level. Colorectal surgery patients are often malnourished due to advanced malignancy or inflammatory bowel disease that results in poor oral intake, intestinal blockages, intestinal fistulas, poor absorptive capacity, and large volume losses from the GI tract^[32]. Kudsk *et al.*^[25] emphasized the potential for bias if the surgical site is not considered. Malnutrition is observed in up to 80% of patients with advanced colorectal cancer putting them at increased risk for postoperative complications^[33-35]. Burden *et al.*^[36] showed that 1 in 5 pre-operative colorectal cancer patients undergoing surgery were malnourished when measuring body weight (weight loss > 10%) and had a significantly lower handgrip strength ($P = 0.013$), a measure of nutritional status^[37]. Hypoalbuminemia has also been associated with delayed recovery of postoperative bowel function, further worsening postoperative nutritional recovery^[38]. Preoperative albumin levels have been shown to be the best predictor of mortality after colorectal cancer surgery^[12,39]. It is important to concede that the current research surrounding albumin levels is limited and heterogeneous; each study uses different qualifications and methods. Below is a review of the current literature surrounding hypoalbuminemia and its relationship to colorectal surgery.

COMPLICATIONS

Although the classic definition for hypoalbuminemia is < 3.0 g/dL, studies' definitions vary widely from < 2.7 in some studies to < 3.5 g/dL in others^[12,40,41]. Using

the American College of Surgeons National Quality Improvement Program (NSQIP) database to measure 30-d postoperative surgical outcomes, Moghadamyeghaneh *et al.*^[12] emphasized the effect of modest hypoalbuminemia as defined by serum albumin levels between 3.0 and 3.4 g/dL. The mortality rate in patients with modest hypoalbuminemia and without hypoalbuminemia was 6% and 1.7% respectively, and the morbidity risk was greater as well [adjusted odds ratio (AOR) = 1.876; 95%CI: 1.51-2.05; $P < 0.01$]. Not surprisingly, the highest morbidity (60.4%) and mortality (26.2%) rates occurred at serum albumin levels lower than 2 g/dL. Additionally, this study showed a linear correlation between albumin level and postoperative mortality, meaning any decrease in serum albumin level from the normal value (> 4 g/dL) had serious effects on the outcomes following colorectal resections. The rate of increase in mortality and morbidity was estimated to be approximately 49% and 24% respectively for each 1 g/dL decrease in albumin level ($P < 0.05$). Colon cancer patients had a higher rate of modest hypoalbuminemia compared to rectal cancer patients (AOR = 1.55; $P < 0.01$).

HOSPITAL STAY

Two studies published in 2010 evaluated the association between albumin level and length of hospital stay. Using a cohort of 95 patients admitted for either upper GI surgery or colorectal surgery over a 19-mo period in Australia, Garth *et al.*^[11] showed that preoperative albumin level was linear and inversely related to the length of hospital stay ($R = -0.325$; $P < 0.01$). Interestingly, grouped analysis revealed upper GI patients presented with significantly lower albumin than colorectal patients. Thirty-one percent of the upper GI group had albumin levels < 3.5 g/dL vs 14% of the colorectal group ($P < 0.05$). Hennessey *et al.*^[16] showed that an albumin level < 3.0 g/dL was associated with prolonged inpatient stay with a negative linear relationship (19.5 d vs 12 d; $P < 0.001$; $R^2 = -0.319$; $P < 0.001$). Additionally, in 2014 a compilation of 108,898 patients, the largest sample to date of hypoalbuminemic colorectal surgery patients by Moghadamyeghaneh *et al.*^[12] showed that the median length of stay after surgery was an average of 2 d longer in patients with even modest hypoalbuminemia (albumin 3.0-3.4 g/dL) compared to patients with serum albumin > 3.4 g/dL (95%CI: 1.83-2.34; $P < 0.01$). A study from Thailand showed that an albumin level < 3.5 g/dL increased the length of hospital stay from 6.8 ± 2.6 to 9.6 ± 4.7 d ($P = 0.001$)^[38].

ILEUS

Postoperative bowel function is a major determinant of the length of hospital stay and nutritional recovery of a patient. A key retrospective study of 80 patients undergoing right hemicolectomy by Lohsiriwat *et al.*^[38] showed that an albumin level < 3.5 g/dL compared to

an albumin > 3.5 g/dL was associated with increased postoperative complications (0 and 14 respectively; $P < 0.001$), time to first bowel movement (55.3 and 69.5 h respectively; $P = 0.018$), and time to resume a normal diet (4.0 to 4.9 d respectively; $P < 0.001$). In multivariate analysis, only delayed time to first bowel movement was associated with preoperative hypoalbuminemia. Similarly, Millan *et al.*^[42] showed that albumin levels < 35 mg/dL were significantly associated with postoperative ileus ($P = 0.042$) in a retrospective study of 773 patients. Kronberg *et al.*^[43] also showed in a study of 413 patients that preoperative serum albumin concentration was lower in patients who developed postoperative ileus (3.83 mg/dL vs 4.09 mg/dL; $P = 0.039$; OR = 0.90). Prolonged postoperative ileus symptoms include nausea and vomiting, inability to tolerate an oral diet, abdominal distention, and delayed passage of flatus and stool^[44,45]. Decreasing preoperative albumin was a predictor for prolonged postoperative ileus (OR = 1.11 per gram per litre unit change; 95%CI: 1.02-1.22; $P = 0.047$)^[46].

SURGICAL SITE INFECTION

A study of 524 patients undergoing GI surgery [of which 339 (64%) underwent colorectal surgery] in 4 institutions in Ireland showed that patients who developed a surgical site infection had a lower median preoperative serum albumin than those who did not develop an infection, 3.0 g/dL and 3.6 g/dL respectively ($P < 0.001$)^[16]. One hundred and thirty-eight patients (26.3%) had a low pre-operative albumin level (< 3.0 g/dL) and were found to be at increased risk for severe surgical site infections. Of the patients developing a superficial wound infection, 46.4% had a low albumin level ($P = 0.001$). In those with deep wound infections, 80% had low albumin levels ($P = 0.004$), and in those with organ space infection, 83.3% had low albumin levels ($P = 0.397$).

FISTULAS

Enteric or enterocutaneous fistulas are abnormal communications between the gastrointestinal tract to another cavity or through the skin respectively. Although uncommon, they are a significant concern within colorectal surgery due to their relatively high incidence and considerable morbidity and mortality, first described in a classic case study of 157 patients in 1960^[47-49]. An estimated 75%-85% of enterocutaneous fistulas are postoperative complications following bowel injury *via* inadvertent enterotomy and/or anastomotic leakage^[50] and 30%-80% eventually require surgical treatment despite advances in medical treatment^[51-53].

Not surprisingly, serum albumin level has been shown to be a vital prognostic factor of healing enteric fistulas^[49,54]. In a retrospective chart review of 53 GI cancer patients with postoperative enteric fistula complications, Lu *et al.*^[49] showed a significant corre-

lation between enteric fistula healing/recovery and an increased serum albumin level ($P = 0.029$) and lower fistula drainage amount (< 500 mL/d) ($P = 0.013$) after multivariate analysis. Additionally, amongst patients with both increasing albumin levels and < 500 mL/d of fistula drainage, over 90% of fistulas fully resolved with conservative therapy after total parenteral nutrition (TPN)^[49,55]. However, although TPN nutritional support has been shown to aid recovery, careful monitoring for underlying or uncontrolled sepsis is required as patients are prone to rapidly deteriorate^[52].

Once it is obvious that operative repair is unavoidable, the decision between early surgical fistula treatment vs initial nutritional support with delayed surgery is a difficult one. In a report of 135 consecutive patients with enterocutaneous fistulas by Visschers *et al.*^[53,56] hypoalbuminemic patients failed to recover well after restorative surgery. Patients with an albumin level below 2.5 g/dL continued to show signs of inflammation postoperatively despite being treated for infection, which lead to eventual deterioration and death in the majority (17/25; 68%) of patients while those who had albumin > 2.5 g/dL had lower mortality (8/25; 32%). Operative fistula repair in hypoalbuminemic patients is therefore recommended only after a nutritive recovery period of at least 6 wk.

DEEP VEIN THROMBOSIS/PULMONARY EMBOLISM

There is limited data regarding the predictive factors of postoperative venous thromboembolism in patients undergoing colorectal resection. Using data from the large national NSQIP database from 2005 to 2011, Moghadamyeghaneh *et al.*^[41] showed that a serum albumin < 3.5 mg/dL significantly increased the risk of developing a postoperative deep vein thrombosis (DVT) (AOR = 1.69; 95%CI: 1.49-1.93; $P < 0.01$). Additionally, hypoalbuminemia was also associated with an increased risk of pulmonary embolism (PE) (AOR = 1.21; 95%CI: 1.02-1.42; $P < 0.02$) although the strongest risk factor for PE was not surprisingly a DVT.

INFLAMMATORY BOWEL DISEASE AND HYPOALBUMINEMIA

Inflammatory bowel disease is broadly classified into two variants, ulcerative colitis (UC) and Crohn's disease (CD). The mainstay of UC and CD therapy is medical management, however up to 1/3 of Crohn's patients will undergo abdominal surgery within the first 5 years of diagnosis^[57]. In CD, hypoalbuminemia has been shown to be a predictor of intraabdominal septic complications after intestinal anastomosis by Yamamoto *et al.*^[58] in a retrospective chart review of 343 patients undergoing 1008 intestinal anastomoses between 1980 and 1997. In this study, albumin levels < 3.0 g/dL were considered hypoalbuminemic and significantly affected

the incidence of intra-abdominal sepsis in univariate and multivariate analysis with *P* values of 0.01 and 0.04 respectively. Intraabdominal sepsis occurred in 21% of patients with hypoalbuminemia in contrast to 12% in those without. If all significant risk factors in this study (hypoalbuminemia, steroid use at least one month immediately before surgery, and abscess or fistula at the time of laparotomy) were present, the incidence of sepsis reached 50%. Because reoperations for early postoperative complications were not included in this study, the impact of serious postoperative or refractory hypoalbuminemia could not be assessed.

Intraabdominal sepsis and delayed wound healing are significant consequences of hypoalbuminemia in IBD patients^[59]. For these reasons, ileal pouch anal anastomosis (IPAA), the treatment of choice for UC, has traditionally been avoided due to the large number of suture or staple lines and wide pelvic dissection in malnourished patients^[60,61]. An 8-year single-institution prospective study identifying 405 patients showed that an albumin level < 3.5 g/dL was significantly associated with IPAA pouch failure within 30 d to 10 years, development of anastomotic leak, postoperative transfusion, and prolonged inpatient stay using univariate analysis^[62]. Multivariate analysis revealed preoperative hypoalbuminemia as a strong predictor for anastomotic leak and prolonged median length of stay after pouch surgery, which was 60% longer than in patients with normal albumin levels.

Because of the high complication rate of pouch creation in IBD patients, a staged operation is favored. Nisar *et al*^[62] showed that hypoalbuminemic patients with IBD who underwent a single-stage total proctocolectomy (TPC) with concurrent pouch creation had a significantly longer inpatient stay and increased postoperative transfusion requirements compared to two-stage subtotal colectomy (STC) with subsequent completion proctocolectomy and IPAA. A higher risk of anastomotic leak in hypoalbuminemic patients was found in single-stage TPC and IPAA (22%) compared to initial STC with follow-up completion proctectomy and IPAA (11%). However, the sample only comprised 24 TPC patients and 10 with STC. Interestingly, this study was one of very few which analyzed serum albumin levels as a continuous variable and thus found that the improvement in albumin between the time of STC and IPAA correlated significantly with the baseline albumin ($R^2 = 0.814$), ($P < 0.0001$).

In a retrospective case series of 78 patients with CD but without hypoalbuminemia, Zerbib *et al*^[63] showed that weaning steroids and applying enteral nutrition at > 30 kcal/kg ideal body weight/day in intestinal non-occluded patients or TPN in patients with intestinal occlusion together with abscess drainage and antibiotic therapy for 2-3 wk preoperatively minimized the usage of a temporary diverting stoma [7.7% (6/78) of patients] while achieving uneventful operative outcomes in 58% of the total patients. This rate of diverting stoma utilization was significantly lower than a previously

reported series for penetrating CD by Goyer *et al*^[64] who reported a rate of 39%. This suggests a strong correlation between preoperative nutrition and Crohn's disease surgical outcomes.

PREOPERATIVE TREATMENT OF HYPOALBUMINEMIA

While the deleterious effects of hypoalbuminemia on the rate of postoperative complications have been well established, pre-surgical correction of hypoalbuminemia remains a subject of debate. While some believe a low albumin level indicates malnutrition, others postulate that the hypoalbuminemia stems from the chronic disease state and resultant inflammation and is not due to malnutrition, thus hindering any beneficial effects of nutritional therapy^[3]. Although enteral and parenteral nutrition have been shown to improve outcomes in malnourished patients undergoing major elective surgery^[65], preoperative nutrition not been well studied in populations undergoing colorectal surgery. The consensus is to stabilize baseline nutritional status and to administer enteral or parenteral nutrition to severely hypoalbuminemic patients preoperatively, even if a delay in surgery is necessary.

In 1982, a study by Rombeau *et al*^[66] of 33 consecutive IBD patients demonstrated that preoperative TPN given for at least 5 d resulted in significantly fewer postoperative complications ($P < 0.05$). All patients had an albumin < 3.5 g/dL or a transferrin level < 150 mg/dL. In a case series by Jacobson, 15 consecutive CD patients given preoperative TPN were compared to 105 control patients matched for known postoperative complication factors^[67]. TPN was given between 18 and 90 (avg = 46) d preoperatively before undergoing intestinal resection with primary hand-sewn anastomoses. In this study the average albumin level was significantly increased from 3.4 to 3.9 g/dL ($P < 0.01$) through TPN. There was a significantly higher rate of complications in the non-TPN group (29/105) compared to the TPN group (0/15) ($P < 0.05$). Although the TPN group was without postoperative complications, the risk of preoperative complications should be recognized. In the TPN group, repeated central venous catheter thromboses requiring up to 5 replacements occurred in 4 patients and a pneumothorax which resolved after 5 d of evacuation occurred in one other patient.

Lashner *et al*^[68] further quantified the significance of preoperative TPN. In a retrospective single-center/single-surgical team study of 103 CD patients, preoperative TPN was only beneficial to CD patients by reducing the length of bowel resection during small bowel resection by more than 20 cm ($P < 0.04$). There was no difference in complication rates. During ileocectomy, TPN patients had a shorter resection by approximately 11 cm when compared to non-TPN patients ($P < 0.02$). However, it appears that the cost of shorter bowel resections in TPN patients was longer hospital stays (12 d; $P < 0.001$). Although this study included patients undergoing

large bowel resection, none of them received preoperative TPN. In this study, TPN was given between 5-7 d and administration > 10 d was not recommended. In contrast, the European Society for Clinical Nutrition and Metabolism guidelines state that if a severe nutritional risk is present, preoperative nutrition therapy, if possible, by enteral route for 10-14 d before surgery is recommended even if the surgery has to be delayed^[69]. Additionally, Visschers *et al.*^[53] recommended delaying enterocutaneous fistula repair at least 6 wk to stabilize baseline nutritional status in severely malnourished patients.

NEW COLORECTAL SURGERY SCORING SYSTEMS

Broad efforts have been made to use albumin levels together with other clinical markers to create a scoring system predicting postoperative morbidity or mortality. The Subjective Global Assessment (SGA) scale combines both subjective aspects of the patient's history such as gastrointestinal symptoms and dietary change and objective aspects such as ankle edema, albumin levels, and tumor grade^[70]. The SGA stratifies patients into A, B and C categories yielding significant differences in median survival in their cohort of 235 patients (log rank 13.36; $P = 0.0013$). The SGA provides useful prognostic information in patients with advanced colorectal cancer and may identify malnourished patients quickly but suffers due to the inclusion of subjective measures exposing it to observer bias.

The modified Glasgow Prognostic Score (mGPS) ranges from 0-2 and is composed of C-reactive protein (CRP) and albumin levels. mGPS was shown by Park *et al.*^[71] in a retrospective single-center study to tightly correlate with overall survival (OS) in patients undergoing elective resection of colon cancer ($P < 0.001$). When mGPS and tumor-node-metastasis (TNM) staging were combined, they effectively stratified outcomes of patients undergoing potentially curative resection of colorectal cancer. A TNM stage I /mGPS = 0 yielded a 5-year cancer specific survival (CSS) and overall survival of 97% and 87% respectively; whereas a TNM stage III /mGPS = 2 exhibited a 5-year CSS and OS of 32% and 26% respectively ($P < 0.001$). Additionally, the mGPS stratified the survival of patients who received adjuvant chemotherapy after resection of stage III colon cancer. Patients with mGPS = 0 had a 50% relative increase in survival at 5 years with adjuvant therapy, whereas those with mGPS = 1-2 received no benefit ($P = 0.003$). The mGPS provides important prognostic information in patients undergoing colorectal resections and can help guide adjuvant therapy, especially when combined together with TNM staging.

The Colorectal preoperative Surgical Score (CrOSS) was proposed by Kong *et al.*^[39] in 2015 as a response to other scoring systems, which require postoperative variables or may be too complex or difficult to assess

at the patient's bedside. Their multivariate logistic regression analysis of 46 variables yielded 4 independent predictors for mortality following colorectal surgery: Age ≥ 70 , urgent surgery, albumin level ≤ 3.0 g/dL, and congestive heart failure, together composing the CrOSS score. CrOSS accurately predicted mortality with a receiver operating characteristic (ROC) of 0.870 and calibration P -value of 0.937. The score was internally and externally validated to the Portsmouth and Colorectal Physiological and Operative Severity Score for enUmeration of Mortality and Morbidity and the 2012 Barwon Health model (ROC = 0.788, $P = 0.24$). CrOSS offers a simple yet robust preoperative risk stratification model, specifically tested in colorectal surgery.

NEW MARKERS FOR MALNUTRITION AND INFLAMMATION

Although albumin remains the widest studied marker for malnutrition, several other markers have been proposed to aid perioperative assessment of a colorectal surgery patient. Prealbumin, transferrin and retinol binding protein are considered traditional markers of nutrition; however, recent data demonstrates their poor relationship to nutrition status^[9]. Because the markers for a patient's nutrition status are often negative acute-phase reactants, efforts have been made to quantify a patient's inflammatory status as an indirect measure of nutrition and postoperative morbidity and mortality.

In 2012, Oberhofer *et al.*^[72] showed an increase in CRP in the early postoperative period after colorectal surgery was correlated with a significant increase in complication rates ($P < 0.001$), which agreed with Welsch *et al.*^[73] who demonstrated that CRP values greater than 140 mg/L on postoperative day 3 or 4 predicted infectious complications and anastomotic leaks after colorectal surgery. Conversely, preoperative CRP levels were not correlated with postoperative complication incidence. Oberhofer *et al.*^[72] also concluded that postoperative procalcitonin increased significantly more in patients with postoperative complications than those patients without complications, with the highest predictive value on postoperative day 5 ($P < 0.001$). Procalcitonin is also a reliable laboratory marker for early diagnosis of surgical site infection and sepsis after colorectal cancer surgery ($P < 0.001$)^[74,75].

Prealbumin (PAB), also known as transthyretin, is a visceral protein and a negative acute phase reactant similar to albumin. PAB's advantage over albumin is its shorter half-life (2-3 d), thus it may be more useful for detecting acute changes in nutritional status. However, similar to albumin, PAB has been shown to be a poor marker of nutritional status as evidenced by studies of extreme cases of starvation, which fail to show consistent or reversible decreases in PAB levels^[9,76,77]. In addition, PAB has been shown to be inferior to albumin as a predictor of colon cancer recurrence. A study of 158 patients with operable colorectal carcinoma in Japan,

56 patients (35.4%) with decreased preoperative PAB and 15 patients (9.5%) with decreased preoperative albumin levels, showed that both a low preoperative serum PAB and albumin were associated with early disease recurrence ($P = 0.0005$ and $P = 0.0002$ respectively)^[78]. However, only albumin maintained its significance in multivariate analysis ($P = 0.048$) while PAB lost significance, indicating that only albumin is an independent predictor of early colorectal carcinoma recurrence.

Additionally, interleukin-6 has recently been shown to correlate with more advanced colorectal cancer^[79] and was found to cause reactive thrombocytosis, upregulation of CRP, and downregulation of albumin production by the liver, all processes of acute inflammation^[80]. Preoperative thrombocytosis with a platelet count greater than $300 \times 10^9/L$ was related to overall survival in multivariate analysis ($P = 0.039$; OR = 1.642; 95%CI: 1.025-2.629)^[81].

Recent studies demonstrate positive survival outcomes after colorectal surgery by targeting the systemic inflammatory response with anti-inflammatory agents such as broad-spectrum nonsteroidal anti-inflammatory drugs or aspirin^[82,83]. Adequate dietary habits are also associated with both decreased colorectal cancer risk and postoperative outcomes. Increased marine n-3 polyunsaturated fatty acids consumption was protective against postoperative complications after colorectal cancer surgery^[84-86].

CONCLUSION

Although albumin remains a flawed marker of nutrition, it offers clear prognostic value in predicting patient outcomes after colorectal surgery. Hypoalbuminemia significantly influences the length of hospital stay and complication rates, specifically surgical site infection, enterocutaneous fistula, and DVT formation. However, these studies are mostly small-cohort non-randomized retrospective studies or large scale studies using national data bases and this topic would benefit from further study. Although clinical hypoalbuminemia is classically defined as serum concentrations < 3.0 g/dL, clinical judgment must account for albumin levels ≤ 3.4 g/dL as even modest hypoalbuminemia can affect outcomes. Surgical delay for preoperative nutrition has been shown to improve the morbidity and mortality in patients with severe nutritional risk. Hypoalbuminemic patients may benefit from a staged colorectal resection vs a single operation, especially in the setting of IBD. Efforts to quantify a patient's nutritional status indirectly with inflammatory markers show promise, but the data is superficial and overall inferior to albumin. However, addressing systemic inflammation with anti-inflammatory agents has demonstrated positive survival outcomes in pilot studies. How these developing new markers will be used in combination with albumin is an interesting frontier, meanwhile the SGA, mGPS, and cROSS scoring systems provide convenient and valuable

prognostic information that may help in the counseling and risk adjustment of patients undergoing colorectal surgery.

Abstract

Anti-tumour necrosis factor (TNF)- α therapy has revolutionized inflammatory bowel disease (IBD) treatment. Infliximab and adalimumab either as monotherapy or in combination with an immunomodulator are able to induce clinical and biological remission in patients with moderate and severe Crohn's disease (CD) and ulcerative colitis (UC). These new therapies have led to a shift in the goals of IBD management from just

controlling clinical symptoms to preventing disease progression. However, despite these advances in medical therapy, surgery is still required in 30%-40% of patients with CD and 20%-30% of patients with UC at some point during their lifetime. While biologics certainly play a major role in the medical treatment of IBD, there is concern about the effects of these anti-TNF- α agents on postoperative complications and morbidity. The purpose of this article is to review the role of surgery in the treatment of IBD in the age of biologics and the impact of these medications on per-operative outcomes. In this manuscript we review the relationship between biologic agents and surgery in the treatment of IBD. We also discuss in detail the perioperative risks and complications.

Key words: Inflammatory bowel disease; Anti-tumour necrosis factor alpha agents; Ulcerative colitis; Crohn's disease; Infliximab

INTRODUCTION

Anti-tumour necrosis factor (TNF)- α therapy has revolutionized inflammatory bowel disease (IBD) treatment. Infliximab (IFX) and adalimumab (ADA) either as monotherapy or in combination with an immuno-

modulator are able to induce clinical and biological remission in patients with moderate and severe Crohn's disease (CD)^[1-6] and ulcerative colitis (UC)^[7,8]. These new therapies have led to a shift in the goals of IBD management from just controlling clinical symptoms to preventing disease progression.

The concept of composite or deep remission based on clinical and biological remission and mucosal healing has recently emerged. The ability to achieve composite remission seems to be correlated with better long-term outcomes, improved quality of life, and fewer surgical operations^[6].

However, despite these advances in medical therapy, surgery is still required in 30%-40% of patients with CD and 20%-30% of patients with UC at some point during their lifetime^[9,10]. In CD patients, the risk for surgery seems to be related to stenosing phenotype, perianal disease, smoking, younger age at diagnosis, and delay in biologic therapy^[11]. Surgery in patients with CD is not curative but is necessary when medical therapy is unable to achieve symptomatic control. For patients with UC, surgery is curative and indicated for failure of medical management, acute complication including fulminant colitis, perforation, severe bleeding and toxic megacolon, and chronic conditions such as development of dysplasia or malignancy.

While biologics certainly play a major role in the medical treatment of IBD, there is concern about the effects of these anti-TNF- α agents on postoperative complications and morbidity. The purpose of this article is to review the role of surgery in the treatment of IBD in the age of anti-TNF- α agents and the impact of these medications on peri-operative outcomes.

CD

Luminal disease

Medical treatment for luminal CD focuses on the achievement of composite remission, which is best obtained through initiation of combination therapy with anti-TNF- α agents (IFX or ADA) and immunomodulators within 18-24 mo of diagnosis in patients with moderate to severe CD. Composite remission is correlated with fewer-hospitalization and CD-related surgeries and better quality of life. In the ACCENT I trial^[2] scheduled IFX was associated with a two-fold lower rate of surgery at 54 wk compared with on demand treatment (3% vs 7.5% respectively, $P = 0.01$). In the CHARM trial^[5] the rate of surgery at one year was 9 times lower in the group treated with ADA than in the placebo group (0.6% vs 3.8% respectively, $P = 0.001$).

However, despite improvements in medical management at least 30%-40% of patients with CD require surgery at some point during their lifetime^[9,10]. Schnitzler *et al.*^[12] found that of 614 patients treated with IFX, 24% had required major abdominal surgery at a median follow-up of 4.6 years. Peyrin-Biroulet *et al.*^[13] followed 296 patients diagnosed with CD and reported that 26% underwent at least one major abdominal surgical

procedure at a median follow-up of 57 mo. In addition, among patients treated with ADA as a second line therapy after IFX failure, the rate of surgical intervention was 18% at 130 wk^[14]. Given the continued role of surgery and the increasing use of biologic therapy in the management of CD, it is imperative to understand how these treatments influence each other.

Postoperative complications

Studies on the effect of biologic agents on postoperative complications have yielded conflicting results^[15-29]. Appau *et al.*^[15] analyzed 389 patients who underwent ileocolonic resection for CD, 60 patients had been treated with IFX within 3 mo of surgery and 329 patients had not. The IFX group appeared to have a higher rate of postoperative sepsis (20% vs 5.8%, $P = 0.021$), anastomotic leak (10% vs 1.4%, $P = 0.049$) and hospital readmission (20% vs 2.9%, $P = 0.007$).

On the contrary, a recent multicenter trial including 6 tertiary referral centers^[21] encompassing 298 patients with CD treated with IFX or ADA showed no differences in major or minor complications between patients who received biologics within 2 mo of surgery compared to patients who received biologics more than 2 mo before surgery. The rate of anastomotic leak was similar between the two groups, 7.2% in the biologic group and 8% in the non-biologic group ($P = 0.976$), and they concluded that the use of anti-TNF- α agents within 2 mo of surgery for CD with intestinal anastomosis did not increase the risk of anastomotic, infectious, or other complications. Canedo *et al.*^[17] studied 225 CD patients who underwent surgery and divided them into 3 categories based on exposure to IBD medications within 90 d of surgery: IFX, other drugs including steroids and/or immunosuppressive agents (OD), and no drugs (ND). Ileocolonic resection was the most common procedure followed by total colectomy and proctectomy. Laparoscopy was performed in 47.7%, 45.9% and 29.3% of patients in the IFX, OD and ND groups respectively ($P = 0.04$). There was no statistically significant difference in the incidence of intra-operative complications or length of hospital stay in the three groups. In addition rates of postoperative pneumonia ($P = 0.14$), wound infection ($P = 0.35$) and abscess ($P = 0.34$) were similar between the three groups. Anastomotic leak was reported in 5.7%, 6.66% and 2.43% of patients respectively for the IFX, OD and ND groups ($P = 0.39$).

Kasperek *et al.*^[22] recently analyzed their experience in 96 patients with CD of which 48 patients had received IFX within 3 mo of a Crohn's related abdominal surgery, with a median of 60 d (range 1-90 d) between the last IFX dose and surgery and compared them to a control group who had undergone abdominal surgery for CD without prior IFX treatment. They evaluated minor complications, including wound infections, urinary tract infections and paralytic ileus, and major complications such as anastomotic leak, intra-abdominal abscess, postoperative hemorrhage, small bowel enterocutaneous fistula, and death. There was a trend toward a greater

rate of anastomotic leaks and intra-abdominal abscesses in the control group (13% vs 4%, $P = 0.27$), but it did not reach statistical significance. Analysis of the interval between the last administered dose of IFX and surgery demonstrated no difference in complication rates. They recommended scheduling elective surgery halfway between infusions, 4 wk after IFX infusion assuming an 8-wk interval for maintenance therapy, and re-initiating IFX 4 wk post-operatively in the absence of complications.

We recently published our experience^[29] of 518 IBD patients, 143 treated with IFX within 12 wk of surgery (IFX group) and affected by CD (63), UC (71) and indeterminate colitis (8), and 376 not treated with biologics [non-IFX (NIFX) group]. Total abdominal colectomy followed by proctocolectomy and ileocolonic resection was the most frequent operations performed and all procedures were done laparoscopically. Operative time and blood loss were similar between the 2 groups ($P = 0.50$ and $P = 0.34$ respectively). In addition the incidence of infectious complications (12% vs 11.2%, $P = 0.92$), anastomotic leak (5.2% vs 2.9%, $P = 0.69$), and thrombotic complications (3.5% vs 5.6%, $P = 0.46$) was not statistically different between the IFX and NIFX groups. Subgroup analysis confirmed similar rates of overall, thromboembolic, anastomotic, and infections complications regardless of whether the patients had CD or UC.

With the emerging trend toward initiating biologic therapy early in the course of disease and a resultant increase in the proportion of patients on these agents pre-operatively, there has been increased debate regarding not only whether anti-TNF- α therapy needs to be discontinued prior to elective surgery but if so what the minimum interval should be between the last dose of the biologic agent and the surgery. Depending on individual metabolism, the half-life of IFX is 7-18 d^[28] and serum antibodies disappear at 3 mo.

In a series of 195 patients with IBD Waterman *et al*^[19] compared postoperative complications and infections between patients exposed to biologics (IFX or ADA) within 14 d, 15-31 d, and 31-180 d before surgery. Most of these patients receive concomitant thiopurine (double therapy) or thiopurine and corticosteroids (triple therapy). They found that biologic therapy alone was not associated with an increased rate of 30-d postoperative infectious complications, hospital stay, readmission, reoperation or anastomotic leak. However, combination therapy with thiopurine and biologics increased rates of postoperative complications including urinary tract infection, wound infection, bacteremia and the need for postoperative antibiotics. In addition, a shorter interval between the last dose of anti-TNF- α therapy and surgery did not increase postoperative complications. They concluded that it is not necessary to delay surgery until anti-TNF- α washout has been achieved. Several other recent trials have been demonstrated no correlation between overall postoperative infections or anastomotic leaks and the interval (ranging from 1-12 wk) between

last IFX administration and surgery^[17,21,22,29].

Postoperative recurrence

Several factors are related to recurrence: smoking, the *NOD2/CARD15* gene mutation, young age at diagnosis, short duration of disease prior to an operation and multiple sites of disease^[11,30-34]. Rate of recurrence may also be influenced also by surgical technique^[30,34] including the type of anastomosis, resection margin and the decision to perform a stricturoplasty vs a resection^[35]. The role of biologic therapy in reducing the incidence of surgical recurrence is yet unknown but we can infer the impact that anti-TNF- α agents may have based on mucosal healing. Early observational studies have demonstrated reduced rates in endoscopic and clinical recurrence in patients post-operatively treated with IFX^[36], Regueiro *et al*^[37] demonstrated in a placebo-controlled randomized trial that endoscopic recurrence was significantly lower in the IFX group compared to controls at 1 year (9.1% vs 84.6%, $P = 0.0006$) but the sample size was too small to detect differences in clinical recurrence. Yoshida *et al*^[38] also conducted a randomized control trial comparing IFX to placebo and found the clinical remission rate with IFX was 100% vs 68% in the placebo group ($P < 0.03$) at one year^[38].

Recently, Savarino *et al*^[39] published the results of a prospective randomized study in which 51 patients with CD who had undergone an ileocolonic resection were assigned to receive ADA at a dose of 160/80/40 mg every two weeks, azathioprine (AZA) at 2 mg/kg per day, or mesalamine at 3 g/d starting 2 wk after surgery. Patients were followed for 2 years. The rate of endoscopic recurrence was lower in the ADA group (6.3%) compared with both the AZA (64.7%; OR = 0.036; 95%CI: 0.004-0.347) and mesalamine groups (83.3%; OR = 0.013; 95%CI: 0.001-0.143). In addition patients in ADA arm had a lower rate of clinical recurrence (12.5%) compared with the AZA (64.7%; OR = 0.078; 95%CI: 0.013-0.464) and mesalamine groups (50%; OR = 0.143; 95%CI: 0.025-0.819).

The role of IFX in preventing relapse of CD after surgical resection is currently being evaluated in the multicentric randomized prevent trial^[40,41]. In this study, patients are post-operative assigned to receive either IFX or placebo. Patients in both groups are treated according to their treatment arm at week 0 and then every 8 wk through week 200. However if a patient initially randomized to the placebo group relapses, IFX therapy may be initiated. Data collection for this trial has been completed and the results are being awaited.

Perianal disease

Perianal CD (PCD) is considered an aggressive and disabling phenotype, which manifests in about 40% of patients diagnosed with CD. Quality of life is often compromised due to anal pain, discharge and fecal incontinence^[41]. Before the introduction of biologics, 40% of patients with PCD underwent proctectomy. Recently anti-TNF- α agents have been demonstrated

to induce and maintain perianal fistula closure in two randomized control trials^[42,43].

Perianal fistulas may be classified as simple if a single, low, transphincteric tract without abscess, stenosis or inflammation is present, or complex if there is more than one tract, granulomatous inflammation, presence of an abscess or it is rectovaginal^[44]. The majority of Crohn's patients experience complex fistulas during their disease course.
