Abstract

AIM: This study aimed to determine whether metabolic syndrome is directly or indirectly, through fatty liver, associated with elevated gamma-glutamyl transpeptidase (GGT) levels in Japanese women.

METHODS: From 4 366 women who received their annual health check-up, 4 211 women were selected for analysis. All 4 211 women were negative for both hepatitis B surface antigen and antibody to hepatitis C virus. Clinical and biochemical variables were examined by using univariate and multivariate analysis.

RESULTS: A raised GGT level (>68 IU/L) was seen in 258 (6.1%) of the 4 211 women. In univariate analysis, all variables examined (age, body mass index, blood pressure, hemoglobin concentration, fasting blood glucose, glycosylated hemoglobin A1c, cholesterol, triglyceride, and uric acid) were associated with the elevated GGT level, whereas in multivariate analysis, four variables (age 50 yr, hemoglobin 14 g/dL, triglyceride 150 mg/dL, and presence of diabetes) were significantly and independently associated with raised GGT level. Clinical variables predicting the presence of ultrasonographic evidence of fatty liver were also examined by multivariate analysis; four variables were associated with the presence of fatty liver: BMI 25 kg/m^2, hemoglobin 14 g/dL, triglyceride 150 mg/dL, and uric acid 7 mg/dL. There was no significant association between the raised GGT level and the presence of fatty liver. Hypertriglyceridemia was significantly and independently associated with both the raised GGT level and the presence of fatty liver.

CONCLUSION: Metabolic syndrome seemed to be directly, not indirectly through fatty liver, associated with the raised GGT level in Japanese women.

INTRODUCTION

The prevalence of overweight persons is increasing in developed and developing countries[1-3]. Obesity is strongly associated with insulin resistance[4-6], which is known to be associated with an elevated gamma-glutamyl transpeptidase (GGT) level[7,8]. However, the mechanism of the relationship between insulin resistance and GGT elevation has not yet been clarified. Metabolic syndrome is associated with insulin resistant status[4-6], and is increasing recently in Japan together with an increase in the prevalence of obesity[2]. It is well known that insulin resistance is associated with fatty liver[9,10]. Furthermore, fatty liver is associated with elevated GGT levels[8]. Hence, the following question emerged: is insulin resistant status directly or indirectly, through fatty liver, associated with GGT elevation? Few population-based studies have been performed on the association between raised GGT level and metabolic syndrome[7,8]. Moreover, these studies usually dealt with men[8, 11]. It is well known that GGT elevation is frequently induced by habitual alcohol intake and drinkers are more frequently included among men than women. Most raised GGT levels seen in ordinary women are not caused by alcohol, because women with a history of regular alcohol intake in Japan are rare[12]. However, nonalcoholic steatohepatitis (NASH), a severe form of nonalcoholic fatty liver disease, is known to be associated with female gender, metabolic syndrome, and raised GGT level[10]. Hence, a general population study on the association of raised GGT level with risk factors of metabolic syndrome among women is urgently needed.

The aim of this study was to determine whether metabolic syndrome is directly or indirectly, through fatty liver, associated with GTP elevation in Japanese women.

MATERIALS AND METHODS

Subjects

From January 2000 to December 2000, 4 366 women received their annual health check-up at the Okinawa General Health Service Association. They were all Japanese aged between 21 and 88 years: 87% were 40 years of age or older.

Methods

For all women, the body mass index (BMI; kg/m^2) was calculated. Obesity was defined as BMI 25 kg/m^2 as recommended by the Japan Society for Obesity[13].

Laboratory tests included peripheral blood cell counts, liver function tests (aspartate aminotransferase (AST), alanine aminotransferase (ALT), GGT, alkaline phosphatase (ALP), fasting glucose, cholesterol and triglyceride levels, uric acid, glycosylated hemoglobin A1c (HbA1c), hepatitis B surface antigen (HBsAg), and antibody to hepatitis C virus (anti-HCV).

Blood samples were obtained in the morning after an overnight fast. Standard liver tests were performed on a multichannel autoanalyzer (Hitachi 7250). HBsAg was measured by a commercially available enzyme immunoassay (Enzygnost, Berling, Germany). Anti-HCV was tested by a

second generation enzyme immunoassay (Ortho Diagnostics, Raritan, NJ).

Diagnosis of fatty liver was made using ultrasound according to Saverymuttu *et al*[14]. The criterion for fatty liver was hyperechoic liver tissue with fine, tightly packed echoes. The degree of fatty change was assessed by the fall in echo amplitude with depth, increasing discrepancy of echo amplitude between liver and kidney, and loss of echoes from the wall of the portal veins.

The presence of diabetes mellitus was defined as fasting blood glucose 126 mg/dL and/or HbA1c 6.1[15,16]. The presence of high blood pressure was defined as systolic blood pressure 140 mmHg and/or diastolic blood pressure 90 mmHg.

The main endpoint was the identification of the presence or absence of an elevated GGT level combined with clinically associated variables: age, BMI, hypertension, hemoglobin, total cholesterol, triglyceride, uric acid, diabetes mellitus, and fatty liver. All variables were included in a multivariate forward stepwise logistic regression analysis to find the independent predictors of the presence of an elevated GGT level.

Statistical analysis

The continuous variables were compared between the women with and without an elevated GGT level using the 2-tailed Student's *t* test. Correlation among these variables was analyzed by Pearson's correlation coefficient. Categorical variables were compared with Fisher's exact test. Multivariate analysis was tested using forward stepwise logistic regression analysis. The SPSS statistical software was used for statistical analysis. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Among 4 366 women who received a health check-up, 141 were positive for HBsAg and 14 were positive for anti-HCV (None was positive for both HBsAg and anti-HCV). Persons with either HBsAg or anti-HCV were excluded from this study; the data of the remaining 4 211 women was used for the analysis.

Factors correlated with GGT elevation

Univariate analysis Of the 4 211 women without hepatitis virus markers, 258(6.1%) showed an elevated GGT level (>68 IU/L, reference range: 10-68 IU/L). In comparison, the frequency of raised GGT level in 6 620 male health check-up participants (all were negative for both HBsAg and anti-HCV) was 30.2%. When classified into two categories (normal or abnormal, present or absent, above or below), several variables were associated with GGT elevation (Table 1).

Fatty liver was detected in 391(9.3%) of the 4 211 women by using ultrasound. Among the 391 women with fatty liver and 3 820 women without fatty liver, correlations of the GGT level with several quantitative variables were assessed. Among the women with fatty liver, age and BMI were not correlated with the GGT level, whereas all variables examined were correlated well with the GGT level in the women without fatty liver. The GGT level was strongly correlated with both AST and ALT, and the correlations were both stronger than that between GGT and ALP (Table 2).

When the women were divided into 2 groups according to the presence or absence of an elevated triglyceride level, the frequency of GGT elevation did not differ between the women with and without fatty liver. However, the mean GGT level in the women with fatty liver was significantly higher than that in the women without fatty liver (Table 3).

Multivariate analysis In multiple regression analysis, all

independent variables but age were correlated with the GGT level. Although fatty liver was associated with GGT level, the association was weaker than those between the GGT level and the other independent variables (Table 4).

Table 5 Factors contributing to elevated GGT level in women (n=4 211)

	Odds ratio	95% CI	P
Age 50 years	1.4	1.1-1.9	0.016
Hemoglobin 14 g/dL	1.6	1.3-2.1	<0.0001
Triglyceride 150 mg/dL	2.3	1.7-3.1	<0.0001
Diabetes	2.2	1.5-3.4	<0.0001

Table 6 Factors contributing to fatty liver in women (n=4 211)

	Odds ratio	95% CI	P
BMI 25 kg/m^2	3.3	2.8-3.9	<0.0001
Hemoglobin 14 g/dL	1.6	1.2-2.0	<0.0001
Triglyceride 150 mg/dL	2.3	1.8-2.9	<0.0001
Uric acid 7.0 mg/dL	1.9	1.2-2.8	0.003

Although all variables were associated with GGT elevation in univariate analysis (Table 1), the stepwise logistic regression analysis indicated that four variables (age 50 years, hemoglobin 14 g/dL, triglyceride 150 mg/dL, and presence of diabetes) were significantly and independently associated with GGT elevation (Table 4). The presence of fatty liver was not independently associated with GGT elevation. In the women with fatty liver (n=391), only two variables, triglyceride 150 mg/dL and presence of diabetes, were significantly and independently associated with elevated GGT level (P=0.003 and P=0.023, respectively).

Clinical variables predicting the presence of ultrasonographic evidence of fatty liver were also examined by stepwise logistic regression analysis. In all women, four variables were independently associated with the presence of fatty liver: BMI 25 (P<0.0001), hemoglobin 14 g/dL (P=0.002), triglyceride 150 mg/dL (P<0.0001), and uric acid 7.0 mg/dL (P<0.0001). The elevated GGT level was not independently correlated with fatty liver.

DISCUSSION

GGT is one of the biliary enzymes, and is synthesized in epithelial cells of the intrahepatic bile duct[17]. A raised GGT level is usually seen in association with cholestasis and liver cell necrosis[17]. Although GGT is a biliary enzyme, the levels in this study were more strongly associated with transaminase levels, which are associated with liver cell necrosis, as compared with ALP.

Recently, an association between GGT and metabolic syndrome: hypertension[8], dyslipidemia[7], diabetes mellitus[11],

has been reported. The mechanism of the association was still unknown, but one of the likely mechanisms proposed is that GGT is associated with fatty liver, which is also related to hepatic insulin resistance leading to insulin resistance syndrome[11].

In this study, the serum GGT level was correlated with metabolic syndrome (hypertension, diabetes mellitus, and dyslipidemia) and risk factors for metabolic syndrome (age, BMI, blood glucose level, and uric acid concentration) in the univariate analysis, whereas, in the multivariate analysis, only four variables were independently associated with the raised GGT level: age 50 yr, hemoglobin 14 g/dL, triglyceride 150 mg/dL, and presence of diabetes mellitus. Age 50 yr was one of the factors independently associated with GGT elevation, but the association was not seen in the multiple regression analysis. The reason for this discrepancy may be the unique distribution of the age-related prevalence of GGT elevation. The abnormally raised GGT level was most frequently seen in the women of 50-59 years of age.

A relationship between the ultrasonographic evidence of fatty liver and raised GGT level was seen in the univariate analysis, but the relationship was not observed in the multivariate analysis. The triglyceride level was strongly correlated with GGT level and also well associated with fatty liver. The association between the elevated GGT level and fatty liver might be influenced by the strong association between triglyceride and GGT and fatty liver. When the women were divided into two groups according to presence or absence of raised triglyceride level, the frequency of GGT elevation did not differ between the women with and without fatty liver. However, the mean GGT level in the women with fatty liver was significantly higher than that in the women without fatty liver, indicating the positive correlation between GGT level and fatty liver within its normal range.

Both hypertriglyceridemia and diabetes mellitus were independently associated with GGT elevation. Triglyceride level and diabetes mellitus are known to be strongly associated with insulin level and are included in metabolic syndrome[8,18]. Moreover, hyperinsulinemia was reported to be associated with raised GGT level[7]. Raised GGT level is associated with insulin resistance, which is related to an increase in oxidative stress, which leads to liver cell necrosis by stimulating inflammatory cytokines[10]. Fatty liver may not always mediate between insulin resistance and raised GGT levels. For example, diabetes mellitus is the representative condition of the sequelae of insulin resistance and independently associated with raised GGT level, but many diabetic persons do not have fatty liver.

In this study, GGT was correlated with an elevated hemoglobin level. Insulin resistance status increases delivery of free fatty acids to the liver[10], which leads to the formation of free radicals[10]. Formation of free radicals is also induced by iron overload[19], which is associated with insulin resistance[20,21]. Liver iron concentration is correlated with serum ferritin levels and peripheral hemoglobin concentration[21,22]. Obesity, which is linked with an elevated hemoglobin level, is associated with arterial hypoxemia, which may result from reduced pulmonary function[23,24]. Sleep apnea syndrome is frequently seen in obese persons[25,26], and is associated with hypoxemia and elevated levels of hemoglobin.

The serum GGT level is a well known indicator of excess alcohol intake. GGT is also raised in patients with various liver diseases: fatty liver, chronic viral hepatitis, drug-induced liver injury and primary biliary cirrhosis (PBC). These liver diseases are usually asymptomatic, and can be included in general-population studies[27]. Patients with chronic viral hepatitis were supposed to be excluded from this study because all women included in this study were negative for both HBsAg and anti-HCV. However, we did not take a history regarding past or current medication, nor did we examine anti-mitochondrial

antibody. Hence, our study population might contain patients with subclinical drug-induced liver injury and those with asymptomatic PBC. Nevertheless, the influence of the presence of these liver diseases might be small because of the rarity of these liver diseases in a population-based study.

In this study, we enrolled only women, but the annual health check-ups include many men. General population studies from Japan showed that 73% of males having health check-ups drank alcohol and that 12.5% of them drank more than 453 mL/wk[8,10]. Obtaining information on alcohol intake from family members who are in close contact with each other is difficult in population-based studies. We therefore excluded male health check-up participants from this study to minimize the possibility of including alcohol-related liver disease. Most female health check-up participants had no regular alcohol intake. We previously interviewed 140 female health check-up participants who had an elevated GGT level and only two (1.4%) of them had a history of regular alcohol intake. The subjects of this study may have included some women with a history of regular alcohol intake, but the influence of alcohol might be quite small and might not affect the whole data.

In conclusion, GGT elevation was independently associated with hypertriglyceridemia and diabetes mellitus but not associated with the ultrasonographic evidence of fatty liver. Metabolic syndrome seemed to be directly, not indirectly through fatty liver, associated with the raised GGT level in Japanese women.

Abstract

AIM: Our aims were to determine the normal limits of subepithelial basement membrane (SEBM) thickness in order to more accurately diagnose collagenous colitis in the population from southern Turkey and to investigate into links between SEBM thickness and age, and sex.

METHODS: The study included 100 patients (mean age 50.0 ± 13.3 years; male, 34; female, 66) with miscellaneous gastrointestinal symptoms, and normal colonic mucosal appearance in colonoscopic evaluation. Biopsies were taken from five different regions of the colon. SEBM was measured with a calibrated eyepiece on specimens prepared with specific stains for collagen. Intensity of inflammatory cells was graded semiquantitatively. Differences in SEBM thickness among the different colon regions, and relationships between SEBM thickness and age, sex, and density of inflammatory cells were statistically evaluated.

RESULTS: The cecum and rectum showed the largest amounts of infiltrate. None of the specimens showed histologic findings of collagenous colitis. The SEBM thicknesses measured for each case ranged from 3-20 μm. The biggest thickness was observed in rectal mucosa (median value: 10 μm). Cecum and ascending colon showed similar SEBM thickness (median value: 5 μm). SEBM thickness was not correlated with patient age or sex, but was positively correlated with the intensity of inflammatory cells in each colon segment.

CONCLUSION: In this patient group from southern Turkey, SEBM was thickest in the rectum. Our results indicate that, in this population, SEBM thickness is not correlated with age or sex, but is positively correlated with severity of inflammation. The findings also support the concept that measuring SEBM thickness at one segment in the colon is inadequate and may be misleading.

INTRODUCTION

Lindstrom introduced the term "collagenous colitis" to describe a colon biopsy that showed hyalinized substance, known as a collagen band, between the transition zone of the subluminal basement membrane and the lamina propria[1-8]. The English literature contains approximately 200 reports of this condition[7]. Collagenous colitis is most often diagnosed in middle-aged women[3,6-10]. In some patients this condition is associated with autoimmune diseases, such as diabetes mellitus, primary biliary cirrhosis, rheumatoid arthritis, and gluten-sensitive enteropathy[3]. Some of the cases linked with histories of smoking, or antibiotic or non-steroidal anti-inflammatory drug (NSAID) ingestion[1,3,6,7,9,11].

In healthy adults, the subepithelial basement membrane (SEBM) of the colon consists of collagen types I and IV, laminin, and fibronectin. The thickness of this layer varies from 0 to 7 μm[3,5-7,12], and is slightly greater in the settings of hyperplastic polyps, colonic diverticulum, and congenital megacolon[3,6]. In this study, we investigated SEBM thickness in biopsies from five different colonic sites in patients from the southern Anatolia region of Turkey. One of our aims was to determine the normal limits of SEBM thickness in this region in order to more accurately diagnose collagenous colitis in the population. Another objective was to investigate into links between SEBM thickness and age, and sex.

MATERIALS AND METHODS

The study included 100 patients who were admitted to our gastroenterology clinic with non-specific symptoms, such as chronic constipation, diarrhea, and abdominal distension and discomfort. Only two individuals had experienced short episodes of diarrhea. All the participants gave their informed consent for diagnostic colonoscopy. The protocol was carried out in accordance with the Helsinki Declaration as revised in 1989.

Each individual underwent colonoscopy and biopsies were collected from five different regions of the colon: the cecum, the ascending, transverse, and descending colon, and the rectum. Two biopsies were obtained from each segment. The specimens were fixed in 40 g/L neutral buffered formaldehyde, embedded in paraffin, and stained with hematoxylin-eosin, and slides were examined under the light microscope. Each slide was assessed for type of inflammation, intensity of inflammatory cells, superficial epithelial damage, cryptitis, and crypt abscesses. The finding of few lymphocytes, plasma cells, eosinophils, macrophages and scattered mast cells in lamina propria is considered to be normal in histopathological examination. Taken such a scene as normal (grade 0), intensity of inflammatory cells was graded on a three-tier scale. The predominant cell type (lymphocyte, eosinophil, or neutrophil) in the inflammatory infiltrate was also noted.

All the specimens were also histochemically prepared with periodic acid-Schiff (PAS), Masson's trichrome, and crystal violet stains. A calibrated eyepiece was used to measure SEBM thickness on the sections stained with Masson's trichrome at ×400 magnification. On every slide, we measured the thickest

part of the SEBM in non-tangential areas of tissue section that were distant from the crypts. The SEBM thickness for each segment in each patient was recorded. Also, for each patient, two of the same biopsied regions were randomly selected and the average SEBM thickness for these two sites was recorded. PAS stain was used to demonstrate intestinal parasites and fungi, and crystal violet was used to reveal the presence of amyloid. Differences among SEBM thickness in the different colon regions, and relationships between SEBM thickness and age, and sex were statistically evaluated. The data of SEBM thickness are reported as medians (ranges). Comparisons between median values of SEBM thickness belonging to each colon segment were performed using Mann-Whitney *U* test. The relationships between SEBM thickness and demographic parameters (age and sex), and SEBM thickness and intensity of inflammation were tested with Spearman' s correlation. *P* values <0.05 were considered statistically significant.

RESULTS

The mean age in the study group was 50.0 ± 13.3 yr (range, 18-82 yr). Of the 100 patients, 34 were men and 66 were women. In 93 of the cases, the mucosa appeared normal on colonoscopy. Of the 7 cases with abnormal findings, 3 showed mildly hyperemic mucosa, 2 exhibited colonic diverticula, 1 had a polyp, and 1 had a superficial ulcer. In the biopsy specimens, eosinophils were as numerous as lymphocytes in the inflammatory infiltrates. The cecum and rectum showed the largest amounts of infiltrate. In most cases, the inflammatory infiltrate in the rectal biopsies contained lymphocytes, plasmocytes, and neutrophils. None of the specimens showed amyloid deposition, intraepithelial lymphocytosis, epithelial vacuolization, desquamation, mucin loss, pseudostratification, or focal neutrophilic cryptitis.

The range and median SEBM thickness in each of the five colon segments are summarized in Table 1. The median SEBM thickness for the separate segments differed. The largest thickness was observed in rectal mucosa. The difference between rectum and transverse colon did not reach statistical significance, but there was a trend towards greater thickness in rectum. Cecum and ascending colon showed similar SEBM thickness. SEBM thickness was not correlated with patients' age or sex, but was positively correlated with intensity of inflammatory cells in each colon segment (Table 2). The thickness measured for each case ranged from 3-20 μm (Figure 1). In 1 of the 2 individuals with colonic diverticula, the SEBM in the descending colon and rectum was greater than 10 μm thick. In the 1 patient who had a polyp, the SEBM thickness in the rectum was 12 μm. In 2 cases, SEBM thickness was 15-20 μm in all segments of the colon. Both these individuals (a 50-year-old male and a 69-year-old woman) had long histories of chronic constipation and intermittent ingestion of NSAIDs. The colon biopsies in these 2 cases showed mild eosinophil infiltration.

Table 1 The median values of SEBM thickness in various colon segments

Colon segment	SEBM thickness (μm)	
	Median	Range
Cecum	5[*]	3-12
Ascending colon	5[*b]	3-20
Transverse colon	8[aω]	3-20
Descending colon	8[bad]	3-20
Rectum	10[dω]	3-20

*: NS, [b]P=0.001, [a]: SEBM was thicker in transverse colon compared to descending colon P=0.04, [d]P<0.001, [ω]P=0.07.

Table 2 The Spearman' s correlation coefficients for the relationship between SEBM thickness and severity of inflammation in various colon segments

| Colon segment	Correlation coefficient (r)	P
Cecum	0.499	<0.0001
Ascending colon	0.642	<0.0001
Transverse colon	0.699	<0.0001
Descending colon	0.620	<0.0001
Rectum	0.553	<0.0001

Figure 1 Photomicrograph of colonic mucosa showing normal SEBM (3-4 μm) just beneath the surface epithelium (Masson' s trichrome ×400).

DISCUSSION

The main histopathological criteria for collagenous colitis include the characteristic findings of a thick, continuous, hypocellular, eosinophilic, linear fibrous band beneath the surface epithelium, as well as intraepithelial lymphocytosis, epithelial vacuolization, and desquamation[1,3,5-7,11]. One of the difficulties in diagnosing collagenous colitis is that different sources cite different SEBM thickness as one of the main criteria for diagnosis[9]. Thus, sampling error is a probable cause of under diagnosis in collagenous colitis. Some investigators consider thickness >10 μm to be diagnostic, whereas others use >15 μm, and still others >30 μm[3,5-7,11]. The SEBM thickness documented in cases of collagenous colitis in the English literature range from 11.5 to 60 μm[6,13-18]. In a study of 564 patients conducted in 1982, the authors identified >10 μm in thickness as abnormal[14]. In a series of 33 patients with collagenous colitis, Tanaka *et al*[9] observed that 82% exhibited >10 μm in SEBM thickness in at least one area of the left colon. The rectum appeared normal in 72% of these cases, and only three patients showed a collagen band in the cecum. Tanaka *et al* used <7 μm as the criterion for normal SEBM thickness, and identified mucosal inflammation and SEBM thickness >10 μm as diagnostic criteria for collagenous colitis[9].

SEBM thickness in the healthy population in the various studies in the literature ranges from 0 μm to 7 μm[3,6,15]. In some of these investigations, estimates of SEBM thickness in the general population were derived from autopsy series[6,14]. In a series of 457 patients that included adenocarcinoma, polyp, and megacolon cases as well as autopsy cases, Gledhill and Cole were only able to determine SEBM thickness in 190 of the subjects (6). In this group, SEBM thickness was <10 μm in 171 cases, between 10-15 μm in 12 cases, and >15 μm in 7 cases. Six of the 7 patients with collagen band thickness >15 μm and 6 of the 12 patients with thickness between 10-15 μm had diarrhea. The maximum SEBM thickness recorded by Gledhill and Cole was 80 μm, and the average in the 190 patients was 22.5 μm. Consistent with our study, the authors found that SEBM thickness >10 μm was associated with non-specific colitis, colonic diverticula, and epithelial polyp; however, they

presented no data related to inflammation[6]. All the cases in our study exhibited SEBM, that is, no 0 μm values were recorded. The lowest value of SEBM thickness we observed was 3 μm, and the intensity of inflammation predominant in the tissue section with SEBM thickness of 3 μm was 0-1. Gledhill and Cole found that SEBM thickness was not correlated with age or sex[6], similar to our results.

Our aims in this study were to determine the normal limits of SEBM thickness in the southern Anatolia region of Turkey, and to investigate for possible links between SEBM thickness and age, and sex. Studies of collagenous colitis patients in Europe and the United States have revealed substantially different SEBM thickness in these geographic regions. The nutritional habits of people in south and southeast Anatolia differ from those in Europe and the United States. The main nutritional sources in southern Turkey are animal protein and wheat products. The prevalence of parasitic infection, and particularly amebiasis, is very high in this area. In one study of 35 172 patients with diarrhea who were from south and southeast Anatolia, 26.4% had amebiasis (19). The same authors investigated infectious diseases transmitted by drinking water in a study that was conducted between 1994 and 1995 in southern Turkey. The results showed 7 281 new amebiasis cases during this 1-yr period, and revealed a rise in incidence of up to 41% during the summer[20]. In our study, histological examination revealed colonic amebiasis in only 3 of 100 cases. In these 3 patients, rectal SEBM thickness ranged from 10-12 μm and the rectal biopsies all showed an eosinophil-rich inflammatory response.

Patients with collagenous colitis show different SEBM thickness in different segments of the colon. Most studies have shown that this collagenous layer is thicker in the distal colon than in the proximal regions[3,5-7,11]. Research has also revealed that patients with collagen deposition of at least 15-μm in thickness in more than 30% of multiple colon biopsies eventually develop the clinical syndrome[1,3]. In our study, the SEBM was thickest in the rectum, followed by the transverse colon, descending colon, ascending colon, and cecum, respectively. The same sequence did not apply to intensity of inflammation, i.e, cecum was the second site exhibiting relatively higher count of inflammatory cell after rectum compared to other sites. This discordance may be explained by the absence of morphometric analysis, which could give more specific result about the count of inflammatory cells than routine light microscopic evaluation. Inflammatory response, parasitic infection such as amebiasis, and nutritional factors are all elements that potentially contribute to increased basement membrane thickness. Two of our patients with SEBM thickness between 12-15 μm in any colonic segment exhibited polyp and colonic diverticula, respectively. In 2 other cases with 15-20 μm SEBM thickness, there was a history of NSAID treatment but no history of diarrhea. The colon biopsies from the latter 2 patients showed moderate inflammatory response with eosinophils predominant in the infiltrate.

In summary, of the five colon segments studied in this patient group from southern Turkey, SEBM was thickest in the rectum. Our results indicate that, in this population, SEBM thickness is not correlated with age or sex, but is positively correlated with intensity of inflammation. This study provides more evidence that SEBM thickness varies according to geographic region, and that these differences may be culture-related. The findings also suggest that measuring SEBM thickness at one segment of the colon is inadequate and may be misleading. The mean SEBM thickness for the separate colon segments differ, similar to established characteristics of collagenous colitis. The histopathological diagnosis of collagenous colitis should be made by measuring collagen band thickness in at least 3 or more non-tangential areas that are distant from the crypts. In addition to collagen band thickness, diagnosis of this condition must be based on characteristic clinical and histologic findings. The latter include superficial desquamation, intraepithelial lymphocytosis, and epithelial vacuolization.

Abstract

AIM: To investigate the pattern of symptoms, predominant bowel habits and quality of life (QOL) by the Chinese version of the SF-36 in irritable bowel syndrome (IBS) consulters in Zhejiang province.

METHODS: From January 2001 to January 2002, 662 Roma II criteria-positive IBS patients were enrolled by gastroenterologists in 10 hospitals from Digestive Disease Center of Zhejiang (DDCZ). Patients were classified into constipation predominant IBS (IBS-C), diarrhea predominant IBS (IBS-D) and alternating constipation and diarrhea IBS (IBS-A) according to the predominant bowel habits. All patients were evaluated for the demographic checklists, IBS bowel symptoms, extra-colonic symptoms, and QOL by Chinese version of the SF-36 questionnaire.

RESULTS: (1) Besides abdominal pain, the predominant colonic symptoms were in order of altered stool form, abnormalities of stool passage, abdominal distension and passage of mucus in IBS patients. Also, IBS subjects reported generalized body discomfort and psychosocial problems including dyspeptic symptoms, poor appetite, heartburn, headache, back pain, difficulty with urination, fatigue, anxiety and depression. (2) IBS-C and IBS-A are more common among female patients, whereas male patients experienced more cases of IBS-D. In regards to the IBS symptoms, there were significant differences among IBS subgroups. Abdominal pain (frequency ≥2 days per week and duration ≥1 hour per day) was frequent in IBS-A patients ($P=0.010$ and 0.027, respectively), IBS-D patients more frequently experienced the passage of mucus, dyspeptic symptoms and anxiety ($P=0.000$, 0.014 and 0.015, respectively). (3) IBS patients experienced significant impairment in QOL, decrements in QOL were most pronounced in vitality, general health, mental health, and bodily pain. Compared with the general population (adjusted for gender and age), IBS patients scored significantly lower on all SF-scales ($P<0.001$), except for physical function scale ($P=0.149$). (4) QOL was impaired in all subgroups, particularly in scales of vitality, general health and mental health. Compared with IBS-D, QOL in IBS-C scored significantly lower on physical function, role physical, general health, role emotional, and mental health scales ($P=0.037$, 0.040, 0.039, 0.005 and 0.026, respectively).

CONCLUSION: Besides colonic symptoms, IBS could cause generalized body discomfort and psychosocial problems. The IBS subgroups based on predominant bowel habits are helpful to identify clinical distinction of the IBS. QOL is significantly impaired in IBS patients. The Chinese version of the SF-36 health survey scales may be a useful measurement of IBS patients.

INTRODUCTION

Irritable bowel syndrome (IBS) comprises a group of functional bowel disorders, in which abdominal pain or discomfort is associated with defecation or a change in bowel habits, and with features of disordered defecation[1]. In developed countries, IBS is the most frequent reason for referrals to gastroenterologists, and the diagnosis of IBS has been noted in up to 4-30% of the general population in Western Europe and North America[2-6]. A stratified randomized study in China reported that the prevalence of IBS in Beijing is 7.26% according to Manning criteria[7]. However, there were no large-scale studies to evaluate IBS patients who consulted physicians in China.

On clinical grounds, it has been proposed that patients with IBS can be further subdivided into those who have either predominant constipation or diarrhea or an alternating bowel pattern. Differences between these subgroups have been observed regarding viscerosensory processing[8,9] and autonomic function[10-12]. But clinical relevance of IBS subgroups by predominant bowel habits was not so well covered in the literature.

IBS patients could manifest gastrointestinal disorders and be accompanied with psychosocial problems. The QOL consists of all aspects of patients' disorders and can evaluate the health status in detail. Although IBS is not a life-threatening condition, for most patients it is a chronic recurrent illness that is often accompanied by severe impairment in QOL. Generic QOL measures, such as SF-36 health survey, are designed to evaluate aspects of function status and well-being applicable to a population in general, which is also a well–standardized questionnaire for assessing the QOL of IBS[6,13-16]. As we known, there were no prior studies that evaluated the QOL by the Chinese version of SF-36 in IBS patients.

In the present study, we aimed at evaluating the pattern of symptoms and QOL of the IBS-consulters in Zhejiang, in particular with respect to different IBS subgroups.

MATERIALS AND METHODS

Subjects

From January 2001 to January 2002, 662 consecutive Roma II

criteria positive IBS patients were enrolled by gastroenterologists from 10 hospitals in urban, suburban, island, and rural areas of Digestive Disease Center in Zhejiang (DDCZ). Patients were classified into three subgroups according to the following criteria[6,17,18]: (1) Constipation- predominant IBS (IBS-C) indicated of patients who had at least two of the four symptoms 3 months, such as straining, hard or lumpy stools, incomplete evacuation 25% of the time, and/or two or less bowel movements per week, and no concurrent diarrhea symptoms as defined below; (2) Diarrhea-predominant IBS (IBS-D) was diagnosed by the presence of loose/watery stools >75% of the time, three or more diarrhea in a week, in the absence of constipation symptoms; and (3) Patients with mixed patterns of both constipation and diarrhea were classified as alternating-IBS (IBS-A). Patients with organic diseases related to IBS bowel symptoms were excluded. All patients completed the demographic checklists, symptom questionnaire, and SF-36 questionnaire.

Demographic checklists
Patients completed 5 demographic questions regarding their age, gender, profession, marital status and the level of education. The demographic data of general population in Zhejiang province were provided by Demographic Center of Zhejiang Province.

Symptom Questionnaire (SQ)
The SQ was divided into symptoms compatible with IBS and extra-colonic symptoms.
Symptoms compatible with IBS This symptom category included the following symptoms in the prior year (referred to Roma II symptom criteria): (1) the duration of abdominal pain per day (none, <1 h, 1-8 h, >8 h); (2) the frequency of abdominal pain per week (none, <2 d, 2-5 d, >5 d); (3) the frequency of altered stool forms including lumpy/hard or loose/ watery stool (none, <25%, 25-75%, >75%); (4) the frequency of altered stool passage pattern including staining, urgency, and feeling of incomplete evacuation (none, <25%, 25-75%, >75%); (5) the frequency of passage of mucus (none, <25%, 25-75%, >75%); and (6) the frequency of bloating or abdominal distension (none, <25%, 25-75%, >75%).
Extra-colonic symptoms Patients were asked if they experienced dyspeptic symptoms, poor appetite, or heartburn. In addition, patients were asked if they had any back pain, headache, difficulty in urination, fatigue, depression, or anxiety.

Health status SF-36 questionnaire
The validated SF-36 in Chinese version was provided by professor Li Lu in Social and Demographic Department in Zhejiang University. The SF-36 included 8 multi-item dimensions: physical function, role-physical (functional limitations due to physical health problem), bodily pain (limitation due to body pain), general health, vitality (energy/fatigue), social function, role emotional (functional limitations due to emotional problems), and mental health (psychological distress and psychological well-being). The SF-36 scored from 0 to 100, with higher scores indicating better QOL.

We compared the QOL of patients with IBS with previously published SF-36 data of Zhejiang general population (*n*=1 972).

All subjects were evaluated after giving informed consent by Zhejiang University School of medicine.

Statistical analysis
All of the statistical analyses were conducted using the SPSS 10.0 statistical software passage. Prevalence of symptoms was expressed in percentages. Comparisons between different IBS subgroups patients were performed using χ^2 test for categorical data and *t* test or ANOVA test for continuous data. $P<0.05$ was considered significant.

RESULTS
Demographic characteristics
The mean age of 662 subjects was 44.78±13.71 years, with 52.9% of the sample being woman. The majority of the subjects were in the age of 25-50 years (68.4%). Further information detailing the marital status, education level, and profession are provided in Table 1. Compared with the general population in Zhejiang, IBS were more common in the intellectuals and cadres ($P<0.001$), the young adulthood (25-50 years, $P<0.001$), and in females ($P<0.05$).

Table 1 The basic characteristics of IBS consulters

Characteristics	IBS sample (*n*=662)
Age (yr, %)	44.78±13.71
<20	1.5
20-29	9.5
30-39	30.4
40-49	25.8
50-59	17
60-69	10.5
70-79	5
>80	0.3
Gender (*n*, %)	
Male	312 (47.1)
Female	350 (52.9)
Marital status (*n*, %)	
Never married	51 (7.7)
Married	585 (88.4)
Widow	19 (2.8)
Divorced or separated	7 (1.1)
Education level (*n*, %)	
Illiterate	87 (13.1)
Primary school	129 (19.5)
Junior middle school	184 (27.7)
Senior middle school	155 (23.5)
College or graduated	107 (16.2)
Profession (*n*, %)	
Peasants	211 (31.8)
Workers	75 (11.3)
Cadres	62 (9.4)
Intellectuals	58 (8.7)
Merchants	105 (15.9)
Soldiers	57 (8.6)
Student	20 (3.0)
Retired and jobless	74 (11.3)

Prevalence of symptoms
The frequency of symptoms were in order of altered stool form (79.1%), abnormalities of stool passage (67.9%), abdominal pain duration ≥1 h/d (67.7%), abdominal distension (63.2%), abdominal pain frequency ≥2 d/wk (57.5%) and passage of mucus (49.8%) in IBS patients. A few IBS subjects reported having extra-colonic symptoms including fatigue (72.7%), dyspeptic symptoms (64.1%), anxiety (54.2%), depression (44.1%), poor appetite (38.2%), headache (29.0%), back pain (26.1%), heartburn (25.0%), and difficulty with urination (11.0%).

Abdominal pain duration ≥1 h/d was reported more common among female IBS than male patients (61.1% *vs* 53.7%, *P*<0.05). Women also more frequently reported headache and poor appetite (both *P* <0.05). More male patients reported difficulty in urination (*P*<0.05). The data are shown in Table 2.

Table 2 Symptoms characteristics of IBS by gender

Symptoms (%)	Male (*n*=305)	Female (*n*=311)	*P*
IBS compatible symptoms			
Abdominal pain≥1 hour/day	53.7	61.1	0.039
Abdominal pain≥2 days/week	67.2	68.2	0.434
Altered stool form	80.0	78.1	0.312
Altered stool passage	66.8	68.8	0.325
Abdominal distension	60.7	65.6	0.118
Passage of mucus	51.1	48.2	0.260
Extra-colonic symptoms			
Dyspeptic symptoms	63.1	65.3	0.319
Poor appetite	33.6	43.0	0.011
Heartburn	28.4	21.3	0.066
Headache	24.1	33.6	0.024
Back pain	24.4	27.5	0.426
Difficulty in urination	15.6	6.2	0.000
Anxiety	51.0	57.1	0.200
Depression	40.2	47.7	0.114
Fatigue	72.0	73.7	0.897

Prevalence of IBS subgroups

Patients consisted of IBS-C (20.0%), IBS-D (47.7%), and IBS-A (32.3%) according to the predominant bowel habits. The IBS-C and IBS-A patients were composed mainly of women, which were 64.2% and 56.9%, respectively. But in the IBS-D,

more subjects (56.8%) were male. The distribution of IBS compatible symptoms and extra-colonic symptoms among the IBS subgroups are summarized in Table 3. Abdominal pain (frequency ≥2 days per week and duration ≥1 hour per day) consisted of 64.9% and 75.9% respectively in IBS-A patients (*P*<0.05), while there was 58.1% of IBS-D patients with the passage of mucus (*P*<0.05). Compared with other two subgroups of IBS, IBS-D patients more frequently experienced of dyspeptic symptoms (70.2%) and anxiety (62.0%) (*P*<0.05).

Table 3 Symptoms in the IBS subgroups

Symptoms (%, *n*)	IBS-C (*n*=108)	IBS-D (*n*=258)	IBS-A (*n*=174)
Gender[b]			
Male	38 (35.8)	147 (56.8)	75 (43.1)
Female	69 (64.2)	111 (43.2)	99 (56.9)

The SF-36 questionnaires

For IBS patients, the lowest mean scale scores were 37.9 in vitality and 41.0 in general health. The bodily pain and role emotional scales scores were also quite low (47.4 and 50.9, respectively). Compared with the general population (adjusted for gender), the IBS patients scored significantly lower on 7 SF-scales ($P<0.001$), with the exception of physical function scale. Adjusting for age, the decrement of scale score in IBS patients ($\leqslant65$ years) are most pronounced in 7 categories of SF-36 except the physical function scale, while patients >65 years scored significantly lower on vitality, general health, bodily pain, social function and role emotional scales ($P<0.001$), as shown in Table 4 and Table 5.

QOL was impaired in all subgroups. The QOL in three subgroups are pronounced impaired in vitality, general health and mental health. Among different subgroups, IBS-C had poor QOL. Compared with IBS-D, QOL in IBS-C scored significantly lower on physical function, role physical, general health, role emotional and mental health scales ($P<0.05$). Compared with IBS-A, the 6 scales of QOL in IBS-C were more impaired, but there was no significant difference ($P>0.05$). As shown in Figure 1 and Table 6.

Figure 1 SF-36 scale score in different IBS subgroups compared with general population.

Table 6 SF-36 scale scores (mean±SD) among different IBS subgroups

SF-36	IBS-C	IBS-D	IBS-A	General population	P
PF	77.4 (22.1)	82.2 (17.6)	79.7 (20.7)	82.2 (19.8)	0.104
RP	47.1 (39.2)	61.3 (41.6)	50.9 (43.4)	81.2 (33.6)	0.043

MH	42.6 (30.9)	48.7 (18.0)	47.9 (18.7)	59.7 (22.7)	0.061

DISCUSSION

IBS is important because it is associated with considerable morbidity, cost and poor QOL. IBS patients who consulted physicians (IBS-consulters) got more severe IBS symptoms[19] and higher psychological discomfort[20] compared to the non-consulters. Studies have reported that IBS- consulters had poor QOL than the non-consulters[21]. Therefore, more and more studies were focused on evaluating the IBS-consulters patients. The data obtained in our study represents the reality of IBS-consulters in general population in Zhejiang province.

We demonstrated that male to female ratio was 1:1.21. Compared with the general population, IBS are more common among people between the age of 25 to 50 years (68.4% *vs* 51.9%,

$P<0.01$), and between the intellectuals and cadres ($P<0.001$). A few studied have shown IBS is more prevalent in women than in men[3,6,7]. The majority of the subjects being the intellectuals and in the age of 18-40 years (51.6%) was also observed in recent study in Beijing[7]. In the present study, we found that the most frequent symptom was altered stool form (79.1%), in order of abnormalities of stool passage (67.9%), abdominal pain (67.7%), abdominal distension (63.2%) and passage of mucus (49.8%) in IBS patients. IBS could reflect a wide range of symptoms, and abdominal pain was not the essential symptom. Although only colonic symptoms are used in the Manning or Rome criteria for the diagnosis of IBS, noncolonic symptoms arising elsewhere in the gastrointestinal tract or viscerosensory symptoms are common in IBS. It was considered that a large proportion of IBS patients complain of functional disorders of obscure origin, such as headache, low back pain, dysuria, depression, sleeping disorders, anxiety, and attention fatigue[22-25]. Our study showed that IBS patients commonly presented with fatigue (72.7%), dyspeptic symptoms (64.1%), anxiety (54.2%), depression (44.1%), headache (29.0%), back pain (26.1%), heartburn (25.0%), and difficulty in urination (11.0%). In addition, an increased prevalence of extra-colonic symptoms, including headache and poor appetite were seen in female IBS patients.

IBS could be subdivided into IBS-C, IBD-D and IBS-A according to the predominant bowel habits. We found IBS-D (48.3%) to be the predominant habits, in order of IBS-A (32.7%) and IBS-C (19.0%). Lembo *et al*[26] using Rome I diagnostic criteria, who suggested the IBS-A in 49%, IBS-D in 33%, and IBS-C in 18%. Another study found that the IBS-A in 38%, IBS-C in 37%, and IBS-D in 25% by Rome II criteria[27]. The different prevalence may be due to the bias of sample of population or diagnostic criteria. We postulate that subjects with different bowel habits have different pathophysiologic conditions and therefore will differ with respect to their clinical characteristics, and designed to evaluate the gender distribution and symptoms as well as QOL among all subgroups. Results demonstrated that females had higher proportion of IBS-C and IBS-A, while there was a trend towards a higher proportion of being IBS-D in male patients. The data was continent with recent studies of IBS in Europe and U.S.A[8,17]. Several physiological factors may play a role in these gender-related differences in self-reported bowel habits, including difference in central autonomic control, enteric nervous system physiology, and smooth muscle physiology[28]. The subgroups had significant difference in IBS predominant bowel symptoms according to Roma-II criteria and extra-colonic symptoms. Abdominal pain (frequency $\geqslant2$ days per week and duration $\geqslant1$ hours per day) consisted of 64.9% and 75.9%, respectively in IBS-A patients, which was discriminates among the subgroups. It is of note that IBS-A patients were affected more by abdominal pain than were those with other subgroups. Mearin *et al*[27] also reported that abdominal discomfort/pain were greater in the IBS-A subgroup than in the other two IBS subgroups, whereas IBS-D patients more frequently experienced of passage of mucus (58.1%), dyspeptic symptoms and anxiety ($P<0.05$). Conversely, another study showed that IBS-C patients accompanied with more higher severity of upper gastrointestinal symptoms and higher severity of lower gastrointestinal bloating than IBS-D patients, suggested that it may be related to different gastrointestinal transit or central processing of vagal-mediated afferent signals[8]. We found that all three subgroups had impaired QOL. QOL scale score was similar in IBS-D and IBS-A, but lower in IBS-C. Compared with IBS-D patients, QOL in IBS-C scored significantly lower on physical function, role physical, general health, role emotional and mental health scales ($P<0.05$). There was a trend of decreasing of these 6 scales of QOL, but no

significant difference between IBS-C and IBS-A ($P>0.05$). Schmulson *et al*[8] also observed that IBS-C more commonly reported impairment in sleep, appetite and sexual function, but there were no difference in SF-36 scores in different subgroups. Another investigation by Mearin *et al*[27] indicated that QOL was affected similarly in all IBS subtypes. These results were contradicted with each other. So it was critically necessary to apply for universal criteria for the subgroups of IBS. In our present study, there were different gender distribution, clinical symptoms and QOL among the three IBS subgroups. This suggests that subdividing IBS in three groups based on bowel habits may identify clinically distinct entities, but needs to be evaluated in a more detailed study.

There is increasing recognition that what matters to most patients with chronic illness is how well they are able to function and how they feel about their daily life. Therefore, it is essential to understand the impact of IBS on patients' ability to function and well-being. The medical Outcome Study Short Form (SF-36) is a well-standardized questionnaire for assessing quality of life. The Chinese version of the SF-36 health survey scale has achieved conceptual equivalence and satisfied the psychometric scaling assumptions well enough to warrant as a standardized survey in China[29]. As we have known, this is the first study to compare the QOL of patients with IBS and the general population in China by Chinese version of the SF-36. The present study showed that IBS patients have significantly impaired QOL, with the most pronounced decrements in vitality (energy/fatigue), general health, mental health, and bodily pain, furthermore, when compared with the general population in Zhejiang (adjusting for the age and gender distribution), IBS patients also scored significantly lower QOL on 7 SF-scales ($P<0.001$), with the exception of physical function scale. It is continent with the study[16,30] that QOL is low in patients with IBS, dimensions affected are particularly energy/fatigue, role limitation, physical pain and health perception. Gralnek *et al*[30] reported that as compared with the U.S. general population (adjusted to the age and gender characteristics of IBS sample), the IBS patients scored significantly lower on each of the 8 SF-36 scales. Another study in European also showed that all aspects of QOL were adversely affected in IBS patients living in the UK and the United States[31]. On the other hand, recent studies in Hong kong[32,33] showed that only vitality score was lower in men with IBS, and the mental health score was significantly lower in women with IBS, compared with normal control. Our results confirm the findings that IBS had abroad and significant impact on a person's QOL, in addition to the disease activity and symptoms impacts. We postulate that the different results of QOL in studies are due to the cultural or health status perception differences between Eastern and Western countries. Generic QOL questionnaire SF-36, combined with IBS-specific QOL questionnaire will allow a clear understanding of link between IBS and QOL.

In conclusion, the present study offers insight into IBS-consulters patients in Zhejiang. Measurement of QOL in IBS can potentially help both medical decisions makers and policy planners allocated medical resources for treatment of patients.

Abstract

AIM: To study the prevalence of Barrett's esophagus in Chinese and its correlation with gastroesophageal reflux.

METHODS: This study was carried out in a large prospective series of 391 patients who had undergone upper endoscopy. The patients were divided into 3 groups according to the position of squamocolumnar junction (SCJ). Reflux esophagitis (RE) and its degree were recorded. Intestinal metaplasia (IM) in biopsy specimen was typed according to histochemistry and HE and alcian blue (pH2.5) staining separately. Results correlating with clinical, endoscopic, and pathological data were analysed.

RESULTS: The prevalence of IM endoscopically appearing Long-segment Barrett's Esophagus (LSBE) was 26.53%, Short-segment Barrett's Esophagus (SSBE) was 33.85% and gastroesophageal junction (GEJ) was 34.00%. IM increased with age of above 40 years old and no difference was found between male and female. Twelve were diagnosed as dysplasia (7 low-grade, 5 high-grade), 16 were diagnosed as cardiac adenocarcinoma and 1 as esophageal adenocarcinoma. The more far away the SCJ moved upward above GEJ, the higher the prevalence and the more severe the RE were.

CONCLUSION: There was no difference of the prevalence of IM in different places of SCJ, and IM increased with age of above 40 years old. It is important to pay attention to dysplasia in the distal esophagus and gastro-esophageal junction, and adenocarcinoma is more common in cardia than in esophagus. BE is a consequence of gastroesophageal reflux disease.

INTRODUCTION

Adenocarcinoma of the esophagus and gastro-esophageal junction (GEJ) is increasing, while the distal gastric cancer has been falling in the past two decades in North America, Europe, Japan and China. In China, the incidence of adenocarcinoma at GEJ is increasing more obviously[1-3].

Adenocarcinomas at the distal esophagus and GEJ differ from those in the rest of the stomach[4]. They share epidemiological characteristics with and often originate from segments of Barrett's esophagus (BE). It is therefore proposed that both of them be called "esophagocardia adenocarcinoma"[5]. It has been well defined that Barrett's esophagus is a premalignant condition for esophageal adenocarcinoma and most adenocarcinomas at GEJ[6,7].

In early studies, BE was defined as the presence of specialized IM in a columnar-lined mucosa encompassing more than 3 cm proximal to GEJ or a LSBE(long-segment Barrett's esophagus)[8]. Any columnar-lined mucosa found less than 3 cm above the GEJ was thought to be a normal variant. However studies in the past years indicate that there is a spectrum of involvement that includes the distal 3 cm of esophagus or a SSBE (short-segment Barrett's esophagus)[9,10].

Although the cause of BE has not been defined finally, it is considered that BE has a strong correlation with chronic GERD (gastro-esophageal reflux disease)[11]. Ten to twelve percent of patients with BE would receive endoscopy because of refluxing symptoms. Great attention has been paid to the studies of BE by overseas scholars. With the rapid development of China, the western food has become popular and fat persons are increasing, so is the GERD. But few studies on BE have been reported about the correlation between BE and GERD in Chinese. We performed a prospective study in order to determine the prevalence of BE in patients and to evaluate the correlation between BE and gastroesophageal reflux.

MATERIALS AND METHODS

Patients

Consecutive patients undergoing gastroscopy at our hospital from August 1, 2000 to August 30, 2001 were enrolled. Exclusion criteria were history of gastro-esophageal surgery and contraindication to performing biopsies. In each case, the following data were obtained: age, sex, and past medical history of ulcer, gastro-esophageal reflux symptoms (either heartburn or acid regurgitation), drug therapy, and past history of surgery.

The study was approved by the ethics committee of our hospital and all patients gave written informed consent prior to inclusion.

Endoscopic definition and biopsy

Endoscopy was performed by the same expert in a standard procedure, with visualization of the esophagus, stomach and duodenum. The appearance of SCJ was carefully studied in prograde view and after retroversion in the stomach. The position of GEJ was the boundary of tubular esophagus turning into stomach. According to the distance from GEJ to SCJ, the extent of the columnar lining, patients were divided into three groups[12]: Group A, 98 patients, whose SCJ was at least 3 cm above GEJ, suggesting a LSBE; Group B, 127 patients, whose SCJ was less than 3 cm above GEJ, suggesting SSBE; Group C, 150 patients, whose SCJ and GEJ were at nearly same level. Endoscopic esophagitis was graded into Grade I as mucosal

hyperaemia, Grade II as non- circumferential mucosal breaks or erosions, Grade III as circumferential erosion or ulcer. Fifteen patients with cardiac adenocarcinoma and one patient with esophageal adenocarcinoma were excluded.

Standard four-quadrant biopsies were performed distal to the SCJ. Separate target biopsies were also taken from any suspicious erosions, nodules or ulcers. Four to six pieces of biopsy specimens were taken from each patient.

Biopsy specimens were fixed in 40 g/L buffered formaldehyde, embedded in paraffin wax, serially sectioned, and then stained with hematoxylin and eosin. BE was defined as the presence of distended, barrel-shaped goblet cells, indicative of intestinal metaplasia[6,13,14](Figure 1). BE was confirmed by further sectioning and staining the biopsies with alcian blue (pH2.5). Each section was reviewed by two experienced gastrointestinal pathologists respectively.

Statistical analysis

Statistical analyses were performed using the SPSS9.0 analysis system. The χ^2 or Fisher's exact test was used when appropriate. $P<0.05$ was considered statistically significant.

RESULTS

These patients consisted of 211 males and 180 females with a mean age of 52.41 yr (range 20-82 yr). Reflux was found in 149 cases, pain at superior belly in 89 cases, dysphagia in 26 cases, nausea and vomiting in 18 cases, melena in 13 cases and emaciation in 5 cases.

Clinic features of study population

There were 103 patients with RE (39 grade I, 35 grade II and 29 grade III),69 with Barrett's esophagus (26 LSBE, 43 SSBE), 51 with IM at GEJ, 12 cases with dysplasia [7 low–grade dysplasia, LGD (Figure 2A,B); 5 high–grade dysplasia, HGD (Figure 2C)], 17 with adenocarcinoma at the gastro-esophageal junction and 1 with adenocarcinoma of esophagus. The age was positively related to the progress from RE→BE→LGD→HGD→adenocarcinoma (Table 1).

Table 1 Clinical features of study population

	Number	Average age(yr)	Male:Female
Total	391	52.41	211:180
RE I	39	52.12	26:13
II	35	53.67	26:9
III	29	55.56	24:5
IM at GEJ	51	54.37	39:12
SSBE	43	54.71	34:9
LSBE	26	58.66	20:6
LGD	7	59.57	5:2
HGD	5	62.00	3:2
Cardiac adenocarcinoma	15	62.64	13:2

LGD: Low grade dysplasia, HGD: High grade dysplasia, IM: Intestinal metaplasia.

Prevalence of IM and dysplasia at different SCJ

There were no significant differences in incidence of IM between three groups and between male and female of each group (Table 2).

Association of age and sex with the incidence of IM in different groups

In this study, IM was not found in patients under 30 years old.

However, it increased in patients over 30 years old and gradually reached the peak over 40 years old. There were no significant differences of the incidence of IM between males and females in different age groups ($P>0.05$)(Table 2).

Relation between RE and different position of SCJ

Comparing the incidence and degree of RE with the different position of SCJ, the positive correlation was found. The longer the SCJ moved upward above GEJ, the higher the prevalence and the more severe the RE were (Table 3).

**Figure 1** Goblet cells with HE stain (10×10).

Figure 2 A: Barrett's esophagus with LGD (10×40), B: Barrett's esophagus with LGD (10×10), C: Barrett's esophagus with HGD and carcinogenesis (top left corner) (10×10).

Table 2 Prevalence of IM and dysplasia at different SCJ positions

Position of SCJ	Number (male/female)	Age(yr)	IM (male/female)	Incidence of IM (%)	Dysplasia	
					LGD	HGD
Group A	98 (61/37)	58.66	26 (20/6)	26.53	2	1
Group B	127 (63/64)	55.05	43 (25/18)	33.85	1	2
Group C	150 (71/79)	54.37	51 (19/32)	34.00	4	2
Total	375 (195/180)		120 (64/56)	32.00	7	5

The incidence between groups and between male and female of each group was compared by χ^2 test and *P*>0.05.

Table 3 Different SCJ positions and RE

Position of SCJ	Number	RE I (%)	RE II (%)	RE III (%)	Total of RE (%)
Group A	98	13(13.26)	19(19.39)	24(24.48)	56(57.14)
Group B	127	17(13.38)	10(7.87)	2 (1.57)	29(22.83)
Group C	150	9 (6.00)	6 (4.00)	3 (2.00)	18(12.00)
The total	375	39(10.40)	35(9.33)	29(7.33)	103(27.46)

Analysis by trend χ^2 test, the incidence and degree of RE and the position of SCJ in groups C, B and A had a positive correlation. *P*<0.05.

DISCUSSION

The point emphasized in original definition of Barrett's esophagus was the length replaced by columnar epithelium of normal squamous mucosa. However, the length is not vital in new definition of Barrett's esophagus, in which what is important is the presence of IM relating to adenocarcinoma[15]. Researches in recent years have implicated the correlation between carcinoma of gastric cardia and Barrett's esophagus as well as IM at GEJ[16,17]. Some researches discovered that about 35-40% carcinomas of gastric cardia were related with Barrett's esophagus, even some advanced esophageal adenocarcinomas at GEJ[18,19]. These findings at least illuminate some correlation. The relationship between Barrett's esophagus and esophageal adenocarcinoma has been confirmed. Whether cardiac carcinoma is a consequence of IM is unclear.

The study population comprised 391 patients who underwent endoscopy. There were 103 patients with RE (39 grade I, 35 grade II and 29 grade III), 120 with Barrett's esophagus (26 LSBE, 43 SSBE), 51 with IM at GEJ, 12 with dysplasia (LGD 7 cases , HGD 5 cases), 15 with carcinoma of gastric cardia. More lesions were found in males than in females. Furthermore, pathologic changes from RE→Barrett's esophagus→dysplasia →canceration were related with increased age of patients.

According to the position of SCJ, the patients were divided into 3 groups in this study. The incidence of LSBE in group A was 26.53%(26/98), and the incidence of SSBE in group B was 33.85%(43/127) and IM in group C was 34.00%(51/150). These results were different from those of other scholars. Dias Percira[20] discovered that the incidence of SSBE in Portuguese was 61.3% and the incidence of IM at GEJ was 25%. The incidence of IM at GEJ in Euramerican varied from 5% to 36%[21,22]. Spechler[23] found that the incidence of LSBE was 65.38%, far higher than that in our study. The high incidence of LSBE was directly related to esophageal adenocarcinoma. Nakamura *et al.*[24] found that the incidence of IM at GEJ was 28% in Japanese, which was close to our result. Of course, the exact position of GEJ is very difficult to locate under gastroscope, even with surgical specimens. The generally accepted view is that the position of GEJ is the boundary of tubular esophagus turning into stomach. Moreover, the number of biopsy specimens also works on the detection rate of IM. The more the number of biopsy specimens are, the higher the detection rate of IM is. The numbers of biopsy specimens are directly related to the identification of Barrett's esophagus, however there are still no criteria as to how many biopsy specimens should be taken from one patient. Many scholars have suggested that more specimens should be taken in suspect lesions and one piece of specimen should be taken at least every 2 cm respectively from each quadrant. Paull *et al.*[25] found that IM was usually distributed in the proximal mucosa of lesion adjacent to squamoucolumnar junction (SCJ). Specimens adjacent to SCJ are helpful to increase the detection rate of IM. In this study, at least one piece of specimen was taken respectively from each quadrant of distal columnar mucosa adjacent to SCJ and more specimens were taken if there were questionable lesions. So, 4-6 biopsies were taken from each patient. For biopsy specimens, the goblet cell secreting acidic mucus could be dyed blue by AB (pH2.5) staining, which was beneficial to the diagnosis of IM[26].

Increasing researches considered that IM at GEJ had two origins, SSBE and IM of gastric cardia[27]. Whether it is necessary to study SSBE and IM at GEJ separately or whether they are the same lesion is unknown. Besides, there are no exact definitions of IM at distal part of esophagus and at gastric cardia. Researches in recent years showed that the development of IM at GEJ might be related with infection of *H pylori*[28]. The infection of *H pylori* in China is common, therefore, it is necessary to do more investigations.

In this research, IM was not found in patients younger than 30 years old. The incidence of IM increased with the age and reached the peak at the age of 50-70 yr, but the incidence of IM had no significant differences between males and females in different age groups and at different SCJ positions (*P*>0.05). It was reported that attacks of Barrett's esophagus were seldom found in children and young people, but it would increase with the age. It will take about 20 yr to develop from Barrett's esophagus to esophageal adenocarcinoma[29].

Researches showed that Barrett's esophagus was a precancerous lesion of esophageal adenocarcinoma and gastric cardia carcinoma. Pathologic researches discovered that canceration of Barrett's esophagus would undergo a pathologic process from SIM→LGD→HGD→carcinoma *in situ*→advanced adenocarcinoma. Some researches discovered that it took 1.5-10 yr to develop into adenocarcinoma from HGD[30,31]. A few patients would remain at the stage of HGD for many years. Part of patients would develop into adenocarcinoma from IM in 3-10 years[30,32]. Seven patients with LGD and 5 with HGD were diagnosed in this study and the follow-up for the patients with dysplasia should be strengthened. The patients with HGD should be followed up every 1-3 mo and multipoint biopsy should be taken to avoid delaying the diagnosis of tumors. We diagnosed 15 cases of cardiac adenocarcinoma and 1 case of esophageal adenocarcinoma, which showed that adenocarcinoma of cardia was more common than that of esophagus in China.

It is recognized by most scholars that RE leads to Barrett's esophagus. In our study (Table 3), the incidence of RE in group A (57.14%) was higher than that in group B (22.83%) and was higher in group B than in group C (12.00%). Furthermore, the incidence of RE III was also far higher in group A (24.48%) than in group B (1.57%). Dias found that the occurrence of RE in group of SSBE was higher than that in group of GEJ, which was similar to our conclusion[20]. We examined the incidence and degree of RE as well as the SCJ position in groups C, B, A and found that they had a positive correlation (*P*<0.05), that is, the longer the SCJ moved upward above GEJ, the higher the prevalence and the more severe of RE were. The result in this study conformed to the viewpoint of most researchers that the squamous epithelium of lower esophagus was replaced by columnar epithelium and then developed into intestinal metaplasia. There is no exact conclusion about whether IM at GEJ has relation to RE or not.

In a word, it is important to pay attention to the diagnosis of dysplasia in the distal esophagus and esophagogastric junctions. Cardia adenocarcinoma is more common than that of esophagus. BE is a consequence of gastroesophageal reflux disease.

Abstract

AIM: An insertion mutation at nucleotide 3020 (3020insC) in the Caspase recruitment domain gene (CARD15), originally reported as NOD2, is strongly associated with Crohn's disease. The C-insertion mutation at nucleotide 3020 (3020inC) in the leucine-rich repeat (LRR) region results in a frameshift in the 10th LRR followed by a premature stop codon. This truncation mutation is responsible for the inability to activate nuclear factor (NF)-κB in response to bacterial lipopolysaccharide (LPS). The present study aimed to genotype NOD2/CARD15 gene 3020insC frameshift mutation in Chinese patients with inflammatory bowel disease.

METHODS: We genotyped an insertion polymorphism affecting the leucine-rich region of the protein product by the allele specific PCR in 74 unrelated patients with ulcerative colitis of Han nationality in Hubei Province of China, 15 patients with Crohn's disease and 172 healthy individuals.

RESULTS: No significant differences were found in the genotype and allele frequencies of the C-insertion mutation of NOD2 gene among patients with Crohn's disease and ulcerative colitis and healthy controls.

CONCLUSION: NOD2 gene 3020insC frameshift mutation is not a major contributor to the susceptibility to both Crohn's disease and ulcerative colitis in Chinese Han patients.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic intestinal inflammatory disorder that is clinically classified into Crohn's disease (CD), ulcerative colitis (UC) and indeterminate colitis. IBD is characterized by a dysregulated mucosal immune response and its pathogenesis has not been fully illustrated, but several epidemiological and genetic studies have suggested that IBD is predisposed by certain environmental and genetic factors[1-3]. IBD1 was the first susceptible locus linked to Crohn's disease. Utilizing genome-wide linkage studies among families with multiple affected members, Hugot *et al.*[1] mapped the IBD1 gene to the proximal region of the long arm of chromosome 16 (16q12) in the white population. In Jewish families, the IBD1 locus was demonstrated to be significantly associated with CD[4], but not with ulcerative colitis. Hugot *et al.*[5] identified nucleotide oligomerisation domain (NOD2) as the IBD1 gene through routine positional cloning methods, the same finding was also reported in several other studies[6,7]. NOD2, a member of the NOD1/APAF1 gene family, comprises an amino-terminal effector domain, a nucleotide-binding domain and leucine-rich repeats (LRRs)[8]. Recently, NOD2 has been known as Caspase activating recruitment domain (CARD) 15. NOD2/CARD molecule is expressed exclusively in monocytes and activates NF-κB through the interaction with its N-terminal CARDs[8]. As studies have shown that the signaling by tumor necrosis factor (TNF) and activation by nuclear factor (NF)-κB play a key role in IBD, NOD2 mutation may lead to the variation of NF-κB activation. Three mutations (R702W, G908R, 1007fs, respectively at SNP8, 12, and 13) have been identified in NOD2/CARD15, which were shown to be independently associated with CD. One of the mutations predisposing to CD is 1007fs, the C-insertion mutation at nucleotide 3020 (3020inC) in the leucine-rich repeat region, results in a frameshift in the 10th LRR followed by a premature stop codon. This truncation mutation may result in the inability to activate NF-κB in response to bacterial lipopolysaccharides (LPS). Therefore, NOD2 is considered to play a role in the pathogenesis of CD.

Studies by Japanese and Hongkong researchers, however, have failed to identify the insertion mutation both in patients and in control subjects[9,10]. Greek has shown that NOD2 is not significant in the pathogenesis of CD[11]. These studies support that CD possesses genetic heterogeneity among different populations. In this present study, we genotyped the 3020insC mutation of NOD2 gene in CD and UC in Chinese subjects of Han nationality in Hubei Province, to identify the susceptible gene for Chinese.

MATERIALS AND METHODS

Patients

A total of 15 unrelated patients with CD and 74 patients with UC were included in this study. As a control group 174 healthy individuals were also recruited from medical staff and students in Zhongnan Hospital of Wuhan University, as well as from healthy volunteers in Wuhan city. The diagnosis of either UC or CD was established and verified by clinical, radiological, endoscopic and histological examinations in accordance with the criteria by Lennard-Johns[12]. All the subjects included in this study were unrelated Chinese of Han nationality in Hubei Province. This study protocol was approved by the Ethic Committee of Medical School of Wuhan University.

Methods

DNA was isolated from peripheral blood leukocytes by conventional proteinase K digestion and phenol/chloroform

extraction methods. Allele-specific PCR was employed to detect the 3020insC mutation of NOD2 gene[6] and to generate a nonspecific 533-bp product, along with a 319-bp fragment (wild type) and/or a 214-bp fragment (3020inC). The primers used for PCR are listed in Table 1. PCR was performed in a reaction system in a volume of 25 μL containing sense and antisense primers (each in a volume of 0.5 μL at the concentration of 20 pmol/μL), wild-type sense and 3020insC antisense primer respectively (each in a volume of 0.25 μL at the concentration of 20 pmol/μL), 2.5 μL of 10×buffer, 0.5 μL of 10 mmol/L dNTPs, 1 μL of template DNA, 0.5 μL of AmpliTaq DNA polymerase (MBI Fermentas), and 19 μL of ddH$_2$O. Amplification was carried out with a Perkin-Elmer thermocycler. The cycling was performed with an initial denaturation for 5 min at 94 ℃, followed by 35 cycles at 94 ℃ for 45 s, at 59 ℃ for 45 s, at 72 ℃ for 45 s with a final extension at 72 ℃ for 7 min. The PCR products were identified by electrophoresis in non-denaturing polyacrylamide gels containing 8% acrylamide-bisacrylamide (29:1), 0.5× Tris-borate-EDTA (TBE), 100 g/L ammonium persulfate, and TEMED at 150 V for 1.5 h. The gels were then subjected to silver staining. The PCR products used for sequencing analyses were purified and analyzed using an ABI377 automated sequencer (Applied Biosystems, USA). DNA samples for genotype control analysis were kindly provided by the Laboratory of Immunogenetics of Free University of Amsterdam, Netherlands.

Table 1 Primers used for multiplex PCR

Primer	Sequence
Sense primer	5'-CTGAGCCTTTGTTGATGAGC-3'
Antisense primer	5'-TCTTCAACCACATCCCCATT-3'
Wild-type sense primer	5'-CAGAAGCCCTCCTGCAGGCCCT-3'
3020insC antisense primer	5'-CGCGTGTCATTCCTTTCATGGGGC-3'

Statistical analysis

Statistical analysis was performed with SPSS 11.5 software package. The data were analyzed by χ^2 test or Fisher's exact test. A P value less than 0.05 was considered statistically significant. The confidential intervals (CI) for the odds ratios (OR) were calculated by Woolf formula.

RESULTS

The results of the genotypes and allele frequencies of the 3020insC mutation in CD and UC patients and in ethnically matched Chinese healthy controls are shown in Table 2. Two heterozygotes of the mutation in UC patients and one in CD patients were identified, whereas only one heterozygote mutation was found in healthy controls. No significant associations were noted in genotypes and allele frequencies of the 3020insC mutation in UC (P=0.2165) or CD (P=0.1542) in comparison with the healthy controls. The NOD2 3020insC mutation was not associated with CD or UC in Hubei Han population.

Table 2 3020insC mutation in healthy controls and ulcerative colitis and Crohn's disease in Chinese Han population

| Genome	Healthy controls (n=172)	Ulcerative colitis (n=74)	Crohn's disease (n=15)
Wild type	171	72	14
Heterozygote	1	2	1
3020insC mutation homozygote	0	0	0
Wild type allele frequency	99.7%	98.7%	96.7%
Mutative allele frequency	0.3%	1.3%	3.3%

Figure 1 Identification of frameshift NOD2 mutation in Chinese population by allele specific PCR. Multiplex PCR was used to generate a nonspecific 533-bp and allele-specific amplified products, a 319-bp fragment (wild type) and a 214-bp fragment (C-insertion type). Lane 1: pBR322 DNA/*Msp*I markers; Lane 2: Heterozygous for 3020insC; Lane 3: Wild-type control; Lane 4: Homozygote for 3020insC. Numbers on the left are the lengths of the fragments.

DISCUSSION

In this study, we did not find any evidence suggestive of the association of NOD2 frameshift mutations with CD or UC. The allele frequency of 3020insC mutation was slightly increased in CD and UC patients when compared with the healthy controls, but there were no statistically significant differences among these three groups. After the initial report of the associations between mutations in the NOD2 gene and susceptibility to CD[5,6], a German and British study[7] soon found evidence to show that the insertion mutation in the NOD2 gene was responsible for a substantially increased susceptibility to CD but not to UC. Other studies have suggested that attributive risks of the 3020insC mutation of NOD2 differ in different ethnic nationalities and countries. A large-scale study in Japanese failed to identify the insertion mutation both in patients and in controls[9], the same result was also reported by Leong et al.[10] in Chinese population in Hong Kong. A study in a Cretan showed that NOD2/CARD15 was not significant in the pathogenesis of CD[11]. All these data and the results of this study demonstrate that CD has genetic heterogeneity among different nationalities.

NOD2 was recently identified as a susceptible gene of CD in most Western countries, which provided an opportunity to study the relationship between NOD2 gene and innate immunity in CD. NOD2 was located in the peak region of linkage on chromosome 16q12 and a member of the NOD1/APAF1 gene family[8], expressed primarily in monocytes and functioned to activate NF-κB in response to LPS stimulation[13,14]. 3020insC, which resulted in a frameshift mutation at the second nucleotide of codon 1007, a Leu1007→Pro substitution in the tenth LRR and followed by a premature stop codon, encoded a truncated NOD2 protein and led to a weakened innate immune response in CD[8]. In our study we did not find any statistically significant association between the 3020insC mutation and CD. Other mechanisms of CD involving the susceptible gene and innate immunity have been suggested in Chinese Han nationality in Hubei Province.

Abstract

AIM: To evaluate the feasibility of a new strategy of endoscopic variceal ligation combined with partial splenic embolization (EVL-PSE) for patients with cirrhosis and portal hypertension.

METHODS: From May 1999 to May 2002, 41 cases with cirrhosis and portal hypertension underwent EVL-PSE. Hemodynamics of the main portal vein (MPV), the left gastric vein (LGV) and azygos vein, including maximum velocity, flow rate and vein diameter, were assessed by Doppler ultrasonography.

RESULTS: One case died from pulmonary artery embolism. One case complicated with splenic abscess was successfully managed by laparotomy. The esophageal varices and hypersplenism were well controlled after EVL-PSE in other patients. After EVL-PSE, the flow rate and velocity of MPV was significantly reduced ($P<0.05$), as well as the flow rate of the LGV and azygos vein. During the follow-up, no recurrent bleeding was found.

CONCLUSION: Being more convenient and less invasive, EVL-PSE is hopeful to be a proper intervention strategy for portal hypertensive patients with impaired hepatic function or those intolerant to shunting or devascularization surgery.

INTRODUCTION

Recently, various non-surgical and less invasive treatments for liver cirrhosis and portal hypertension have been developed and accepted world-wide. However, these more up-to-date methods have their drawbacks, respectively. We introduced a new strategy combining endoscopic variceal ligation with partial splenic embolization (EVL-PSE) and examined its therapeutic features. The present study was thus designed to determine, in a controlled and prospective manner, whether this intervention would decrease the risk of variceal bleeding and improve the hypersplenism in cirrhotic patients effectively. In the meantime, we investigated the portal hemodynamic changes before and 1 week after EVL-PSE by Color Doppler Flow Imaging (CDFI).

MATERIALS AND METHODS

Patients

Between May 1999 and May 2002, 41 patients with portal hypertension underwent EVL-PSE in the Third Hospital Affiliated to Sun-Yet-San University, China. Data of the patients and control subjects are given in Table 1. Hepatitis induced cirrhosis was the main cause of portal hypertension. Functional hepatic reserve was classified according to the Pugh-modified Childs' scales. All patients met the following criteria: (1) history of at least once upper gastrointestinal hemorrhage; (2) varices of size III or IV; (3) without other diseases (*e.g.* cancer) decreasing one's life expectancy.

All patients in the EVL-PSE group had hypersplenism of various degrees and 15 cases presented with active variceal bleeding seen directly by endoscopy at admission. After a thorough clinical and physical examination, 40 volunteers without obvious defect in cardiovascular or digestive system were studied as control group.

Table 1 Clinical characteristics of cirrhotic patients and control subjects

	EVL-PSE group (n=41)	Control group (n=40)
Sex:male／female	32／9	29／11
Age:mean,range(years)	43,34-67	37,18-68
Childs' class:A／B／C	5／26／10	0
Etiology		
Viral hepatitis	37	0
Primary biliary cirrhosis	1	0
Schistosomiasis	4	0
Virix grading (III／IV)	14／26	
Red color sign	15	0

Procedures of EVL-PSE

(1) The procedure of EVL has been described in detail elsewhere[1-6]. Ligation was performed at 1 to 5 cm above the gastroesophageal junction with 6 to 12 ligation sites per individual. EVL was repeated biweekly until all esophageal varices were ligated. (2) PSE was performed about 1 week after successful hemostasis by first EVL. (3) The PSE procedures: Selective splenic arterial cannulation and angiography were accomplished with a Seldinger's puncture of femoral artery[7] to evaluate the mass of the spleen and its vascular supply. The catheter reached the far end of the splenic artery as possible, through which granules of Gelfoam (1-2 mm³) soaked in certain antibody were injected so as to make the peripheral branches embolized. According to the area differences judged from the angiography before and after PSE as well as the CT results, we estimated the infarction size. In our study, 30-60% of the spleen parenchyma were infarcted. (4) Antibiotics were used as routine systemically and locally before and after the operation. Intestinal preparations were done just like a colonic operation. (5) We measured hemodynamic parameters of the main portal vein (MPV), left gastric vein(LGV) and azygos vein, including maximum velocity, flow direction and vein diameter by Color Doppler ultrasonography (Philip SD 800, Holland), with a 2.0-7.5MHZ convex array transducer.

Scanning was performed with patients in a supine position and the portal vein and left gastric vein were visualized via a transabdominal way while imaging of the azygos vein was through suprasternal fossa. The blood flow velocity was calculated from Doppler spectral traces of 4-6 s with 1 to 10 mm sampling volume adjusted according to the respiration and the mean values were calculated as the mean blood flow velocity. To avoid equipment and operator variability, all examinations were performed using the same equipment by the same ultrasonogist.

Statistical analysis

Analyses were performed by using SPSS10.0 statistical packages. The results are presented as mean±SD and were considered to be significant if $P<0.05$. The data analyses before and 1 week after EVL-PSE of portal hypertensive patients were made using the paired *t*-test. Analysis of variance was used to verify differences between groups.

RESULTS

Efficacy of EVL-PSE on varices occlusion and bleeding control

EVL-PSE was performed successfully in all 41 cases. A total of 128 EVLs were done, with a mean of 3.1 (2-5) EVLs per patient. All esophageal varices were occluded. Nine cases with active variceal bleeding underwent successful emergent EVL. One patient suffered a recurrent bleeding 11 d after the initial intervention and received a repeated EVL with perfect result. No recurrent bleeding was observed in the other 40 cases during hospitalization, and no case presented with another hemorrhagic event during 2-24 mo follow-up (mean 9.9 mo).

Changes of laboratory parameters after EVL-PSE

The effect on blood routine examination is shown in Table 2, where a significant increment was observed both for leukocyes and thrombocytes 1 and 2 weeks after EVL-PSE. The changes of the hemoglobin contents throughout the operation was of nostatistical significance.

Table 2 Changes of laboratory parameters after EVL-PSE

	Hemoglobin (g/L)	WBC (×10⁹/L)	Platelet (×10⁹/L)
Before EVL-PSE	104±14	2.9±0.6	55±11
1 wk after EVL-PSE	117±12	7.4±1.5[a]	102±18[a]
2 wk after EVL-PSE	119±16	6.1±1.2[a]	120±24[a]

[a]$P<0.05$ *vs* before EVL-PSE.

Gross and pathologic changes of spleens

Forty cases showed significantly smaller spleens after PSE, and the shrinkage degree correlated well with the infarcted area. One patient underwent splenectomy 2 wkafter PSE. Grossly the spleen presented with grey regions of segmental infarction, and microscopic examination suggested degeneration and necrosis of the splenic parenchyma with proliferation of surrounding fibrous tissue.

Adverse effects and complications

The majority of patients had EVL-related mild angina and/or retrosternal pain, which usually palliated spontaneously 3-5 d later without any special management. Forty cases had different degrees of fever and pain in left upper quadrant. The fever was usually around 38 ℃ and lasted 3-7 d with an exception of 28 d. One patient had splenic abscess and recovered after operation. Another case died 2 d after PSE due to pulmonary arterial embolism.

Color doppler ultrasound changes

Comparisons of Doppler parameters before EVL-PSE between the cirrhotic patients and controls are listed in Table 3. Significant differences were found in blood flow, blood flow rate and diameters of the main portal vein (MPV), left gastric vein (LGV) and azygos vein between the two groups. Table 4 presents the effects of EVL-PSE on the collateral branches of main portal vein and azygos vein. The diameters of MPV before and after the operation showed no difference, while the blood flow and blood flow rate decreased significantly, as well as the blood flow-rates of LGV and azygos vein.

DISCUSSION

What is the therapeutic strategy for portal hypertension? As medical doctors, we have been working on it assiduously. Poor hepatic function and impaired tolerance to the operation make it very important and of great clinical significance to explore an optimal strategy both effectively and the least invasively for portal hypertensive patients.

EVL is the widely accepted treatment for the bleeding of esophageal varices because of its definite efficacy, more convenience and safety and minor invasiveness. it, however, had a much longer course of treatment and the rate of recurrent hemorrhagic events in the short term was as high as 15-36%, especially before the varices were completely occluded[8-10]. EVL alone had no effect on hypersplenism, either. PSE is a new interventional radiological method for the treatment of hypersplenism secondary to portal hypertension. Generally,

[1]$P>0.05$, [a]$P<0.05$, [b]$P<0.01$.

30-40% of splenic infarction by PSE could improve hypersplenism, and 50-60% would affect favourably the portal pressure[7]. We discovered that the hypertrophic spleen would shrink more or less when the infarcted area reached 30-60%, with a significant increase of white blood cells and platelets in the peripheral blood ($P<0.05$), which suggested that PSE could improve the hypersplenism effectively. Former study demonstrated similar results. The content of hemoglobin changed little during PSE, because it was correlated much closely with the patients' bleeding history and the amount of transfusion.

The current study revealed no changes of the diameters ($P>0.05$) of MPV as well as its significantly lower blood flow velocity and decreased blood flow rate ($P<0.05$) after EVL-PSE. Traditional opinions held that portal blood flow after splenectomy or devascularization procedures would not decrease even would increase, while more up-to-date researches discovered that portal blood flow decreased as a result of devascularization, similar to that of decompressive shunts surgery[11-13]. We found the similar results to a further degree, that is, the diameter of MPV after PSE showed no difference, the portal blood flow decreased significantly, however. Some held the opinion that the increased blood flow in portal hypertension come mainly from the splenic vein. PSE decreased the reflux of splenic vein, therefore, the blood flow of MPV decreased as well as its pressure. EVL-PSE decreased the blood flow and pressure of MPV equivalent to the conjoint effects of splenectomy and devascularization. The hemodynamic changes of MPV may be not quite the same because of individual difference, from which some scholars concluded that interventional therapy should be based on the patients' hemodynamic conditions individually. We found in the portal hypertension group enlarged LGVs and hepatofugal blood flow in the pre-operation examination, which both indicated the patency of the esophagocardiac collateral circulation. LGV dilated and its blood flow decreased after EVL-PSE, which probably were results of the increased blood flow of the mucosa in the fundus and gastric body after repeated ligation. The gastric mucosa might be damaged more severely as a consequence. We should go further to identify its long-term effects. The diameter and blood flow velocity were strikingly higher in portal hypertension patients than controls before EVL-PSE ($P<0.01$). Some studies reported the same conclusions. They considered that measurement of the azygos blood flow was of importance for the patients' treatment and prognosis[14]. Main branches of the portosystemic collateral circulation being cut-off, the diameter and blood flow-rate of azygos vein decreased significantly after EVL-PSE ($P<0.01$). However, they were still higher than that of the controls, indicating that other shunts for the superior vena cava, such as the periesophageal veins and abdominal wall veins accounted for the flow of azygos vein to a great extent.

Except for an ectopic embolism resulting from inappropriate operation, the main complications in our study were PSE-related pain in left upper quadrant and mild to moderate fever, which could be relieved by a small dose of NSAID such as mezolin, etc. satisfactorily. Splenic abscess was diagnosed 2 wk after EVL-PSE in one case, and the patient whose spleen parenchyma was infarcted very much (about 70%) was recovered and discharged after splenectomy. Infarcted area more than 60% would induce more complications. Strengthened antibiotic use together with intestinal preparation and especially, perfect operation were the key points for a favorable result with less complications.

The esophageal varices were completely obliterated by EVL-PSE in 40 patients, with an average of 3.1 EVLs per patient. No case except one suffered recurrent bleeding during hospitalization and follow-up. In contrast, the obliteration rate of esophageal varices was 80-91% by EVL alone, with an average of 4 EVLs per patient, and with a recurrent bleeding rate as high as 15-17.1%[1]. EVL-PSE was superior to EVL alone. The underlying mechanism might be that PSE could decrease the blood flow of MPV, and the consequent pressure lowering of portal vein made varices less viable to recur.

Conclusively, EVL-PSE was effective in the treatment of esophageal variceal hemorrhage and hypersplenism secondary to portal hypertension, and it could also decrease the total EVLs needed to make the varices occluded and the rate of short-term recurrent bleeding. The reduction of blood flow of MPV lowered the risk of recurrent bleeding after EVL. Being very convenient and little invasive, EVL-PSE is probably the first choice of intervention at strategy for portal hypertensive patients with impaired hepatic function or those intolerant to shunting or devascularization surgery.

Abstract

AIM: To investigate the resistance rate of *Helicobacter pylori* (*H pylori*) to clarithromycin, metronidazole, amoxicillin and tetracycline to guide clinical practice, and to study the mechanism of *H pylori* resistant to clarithromycin.

METHODS: Thirty *H pylori* strains were isolated from the mucosa of peptic ulcer, gastric tumor and chronic gastritis patients, then the minimal inhibitory concentration (MIC) to clarithromycin, metronidazole, amoxicillin and tetracycline was evaluated by E-test method. The sequence analysis of PCR fragments was conducted in 23S rRNA gene of *H pylori* resistant to clarithromycin to get the resistance mechanism of the bacteria.

RESULTS: Among 30 *H pylori* strains, 7 cases were resistant to clarithromycin, 12 to metronidazole, 2 to tetracycline and no strain was found to be resistant to amoxicillin. The resistance rates were 23.3%, 40%, 6.7% and 0%, respectively. Three new mutation points were found to be related to the clarithromycin resistance in *H pylori* isolates, which were G2224A, C2245T and T2289C.

CONCLUSION: In northeast China, *H pylori* shows high resistance to metronidazole, while sensitive to amoxicillin. The mechanism of resistance to clarithromycin may be related to the mutation of G2224A, C2245T and T2289C in the 23S rRNA gene.

INTRODUCTION

H pylori plays an important role in the pathogenesis of many digestive diseases. The recurrence of peptic ulcer and the development of the gastric cancer are also due to *H pylori* infection[1,2]. In the different eradication therapy regimen including PPI and multiple antibiotics, cases of eradication failure due to resistance of *H pylori* to antibiotics have been reported keeping increasing. The resistance mechanism of *H pylori* in the former studies showed the mutation from A to G in 2 143 and 2 144 position of 23S rRNA gene. But in our study we found other three new mutation points in 23S rRNA gene related to the *H pylori* resistance to clarithromycin.

MATERIALS AND METHODS

H pylori strain

In the endoscopic examination of the patients with digestive symptoms, we collected such patients with peptic ulcer, chronic gastritis and gastric carcinoma as our subjects. Firstly, one piece of gastric antra mucosa biopsy specimen was obtained from the patients for the purpose of rapid urease enzyme test. Then two pieces of antra mucosa biopsy specimens were obtained from the same patient with *H pylori* infection diagnosed by the positive rapid urease enzyme test. The biopsy specimens were cut up in sterile plate and then cultured on the Columbia agar base with 100 mL/L no-fiber fresh rabbit blood and 3 mg/L bacitracin at 37 ℃ for 3-5 d under microaerobic conditions (50 mL/L O_2, 100 mL/L CO_2, 850 mL/L N_2). The organisms were identified as *H pylori* by Gram stain morphology, colony morphology and positive urease, catalase and oxidase activities. The typical bacteria were subcultured to obtain the pure *H pylori* isolates.

Antibiotics susceptibility test

The pure *H pylori* suspension of 1 McFrand unit was prepared with sterile 9 g/L natrium chloride, and spread onto the Mueller-Hinton agar base with 100 mL/L fresh rabbit blood. The minimal inhibitory concentration (MIC) of *H pylori* to different antibiotics was evaluated with E-test strips. Strains were considered resistant to clarithromycin, metronidazole, amoxicillin and tetracycline if the MIC was ≥8 μg/mL, 8 μg/mL, 2 μg/mL and 8 μg/mL respectively.

Resistance mechanism analysis

Three clarithromycin resistant *H pylori* isolates and one sensitive *H pylori* isolate were chosen, that is, No.13 (MIC 8 mg/L), No. 17(MIC 64 mg/L), No.22 (MIC>256 mg/L) and No.33 (MIC 0.125 mg/L). The DNA was extracted from the bacteria with the phenol-chloroform extraction method. We designed primers according to the 23S rRNA gene sequence reported by Hiratsuka (GeneBank accession number U27270). The primers were synthesized by Shanghai Sangon corporation and the sequences were as follows: forward primer: 5' -CTG CAT GAA TGG CGT AAC GAG-3' (complementary to 23S rRNA gene sequence from 2 047 to 2 067);and reverse primer: 5' -GAG CGA CCG CCC CGA TCA AAC-3' (complementary to 23S rRNA gene sequence from 2 327 to 2 347), which will generate a 301 bp product. PCR amplification reaction mixture (20 μL) contained 13.8 μL double distilled H_2O, 2.5 μL 10× PCR buffer, 2 μL dNTPs (2.5 mmol/L), 0.2 μL Ex-Taq polymerase (5u/μL), 1.5 μL primer (1:5×) and 0.5 μL DNA sample. PCR cycle conditions were 32 cycles of 94 ℃ for 40 s, 61.5 ℃ for 1 min,72 ℃ for 1 min after 94 ℃ for 4 min once at

first, then followed by a final extension step at 72 ℃ for 7 min. The purification of PCR products was observed by electrophoresis on an 80 g/L polyacrylamide gel. Then PCR products were sent to Sangon Corporation to conduct the sequence analysis. The amplified 23s rRNA gene sequence of resistant *H pylori* was compared to that of sensitive ones in order to find out the difference between them.

RESULTS

There were 7 cases among 30 *H pylori* isolates resistant to clarithromycin (MICs were from 8 mg/L to 256 mg/L), 12 cases of the isolates was resistant to metronidazole (MICs were from 24 mg/L to 256 mg/L), 2 cases resistant to tetracycline (MICs were 16 mg/L and 32 mg/L) and no case resistant to amoxicillin. The resistance rates to the above 4 different antibiotics were 23.3%, 40%, 6.7% and 0%, respectively.

No.33 *H pylori* isolate was sensitive to clarithromycin, while No.13, No.17, and No.22 isolates were all resistant to clarithromycin. Point mutations appeared at three positions of the intended DNA fragments of clarithromycin resistant *H pylori* 23s rRNA gene. In comparison with the sequence of sensitive *H pylori*, No.13 resistant isolate with MIC 8 mg/L had one point mutation from T to C at 2289 (T2289C), No.17 isolate with MIC 64 mg/L had two point mutations which were G to A at 2 224 position (G2224A) and T to C at 2 289 position (T2289C), and No.22 isolate with the highest MIC >256 mg/L had three point mutations, and these were mutations from G to A at 2 224 position (G2224A), from C to T at 2 245 position (C2245T) and the mutation from T to C at 2 289 position (T2289C). With the increasing resistance of *H pylori* to clarithromycin, the number of point mutation were increased (Figure 1).

DISCUSSION

The prevalence of *H pylori* infection is about one-half of the world's population[3], and still higher in the developing countries and low socio-economic populations[4-6]. It has been demonstrated that *H pylori* is an important etiologic factor of digestive diseases. *H pylori* infection is also correlated with cardio-cerebrovascular and pulmonary disease[7-10]. So eradication of *H pylori* becomes very important in the cure of the above diseases, especially peptic ulcer. But recently, cases of eradication failure become more and more due to the resistance of *H pylori* to antibiotics in the triple regimens.

Tsuneoka *et al*[11] reported that *H pylori* strains from 19 cases (82.6%) out of 23 of failed eradication therapy became resistant to clarithromycin. Reports have shown that about 3-14%[12-14] of *H pylori* isolates are resistant to clarithromycin, 12-44%[13-16] are resistant to metronidazole. But no *H pylori* was found primary resistant to amoxicillin. The study showed that tetracycline resistance rate was ranging from 0 to 11%[13,16,17].

In our study, we isolated 30 *H pylori* strains from patients of peptic ulcer, chronic gastritis and gastric carcinoma and determined their MICs to clarithromycin, metronidazole, amoxicillin and tetracycline by E-test, respectively. Results showed a higher clarithromycin resistance than that in Europe (23.3%, 7/30). It is acknowledged that resistant clarithromycin *H pylori* strains become predominant because of antibiotics selective pressure. Clarithromycin frequently appearing in *H pylori* eradication therapy regimens led to the increasing of clarithromycin resistance. While in China, especially in northeast China, clarithromycin is rarely applied in clinic. How did the high resistance to clarithromycin generate? Is it associated with the extensive application of the other macrolide agents, such as erythromycin, azithromycin, and so on? Dose cross-resistance to macrolide exist among *H pylori* strains? Midolo and Saika *et al*[18,19] have demonstrated the existence of this phenomenon. But no study on this aspect has been done in China. The high resistance to clarithromycin should be considered in selecting *H pylori* eradication therapy regimen.

Metronidazole has been extensively used to treat anaerobic and parasitic infections for a long time, especially in the developing countries. It has been demonstrated that previous exposure of *H pylori* to metronidazole *in vivo* results in the emergence of resistant strains. Metronidazole resistant rate was reported ranging from 12 to 44%, similar to that in this study (40%). But it was also reported that metronidazole resistance as determined by E-test was significantly higher than that determined by agar dilution. Houben *et al*[20] found whether resistant to metronidazole could not affect the therapy outcome of OMC (omeprazole, metronidazole, clarithromycin) regimen. While in another study[21], it showed that the eradication rates were higher than the sensitive rates compared with resistant strains.

Almost all the studies *in vitro* showed high susceptibility of *H pylori* to amoxicillin. This study had the same results. In 30 isolates *H pylori* strains, only 1 strain's MIC to amoxicillin was 4 μg/mL, and other MICs were all very low, between <0.016-0.75 μg/mL. The influence of gastric acid on bactericidal effects was little against amoxicillin compared with macrolide.

Furthermore, its activity *in vivo* is considerably enhanced when given concomitantly with proton pump inhibitors (PPI)[22]. So amoxicillin is still a selection of optimal drugs for the eradication of *H pylori*. Tetracycline is seldom applied in clinical practice at present. So studies on it were also rare. Perhaps due to less application, tetracycline resistance was very low, similar to this study. It was reported that the effect of the combination of macrolide agents with tetracycline was favorable[23].

The mechanism of *H pylori* resistance to clarithromycin was demonstrated to be associated with the mutation of A2143G or A2144G in 23S rRNA gene[24]. Some other mutation points were also reported after that, such as A2142C, A2143C, A2143T, A2115C and G2141[25]. Fontana[26] found that T2717C mutation was related to the *H pylori* resistance. It was known that the genetic character of *H pylori* in the different area was different[27,28], so did the genetic character of resistance *H pylori* strains[29]. Using gene segment analysis directly to determine the mutation position has still not been reported in China yet. We found in our study that the number of mutation points increased with the MIC of the resistant strains. The higher MIC is, the more mutation points are. This result has not been reported in other studies. The further investigation is still required to demonstrate the geographic differences existing in *H pylori* from different countries.

INTRODUCTION

Schistosomiasis is a chronic parasitic disease caused by a trematode blood fluke of the genus schistosoma that belongs to the schistosomatidae family. The ancient Egyptians contracted the disease more than 4 000 years ago. It was recognized through haematuria, the main sign of urinary bilharziasis was recorded in the Kahun papyrus 1900 B.C. as "â-a-â" disease[1].

One of the milestone events in the history of bilharziasis occurred in 1851, Theodor Bilharz, a German physician working at Cairo Medical School, saw the fluke in the mesenteric veins of post-mortem of an Egyptian boy[2,3], then described two types of ova, one with a terminal spine, and the other with a lateral spine, which he considered to be the mature and immature ova, respectively, produced by the female worms of the same species[2].

The controversy was finally settled by Leiper (1915-1918), when he demonstrated the presence of two species of Bilharzia that were different with regard to the morphology of the adult worms, the type of ova, the molluscan intermediate host, and the human habitat (*i.e.* the urogenital versus the intestinal tract)[4].

Another milestone was the introduction by McDonagh (1918), of antimony as an antibilharzial agent, and the popularization of the drug by Christopherson (1918) in Egypt[5,6].

In the life cycle, the adult worms live in terminal venules of the bowel (*S mansoni, S japonicum*) or bladder (*S. haematobium*). When eggs passed in feces or urine reach fresh water, a larval form is released that subsequently infects snails, the intermediate host. After development, infective larvae (cercariae) leave the snails, enter water, and infect exposed persons through the skin or mucous membranes. After penetration, the cercariae become "schistosomula" that reach the portal circulation in the liver, where they rapidly mature. After a few weeks, adult worms pair, mate, and migrate mainly to terminal venules of specific veins, where females deposit their eggs. By means of lytic secretions, some eggs reach the lumen of the bowel or bladder and are passed with feces or urine. Others are retained in the bowel or bladder wall, while still others are carried in the circulation to the liver, lung, and (less often) to other tissues.

PATHOGENESIS

Schistosomiasis is characterized by the formation of inflammatory granulomas around deposited parasite eggs[7].

Granuloma formation is a cell-mediated immune response that is dependent on CD4$^+$ T cells sensitized to schistosomal egg antigens[8,9]. This T cell-mediated granulomatous response gets to the peak between 8 and 10 wk after exposure in mice. This acute stage granuloma is characterized by dense cellularity and maximum cytokine production[7,10,11]. As the infection progresses into the chronic stage (16-20 wk postinfection), cytokine production and cellularity decrease while the fibrotic components of the immunopathologic process increase[7,10,11]. Thus the end result of host responses to schistosome eggs in the liver is advanced portal fibrosis with dense deposits of collagens in greatly expanded portal tracts.

Hepatosplenic schistosomiasis (HSS)

Schistosomal involvement of the liver is an excellent model of the study of immunologic liver injury, fibrosis and hemodynamic disturbances in the absence of parenchymal injury[12]. It may occur with all species of human schistosomiasis but is especially severe with *S. mansoni and S. japonicum*, both in acute and chronic phases of the disease[13].

HSS is a chronic liver disease characterized by granulomatous reaction, portal fibrosis, pre-sinusoidal portal hypertension, splenomegaly, hypersplenism, esophageal varices and haemorrhage[14]. The relative risk to develop hepatosplenomegaly in persons infected with *S. mansoni* have been reported in correlation with HLA-A1 and B5[15].

In advanced HSS, there is excess collagen deposition, mainly in the portal tract and Disse' s space with obstruction of sinusoidal fenestration, resulting in fibrosis and capillarization of sinusoids[16]. According to whether the larger or small portal tract is mainly involved, Hashem[17] classified schistosomal hepatic fibrosis into coarse (first described by Symmers in 1903)[18] and fine types.

The term schistosomal cirrhosis is no longer used, as nodular regeneration and diffuse distortion of hepatic lobular architecture are not the features of hepatic schistosomiasis. The parenchyma between fibrotic areas is typically well preserved, correlating with the maintenance of nearly normal hepatic function, one of the clinical hallmarks of HSS[19].

Diagnostic procedures include demonstration of ova in stool or in rectal snip, ultrasonography of the liver which reveals characteristic periportal fibrosis and sometimes distention of portal and splenic veins exceeding 12 or 10 mm width respectively, upper GI endoscopy which demonstrates esophageal and/or fundal varices and finally liver biopsy which shows Symmer' s or pipe-stem fibrosis.

Concomitant infections with schistosomiasis

Several authors reported a higher frequency of chronic hepatitis B or C in patients with hepatosplenic schistosomiasis than in normal control subjects[20-23]. A statistical correlation between previous parenteral therapy for schistosomiasis and the presence of HBsAg and HCV-Ab were reported in many studies[23-26]. It was also proposed that these patients had an impaired immune response that enhanced their susceptibility to becoming chronic carriers[27]. Concomitant infection with both schistosomiasis and hepatitis B or C causes more severe liver disease than infection with schistosomiasis alone[28]. The prognosis for this group of patients was worse than that
Figure 1 Impact of pathogenic mechanisms, therapeutic and control meaures of schistosomiasis on the liver (El-Zayadi, 1998).

observed by either schistosomiasis or chronic hepatitis B or C as isolated problems[29].

Depressed immunity may also account for chronic salmonellosis infection that often complicates advanced hepatosplenic schistosomiasis. There are prolonged fever and positive blood culture lasting for months and raised level of transaminases as a manifestation of non-specific hepatitis. It can only be cured by both antibacterial and antischistosomal agents[30].

Curse of schistosomiasis on Egyptian liver

The curse of schistosomiasis on the liver involves both direct offensive effect as well as indirect effect of both intravenous therapy and molluscicides used for combating the snail intermediate hosts. The direct effect is represented by ova deposition in the portal tributaries with granuloma formation, which is replaced overtime by periportal fibrosis and hepatosplenomegaly. Subsequently, portal hypertension may result in the development of esophageal varices and variceal bleeding. Ascites and hepatic coma are the end-stage findings. The indirect effect is represented by both transmission of hepatitis B and hepatitis C through improperly sterilized glass syringes[31] used at that time. In the meantime schistosomiasis induced immune suppression could result in increased persistence of viraemia following acute infection of both hepatitis B and C[32]. This could partially explain the increased prevalence of HCV in Egypt. El-Zayadi et al., 1986[33] pointed out that the hepatotoxic effect of K antimony tartarate (tartar emetic) was a heavy metal like arsenic used as therapy in the development of portal fibrosis and angiosarcoma. Furthermore, the spray of cupper sulphate in canals to combat the snail intermediate hosts has been proved to have a hepatotoxic effect

which was incriminated in the pathogenesis of angiosarcoma, hepatocellular carcinoma and cirrhosis[34].(Figure 1).

Recently, this gloomy picture has been dramatically changed with adoption of effective control measures and the use of oral therapy for schistosomiasis. In the meantime, the use of disposable syringes has reduced the risk of transmission of HBV and HCV.

Abstract

Hypoxia-inducible factor-1 (HIF-1), composed of HIF-α and HIF-β subunits, is a heterodimeric transcriptional activator. In response to hypoxia, stimulation of growth factors, and activation of oncogenes as well as carcinogens, HIF-1α is overexpressed and/or activated and targets those genes which are required for angiogenesis, metabolic adaptation to low oxygen and promotes survival. HIF-1 is critical for both physiological and pathological processes. Several dozens of putative direct HIF-1 target genes have been identified on the basis of one or more *cis*-acting hypoxia-response elements that contain an HIF-1 binding site. A variety of regulators including growth factors, genetic alterations, stress activators, and some carcinogens have been documented for regulation of HIF-1 in which several signaling pathways are involved depending on the stimuli and cell types. Activation of HIF-1 in combination with activated signaling pathways and regulators is implicated in tumour progression and prognosis. This review presents a summary of the structure and function of HIF-1α, and correlation among specific regulators and their signaling pathways.

INTRODUCTION

Angiogenesis is the development of new blood vessels from an existing vascular network. It is mostly related to pathological processes (wound healing, cardiac ischemia, diabetic retinopathy, and tumour growth and metastasis). Usually a developing tumour does not reach a threshold size of around 1-2 mm^3 as lack of oxygen and nutrients and accumulation of waste products. Blood vessels in tumour are usually disorganized and lack of structural integrity and prone to collapse, which result in areas of inadequate perfusion and transient hypoxia.

However, in order for a macroscopic tumour to grow, adequate oxygen delivery must be effected via tumour angiogenesis that results from an increased synthesis of angiogenic factors and a decreased synthesis of anti-angiogenic factors. The metabolic adaptation of tumour cells to reduced oxygen availability by increasing glucose transport and glycolysis and shif the balance between pro- and anti-apoptotic factors to promote survival are also important consequences

in response to hypoxia. In this regard, HIF-1, induced by many factors is mainly implicated in tumour angiogenesis. This review mainly sets out to summarize the regulators of HIF-1α and signaling pathways involved based on its structure and function.

HYPOXIA AND HIF-1

Hypoxia is one of the major drivers to tumour progression as hypoxic areas form in human tumours when the growth of tumour cells in a given area outstrips local neovascularization, thereby creating areas of inadequate perfusion. Although several transcriptional factors have been reported to be involved in the response to hypoxic stress such as AP-1, NF-κB and HIF-1, HIF-1 is the most potent inducer of the expression of genes such as those encoding for glycolytic enzymes, VEGF and erythropoietin[1-3].

HIF-α subunit exists as at least three isoforms, HIF-1α, HIF-2α and HIF-3α. HIF-1α and HIF-2α can form heterodimers with HIF-β. Although HIF-β subunits are constitutive nuclear proteins, both HIF-1α and HIF-2α subunits are strongly induced by hypoxia in a similar manner. HIF-1α is up-regulated in hypoxic tumour cells and activates the transcription of target genes by binding to *cis*-acting enhancers, hypoxic responsive element (HRE) close to the promoters of these genes with a result of tumour cellular adaptation to hypoxia and tumour angiogenesis, and promotion of further growth of the primary tumour. Studies have shown HIF-1α to be over-expressed by both tumour cells and such stromal cells as macrophages in many forms of human malignancy[4,5].

STRUCTURE OF HIF

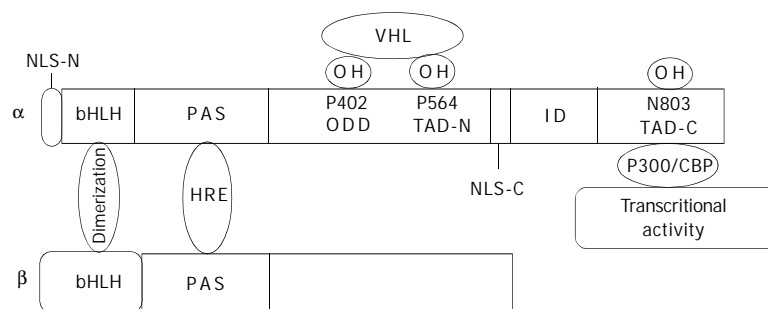
Both of the two subunits of HIF belong to a family of bHLH-PAS. Interactions between HLH-PAS domains from the two subunits mediate their dimerization, and individual basic regions of the two subunits then make contact with their corresponding DNA sequences, namely HRE. Specific interactions between three amino acids (Ser22, Ala25, Arg30) of the HIF-1 subunit and DNA bases were identified[6]. However, a major contribution towards the structure of HIF is attributed to a structure-function analysis of HIF-1α, which has revealed: (1) The N-terminal half of the molecule (amino acids 1-390) containing the bHLH-PAS domain was required for dimerization and DNA binding[7]. (2) The domains in C-terminal were required for hypoxia-induced nuclear localization, protein stabilization and transactivation[8]. Further study suggested that amino acids 401-603 of HIF-1α constituted an oxygen-dependent degradation domain (ODD), as presence or absence of this region had significant effects on the protein stability under non-hypoxia conditions[9]. (2) There are two nuclear location signals (NLS) located within N-terminal (amino acids 17-33) and C-terminal (amino acids 718-721) respectively. However, only the one within C-terminal was responsible for inducible nuclear accumulation of HIF-1α[10]. (4) HIF-1α has been found to contain two transactivation domains (TAD) at the C-terminal (amino acids 531-575 and 786-826)[8]. The transcriptional activation domains were separated by an amino acid sequence (amino acids 575-786) that inhibits transactivation (Figure 1)[8].


Figure 1 Molecular structure of HIF-1α and HIF-1β. bHLH domain mediates dimerization of the two subunits. PAS domain is responsible for DNA binding. Proline residues of 402 and 564 at ODD domain are hydroxylized by proline hydroxylase and recognized by VHL and then targeted to the ubiquitin proteasome pathway. Asn803 at the C-terminal transactivation domain (TAD-C) is hydroxylized by FIH-1 (factor inhibiting HIF-1) with a result of inhibition of HIF-1α interaction with co-activator p300 and consequently inhibits transcriptional activity. The nuclear location signal at C-terminal functions in HIF-1α translocation into nuclei.

REGULATION OF HIF-1

The first regulator of HIF-1 is oxygen. HIF-1α appears to be the HIF-1 subunit regulated by hypoxia. The oxygen sensors in the HIF-1α pathway are two kinds of oxygen dependent hydroxylases. One is prolyl hydroxylase which could hydroxylize the proline residues 402 and 564 at the oxygen dependent domain (ODD) of HIF-1 in the presence of oxygen and iron with a result of HIF-α degradation[11]. The other is hydroxylation of Asn803 at the C-terminal transactivation domain (TAD-C) by FIH-1, which could inhibit the interaction of HIF-1α with co-activator p300 with a subsequent inhibition of HIF-1α transactivity[12]. Chan *et al* employed a novel hydroxylation-specific antibody to detect hydroxylized HIF-1α and their study further confirmed the hydroxylation of proline 564 at ODD of HIF-1α under normoxia[13].

Oncogene comes as the second regulator. Many oncogenes have effects on HIF-1α. Among them, some function in regulation of HIF-1α protein stability or degradation, others play roles in several activated signaling pathways. Tumour suppressor genes as p53 and von Hippel-Lindau (VHL) influence the levels and functions of HIF-1. The wild type (wt) form of p53 protein was involved in inhibiting HIF-1 activity by targeting the HIF-1α subunit for Mdm2-mediated ubiquitination and proteasomal degradation[14], and in inducing inhibitors of angiogenesis such as thrombospondin-1[15], while loss of wt p53 (by gene deletion or mutation) could enhance HIF-1α accumulation in hypoxia, and augment HIF-1 dependent expression of VEGF in tumour cells[16]. The pVHL gene product could also regulate the stability of HIF-α for oxygen-dependent proteolysis[17]. In the presence of oxygen, pVHL could bind to and target prolyl hydroxylized HIF-α subunits to the ubiquitin proteasome pathway[18]. This process involved interaction between conserved sub-sequences within the oxygen-dependent degradation domains of HIF-α subunits and the β-domain of pVHL, with pVHL acting as the recognition element of a multicomponent E3 ubiquitin ligase[19]. Furthermore, in VHL-deficient cells, Pro-564 in HIF-1α had a detectable amount of hydroxylation following transition to hypoxia, indicating that the post-translational modification is not reversible[13]. In addition, inactivation of other tumour suppressors such as PTEN which is an antagonist of PI-3K signaling could function by removing phosphate at the 3rd position of phosphatidylinositol biphosphate and triphosphate. Loss of the tumour suppressor function of PETN would augment HIF-1 mediated gene expression[20] and restoration of PTEN could inhibit the expression of HIF-1α[21]. Amplification of Akt1 and Akt2 is quite common in human tumours which express a high level of HIF-1α. While activation of a variety of oncogenes and growth signaling pathways can induce the HIF system in non-hypoxic cells or amplify the response to hypoxia. Indeed, introduction of v-Src or RasV12 oncogenes resulted in

stabilization of normoxic HIF-1α[17] and loss of hydroxylated-Pro-564 demonstrated that oncogenes induced stabilization of HIF-1α signals by inhibiting prolyl hydroxylation[13].

The third regulator is a battery of growth factors and cytokines from stromal and parenchymal cells such as EGF[22], transforming growth factor-α[23], insulin-like growth factors 1 and 2[24], heregulin[25], and interleukin-1β[26] via autocrine and paracrine pathways. These regulators not only induce the expression of HIF-1α protein, HIF-1 DNA binding activity and transactivity, but also make HIF-1 target gene expression under normoxia or hypoxia. In addition, some of the growth factors are HIF-1 target genes such as IGF-2, IGF-BP1, 2 and 3, and TGF-α as well as VEGF, which make HIF-1 contribute to autocrine-signaling pathways.

The fourth one is a group of reactive oxygen species (ROS) resulting from carcinogens such as Vanadate[27] and Cr (VI)[28] or stimulation of cytokines such as angiotensin[29] and TNFα[30]. However, it seems controversial when it comes to the production of ROS under hypoxia and their individual role in regulation of HIF-1α. Some studies have provided experimental evidence in supporting the hypothesis that ROS generated from mitochondria increased under hypoxia and is required for HIF-1 activity and transcription of its downstream target genes[31,32]. An alternative model proposed that hypoxia resulted in decreased production of ROS due to nicotinamide adenine dinucleotide phosphate (NADPH) oxidases[33]. It is well known that ROS plays an important role in carcinogenesis induced by a variety of carcinogens. This was examplified by Cr(VI) complex[28], which could induce HIF-1α activation and stabilization via ROS including O_2-, H_2O_2, and OH[28], suggesting that HIF-1α may play its role in carcinogenesis.

HIF-2α, a homologue of HIF-1α initially described as endothelium and fetus specific and named endothelial PAS protein-1/HIF-related factor/HIF-like factor, has also been cloned and shown to form a transcriptionally active complex with ARNT by transient transfection assay[34]. Structurally and functionally HIF-2α is highly similar to HIF-1α, yet exhibits more restricted tissue-specific expression.

It has been shown that HIF-3α also exhibits conservation with HIF-1α and HIF-2α in HLH and PAS domains, but does not possess a hypoxia-inducible domain[35] and might function primarily as an inhibitor of HIF-1α[36].

SIGNALING PATHWAYS INVOLVED IN REGULATION OF HIF-**1a**

HIF-1 is a phosphorylated protein and its phosphorylation is involved in HIF-1α subunit expression and/or stabilization as well as in the regulation of HIF-1 transcriptional activity. Three signaling pathways involved in the regulation of HIF-1α have been reported to date.

The PI-3k pathway has been mainly and frequently implicated in regulation of HIF-1α protein expression and stability[26], although it was also involved in regulation of HIF-1α transcription in a couple of studies[37]. PI-3K is activated by ligation of a variety of growth factors to their cognate receptor tyrosine kinases with a subsequent phosphorylation and activation of its downstream signaling pathways such as a serine-threonine protein kinase Akt (protein kinase B) and FRAP (FBKP-12 rapamycin associated protein, also known as mammalian target of rapamycin) pathway.

Akt is also activated by hypoxia, yet its mechanism is still not clear. Activated Akt initiates two different pathways in regulation of HIF-1α. The function of these two pathways appears to show consistent impact on HIF-1α activation. In this regard, phospho-Akt either inhibits the function of GSK, a downstream target of Akt, via phosphorylation with a result of increased HIF-1α stability under hypoxia in a time dependent manner[22] or protein synthesis[38,39], or activates FRAP pathway resulting in an increased HIF-1α synthesis[40].

A recent study performed by Sodhi showed that there was a potential consensus site in the oxygen-dependent degradation domain of HIF-1α for GSK3β and that this site could play a role in the regulation of HIF-1α protein stability, highlighting the effect of PI-3K/Akt/GSK pathway on HIF-1α[41]. It was further confirmed by co-transfection of an HIF-1 reporter plasmid either with the p85 or with the Akt dominant negative vector that the disruption of the PI-3K/Akt pathway impaired the activation of HIF-1 as well as VEGF gene transcription in hypoxic NIH3T3R cells[20]. Besides, in a renal cancer cell line mutant for VHL, HIF-1α was constitutively stabilized, and the PI-3K inhibitor still down-regulated HIF-1α expression, suggesting a novel pathway for HIF-1α protein regulation independent of VHL[17]. HIF-1α expression induced by EGF and insulin or loss of function of PTEN through PI-3K pathway[20,22,42] provided an additional evidence.

In contrast, an alternative study showed that although serum stimulation could induced a slight accumulation of HIF-1α protein in a PI-3K/Akt pathway dependent fashion, hypoxia induced much higher levels of HIF-1α protein and HIF-1 DNA binding activity independent of PI-3K and mTOR activity and high levels of Akt signaling could modestly increase HIF-1α protein, but this increase did not affect HIF-1 target gene expression. Besides the effects of constitutively active Akt on HIF-1 were cell type specific, drawing a conclusion that PI-3K/Akt pathway was not exclusive for hypoxic induction of HIF-1 subunits or activity, and constitutively active Akt was not itself sufficient to induce HIF activity[43], suggesting that the involvement of PI-3K/Akt pathway in regulation of HIF-1α is a much more complicated process which not only exhibits a cell type- and stimulus type- dependency, but also may have a cross talk with other unknown signaling pathways.

The Raf-1/MEK1/ERK pathway appears mainly to regulate HIF-1 transactivation and DNA binding activity and the C-terminal domain of HIF-1α encompassing the transactivation domains of the protein, was demonstrated to be directly phosphorylated by ERK1 by an in vitro kinase assay[44]. Although HIF-1α phosphorylation was not required for HIF-TAD/p300 interaction, MAPK was required for the transactivation activity of HIF-1α. Furthermore, inhibition of MAPK could disrupt the HIF-p300 interaction and suppress the transactivation activity of p300[45] and overexpression of MEK1, an upstream ERK activator, could stimulate the transactivation of both p300 and HIF-1α[45]. Reporter gene assays and EMSA experiments in vitro have demonstrated that the MEK1 inhibitor PD98059 or ERK dominant negative mutants together with an HIF-1 reporter gene were able to block the transcriptional activity of HIF-1 without affecting its DNA binding activity[28,44,46].

Mammalian cells respond to a variety of noxious stimuli such as chemicals, radiation, osmotic shock, and hypoxia by induction of stress activated protein kinases (SAPKs/JNK). Among them, both of p38 and JNK1 play critical roles in responding to cellular stress and promoting cell growth and survival. JNK1 and p38 are also serine/threonine protein kinases that phosphorylate nuclear transcriptional factors which regulate target genes in response to cellular stress. It has been shown that JNK1 and p38 were activated by hypoxia and involved in induction of HIF-1α expression[47]. Additional evidence indicated that HIF-1α phosphorylation by p38 could be involved in inhibition of the inhibitory domain located within the C-terminal region of HIF-1α[48]. Another study showed that p38 signaling mediated HIF-1α and VEGF induction by Cr (VI) in DU145 human prostate carcinoma cells[28].

In addition, a calmodulin dominant negative mutant and W7, a calmodulin antagonist, as well as BAPTA, an intracellular calcium chelator, inhibited hypoxia-induced HIF-1 activation. A MEKK1 (a kinase upstream of JNK) dominant negative mutant had no effect. Moreover, BAPTA, calmidazolium, a calmodulin antagonist and PD98059 inhibited VEGF secretion in hypoxic HepG2 cells. These results indicate that elevated calcium in hypoxia could participate in HIF-1 activation, suggesting that calcium and calmodulin act on the upstream of ERK in the hypoxia signal transduction pathway[28].

One study in T47D cell indicated PI-3K/Akt was not activated under hypoxic condition[17]. While our study in the same cell line showed that ERK1/2 was not activated by hypoxia either. However, bFGF activated PI-3K/Akt, ERK1/2 and p38 pathways both under normoxia and hypoxia. Under hypoxia, bFGF synergized with hypoxia in regulation of HIF-1α protein expression and transactivation. While under normoxia, bFGF increased HIF-1α protein synthesis and transactivation depending on PI-3K/Akt and ERK1/2 pathways respectively. p38 pathway had no effect on HIF-1α and VEGF. Our result further confirmed the role of PI-3K/Akt and ERK1/2 in regulation of HIF-1α was induced by growth factors and that activation of PI-3K/Akt and ERK1/2 by hypoxia was not a universal phenomenon (Figure 2).

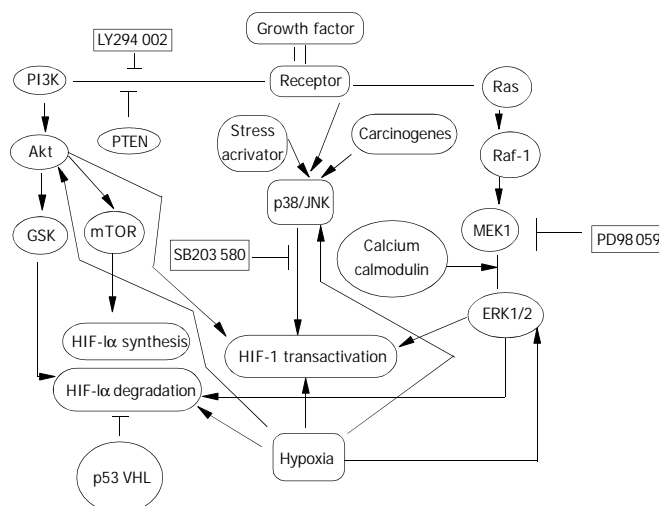

Figure 2 Signal transduction pathway in HIF-1α regulation. Oncogenes, growth factors and hypoxia have been documented to regulate HIF-1α protein and increase its transactivity. PI-3K/Akt, Raf-1/MEK/ERK1/2 and p38/JNK pathways were activated in response to oncogenes, growth factors and stress activators such as hypoxia, and carcinogens to different extent in a cell type- and stimulus type-specific manner. GSK and mTOR were two target events of Akt and could contribute to decreasing HIF-1α degradation and increasing HIF-1α protein synthesis. Activated ERK1/2 could mainly up-regulate

HIF-1α transcriptional activity. Calcium and Calmodulin could act on HIF-1α indirectly as upstream events of ERK1/2. While the effect of p38/JNK pathway on HIF-1α is controversial depending on stimulus and cell type. Some oncoproteins themselves are inter-events of those signal pathways. Amplification of p110, a subunit of PI-3K, Akt and loss of PTEN could contribute to activation of PI-3K pathway, while mutation of RAS and amplified Raf-1 and ERK1/2 could activate the extracellular-signal regulated kinase (ERK1/2). In addition, mutation of p53 and loss of VHL could decrease HIF-1α degradation, although the signal pathways involved are poorly understood.

HIF-1**a**, ANGIOGENESIS AND TUMOUR PROGNOSIS

HIF-1 has been taken as a key factor in regulation of VEGF and VEGFR and other angiogenic factors. Immunohistochemical analysis of human tumour biopsies revealed that dramatic overexpression of HIF-1α was seen in common cancers[49] and associated with tumour VEGF expression and vascularization[50,51]. Constitutively expressed VEGF increased the number of new capillaries around hepatic sinuses[52]. HIF-1 activity has also been manipulated in human cancer cell lines. Expression of VEGF, xenograft growth and angiogenesis were markedly increased in HCT116 colon cancer cells transfected with an expression vector encoding HIF-1α[53]. In addition, emerging evidence has suggested that loss or gain of HIF-1 activity is negatively and positively correlated respectively with tumour growth and angiogenesis[50,54-56].

VEGF overexpression in several tumours has been correlated with high vascularity, lymph node metastasis, and liver metastasis, and a poorer prognosis than VEGF-negative tumours[57,58] and a direct relationship between angiogenesis and metastasis in a large and diverse array of other tumours, including melanomas, gliomas, cancers of the lung, bladder and prostate, and many others[59,60] was established. Many reports have shown that intratumoural microvessel density (IMD) is a significant and independent prognostic indicator in human breast cancer.

In a study of ovarian cancer, HIF-1α expression was correlated with apoptosis in most tumours. Besides, according to the identification of a *cis*-acting hypoxia-response element containing an HIF-1 binding site, a variety of proteins targeted by HIF-1 were involved in tumour cell proliferation, survival, adhesion and mobility, implicating the role of HIF-1 in these processes. A correlation of a reduced inducibility of HIF-1α and HIF-2α and an increased survival of the breast cancer cell lines under hypoxia was reported[61].

In addition, HIF-1α overexpression in combination with deficiency or mutation of tumour suppressor genes such as VHL, p53 and PTEN, and amplification of oncogenes (Akt, Ras, ERK1/2) was frequently seen in human cancer and these genetic alterations have been associated with tumour growth, invasion and metastasis. Clinically, a high level of HIF-1α expression had an association with a decreased overall survival and a disease-free survival in lymph-node-negative breast cancer[62] and an increased mortality in early stage cervical carcinoma[63] and lymph-node-negative breast cancer[50]. Furthermore, HIF-1α overexpression was associated with treatment failure and/or mortality in nasopharyngeal squamous cell cancer[64], suggesting a potential role of HIF-1α in tumour prognosis. Finally, the findings that HER-2/*neu* immunoactivity and gene amplification, VEGF expression, and Ki-67 expression were correlated strongly with HIF-1α positivity in lymph node negative breast carcinoma[62] provided a further evidence. All data above support a hypothesis that the presence of hypoxia in a tumour reflects a poor prognosis[65].

SUMMARY

HIF-1 activation is regulated through different mechanisms from HIF-1α subunit stabilization[18,46], phosphorylation[44], modification of redox conditions to interaction with coactivators[45,66] involving several signal transduction pathways including PI-3K, MAPK (ERK1/2) and p38 pathways. However, it appears that these mechanisms and signaling pathways can be cell-type specific and stimulus-specific. Hypoxia, oncogenes and a variety of growth factors and cytokines increase HIF-1α stability and/or synthesis and transactivation to initiate tumour angiogenesis, metabolic adaptation to hypoxic situation and promote cell survival or anti-apoptosis[67,68] resulting from a consequence of more than sixty putative direct HIF-1 target gene expressions. Taken together, HIF-1 is activated in tumour and plays a critical role in initiation of tumour angiogenesis, tumour growth, progression and metastasis.

The crucial role of HIF-1 in tumour angiogenesis has sparked scientists and clinical researchers to try their best to understand the whole diagram of HIF-1 so as to find out novel approaches to inhibit HIF-1 overexpression. Indeed, the combination of anti-angiogenic agent and inhibitor of HIF-1 might be particularly efficacious, as the angiogenesis inhibitor would cut off the tumour's blood supply and HIF-1 inhibitor would reduce the ability of tumour adaptation to hypoxia and suppress the proliferation and promote apoptosis. Screens for small-molecule inhibitors of HIF-1 are underway and several agents that inhibit HIF-1, angiogenesis and xenograft growth have been identified. Full understanding of the regulators, and signal transduction pathways of HIF-1 and its interaction with other proteins is beneficial to the seeking of novel strategies to cure tumour and other angiogenic diseases.

Abstract

AIM: To investigate the expression patterns of esophageal squamous cell cancer deregulated genes in mid to late stages of C57BL/6J mouse embryogenesis, and the correlation between these genes in embryonic development and tumorigenesis of esophageal squamous cell cancer.

METHODS: Reverse northern screening was performed to examine the expression patterns of esophageal cancer deregulated genes in C57BL/6J mouse embryogenesis. To confirm the gene expression patterns, semi-quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) was carried out for 3 of the randomly picked differentially expressed genes.

RESULTS: Within these esophageal cancer deregulated genes, 4 patterns of expression were observed at 3 stages embryonic d 11.5 (E11.5), embryonic d 13.5 (E13.5) and postnatal d1 (P1). (1) Up-regulation during the E11.5 period, down- regulation during the E13.5 and P1 period (up-down-down), the 10 up-regulated genes during the E11.5 period could be classified into 6 known genes and 4 unknown genes. The known genes included differentiation related genes (S100A8), immunity related gene (IGL), translation and transcription regulation genes (RPL15, EEF1A1), cytoskeletal protein (TUBA1), cysteine protease inhibitor (cystatin B). (2) Up-regulation during the E13.5 and P1 period (down-up-up), such as the SPRR2A which was down-regulated at E11.5. (3) Down-regulation during the E11.5 and E13.5 period (down-down-up), such as RHCG and keratin 4. (4) Fluctuating expression, down initially, up at E13.5, and then down again (down-up-down). EMP1 belonged to such a gene, which was highly expressed at E13.5.

CONCLUSION: The results will be helpful for understanding the function of esophageal squamous cell carcinoma (ESCC) deregulated genes in embryonic development and tumorigenesis. S100A8 and S100A9 may play different roles in early embryonic development. IGL may be an oncofetal protein, and EMP1 relates with neurogenesis at E13.5. The genes identified pertinent to embryonic development may serve as candidate susceptibility genes for inherited esophageal cancer disorders as well as for various heritable disorders of embryonic development.

INTRODUCTION

Esophageal cancer is one of the most lethal malignancies in the world. It exists in 2 main pathological types, esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EADC). ESCC is the predominant histological subtype of esophageal cancer and characterized by high mortality rate and regional variation in incidence in China[1]. Due to the relatively late stage of diagnosis and poor treatment, its five-year survival rate remains below 10%[2]. The development of better treatment modalities and better diagnostic and preventive approaches requires a understanding of the molecular mechanisms of the complex process of esophageal tumorigenesis.

Tumor development involves up-regulation and down-regulation of many genes. The study of these genes is important to understand the complex biological events that take place during the malignant transformation of normal tissues. cDNA microarray technology allows simultaneous determination of the expression level of thousands of genes[3]. Up to date, by using the cDNA array technology, we have identified many genes differentially expressed in esophageal cancer, which potentially play key roles in the malignant behavior of esophagus[4,5]. Investigation into the biological function of these genes could be helpful to understand the molecular mechanisms in tumorigenesis of ESCC.

Mouse is an ideal model system for studying the molecular mechanisms underlying the pathogenesis of human cancer. The generation of transgenic and gene-knockout mice has been instrument in determining the role of major determinants in this process, such as oncogenes and tumor-suppressor genes. In addition, mice at different development levels also provide a useful model for functional study of the genes. Understanding the temporal and spatial expression of a gene in embryogenesis will be useful for further analysis of its function in cancer[6,7]. Here, the expression patterns of some ESCC deregulated genes in 3 embryonic stages were analyzed using reverse northern screening. Selected genes were further confirmed by RT-PCR assays. As a result, we found that genes with specific developmental functions were expressed at specific developmental stages. These genes cover a broad spectrum of cell biology processes including cell growth, differentiation, matrix metabolism, immunity response, and would be of significance to understanding the tumorigenesis of esophagus.

MATERIALS AND METHODS

Animal and tissue specimens

Time-mated C57BL/6J mice were obtained from Animal Institute, Chinese Academy of Medical Sciences. Mice were obtained from in-house breeding programs and maintained on a 12:12-h light-dark cycle and provided standard laboratory food and water. All manipulations of mice were done in accordance with policies of the Institute Animal Care and Use Committee. Timed mating was set up between adult wild-type mice. Females were inspected for plugs on the following day to ensure their successful mating. The day of plug detection was considered as E0.5. Embryo was dissected from pregnant mouse at the age of embryonic d 11.5 (E11.5), 13.5 (E13.5), and postnatal d 1 (P1). Three samples per time point were analyzed for statistical significance. The tissues were immediately frozen in liquid nitrogen until analysis.

Total RNA extraction

Total RNA was extracted from frozen tissues by using TRIzol™ reagent following the protocols of the manufacturer (GIBCO/BRL, New York, USA). The quality of RNA was confirmed on a formaldehyde agarose gel, and concentration was determined by reading the absorbance at 260/280 nm.

cDNA fragment acquisition

Plasmids of interested clones were selected from esophageal cDNA libraries and used as PCR templates. The primers used were T3 (AAT TAA CCC TCA CTA AAG GG) and T7 (GTA ATA CGA CTC ACT ATA GGG C). The average length of cDNA fragments was about 1 kb. The homology of these genes between human and mice was more than 50%.

Reverse northern screening

PCR fragments corresponding to 90 distinct clones were diluted in 0.5 mol/L NaOH and 1.5 mol/L NaCl and 0.2 mL (approximately 40 ng) of every slim was transferred onto duplicate nylon membranes (HyBond-N, Amersham Pharmacia Biotech, Arling-ton Height, IL). The filter membranes were neutralized with 1.5 mol/L NaCl and 0.5 mol/L Tris-HCl (pH 7.5) for 5 min, dried at 80 ℃ for 60 min in the oven. cDNAs corresponding to the housekeeping gene β-actin and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were used as internal controls.

To generate the probes, ^{32}P-labeled cDNA was synthesized from RNA derived from mice of different embryonic period. mRNA was incubated with random hexamers (Promega Corp.) for 5 min at 65 ℃, chilled on ice for at least 1 min, and added to a solution containing 50 U superscript IIRT in 20 mmol/L Tris-

HCl (pH 8.4); 5 mmol/L MgCl$_2$; 0.5 mmol/L each of deoxy (d)-ATP, dTTP, and dGTP, 5 mmol/L dCTP; and 50 mCi [^{32}P] dCTP in a final volume of 20 μL. After 50 min of incubation at 42 ℃, followed by incubation at 70 ℃ for 15 min, parental mRNA was removed from the cDNA synthesis reaction by addition of RNase H and incubation for 20 min at 37 ℃. Unincorporated nucleotides were removed by gel filtration on Sephadex G-25 preloaded spin columns (Amersham Pharmacia Biotech, Uppsala, Sweden). The probe was denatured at 90 ℃ for 5 min before added to the hybridization solution.

The filter membranes were washed in 6×SSC and pre-hybridized for 5 h at 68 ℃ in a buffer containing 6×SSC, 2×Denhardt's (1 g/L each of Ficoll 400, polyvinylpyrrolidone, and BSA), 1 g/LSDS, and 0.1 g/L denatured salmon sperm DNA. Hybridization was carried out for 18 h at 68 ℃ using ^{32}P-labeled cDNA probes added in fresh prehybridization buffer. After the hybridization, the filters were washed (2×SSC and 1 g/L SDS), then exposed to X-ray film at -70 ℃ overnight with an intensifying screen[8]. The images were scanned by Fluor-S MultiImager (Bio-Rad, California, USA) and the original intensity of every specific slim was quantitated with the software Multi-Analyst (Bio-Rad, California, USA). To avoid misinterpretation of the results possibly due to variation in the hybridization, any filter was normalized using 2 housekeeping genes, and a normalization coefficient calculated for each comparison was used to correct the signal intensities. The differential expression was considered as significant when the ratio of the signal from the same spot on different membranes was greater than 2.0.

Semi-quantitative RT-PCR

Total RNA was extracted by the method described above. Five micrograms total RNA of each sample was used to synthesize the first strand cDNA with SuperScript preamplification system for first strand cDNA synthesis kit (GIBCO/BRL, New York, USA). Then 1 μL RT product was used as the template to amplify specific fragments. PCR reaction conditions were optimized individually for each gene studied, and the cycle number for PCR was adjusted so that the reactions fell within the linear range of product amplification. The expression of housekeeping gene GAPDH, was used as an internal control. The RT-PCR reaction product was analyzed by electrophoresis on a 15 g/L agarose gel. Electrophoresis images were scanned by Fluor-S MultiImager (Bio-Rad, California, USA) and the original intensity of every specific band was quantitated with the software Multi-Analyst (Bio-Rad, California, USA). Data were compared after being normalized by the intensity of GAPDH. The sequences of PCR primers and cycle number are listed in Table 1.

Table 1 Primers used for semi-quantitative RT-PCR and conditions of PCR reaction

RESULTS

Reverse northern data

The expression of esophageal cancer deregulated genes during C57BL/6J mouse embryogenesis showed a clear difference. As shown in Figure 1, no signals were visible in the negative control spots, indicating that the hybridization was highly specific. The housekeeping gene density was similar, indicating that the results were credible.

Figure 1 Representatives of esophageal cancer deregulated genes expressed in C57BL/6J mouse embryogenesis by reverse northern screening. Three filters were hybridized with ^{32}P-labeled cDNA probe from E11.5, E13.5 and P1 period. β-actin and GAPDH were used as controls. c1, negative control; c2, β-actin; c3, GAPDH; 1, S100A8; 2, IGL; 3, RPL15; 4, CSTB; 5, SPRR2A; 6, RHCG; 7, keratin 4; 8, EMP1; 9, S100A9.

By reverse northern screening, the results showed that the expression patterns of these genes were diverse and complex (Table 2). Four patterns of expression were seen at the 3 stages of E11.5, E13.5 and P1. (1) Up-regulation during the E11.5 period, down at E13.5 and P1 (up-down-down), the 10 up-regulated genes could be classed into 6 known genes and 4 unknown genes. The known genes included differentiation related genes (S100A8), immunity related gene (IGL), translation and transcription regulation genes (RPL15, EEF1A1), cytoskeleton protein (TUBA1), cysteine protease inhibitor (cystatin B). (2) Up-regulation during the E13.5 and postnatal d 1 period (down-up-up), such as the SPRR2A which was down-regulated at E11.5. (3) Down-regulation during the E11.5 and E13.5 period (down-down-up), such as RHCG and keratin 4.

(4) Fluctuating expression, down initially, up at E13.5, and then down again (down-up-down), such as EMP1,which was highly expressed at E13.5.

Confirmation by RT-PCR

Three genes (S100A8, EMP-1, CSTB) with notable difference, as well as S100A9 were selected randomly for further confirmation by RT-PCR. As a result, the expression of these genes was consistent with the reverse Northern blot results (Figure 2). It indicated that the results of reverse Northern blot analysis were reliable.

Figure 2 Expression patterns of several genes confirmed by multiplex semi-quantitative RT-PCR. All RT-PCR products were analyzed by electrophoresis on 15 g/L agarose gel. The expression of GAPDH was used as internal control and the size of GAPDH gene amplification was 452 bp.

DISCUSSION

Cancer and development are conceptually related. The normal embryonic development process might display many of the properties associated with tumor development and progression, such as rapid proliferation, migration of cells and formation of new blood vessels[9]. Tumor formation in many cases results from the aberrant expression of a developmental program. Events in the tumor have their normal regulatory counterparts in the embryonic development. Thus, research into the molecular change involved in development is important not only for understanding of embryogenesis, but also for understanding and managing cancer. In this study, using the C57BL/6J mouse as a model system, we investigated the expression pattern of esophageal cancer deregulated genes

Table 2 Expression pattern of esophageal cancer deregulated genes during C57BL/6J mouse development

Gene name	Unigene	E11.5	E13.5	P1	Expression pattern	Change in ESCC

IGL, immunoglobulin lambda locus; RPL15, ribosomal protein L15; EEF1A1, eukaryotic translation elongation factor 1 alpha1; TUBA1, tubulin alpha1 (testis specific); ASN, automated sequencing number; SPRR2A, small proline-rich protein 2A; RHCG, Rh type C glycoprotein; EMP1, epithelial membrane protein 1.

during 3 stages of embryogenesis. Esophageal cancer deregulated genes showed several kinds of expression pattern during embryogenesis, which provided useful information on the tumorigenesis of esophageal cancer.

During embryonic development of mice, genes exhibit complex patterns of spatial and temporal expression and direct organ development in a variety of ways. Differentially expressed genes in embryogenesis implicated that they might play important roles in development. Cancer cells resemble embryonic cells morphologically and share some characteristics with each other, such as rapid proliferation, reduced differentiation, and increased motility. The same intercellular signals that control proliferation and differentiation in development can control tumor development. These common signals are the focus of our study. In the present study, many esophageal cancer deregulated genes showed differential expression during mice embryonic development. These genes covered a broad spectrum of biologic functions including cell proliferation (RPL15)[10,11], differentiation (S100A8[5], SPRR2A[12]), immune response (IGL)[13], cytoskeletal protein (TUBA1)[14] migration (cystatin B)[15], *etc*. These findings provided further clues to the possible function of these deregulated genes and the tumorigenesis of ESCC.

The transition from cell proliferation to differentiation in embryonic development is under strict regulation. Cancer has been called a "developmental disorder"[16] because it involves a disruption of the normal developmental program for cells, in terms of both differentiation and proliferation. Esophageal cancer is always characterized by uncontrolled proliferation of epithelial cells and failure to differentiate to the normal phenotype. The genes controlling proliferation and differentiation and their transition are very important. In ESCC, S100A8 and S100A9 are both significantly down-regulated and contribute to tumor progression but their function is not fully understood. It has been reported that S100A8 and S100A9 can form a heterodimer and co-express in neutrophils, monocytes, and some secretory epithelia[17-19]. However, in this study, we found that the expression patterns of 2 members of S100 genes were not completely parallel during the process of embryogenesis. The expression of S100A8 was significantly higher at E11.5 than that of S100A9, but in the periods of E13.5 and P1 the 2 genes' expression patterns were similar. Previous studies have shown that S100A8 mRNA expressed without S100A9 mRNA within fetal cells infiltrating the decidua in the vicinity of the ectoplacental cone between 6.5 and 8.5 d postcoitum[20]. Targeted disruption of the S100A8 gene caused rapid and synchronous embryo resorption by d 9.5 of development in homozygous null embryos, but the S100A9-deficient mice were viable, fertile, and generally healthy[21]. These findings, together with the literature, suggest that S100A8 and S100A9 may play different roles in the embryonic development and process of ESCC.

The proliferative changes in cancer cells are usually accompanied with other changes in cellular activities, including reversion to a less differentiated, more developmentally primitive state. Genes expressed in embryogenesis, down-regulated with tissue maturation and re-expressed in cancer, are designated as oncofetal genes, many of which are used as tumor markers. In this study, we found that IGL was abundantly expressed at E11.5 of fetal life and down-regulated subsequently. Meanwhile, multiple myeloma (MM) related to immunoglobulin (Ig) types and light chain subtypes[22], research proved that kappa and lambda type immunoglobulin light chains could increase the percentage of viable polymorphonuclear leucocytes by inhibiting apoptosis in a concentration-dependent manner[23]. These findings, indicate that IGL may be an oncofetal protein, but the mechanism of IGL overexpression in ESCC is not clear. Its potential usage as a marker of early recurrence

and in gene therapy needs to be further studied. Structural gene is also important in embryogenesis and tumorigenesis. TUBA1 had the largest expression change of all the genes at E11.5, 6.7-fold. As we know[14], microtubules are composed of tubulin alpha and beta. They participate in a large number of intracellular events including cell division, intracellular transport and secretion, axonal transport, and maintenance of cell morphology. The diminution of interphase cytoplasmic microtubules in tumor cells was probably due to the deficiency of microtubule organizing function in interphase tumor cells[24].

Gene expression in specific phase implicates its specific function in that period. In our study, we found that epithelial membrane protein 1(EMP1) was characteristically expressed at E13.5. It has been found EMP1 is a member of the PMP22 (peripheral myelin protein 22) family[25,26]. It was expressed in most tissues of the adult mouse, with highest levels in the gastrointestinal tract and lung[27]. High-level expression of EMP1 was associated with differentiation and growth arrest in squamous cells and the haematopoietic system[28]. At the molecular level, EMP1 was thought to be involved in the regulation of the cell cycle, cell-cell recognition, and cell death[29]. At E13.5, high EMP1 expression was found in the initial fiber tracts of the developing cerebellum[30]. In the second stage of embryonic brain development (E13 to E16), the neuroepithelium remained active, but was coupled with the differentiation of neurons. Hence, the observed increased expression of EMP1 at E13.5 during the second stage of prenatal brain development, is related with the potential function of this molecule during neurogenesis. Whether the absence of EMP1 at P1 and E11.5 is due to down-regulation of expression in maturing cells or EMP1 expression is restricted to some embryonic tissue remains to be elucidated.

In summary, the results from the present study can contribute to our understanding of the function of deregulated genes in ESCC, which are important in both embryonic development and tumorigenesis. These genes identified in the special developmental stage of mice may play some roles in the control of growth, terminal differentiation and may have physiologic or pathological importance during normal development process and the development of ESCC. Finally, the genes identified pertinent to embryonic development may serve as candidate susceptibility genes for inherited esophageal cancer disorders as well as various heritable disorders of embryonic development. Further study is required for the precise relationship between the altered genes and the pathogenesis of esophageal squamous cell cancer and embryonic development.

Abstract

AIM: To study the expression of myeloid-related proteins (MRP)8 and myeloid-related proteins(MRP)14 in human esophageal squamous cell carcinoma and to investigate if there was any correlation between MRP8 and MRP14 expression level and histopathological grade in these tumors.

METHODS: In this study, 65 cases of advanced esophageal squamous cell carcinoma were assessed for MRP8 and MRP14 expression using immunohistochemistry. Statistical analysis was performed for the comparison of MRP8 and MRP14 expression in normal and tumor tissues, and their relationship with clinicopathological features.

RESULTS: Reduced or absent expression of MRP8 and MRP14 was observed in esophageal squamous cell carcinoma, with a significant difference between tumor tissues and normal tissues ($P<0.01$ and $P<0.01$ for MRP8 and MRP14, respectively). Poorly differentiated tumors presented a greater decrease than well and moderately differentiated tumors, with a correlation between their protein level and histopathological grading ($P<0.001$ and $P<0.001$, respectively). However, no significant association was found between MRP8 and MRP14 expression and age or gender ($P>0.05$).

CONCLUSION: These findings suggest that the decreased expression of MRP8 and MRP14 might play an important role in the pathogenesis of human esophageal squamous cell carcinoma, being particularly associated with poor differentiation of tumor cells.

INTRODUCTION

Human esophageal squamous cell cancer (ESCC) is one of the most frequent cancers with a predominant distribution in North China, where the mortality rate ranks second[1]. A wide variety of biological events and mechanisms appear to have roles in the development and progression of ESCC[2-4]. Deregulation of differentiation is another hallmark of multi-step carcinogenesis[5]. Recent studies have demonstrated that the disruption of normal squamous cell differentiation may be one of the mechanisms for esophageal cancer development[6]. In consequence, the defect in the pathway of terminal differentiation is clearly one of the most important abnormalities in esophageal carcinogenesis. In the majority of ESCCs some differentiation- associated mechanisms must be involved to explain the early events leading to the induction of the neoplastic phenotype.

Human esophageal mucosa is lined by a stratified squamous epithelium and its differentiation is a multistep and highly heterogenous process requiring activation and deactivation of multiple and specific genes[7,8]. Therefore it is worthwhile to investigate the tissue-specific molecules involved in the process of differentiation during esophagus tumorigenesis. Systematic approaches using microarray-based global transcriptome analysis might provide a powerful alternative with an unprecedented view scope in monitoring gene expression levels[9]. By analyzing our cDNA microarray data, we have recently identified MRP8 and MRP14 as two down-regulated and differentiation-associated genes in a significant proportion of ESCCs[10,11].

Myeloid-related protein 8 (MRP8; S100A8) and MRP14 (S100A9) are two calcium-binding proteins belonging to the S100 family[12]. These proteins expressed during myeloid differentiation, are abundant in granulocytes and monocytes, and form a heterodimeric complex calprotectin in a Ca^{2+}-dependent manner[13,14]. MRP8 and MRP14 also show a wide range of possible intracellular as well as extracellular functions. They have been shown to inhibit casein kinases I and II, to interact with cytoskeletal components to exert antimicrobial properties, especially against Candida albicans, to be involved in transcellular eicosanoid metabolism and to exhibit growth inhibitory activities against murine bone marrow cells, macrophages, and mitogen-stimulated lymphocytes[15]. Typically, MRP8 and MRP14 are known to be differentially expressed at sites of acute and chronic inflammation[16-19]. However, there is sparse information regarding the deregulation of MRP8 and/or MRP14 in several human common malignancies[20-28]. And little is known about the possibility of abnormal expression of MRP8 and MRP14 in ESCC.

In this study, we investigated the expression of MRP8 and MRP14 immunohistochemically in a set of human esophageal squamous cell carcinoma tissues. We also evaluated the relationship between their expression level and clinicopathological features. Our data suggest that their down-regulation is an important event during ESCC progression, and may be involved in the dedifferentiation of neoplastic cells.

MATERIALS AND METHODS

Tissue samples

Sixty-five specimens of ESCC and adjacent normal mucosa were taken from patients who had not received radiotherapy or chemotherapy before surgery. Fresh samples were dissected manually to remove mixed connective tissues and stored in liquid nitrogen immediately after operation at the Cancer Hospital of Chinese Academy of Medical Sciences and Peking Union Medical College. The clinicopathological characteristics were evaluated by two senior pathologists according to the criteria of the WHO classification (1990).

Antibodies

Following antibodies were used in this study: anti-MRP8 and anti-MRP14 polyclonal antibodies (C-19, Santa Cruz Biotechnology Inc. Santa Cruz, CA). These antibodies were provided as goat polyclonal antibody against MRP8 and MRP14, respectively (Santa Cruz, CA) and were characterized extensively by Western blotting and enzyme-linked immunosorbent assays.

Immunohistochemical analysis

For immunohistochemical analysis, 5 μm thick sections were cut from formalin-fixed paraffin-embedded tissue blocks, deparaffinized, rehydrated, dripped in 30 mL/L hydrogen peroxide solution for 15 min. Before staining, antigen retrieval was performed by heating the specimens in a microwave oven for 20 min in citrate buffer (pH 8.0). Then excess protein was blocked using normal rabbit serum for 30 min at room temperature. Goat anti-MRP8 polyclonal antibody and goat anti-MRP14 antibody were respectively applied to the sections at a 1:150 dilution, and sections were then incubated overnight at 4 ℃. A streptavidinbiotin peroxidase detection system (Zymed Laboratories Inc. Francisco, USA) was used according to the manufacturer' s instructions. 3,3' -diaminobenzidine was used as the chromogen and hematoxylin was used as the counterstain. Primary antibody was replaced by non-immune serum (Zymed Laboratories Inc. Francisco, USA) in the case of negative control[29]. All slides were examined and scored independently by two senior pathologists who were blinded to the pathological and clinical data, and a consensus was obtained between them.

Statistical analysis

The relationship of patients' demographic features, such as age and gender, to MRP8 and MRP14 expression was examined with the Fisher' s exact test. The Chi-square test was used for the comparison of MRP8 and MRP14 expression levels between ESCC and the adjacent normal esophageal mucosa, and among different histopathological grades, including well, moderately and poorly differentiated ESCC. All data were analyzed using SigmaStat software (Jandel Scientific, San Rafael, CA, USA). Differences were considered statistically significant when P-values were less than 0.05.

RESULTS

Patients and tumor characteristics

In this study, we investigated 65 esophageal squamous cell carcinoma patients comprising 46 males and 19 females. The mean age of patients was 57.7 years and the median age was 57 years (between 38 and 75). Tumors were graded according to the World Health Organization classification: 30 tumors were well differentiated, 23 were moderately differentiated, and 12 were poorly differentiated.

MRP8 and MRP14 expression in ESCCs and matched normal esophageal mucosa

To verify the down-regulation of MRP8 and MRP14 in ESCC, we performed an immunohistochemical analysis on 65 advanced esophageal cancer specimens. In matched non-neoplastic esophageal epithelium, staining for both MRP8 and MRP14 started in the deepest suprabasal cells and increased in intensity toward the superficial layers. Staining was most pronounced in apical, more differentiated epithelial layers, but no staining was observed in columnar epithelial cells in the stratum basale (Figures 1A and 2A). Prominent MRP8 and MRP14 expression was also observed in monocytes and granulocytes. Of the 65 ESCC cases analyzed, MRP8 and MRP14 immunostaining was

Figure 1 Immunohistochemistry for MRP8 in esophageal carcinoma tissues and normal epithelia (original magnification: ×400). A: MRP8 expression in suprabasal layers of normal esophageal epithelium. B: MRP8 staining in well differentiated carcinoma, C: MRP8 staining in moderately differentiated carcinoma, D: MRP8 staining in poorly differentiated carcinoma.
Figure 2 Immunohistochemistry of MRP14 in normal esophageal epithelium (A) and well (B), moderately (C) and poorly differentiated (D) carcinoma tissues. Normal esophageal epithelium showed strongly positive staining for MRP14. However, its staining in poorly differentiated carcinoma was significantly weaker than that in well and moderately differentiated carcinomas. Granulocytes and monocytes were also positively stained in all the sections. Original magnification: ×400.

significantly reduced compared to the adjacent benign epithelia. The majority of tumors showed focal positive immunostaining in certain well differentiated areas, and undetectable in other less differentiated sections. In well differentiated carcinomas, the staining for MRP8 and MRP14 was positive in keratinized areas at the center of tumor foci, but decreased or undetectable in the marginal areas. However, in moderately and poorly differentiated carcinomas, the staining was sparsely weak or sporadic only in the well or moderately differentiated regions, whereas in other areas it was completely undetectable. The immunostaining was frequently heterogeneous even within one specimen, both in terms of percentage of positive cells and staining intensity (Figures 1B-D and 2B-D). The staining for MRP8 and MRP14 was predominant in the cytoplasm of benign cells and accumulated more in the nuclei of malignant cells. In surrounding stroma clear MRP8- and MRP14-positive monocytes and granulocytes could also be observed.

Relationship between MRP8 and MRP14 expression and clinicopathological characteristics in ESCCs

We further examined the relationship between MRP8 and MRP14 expression and clinicopathological findings in SCCs of the esophagus. Table 1 compares the expression of MRP8 and MRP14 in ESCC and matched non-neoplastic esophageal tissues. MRP8 was positive in 61(93.8%) of 65 normal mucosae detected and in 49(75.4%) of 65 ESCCs. MRP14 was found in all the normal mucosae detected and in 54(83.1%) of 65 ESCCs. Among ESCC cases, grade 0 staining, which means lack of expression in tumor tissues, was recorded in 24.6% for MRP8 and 16.9% for MRP14 of ESCC. In total, 9.2% and 13.8% of ESCC cases had grade 1+ for MRP8 and MRP14, respectively. Percentage of moderate staining for MRP8 and MRP14 was 44.6% (MRP8) and 32.3% (MRP14). And 21.5% and 36.9% of cases showed strong staining for MRP8 and MRP14. In comparison with ESCC tissue, the matched non-neoplastic esophageal tissue showed 44.6% (29 of 65) and 92.3% (60 of 65) strong staining for MRP8 and MRP14, respectively. These results indicated a significant reduction of

MRP8 and MRP14 expression in malignant *versus* benign tissue (MRP8: $P<0.01$, MRP14: $P<0.01$).

Table 1 Summary of immunohistochemical analysis of MRP8 and MRP14 in esophageal epithelium and tumors. (Fisher's exact test)

Expression Level[1]	MRP8			MRP14		
	Normal (%)	Tumors (%)	*P*-value	Normal (%)	Tumors (%)	*P*-value
3+	29(44.6)	14(21.5)	<0.01[b]	60(92.3)	24(36.9)	<0.01[d]

Poorly	12	4		4	

[b]$P<0.001$ between MRP8 and MRP14 expression and histological grade, respectively.

In addition, we examined the correlation between MRP8 and MRP14 expression and clinicopathological features, and the

results are summarized in Table 2. According to clincopathological grade, 65 primary ESCCs were classified into three groups: well moderately and poorly differentiated ESCC, respectively. To determine whether the altered expression of MRP8 and MRP14 had additional implications for poor differentiation, we performed Chi-square test in the three groups of ESCCs. There was a significant difference in the expression levels of MRP8 and MRP14 among different differentiation grades, being higher in the well differentiated tumors than in moderately and poorly differentiated tumors (MRP8: $P<0.001$; MRP14: $P<0.001$). However, their expression did not correlate with the other parameters such as age and gender ($P>0.05$).

DISCUSSION

Squamous cell differentiation required the coordinated activation and repression of genes specific to the differentiation constitutes, and disruption of this program accompanied neoplasia[30]. A better understanding of the factors and mechanisms regulating differentiation and of their disturbance in carcinogenesis would offer new possibilities to design novel tumor therapeutic strategies in the field of differentiation therapy[5]. According to our cDNA microarray analysis, *MRP8* and *MRP14* were two genes in the down-regulated and differentiation-associated gene cluster, and their genetic alterations might contribute to esophageal tumorigenesis[10,11]. However, information is limited regarding the possible biological significance of the altered expression of MRP8 and MRP14 during ESCC development. In this study, we revealed frequent loss of MRP8 and MRP14 expression in the majority of ESCCs and a significant correlation between MRP8 and MRP14 expression and clinicopathological parameters of ESCC.

MRP8 and MRP14 were preferentially expressed in the normal esophageal epithelia and lowly expressed in ESCCs. Previous reports have subsequently shown that the deregulation of MRP8 and/or MRP14 was associated with several common human malignancies, including carcinomas of the skin, stomach, colon, nasopharynx, lung, liver and anus, and follicular lymphoma as well[20-28]. Therefore, our results further suggest that reduced expression of MRP8 and MRP14 in ESCC cells, but not in normal cells, plays an important role in esophageal carcinogenesis. It is interesting to note that MRP8 and MRP14 staining was decreased in poorly and moderately differentiated ESCCs when compared with well-differentiated ESCCs. These data suggest that loss of MRP8 and MRP14 expression in ESCC generally occurs along with worsening esophageal epithelial differentiation in histological grade. Identification of the grade of tumor malignancy would facilitate treatment strategies and provide important information for predicting the prognosis[31]. To our knowledge, this is the first report on the relationship between MRP8 and MRP14 expression and histopathological grade of ESCC.

Although the fundamental role of MRP8 and MRP14 in myeloid differentiation and keratinocyte hyperproliferation is well established[32,33], the detailed molecular processes that lead to down-regulation of MRP8 and MRP14 in esophageal epithelium during de-differentiation processes remain to be elucidated. Accumulation of MRP8 and MRP14 may play an important role in maintaining the differentiated status of well-differentiated ESCC, and preventing less differentiated ESCC. It is noteworthy that MRP14 expression level has a positive correlation with the differentiation degree of carcinomas derived from glandular cells, such as hepatocellular carcinoma, cholangiocellular carcinoma and pulmonary adenocarcinoma. In poorly differentiated adenocarcinoma (AC) cases, immunoreactivity of MRP8 and MRP14 was significantly higher than that in the moderately and well differentiated AC cases[24,26]. These differences might reflect the different pathways or mechanisms that MRP8 and MRP14 were

involved in tumorigenesis of different cell origin.

The identification of MRP8 and MRP14 in esophageal epithelial cells may facilitate the elucidation of molecular mechanism of esophageal carcinogenesis. In normal human esophageal epithelia, MRP8 and MRP14 were expressed in regions containing differentiated cells but not in regions containing actively dividing cells, suggesting that MRP8 and MRP14 may be upregulated in the cellular differentiation status. Indeed, MRP8 and MRP14 were expressed in a tissue/cell-specific and differentiation-dependent manner, especially in the differentiation of monomyelocytes and keratinocytes[34]. Warner-Bartnicki *et al* have reported that the expression of MRP8 and MRP14 was upregulated during mycophenolic acid and 1α, 25-dihydroxyvitamin D_3-mediated differentiation of HL-60 leukemia cells[35]. Similarly, terminal differentiation of various epithelial cells was also linked to their constitutive expression[17]. Consistent with these notions, our observation of their spatial and temporal distribution in esophageal epithelium also supported that MRP8 and MRP14 might collaboratively act to maintain differentiated progeny, playing a growth-suppressive and differentiation-associated role[36]. Based on these findings, we would propose that MRP8 and MRP14 may be closely associated with the early events in the terminal differentiation of human normal esophageal epithelial cells and the epithelial expression of these proteins is thought to require a certain state of proliferation and/or differentiation.

The *MRP8* and *MRP14* genes, together with other 11 *S100* genes and epidermal differentiation complex (EDC) genes, have been mapped to human chromosome 1q21, which is structurally conserved during evolution. This region has revealed a most remarkable density of genes that fulfill important functions in terminal differentiation of the human epidermis[37]. Among those genes, the expression of *S100A2*, *S100A4*, *S100A12*, *SPRR3*, *TGM-3* and other genes has also been identified to be altered in ESCCs[38-42]. Within this chromosomal region, a number of abnormalities such as deletions, rearrangements or translocations were considered to be associated with neoplasia[43,44]. Thus, 1q21 may be a region of the structural and numerical aberration involved in esophageal carcinogenesis and progression. Furthermore, the clustered organization has posed the question whether each gene is regulated by its own elements or by possible superior locus control elements as suggested for the EDC genes[45].

In summary, reduced expression of MRP8 and MRP14 was observed in a majority of ESCCs, suggesting that their down-regulation is a common event in esophageal carcinogenesis and progression. In addition, there was a significant correlation between MRP8 and MRP14 expression and clinicopathological parameters involved in differentiation of ESCC. Poorly differentiated carcinomas showed markedly reduced expression than well and moderately differentiated carcinomas. Thus we conclude that MRP8 and MRP14 may play a significant role in the dedifferentiation process of esophageal neoplastic cells. Whether MRP8 and MRP14 expression is an important predictor for histological grade needs to be confirmed by clinical follow-up studies.

Abstract

AIM: To compare intensity-modulated radiotherapy (IMRT) with conformal radiotherapy (CRT) by investigating the dose profiles of primary tumors, electively treated regions, and the doses to organs at risk.

METHODS: CRT and IMRT plans were designed for five patients with upper esophageal carcinoma. For each patient, target volumes for primary lesions (67.2 Gy) and electively treated regions (50.4 Gy) were predefined. An experienced planner manually designed one CRT plan. Four IMRT plans were generated with the same dose-volume constraints, but with different beam arrangements. Indices including dose distributions, dose volume histograms (DVHs) and conformity index were compared.

RESULTS: The plans with three intensity-modulated beams were discarded because the doses to spinal cord were lager than the tolerable dose 45Gy, and the dose on areas near the skin was up to 50Gy. When the number of intensity beams increased to five, IMRT plans were better than CRT plans in terms of the dose conformity and homogeneity of targets and the dose to OARs. The dose distributions changed little when the beam number increased from five to seven and nine.

CONCLUSION: IMRT is superior to CRT for the treatment of upper esophageal carcinoma with simultaneous integrated boost (SIB). Five equispaced coplanar intensity-modulated beams can produce desirable dose distributions. The primary tumor can get higher equivalent dose by SIB technique. The SIB-IMRT technique shortens the total treatment time, and is an easier, more efficient, and perhaps a less error-prone way in delivering IMRT.

INTRODUCTION

Esophageal carcinoma is one of the most common cancers in china. Surgery and radiotherapy have always been the main treatment methods[1-4]. Chen *et al*[5] reported that the 5-year survival rate by radiation alone was comparable to that by surgery for patients with operable upper third lesions. Therefore, for diseases located in the upper esophageal region, including cervical and upper thoracic esophagus, radiotherapy is an efficient treatment selection. To give a higher radiation dose of between 60 Gy and 70 Gy to primary tumors and approximately 45 Gy to 50 Gy to electively irradiated lymph nodal regions is necessary for tumor local control. Spinal cord restricts the dose escalation of tumor and may affect the outcome of radiotherapy with conventional techniques, because it is close to cervical and upper thoracic esophagus and its endurance dose is less than 45 Gy. Lung is another dose limit factor in radiotherapy of esophageal cancer. Conformal radiotherapy (CRT) can reduce the irradiation volume of lung. But intensity-modulated radiotherapy (IMRT) is capable of producing more highly conformal dose distribution to a target and steeper dose gradients around the target edges than CRT. This capability makes it possible to give a high dose to the target volume while sparing adjacent normal tissues. Studies have shown benefits of IMRT in the treatment of head-and-neck[6-13] and other cancers[14-20].

The conventional technique for esophageal cancer is to use initial anterior-posterior large field arrangement followed by multi-field technique to boost the primary tumor with field size reduction. The large-field plan and boost plan are created independently. This makes it difficult to determine how the two plans affect each other. Tissues irradiated during the large-field phase receive unwanted additional dose during the boost phase from the beams irradiating the gross tumor. If simultaneous integrated boost (SIB) approach is applied, different dose requirements to the primary tumor and the elective regions can receive different doses within one fraction, and only one plan is needed for the entire course of treatment. Therefore, SIB-IMRT technique can overcome the drawbacks of conventional technique. Further more, it may shorten the treatment course by integrating the boost. The advantages of SIB-IMRT have been demonstrated for head-and-neck and prostate cancers[21-24].

The purpose of our study was to evaluate SIB-IMRT technique for upper esophageal carcinoma and to compare the effect of SIB-IMRT with SIB-CRT. We analyzed the dose distributions of primary tumor and electively treated regions and the doses to lung and spinal cord, and investigated the influence of the number of intensity-modulated beams to the dose distributions.

MATERIALS AND METHODS

Patients were immobilized in supine position. Planning CT scans were performed at 5 mm slice thickness using a dedicated helical CT scanner (Siemens, Somatom Plus 4). The entire lungs were scanned for further plan evaluation. CT images were transferred to the inverse treatment planning system (MDS Nordion, Helax-TMS 6.1) through network (Siemens,

Lantis). Two target volumes, CTV1 and CTV2, were outlined on each set of the CT images. CTV1 included the gross tumor volume (GTV) with a margin of 3 cm in superior and inferior directions and 0.5 cm to 1.5 cm in other directions. CTV2 included correlated lymphatic drainage regions and extended to cricothyroid membrane. Margins of 0.5 cm were added to the CTVs in all directions to generate the planning target volumes (PTVs). The length of PTV1s ranged from 10.5 cm to 14.5 cm, and that of PTV2s ranged from 13 cm to 17 cm. The volume of PTV1s ranged from 167 cm^3 to 251 cm^3, and that of PTV2s ranged from 234 cm^3 to 590 cm^3 (note: PTV1 was surrounded by PTV2. The volume of PTV2 did not include the volume of corresponding PTV1). The patients were numbered in increasing orders with the size of PTV1. The spinal cord and lung were also contoured on the images.

The goal of the treatment was to deliver a prescribed dose of 67.2 Gy to at least 95% of PTV1 in 2.4 Gy fractions, and 50.4 Gy to at least 95% of PTV2 in 1.8 Gy fractions. The maximum dose to the spinal cord was 45 Gy. For the lungs, V_{20Gy} (the volume of the lung received more than 20 Gy) should be less than 25% of lung volume and V_{30Gy} (the volume of the lung received more than 30 Gy) should be less than 20% of lung.

One CRT plan and four IMRT plans were designed for each patient. Beam energy was 6MV X-ray. An experienced planner designed the beam arrangements of CRT plan by using trial and error method. The beam number and directions were manually adjusted to avoid the spinal cord and spare lung, and the beam weights were selected in order to maximize PTVs dose homogeneity. The beam number, directions, wedges and shape were different for these five patients because these parameters were set according to the position and shape of the targets. For example, the CRT plan of patient 1 used eight conformal beams from seven directions (*i.e.* 0º, 45º, 80º, 150º, 225º, 280º and 300º), and that of patient 3 used six conformal beams from five directions (*i.e.* 0º, 70º, 150º, 210º and 305º). Two beams, the large one covering PTV2, and the small one covering PTV1 could be in one beam direction. The beam arrangements of IMRT plans were same for these five patients by using three, five, seven and nine equispaced non-opposed coplanar beams in 360º beginning with 0º, respectively. The gantry angles for each beam arrangement are listed in Table 1. The beams would be delivered in a "step and shoot" mode with multileaf collimators. Delivery sequences were generated under the condition that the number of segments should be no more than 15 for each beam and the intensity levels were 10. The same dose-volume constraints were used for all the plannings during inverse optimization.

Table 1 Beam arrangement of IMRT plans

Number of beams	Gantry angles
3	0º, 120º, 240º
5	0º, 72 º, 144 º, 216º, 288º
7	0º, 52 º, 103 º, 154 º, 206 º, 257 º, 308º
9	0º, 40 º, 80 º, 120 º, 160 º, 200 º, 240 º, 280 º, 320º

For the purpose of comparison, all plans were normalized to make 95% of PTV1 receive the prescribed dose of 67.2 Gy. The following parameters of these plans in each patient were compared, isodose distributions, DVHs, conformity indices (*CI*), mean dose, standard deviation (SD) and D_{95} (lowest dose encompassing 95% of the target) for PTVs, maximum dose for spinal cord, V_{20Gy}, V_{30Gy} and mean dose for lungs.

The equation for calculating conformity index is as follows[9,25]:

$$CI = \frac{V_{T,ref}}{V_T} \times \frac{V_{T,ref}}{V_{ref}} \tag{1}$$

where V_T is the target volume, $V_{T,ref}$ is the target volume covered by the reference isodose line, V_{ref} is the total volume covered by the reference isodose line. The value of *CI* is between zero and one. A *CI* of one represents the ideal situation that the target volume coincides exactly with the treatment volume, a *CI* of zero represents a plan in which there is no overlap between the two volumes. The reference dose was 67.2 Gy for PTV1 and 50.4 Gy for PTV2.

RESULTS

Isodose distributions

Since the plans of these patients had similar results of dose distributions in terms of target volume coverage and OARs sparing, only the isodose distributions and DVHs of patient 3 having the median PTV1 were presented. Figure 1 shows the isodose distributions on axial images for CRT and IMRT plans. PTV1 and PTV2 are shown as white lines. PTV1 was inside PTV2. The isodose lines were displayed on an absolute dose scale, the isodose levels of 67.2 Gy, 50.4 Gy, and 20 Gy were shown. All plans showed similar prescribed dose coverages of PTV1 and PTV2. However, the dose distributions outside the targets were different. For the IMRT plan with three beams, high isodose lines covered more normal tissues, the cervical spinal cord received more than 45 Gy. Some areas near the skin received a dose as high as 50 Gy. The dose to spinal cord exceeded the endurance dose for four of the five patients (*i.e.*

Table 2 Results for CRT and IMRT in five upper esophageal cancer patients(mean±SD)

Stucture	Parameter	CRT	3F IMRT	5F IMRT	7F IMRT	9F IMRT

patient 2 to patient 5). Therefore, three beam IMRT plan was unacceptable. For the CRT plan, high isodose lines covered more normal tissues, indicating that the dose distributions of the 5, 7, and 9 beam IMRT plans were more conformal than CRT plan.

Figure 1 Isodose distributions on axial images for CRT and IMRT plans of patient 3. The white lines represent PTV1 and PTV2. PTV1 was inside PTV2. The isodose levels of 67.2 Gy, 50.4 Gy and 20 Gy were shown. IB stands for intensity-modulated beam.

Targets

DVHs of CRT and IMRT plans for PTV1 and PTV2 of patient 3 are shown in Figures 2A and 2B. The mean results for these

five patients are listed in Table 2. Three beam IMRT plan was presented to show the influence of the number of intensity-modulated beams. The targets' dose homogeneity and conformity of CRT plan were much worse than those of IMRT plans with the beam number no less than five. DVHs were similar to IMRT plans, and the indices did not show any obvious difference as the beam number increased from five to seven and nine. The conformity was improved as the number of intensity-modulated beams increased, but the improvement was marginal when beam number was over five.

Figure 2 DVHs of PTVs for CRT and IMRT plans of patient 3. (A), PTV1; (B), PTV2.

OARs

The mean results of OARs for these five patients are listed in Table 2. The three beam IMRT plans were unacceptable as their doses to spinal cord were lager than the tolerable dose 45 Gy. The results in five, seven, and nine beam IMRT plans were similar and better than those of CRT plan in terms of sparing lung. The mean doses of lung for the five, seven, and nine beam IMRT plans were almost identical.

DISCUSSION

The cervical and upper thoracic esophageal regions are characterized by variation of body thickness, the distance of esophagus to the body surface, and the closeness of the target to the spinal cord. Acceptable SIB-IMRT plans were superior to SIB-CRT plans in treating tumors in these regions. The dose homogeneity of PTV2 improved, the volume of higher dose outside the primary tumor decreased, the dose conformity improved. The difference between SIB-CRT plans and SIB-IMRT plans was due to that SIB-CRT did not compensate for the variations of body thickness and depth of esophagus. It was difficult to protect the spinal cord while keeping the dose uniformity in the target volume with SIB-CRT plans. In addition, the benefit of CRT plan depended greatly upon the planner's experiences, and many trials were required to figure out the beam directions and weights. On the other hand, the planner only arranged the beam directions (Table 1) and set the dose-volume constraints in designing IMRT plan. The other work was done by the inverse treatment planning system.

Therefore, it took less time to design an IMRT plan than to adjust a CRT plan.

The ideal number of beams in an IMRT plan has not been decided. Generally, a larger number of beams would provide more parameters to adjust and, therefore a greater flexibility to achieve a desired dose distribution. However, the more the number of beams was used, the more the effort was required for planning, quality assurance, dosimetric verification and treatment. Practically, it was desirable to reduce the number of beams to as few as possible without compromising the quality of the treatment. Soderstrom and Brahme[26,27] concluded that fewer intensity-modulated beams were needed than uniform beams to achieve the same or even better results, perhaps as few as three beams were sufficient in most cases provided beam angles were optimized. Mohan and Ling[27,28] believed that the ideal minimum number of beams would depend upon a variety of geometrical and biological factors and the desired target dose level to achieve an adequate local control. Studies[8,11,22,29] showed that the beams less than ten were enough for most clinical requirements. Thus, the number of beams used in our study was less than 10. Pirzkall *et al*[30] concluded that the ideal number of beams was influenced by the photon energy for deeply seated targets.

From the results of this study, the plan with three equispaced coplanar intensity-modulated beams could not meet the requirement of OARs and its high dose conformity was worse than those with more beams. It might be due to the fact that the beam directions were not optimized. Five equispaced coplanar intensity-modulated beams were sufficient to get an adequate high dose coverage and a dose homogeneity for both targets of upper esophageal cancer. There was no obvious improvement in target dose homogeneity, conformity and the dose to OARs with more than five beams. Therefore we believed that for SIB-IMRT of upper esophageal carcinoma, five beams were sufficient to deliver a satisfactory dose distribution and further increase of the number of beams would complicate the treatment without significant improvement of dose distribution.

In addition, concomitant boost treatment may offer some radiobiological advantage in terms of a lower dose per fraction to normal tissues while delivering a higher dose per fraction to the targets. In this study, the dose per fraction to PTV1 and PTV2 was 2.4 Gy and 1.8 Gy, respectively. To compare with the conventional fractionation (2 Gy/f), we calculated the normalized total dose (*NTD*)[22,23] that was the biological equivalent dose given in 2 Gy/f by linear-quadratic (LQ) model[31]. The *NTD* for PTV1 and PTV2 was about 70 Gy and 49 Gy, respectively. Therefore, the primary tumor could get a higher dose with SIB treatment while the elective regions had an adequate dose. It was beneficial to tumor local control.

In conclusion, for SIB treatment of upper esophageal carcinoma, IMRT is better than CRT in terms of the target volume coverage, OARs sparing and time cost in treatment planning process. Five equispaced coplanar intensity-modulated beams produce desirable dose distributions. The SIB-IMRT technique not only shortens the total treatment time but also is an easier, more efficient, and perhaps a less error-prone way of delivering IMRT. Primary tumor can get a higher equivalent dose by SIB. The effect of SIB-IMRT is currently under clinical trial in our hospital.

Abstract

AIM: To analyze the clinicopathologic characteristics of surgically resected gastric lymphoma patients.

METHODS: We retrospectively analyzed 57 surgically resected gastric lymphoma patients, dividing them into 2 subgroups: Low grade MALToma (the LG group), High grade MALToma and Diffuse large B cell lymphoma (the HG group).

RESULTS: The numbers of patients were: 20 in the LG group, 37 in the HG group. The diagnostic rate of gastroscopy was 34.8% at primary diagnosis and 50% including differential diagnoses. The positive rates of *H pylori* were similar between the 2 groups (68% *vs* 77%). Multiple lesions were found in 19.3%. The proportion of mucosal and submucosal lesions was 80.0%(16/20) in the LG group, and 24.3%(9/37) in the HG group (*P*<0.001). Lymph node invasion rates were 10.5%(2/19) in the LG group and 44.1%(15/34) in the HG group (*P*=0.031). The numbers of recurred patients were none in the LG group, and 8 in the HG group. By univariant analysis, group (*P*=0.024) and TNM stage (stage I, II *vs* stages III, IV, *P*=0.002) were found to be the significant risk factors. There was a tendency of higher recurrence rate in the subtotal gastrectomy group than in the total gastrectomy group (*P*=0.50).

CONCLUSION: The HG groups had a more advanced stage and a higher recurrence rate than the LG group. Although there was no difference between subtotal and total gastrectomies, more careful assessments of multiplicities and radical resections with lymph node dissections seem to be needed because of multiplicity and LN invasion even in LG group.

INTRODUCTION

Because primary gastric lymphoma has a tendency to be localized in the stomach for a long time, surgical resection remains an important treatment modality[1-3]. *Helicobacter pylori* has been proposed to be an important cause of the formation of mucosa associated lymphoid tissue (MALT) and the development of subsequent lymphoma. About 80% of low grade MALT lymphomas were found to be cured by *H pylori* eradication alone, and there are some reports in which high grade MALT lymphoma was also cured in this manner[4]. Recently, lymphoma related with MALT was classified as ' extra nodal marginal zone B cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)' by WHO[5]. According to the report of Isaacson *et al.*[6] in 1983, gastric lymphoma may be divided into low grade MALT lymphoma, high grade MALT lymphoma, and diffuse large B cell lymphoma. The aim of this study was to analyze the clinicopathologic characteristics of surgically resected gastric lymphoma patients according to the postoperative histopatholgic grades.

MATERIALS AND METHODS

We enrolled 57 gastric lymphoma patients who had undergone operations at Seoul National University Hospital from January 1995 to July 2002.

Primary gastric lymphoma was often divided into 3 categories: low grade MALT lymphoma, high grade MALT lymphoma, and diffuse large B cell lymphoma. Low grade MALT lymphoma was diagnosed when the classic features of MALT lymphoma were evident. The classic features were lymphoid atypical cells and destruction of mucosal walls (lymphoepithelial lesion), and the presence of centrocyte-like cells, lymphoid follicles, monocyte-like B-cells, lympho-plasma cell, centroblast-like cells, and Dutcher bodies[7,8]. When these cells became larger and crowded, and the features of low grade MALT lymphoma were seen partly, such cases were classified as high grade MALT lymphoma. When portions of low grade MALT lymphoma were absent, they were classified as diffuse large B cell lymphoma. (Figure 1) But, it was often difficult to differentiate diffuse large B cell lymphoma from high grade MALT lymphoma because the histopathologic sections from postoperative specimens sometimes did not include the portions of the classic features of low grade MALT lymphoma which were present partly.

We divided the patients into 2 groups according to the post-operative pathologic reports, namely the LG group (low grade MALT lymphoma) and the HG group (high grade MALT lymphoma and diffuse large B cell lymphoma).

Sex, age, operative method, postoperative stage, number of lesions, and recurrence were reviewed retrospectively using

medical records and phone-call surveillance. For postoperative staging, both the TNM staging system for gastric adenocarcinoma and the Musshoff staging system (modified Ann-Arbor stages) were used (Table 1).

Clinicopathologic data were compared using the chi-square test and Fisher's exact test. Survival rates were calculated using the Kaplan-Meier method and analyzed using the log-rank test. P-values of less than 0.05 were considered statistically significant.

Figure 1 A: Low grade MALT lymphoma. Microphotograph showing proliferation of heterogeneous small B-cells, including marginal zone (centrocyte-like) cells, cells resembling monocytoid cells, small lymphocytes, and scattered immunoblast and centroblast-like cells. In epithelial tissue, neoplastic cells typically infiltrated the epithelium, forming lymphoepithelial lesions. B: Diffuse large B cell lymphoma. Microphotograph showing proliferation of large B lymphoid cells in a diffuse pattern. Tumor cells have a large and pleomorphic appearance with prominent nucleoli.

RESULTS

Clinical characteristics

The numbers of patients of the LG group and the HG group were 20(35.1%) and 37(64.9%), respectively. One patient had a synchronous gastric adenocarcinoma and low grade MALT lymphoma.

The male to female ratio was 1.11:1 (30:27) without any significant difference between the groups.

The mean age of the patients in the LG group was 52.6 years, and was 57.7 years in the HG group. There was no significant difference between the 2 groups. (P>0.05) (Table 2).

Table 2 Age and sex distribution of patients

	LG group	HG group	Total	P-value
n (%)	20[1] (35.1)	37 (64.9)	57	
Age (±SD)	52.6 (±11.4)	57.7 (±13.9)	55.9 (±13.2)	n.s.
Sex	10:10	20:17	30:27	n.s.
(M:F)	(1:1)	(1.18:1)	(1.11:1)	

LG group: patients with low grade MALT lymphoma, HG group: patients with high grade MALT lymphoma or diffuse large B cell lymphoma. [1]In 1 case: associated with AGC.

Table 3 Presenting symptoms and duration

Symptom	n (%)
Epigastric pain, discomfort	39 (68.4)
Gastrointestinal bleeding	9 (15.8)
Weight loss	9 (15.8)
Indigestion	7 (12.3)
Nausea／vomiting	4 (7.0)
Anorexia	4 (7.0)
Diarrhea	2 (3.5)
Others	3 (5.3)

Histopathology	Duration of symptom
LG group	11.9±24.9
HG group	5.2±9.0
Total	7.6±16.7 mo

P=n.s.

Table 1 Musshoff's modified Ann-Arbor stage

Stage	Definition
Ie	Involvement of a single extralymphatic organ or site[1]
Ie1	Involvement of mucosa or submucosa
Ie2	Involvement of more than submucosa
IIe	Involvement of two or more lymph node regions on the same side of the diaphragm with localized involvement of an extralymphatic organ and site[1,2]
IIe1	Involvement of regional lymph nodes
IIe2	Involvement of other lymph nodes beyond regional area
IIIe	Localized involvement of a single extralymphatic organ or site with involvement of lymph node regions on both sides of the diaphragm (IIIe) or involvement of the spleen (IIIs) or both (IIIe+s)[1,2]
IVe	Involvement of extranodal site(s) beyond that designated as "e" more than one extranodal deposit at any location, any involvement of liver or bone marrow[1,2]
E	localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow
1	Direct spread of a lymphoma into adjacent tissues or organs does not influence stage. Multifocal involvement of a single extralymphatic organ is classified as stage IE and not stage IV. Involvement of two or more segments of the gastrointestinal tract, isolated and not in continuity, is classified as stage IV (disseminated involvement of one or more extralymphatic organs).
2	The definitions of regional lymph nodes for individual sites of extranodal lymphomas are identical to the definitions of regional lymph nodes for individual sites of gastrointestinal carcinomas. For example, the regional lymph nodes for a primary gastric lymphoma are the perigastric nodes along the lesser and greater curvatures and the nodes located along the left gastric, common hepatic, splenic, and celiac arteries.

Symptoms

Epigastric pain and discomfort were the most common symptoms. The duration of the symptoms of the LG group had a tendency to be longer than that of the HG group, but it was not statistically significant. Among B symptoms specific in lymphoma, only weight loss was found in 9 patients (15.8%), but fever and night sweats were not found. Moreover, the reason of weight loss was obscure, *i.e.*, as to whether it was a part of the B symptoms or a result of the gastrointestinal symptoms (Table 3).

Results of preoperative examination

Forty-six patients were enrolled whose records of preoperative gastroscopic findings were available. The accuracy of the primary diagnosis of lymphoma by preoperative gastroscopy was 34.8%(16/46), and the overall diagnosis rate including differential diagnosis was 50%(23/46) (Table 4).

There were 2 cases of adenocarcinoma in the preoperative pathologic reports. One was misdiagnosed as a adenocarcinoma and later diagnosed as a diffuse large B cell lymphoma postoperatively, and the other was a case of synchronous adenocarcinoma and lymphoma. The accuracy of histological grading of lymphoma with preoperative biopsy was 87.0%(40/46) as compared with the postoperative pathologic reports (Table 5).

To identify relationships with *H pylori*, a pathologic examination with or without a CLO test was used in 38 cases, the serology test (*H pylori* IgG) in 1 case, and both methods in 3 cases.

In our series, 73.8%(31/42) were related with *H pylori*. According to the groups, the positive rate of *H pylori* was 68.8%(11/16) in the LG group and 76.9%(20/26) in the HG group. There was no significant difference between the 2 groups.

Of the patients diagnosed as low grade MALT lymphoma, 5 patients took the regimen for *H pylori* eradication. Four patients had surgical resection later because of remnant lymphoma at follow-up gastroscopy, and 1 patient underwent the operation because of transformation to a higher grade.

Table 4 Preoperative endoscopic findings and diagnosis accuracy

	LG group (%)	HG group (%)	Total (%)
Lymphoma	6 (37.5)	10 (33.3)	16 (34.8)
AGC	4 (25.0)	17 (56.7)	21 (45.7)
EGC	5 (31.3)	2 (6.7)	7 (15.2)
Benign ulcer	1 (6.3)	1 (3.3)	2 (4.3)
Total	16 (100)	30 (100)	46 (100)
Dx. Rate			Lymphoma/total (%)
Primary Dx	6/16 (37.5)	10/30 (33.3)	16/46 (34.8)
D/Dx	8/16 (50.0)	15/30 (50.0)	23/46 (50.0)

Dx: Diagnosis, D/Dx: Differential diagnosis.

Table 5 Comparison between gastroscopic biopsy and post-operative histopathology

Preop. \ Postop.	LG group (%)	HG group (%)	Total (%)
LG group	15 (78.9)	4 (21.1)	19 (100.0)
HG group	2 (7.4)	25 (92.6)	8 (100.0)
Total	17	29	46

Methods and results of operations

Subtotal gastrectomy was performed in 35 patients (61.4%), and total gastrectomy in 22 patients (39.6%), with no significant difference among the groups. Of these 22 patients, 7 also underwent splenectomy (Table 6).

In all groups, the lower third was the most common lymphoma

location, which occurred in 45.6%(26/57). If the patients with additional lesions in the upper or middle third were included, totally 54.4% (31/57) of patients had lesions in the lower third of the stomach. There was no significant difference between the groups (Table 7).

We used both staging systems, namely TNM stages and Musshoff stages (modified Ann-Arbor stages). Regardless of the staging system, patients in the LG group had more proportions of early lesions than those in HG group (Tables 8-9).

Table 6 Operation methods

	LG group (%)	HG group (%)	Total (%)
Subtotal gastrectomy	10 (50.0)	21 (56.8)	30 (52.6)
Other partial gastrectomy	2 (10.0)	3 (8.1)	5 (8.8)
Total gastrectomy	8 (40.0)	14 (37.8)	22 (38.6)
TG	7 (35.0)	8 (21.6)	15 (26.3)
TG + splenectomy	1 (5.0)	6 (16.2)	7 (12.3)
Total	20 (100)	37 (100)	57 (100)

Total	19[1] (100)	37 (100)	56 (100)

[1]The information on the LN status of one patient (mucosal lesion) was not available among 20 low grade MALT lymphoma patients.

Table 9 Musshoff stage

Stage	LG group (%)	HG group (%)	Total (%)
Ie1 (+ no residual)	15 (78.9)	7 (18.9)	22 (39.3)
Ie2	2 (10.5)	15 (40.5)	17 (30.4)
IIe1	1 (5.3)	14 (37.8)	15 (26.8)
IIe2	1 (5.3)	1 (2.7)	2 (3.6)
Total	19[1] (100)	37 (100)	56 (100)

[1]The information on the LN status of one patient (mucosal lesion) was not available among 20 low grade MALT lymphoma patients.

In the LG group, mucosal and submucosal lesions accounted for 80.0%(16/20), lesions invading into proper muscles accounted for 15.0%(3/20). In the HG group, the proportion of lesions within the submucosa was 24.3%(9/37), lesions in proper muscles and subserosal spaces were 62.2%(23/37), and lesions invading serosa were 8.1%(3/37).

In the HG group, one patient had the lesion invading the colon and pancreas, and one patient had a lymphoma directly invading the spleen and pancreas.

The LG group had a lower proportion of LN metastasis than the HG group. The number of patients who had regional LN invasion was 2 of 19 (10.5%, 1 submucosal lesion, 1 proper muscle lesion) in the LG group and 15 of 34(44.1%) in the HG group.

Multiple lesions were found in 11 patients (19.3%) according to the postoperative pathologic reports. In 2 cases, no lymphoma lesion was found in the postoperative specimens, one had a diffuse large B cell lymphoma which received preoperative chemotherapy (COPBLAM #6), and the other was diagnosed as low grade MALT lymphoma preoperatively who did not receive any special therapy before operation. There was no difference in the proportions of multiple lesions among the subgroups. In 11 patients with multiple lesions, 6 had subtotal gastrectomy, and the other 5 had total gastrectomy (Table 10).

Table 10 Number of lesions

Number	LG group (%)	HG group (%)	Total (%)
None or single	17 (85.0)	29 (83.3)	46 (80.7)
0	1 (5.0)	1 (2.7)	2 (3.5)
1	16 (80.0)	28 (75.7)	44 (77.2)
Multiple	3 (15.0)	8 (21.6)	11 (19.3)
2	1 (5.0)	7 (18.9)	8 (14.0)
6	0 (0.0)	1 (2.7)	1 (1.8)
Diffuse	2 (10.0)	0 (0.0)	2 (3.5)
Total	20 (100)	37 (100)	57 (100)

P=n.s.

Postoperative radiotherapy was indicated to those with remnant lesions in their resection margins. Two patients in the LG group and one in the HG group underwent radiotherapy, and remained alive at postoperative 13.5 mo, 66.3 mo, and 66.4 mo, respectively, without evidence of recurrence. Postoperative chemotherapy was applied to one patient with low grade MALT lymphoma invading the proper muscles and the regional LN. Twenty-four patients out of 32 patients (75.0%) in the HG group had postoperative chemotherapy. According to the Musshoff stage, only 1 patient of 19 stage Ie1 patients had postoperative chemotherapy. Ten of 15 stage Ie2 patients and 14 of 15 stage IIe patients received chemotherapy. In most cases, CHOP regimen (cyclophosphamide, doxorubicin, vincristine, prednisolone) was used.

Recurrence and risk factors

Patients were followed up for a mean 75.8 mo. Eight cases had recurrence, no patient in the LG group and 8 patients (21.6%) in the HG group (Table 11).

The locations of the recurrence were the remnant stomach in 1 case, and the intraabdominal lymph nodes in 4 cases. In the other case, the location was presumed to be the intraabdominal area. One case had a recurred lesion in the thorax, and another case in the neck.

Six of 8 patients with recurred diseases died. One died of pneumonia during chemotherapy for a recurred lymphoma, and another died of brain infarct of unknown etiology. The other 4 patients died of recurred disease progression.

Grades (*P*=0.024), TNM stages (stages I, II *vs* stages III, IV, *P*=0.002) were found to be risk factors by univariate analysis. Otherwise, age, sex, size of lesion, depth of invasion, lymph node metastasis, and the presence of multiple lesions, were all unrelated to recurrence (Figures 2, 3). Patients with Musshoff stage IIe lymphoma showed a tendency of lower 5 years disease-free survival rate than those with stage Ie lymphoma (87.1% *vs* 76.1%, *P*=0.139), but it was not significant. None of stage Ie patients in LG group had recurrence, but 4 of stage Ie HG group patients had recurrence (5-year disease-free survival rate 100% *vs* 77.9%, *P*=0.080).

The recurrence rate in the subtotal gastrectomy group (17.1%, 6/35) was slightly higher than that in the total gastrectomy group (9.1%, 2/22). In the HG group, the recurrence rate was 28.6%(6/21) in those with subtotal gastrectomy and 15.4%(2/13) in those with total gastrectomy. But it was not significant (*P*=0.50).

Figure 2 Disease free survival curve according to histopathology (LG group : low grade MALT lymphoma, HG group : high grade MALT lymphoma and diffuse large B cell lymphoma).

DISCUSSION

The stomach is the most common intraabdominal organ for extralymphatic lymphoma in the abdominal cavity, about 20% of extralymphatic lymphomas occur in the stomach. Normally, the stomach has no lymphatic tissue in the mucosa or submucosa. The formation of MALT has been known to be related with *H pylori* and some autoimmune diseases[9,10]. In our study, the proportion of patients with evidences of *H pylori* was 73.8% overall, and 68.8% in the low grade MALT lymphoma group. This result corresponded with the results of Paik *et al*.[11] in Korea, but the figures were slightly lower than the 70-90% obtained elsewhere[12]. The ratio of males to females was 1.11:1. Compared to other results in which the male to female ratios were 1.7:1-2:1, our result showed a higher proportion of female patients.

Some genetic abnormalities such as t(11:18)(q21:q21) have been discovered to be related with the process of MALT lymphoma formation by *H pylori*. t(11:18) existed in about 18-50% of MALT lymphomas. Liu *et al*.[13] reported that low grade MALT lymphoma with t(11:18) was more resistant to *H pylori* eradication regimens. Remstein *et al*.[14] reported that low grade MALT lymphoma without t(11:18) tended to have t(1:14) or to show aneuploidy. Moreover, abnormal manifestations of bcl-6, some trisomies (including trisomy 3), abnormality of P53, and hypermethylation of P15 or P16 are also thought to be related to the formation of MALT lymphoma. Thus, there might be several pathways to the formation of MALT lymphoma[15].

Cabras *et al*.[16] advocated multiple pathways to high grade transformation. The time taken for high grade transformation was estimated at about 10 years by Yoshino *et al*.[17], which was not definite with our study. On the other hand, there were 4 cases in our study who had been diagnosed as low grade MALT lymphoma by preoperative gastroscopy, and they were diagnosed as higher grade lymphoma after *H pylori* eradication or surgery. So, there is a possibility that high grade transformations were observed within a few months.

We could spare the time and cost of attempting to eradicate *H pylori*, if we knew the characteristics of the group whose

diseases were resistant to *H pylori* eradication therapies and tended to transform to higher grades. Currently, t(11:18), *H pylori* with Cag A(+), invasion deeper than the submucosal layer by endoscopic ultrasonography, and lymph node metastasis have been reported to be risk factors of resistance[18]. However, in our series, all 5 patients whose lymphoma invaded the submucosal layer without lymph node metastasis failed *H pylori* eradication and underwent operation, demonstrating the need for further studies on the risk factors involved.

Misdiagnoses could be made in patients with higher grade MALT lymphoma or diffuse large B cell lymphoma once diagnosed as low grade MALT lymphoma preoperatively. Strecker *et al*.[19] reported that the accurate diagnostic rate with grade differentiation was 73% even in the large medical institutes because of the limitations of the small, partial biopsy samples produced by gastroscopic procedures. In our study also, 87% showed the same diagnosis and the same grade before and after operation.

Likewise, among the 19 patients once diagnosed as diffuse large B cell lymphoma preoperatively, 4(21.1%) were diagnosed as high grade MALT lymphoma because the portions of the classic features of low grade MALT lymphoma were found postoperatively. Even more, the histopathologic sections from postoperative specimens could miss the portions of the classic features of low grade MALT lymphoma which were present partly, too. This is the reason why we categorized both diffuse large B cell lymphoma and high grade MALT lymphoma patients into one group.

Eck *et al*.[20] proposed complementary serology testing to confirm the relationship with *H pylori*, because positive results by serologic tests are obtained even in *H pylori*-negative patients by gastroscopic biopsy. We checked 4 cases in which serology testing was performed. Three patients were also positive by biopsy, but one patient had a positive serologic result despite a negative finding by gastroscopic biopsy.

Recently, some have suggested non-operative methods such as *H pylori* eradication, chemotherapy, or radiotherapy as the primary therapeutic strategies instead of surgery[21,22]. Whereas in our study only 3 patients with remnant tumor in the resection margin undertook radiotherapy, Schecheter *et al*.[23] reported the complete resolution of 17 cases of MALT lymphomas in stages I and II with radiotherapy. The German multicenter study GIT NHL 01/92 in 2001 reported no significant difference in the survival or recurrence rates between 79 patients who had surgery alone or surgery with adjuvant chemotherapy and 106 patients who had chemotherapy alone[24].

Investigators who suggested that chemotherapy was the primary strategy believed that there was no difference in the survival rates of surgical resection and chemotherapy, and that those who did not receive radical resection showed significant lower survival rates, and that chemotherapy can reduce the size of a lesion and make the surgery easier, even when it failed to effect a complete cure.

On the other hand, surgical resection as the primary therapy allowed the accurate staging of the lymphoma. Besides, in those patients with serious complications such as perforation and bleeding, surgical procedure became more difficult due to the fragile gastric wall, and the higher risk of postoperative complications. Moreover, peritoneal seeding could theoretically occur via the perforated gastric wall[1-3,25].

We found that the proportion of patients with multiple lesions was 19.3%. In addition, cases in which the MALT lymphoma had spread along the mucosal layer to the esophagus or the duodenum were also reported. In the *H pylori* infected stomach, it is well known that gastric mucosa other than MALT lymphoma lesions, may have B cell monoclonality. Even after *H pylori* eradication therapy, it has been reported that about 50% of patients had B cell monoclonality in their gastric mucosa

[26,27]. It is not certain that this B cell monoclonality reflects the presence of a remnant or pre-malignant lesion. But if B cell monoclonality is a true pre-malignant lesion, we would rather perform total gastrectomy to completely remove possible malignant lesions.

In the clinical setting, some debates exist about the results of subtotal and total gastrectomies. Kodera *et al.*[28] showed that there was no difference in the survival rates of 45 patients with subtotal gastrectomy and 37 patients with total gastrectomy among 82 patients with primary gastric lymphoma in stages I and II. Similar results were reported by Rodriguez-Sanjuan *et al.*[29], and by Colucci *et al.*[30] Bozer *et al.*[31] reported better survival rates in 13 patients with stages I and II primary gastric lymphoma who received total gastrectomy than in 24 patients who underwent subtotal gastrectomy. However, they mentioned the possibility of more complete lymph node dissection in the total gastrectomy group.

In the past, concurrent splenectomy and multiple lymph node biopsies were recommended for staging. But, the local spreading characteristics of primary gastric lymphoma make the splenectomy unnecessary if the spleen is not invaded. These characteristics sometimes make it reasonable to use the TNM staging systems instead of Ann-Arbor staging. There are some controversies on the necessity of multiple intraoperative lymph node biopsy. Chang *et al.*[32] reported that about 40% of low grade lymphomas limited within the submucosal layer had lymph node metastasis. Our series also had 2 low grade lymphoma patients with lymph node metastasis, and 2 of HG group who had no lymph node metastasis (stage Ie) recurred in the intraabdominal lymph nodes. Only 1 patient among those with recurred diseases had recurred lesions in the remnant stomach, and the majority of them had their recurred lesions in lymph nodes. So, wide lymph node dissection must be performed, and additional biopsy for suspicious lymph nodes is recommended.

Therefore, subtotal gastrectomy can be performed safely with sufficient lymph node dissection, but sufficient preoperative searching for multiple lesions by gastroscopy or endoscopic ultrasonography is required, and close postoperative follow-up should be emphasized.

We could not found a definite relationship between the stages and the disease-free-survival rate, because of the small size of the objectives and a high proportion of recurred patients with lymph node negative lymphoma. One of them having a 13 cm×10 cm lymphoma directly invading colon and pancreas was classified as Musshoff stage Ie, and contributed to a high proportion of stage Ie patients in all recurred ones. All the recurred patients in stage-Ie were of HG group and none of LG group had recurred, even though it showed no significant differences. Most of them underwent sufficient lymph node dissection (D2), and the number of dissected lymph nodes was 64, 60, 19, 11, respectively. It implies that high grade lymphoma is more aggressive and has a greater possibility of systemic features than low grade lymphoma, even in early stage.

In conclusion, the majority of patients with low grade MALT lymphoma had early stage disease, which is curable by surgery only. The proportions of advanced diseases that need additional chemotherapy, and the proportions of recurred patients were lower in the LG group than in the HG group. The risk factors of recurrence were pathologic grade and TNM stage. Among the patients with recurred lymphoma, the number of patients who had subtotal gastrectomy was somewhat greater than the number of patients who had total gastrectomy, even though it was not significant. The existence of multiple lesions or lymph node metastasis even in low grade MALT lymphoma emphasizes the need for more thorough preoperative diagnosis, radical surgical resection with lymph node dissection, and careful postoperative follow-up.

Abstract

AIM: To investigate the roles of c-Jun N-terminal kinase (JNK) signaling pathway in vitamin E succinate-induced apoptosis in human gastric cancer SGC-7901 cells.

METHODS: Human gastric cancer cell lines (SGC-7901) were treated with vitamin E succinate (VES) at 5, 10, 20 mg/L. Succinic acid and vitamin E were used as vehicle controls and condition medium only as an untreated (UT) control. Apoptosis was observed by 4′, 6-diamidine-2′-phenylindole dihydrochloride (DAPI) staining for morphological changes and by DNA fragmentation for biochemical alterations. Western blot analysis was applied to measure the expression of JNK and phosphorylated JNK. After the cells were transiently transfected with dominant negative mutant of JNK (DN-JNK) followed by treatment of VES, the expression of JNK and c-Jun protein was determined.

RESULTS: The apoptotic changes were observed after VES treatment by DNA fragmentation. DNA ladder in the 20 mg/L VES group was more clearly seen than that in 10 mg/L VES group and was not detected following treatment of UT control, succinate and vitamin E. VES at 5, 10 and 20 mg/L increased the expression of p-JNK by 2.5-, 2.8- and 4.2-fold, respectively. VES induced the phosphorylation of JNK beginning at 1.5 h and produced a sustained increase for 24 h with the peak level at 12 h. Transient transfection of DN-JNK blocked VES-triggered apoptosis by 52%. DN-JNK significantly increased the level of JNK, while decreasing the expression of VES-induced c-Jun protein.

CONCLUSION: VES-induced apoptosis in human gastric cancer SGC-7901 cells involves JNK signaling pathway via c-Jun and its downstream transcription factor.

INTRODUCTION

Vitamin E is characterized as a fat-soluble membrane antioxidant[1-3]. RRR-α-tocopheryl succinate (vitamin E succinate, VES), a derivative of natural vitamin E, does not possess antioxidant properties unless succinate group is hydrolyzed by specific ester hydrolase. VES has been shown to be a potent growth inhibitor of a variety of malignant cell types *in vitro* and *in vivo*, including avian lymphoid cells[4], murine B16 melanoma cells[5] and EL4 T lymphoma cells[6,7], human monoblastic leukemia cells[8], prostate[9,10], breast[11-13] and gastric cancer cells[14,15]. VES has also been shown to suppress tumorigenesis in hamster buccal pouch[16], mouse forestomach[17] and mammary gland[18]. These antitumor effects seem to be selective for tumor cells since VES treatment is not toxic to normal cell lines[11,19].

The molecular basis or mechanism for the growth inhibition activity of VES remains unclear, but it could be attributed to G1 cell cycle blockage[11,20], DNA synthesis arrest[4,7,21], increased expression of biologically active transforming growth factor-βs (TGF-βs) and their type II cell surface receptors[4,22], the induction of differentiation[23,24] and apoptosis[21,25,26]. VES is a potent inducer of apoptosis in human gastric cancer cells and it appears that at least two signaling pathways to trigger apoptosis may be involved. One of the previous studies in our laboratory have demonstrated that VES activates biologically active TGF-β and then TGF-β increases the kinase activity of c-Jun N-terminal kinase (JNK) followed by phosphorylation of c-Jun, and finally activated c-Jun triggers apoptosis in human gastric cancer cells[27]. The other shows that one of the death receptors, Fas plays an important role in VES-induced apoptosis, in that Fas activates Caspase-8 leading to a proteolytic cascade of Caspases through FADD[28].

It is well established that apoptosis or programmed cell death plays a pivotal role in the development and homeostasis of metazons by eliminating superfluous or unwanted cells[29-35]. Signals in response to stimulus-induced apoptosis or cellular stress affect the activity of transcription factors via several distant signal transduction pathways[36-38]. It is becoming clear that members of mitogen-activated protein kinase (MAPK) family have been shown to mediate almost all the cellular processes from gene expression to cell death[39-42]. In this study, we chose human gastric cancer cell line SGC-7901 as a model for VES-induced apoptosis. The roles of JNK, a member of MAPK family, were determined to further investigate the mechanism of VES-mediated growth inhibition of human gastric cancer cells.

MATERIALS AND METHODS

Materials

VES was purchased from Sigma Co. Ltd. RPMI 1 640 media, LIPOFECTAMINE PLUS™ reagent and prestained protein marker were purchased from Gibco BRL, 4′,6-diamidine-2′-phenylindole dihydrochloride (DAPI) from Roche Diagnostics Co. Proteinase K from Merch Co. JNK and GAPDH rabbit polyclonal antibodies, dominant negative mutant construct of JNK were gifts from Dr. Bob G Sanders and Dr. Kimberly Kline (University of Texas, Austin, USA). Phospho-JNK mouse monoclonal and c-Jun (H79) rabbit polyclonal antibody were from Santa Cruz Biotechnologies.

Methods

Cell culture Human gastric cancer cell line SGC-7901 was maintained in RPMI 1 640 medium supplemented with 100 mL/L fetal calf serum (FCS), 100 kU/L penicillin, 100 mg/L streptomycin and 2 mmol/L L-glutamine under 50 mL/L CO_2 in a humidified incubator at 37 ℃. SGC-7901 cells were incubated for different periods in the presence of VES at 5, 10 and 20 mg/L (VES was dissolved in absolute ethanol and diluted in RPMI 1 640 complete condition medium correspondingly to a final concentration of VES and 1 mL/L ethanol). Both succinic acid and vitamin E dissolved in ethanol were used as vehicle controls and condition medium only was used as an untreated (UT) control.

DAPI staining and apoptotic evaluation Cells were treated with VES at 20 mg/L for 48 h, then harvested, washed with PBS and stained with 2 mg/L DAPI in 1 000 mL/L methanol for 30 min at 37 ℃. Cells were viewed using a fluorescence microscope with ultraviolet (UV) excitation at 300-500 nm. Cells with nuclei containing clearly condensed chromatin or cells with fragmented nuclei were scored as apoptotic.

DNA fragmentation assay DNA fragmentation was determined by extraction of DNA followed by electrophoresis. In brief, cells were collected in an Eppendorf tube and washed twice with PBS. Cells were incubated for 1h at 37 ℃ in 0.5 mL of extraction buffer containing 10 mmol/L Tris· Cl (pH 8.0), 0.1 mol/L EDTA, 20 mg/L trypsin and 5 g/L SDS. The mixture was reincubated with 20 g/L proteinase K for 3 h at 50 ℃. An equal volume of buffer saturated phenol was added and the extracted DNA was collected by centrifugation at 5 000 r/min for 15 min at room temperature. DNA was precipated by the addition of sodium acetate and absolute ethanol. DNA was dissolved in TE buffer and electrophoresed in 10 g/L agarose gel containing ethidium bromide and photographed under UV light.

Western blot analysis SGC-7901 cells treated with VES were harvested, washed with PBS and lyzed in lysis buffer (150 mmol/L NaCl, 1 mL/L NP-40, 5 mg/L sodium deoxycholate, 1 g/L SDS, 50 mmol/L Tris (pH 7.4), 1 mmol/L DTT, 0.5 mmol/L Na_3VO_4, 10 mmol/L phenylmethylsulfonyl fluoride (PMSF), 10 mg/L trypsin, 10 mg/L aprotinin and 5 mg/L leupeptin). Following the centrifugation of 12 000 g for 30 min at 4 ℃, the amount of protein in the supernatant was determined using Biorad DC protein assay. Equal amounts of protein were separated on 100 g/L SDS-PAGE and transferred to different nitrocellulose filters (Gibco BRL, USA) overnight. Blocked with 50 g/L defatty milk, the individual filters were initially incubated with JNK, or with c-Jun, or with GAPDH rabbit polyclonal antibodies, or with phospho-JNK monoclonal antibody and then all were incubated again with horseradish peroxidase-conjugated IgG. Afterwards DAB was added to develop the filters.

Transient transfection SGC-7901 cells were washed twice with serum-free medium without antibiotics and incubated for 3 h in 2 mL of serum-free medium containing 30 μL of L_IPOFECT AMINE reagent and 2 μg of dominant negative JNK or JNK vector. After 3 h, the cells were treated with VES.

RESULTS

VES induced apoptosis in SGC-7901 cells

SGC-7901 cells were cultured for 48 h and collected, and DNA was extracted. Gel electrophoresis of DNA extracted from cells after exposure to UT control, succinate, vitamin E and VES is shown in Figure 1. Fragmentation of chromosomal DNA characterized as a DNA ladder was observed following exposure to VES at 10 and 20 mg/L. DNA ladder in 20 mg/L VES group was more clearly seen than that in 10 mg/L VES group. However, DNA ladder was not detected following treatment of UT control, succinate and vitamin E. These results suggested that VES induced human gastric cancer SGC-7901 cells to undergo apoptosis.

Figure 1 VES induced apoptosis by DNA fragmentation in SGC-7901 cells. Lane 1: Molecular weight marker; Lane 2: UT control; Lane 3: succinate; Lane 4: vitamin E; Lane 5: VES at 5 mg/L; Lane 6: VES at 10 mg/L; Lane 7: VES at 20 mg/L.

Effects of VES at different doses on phosphorylation of JNK

The expression of phospho-JNK (p-JNK) and JNK1/2 in the whole-cell lysates from UT control, succinate, vitamin E and VES-treated cells for 24 h was determined using Western blot analysis. The results revealed that VES increased the expression of p-JNK in an obvious dose-effect relationship. The levels of p-JNK protein in VES-stimulated cells at 5, 10 and 20 mg/L were increased by 2.5-, 2.8- and 4.2-fold over those in UT control-treated cells, respectively (Figure 2A, top panel; Figure 2B). The expression of JNK1/2 among different groups was not significantly different (Figure 2A, bottom panel; Figure 2B).

Figure 2 Expression of p-JNK and JNK in SGC-7901 cells follow-ing treatment of VES for 24 h. Lane 1: molecular weight marker; Lane 2: UT control; Lane 3: succinate; Lane 4: vitamin E; Lane 5: VES at 5 mg/L; Lane 6: VES at 10 mg/L; Lane 7: VES at 20 mg/L.

Effects of VES at different time points on phosphorylation of JNK

Since VES elevated the levels of p-JNK, we investigated whether VES might regulate the expression of p-JNK for 1.5, 3, 6, 12 and 24 h. VES at 20 mg/L induced a prolonged p-JNK expression starting at 1.5 h, peaking at 12 h and returning to the UT control level at 24 h after treatment (Figure 3A, top panel; Figure 3B). The levels of JNK1/2 were not increased by VES (Figure 3A, bottom panel; Figure 3B).

Effects of blockage of JNK on VES-mediated apoptosis

To further address the role of JNK signaling in VES-mediated apoptosis, studies were conducted to determine the effects of specific blockage of JNK with dominant negative mutants. SGC-

7901 cells were transiently transfected with an expression construct containing dominant negative JNK (DN-JNK, pcDNA3-Flag-JNK, tyrosine 185 and threonine 183 required for phosphorylation activity were replaced with alanine and phenylalanine, repectively), followed by treatment of VES at 20 mg/L. For DAPI staining, SGC-7901 cells were transfected with DN-JNK and then treated with VES for 48 h. Then the cells were collected and stained with DAPI and photographed under a fluororescence microscope. DN-JNK reduced VES-induced apoptosis by 52% compared with the apoptotic rate in empty vector control cells (Figures 4A, 4B). In addition, DN-JNK significantly increased the levels of JNK by 18-fold (Figure 5, top panel), while decreasing the expression of c-Jun to a barely detectable level compared with those in the empty vector cells (Figure 5, middle panel). GAPDH protein levels served to verify lane loads (Figure 5, bottom panel).

DISCUSSION

Apoptosis has been found to be an active and physiological process characterized by a series of morphological and biochemical alterations, including condensation of cytoplasm, loss of plasma membrane microvilli, fragmentation of nucleus and extensive degradation of chromosomal DNA into oligomers of 180 bp by endonuclease[43,44]. Characteristic DNA ladder can

be seen on agarose gel by electrophoresis. In this study, evident DNA ladder appeared in VES-treated SGC-7901 cells, especially at 20 mg/L VES. Therefore, VES can induce SGC-7901 cells to undergo apoptosis.

MAPKs are serine-threonine protein kinases that could be activated by diverse stimuli ranging from cytokines, growth factors, neurotransmitters, hormones, cellular stress and cell adherence[45-47]. MAPKs are evolutionarily conserved from yeast to human. MAPK activity is regulated through a three-tiered cascade composed of a MAPK kinase kinase (MKKK), a MAPK kinase (MKK/MEK) and a MAPK. Activated MAPKs could phosphorylate corresponding substrates, the majority of which are transcription factors[48]. Mammalian MAPKs can be subdivided into five groups, namely extracellular signal-regulated kinase (ERK) 1/2, c-Jun amino-terminal kinase (JNK), p38, ERK3/4 and ERK5.

JNK, also known as stress-activated protein kinase (SAPK), is phosphorylated by MKK4/7 activated by various MKKKs. Activated JNK in turn could phosphorylate transcription factors, c-Jun and ATF-2, which are components of the dimeric activating protein (AP)-1[49-51]. Here, we determined the expression of phospho-JNK and JNK in VES-stimulated SGC-7901 cells. The data showed that VES obviously increased the expression of p-JNK with a dose-effect relationship. The p-JNK levels were also elevated for a prolonged period after VES-treatment. VES induced activation of JNK beginning at 1.5 h after VES treatment and produced a sustain increase for 24 h with peak level at 12 h. The duration of JNK activation is critical in determining cell fate. Persistent activation of JNK has been shown to induce apoptosis. Thus, our results indicated a key role of JNK in VES-mediated apoptosis of human gastric cancer cells.

c-Jun transcription factor, a major target of JNK, belongs to an immediate early gene and could be rapidly and transiently induced in response to multiple extracellular stimuli[52-54]. Its expression can form homodimers or associate with other transcription factor partner, including members of Jun, Fos and ATF-2, to form heterodimeric complexes. Its activation through phosphorylation by JNK has been implicated in a variety of processes including embryomic developments, cellular transformation and initiation of apoptosis in response to various stresses[55-59]. JNK could phosphorylate c-Jun on serines 63 and 73 at the NH_2-terminal activating sites. This results in increased stability of c-Jun and an increase in its transactivation potential and DNA binding affinity. Our previous studies showed that VES upregulated the expression of c-jun mRNA and protein in SGC-7901 cells[60]. In this study, transient transfection of dominant negative mutants of JNK (DN-JNK) blocked VES-triggered apoptosis by 52%. In addition, DN-JNK significantly increased the level of JNK, while decreased the expression of VES-induced c-Jun protein, indicating that JNK plays an important role in the regulation of c-Jun upstream.

Taken together, JNK is phosphorylated and activated in VES-induced apoptosis. JNK regulates the expression of c-Jun, a downstream transcription facor. All the data suggest that JNK plays a critical role in VES-induced apoptosis in human gastric cancer SGC-7901 cells. MAPK pathways are involved in a variety of responses affecting cell fate, such as cell proliferation and differentiation, adaptation to environment stress and apoptosis. None of the MAPK pathways including JNK is acting alone in cellular response, they are integrated with many other metabolic changes in the cells. Therefore, additional studies should provide insights into the interactions and significance among MAPK pathways.

Abstract

AIM: The current study was to determine the serum/plasma levels of VEGF, IL-6, malondialdehyde (MDA), nitric oxide (NO), PCT and CRP in gastric carcinoma and correlation with the stages of the disease and accompanying infection.

METHODS: We examined the levels of serum VEGF, IL-6, PCT, CRP and plasma MDA, NO in 42 preoperative gastric cancer patients and 23 healthy subjects. There were infection anamneses that had no definite origin in 19 cancer patients.

RESULTS: The VEGF levels (mean±SD; pg/mL) were 478.05±178.29 and 473.85±131.24 in gastric cancer patients with and without infection, respectively, and these values were not significantly different ($P > 0.05$). The levels of VEGF, CRP, PCT, IL-6, MDA and NO in cancer patients were significantly higher than those in healthy controls and the levels of CRP, PCT, IL-6, MDA and NO were statistically increased in infection group when compared with non-infection group ($P < 0.001$).

CONCLUSION: Although serum VEGF concentrations were increased in gastric cancer, this increase might not be related to infection. CRP, PCT, IL-6, MDA and NO have obvious drawbacks in the diagnosis of infections in cancer patients. These markers may not help to identify infections in the primary evaluation of cancer patients and hence to avoid unnecessary antibiotic treatments as well as hospitalization. According to the results of this study, IL-6, MDA, NO and especially VEGF can be used as useful parameters to diagnose and grade gastric cancer.

INTRODUCTION

Adenocarcinoma of the stomach (ACS) is the second most common cancer worldwide. Efforts directing at prevention, early detection and intensive therapy have been effectively proved early diagnosis saves lives. There are 2 distinct biological and etiologic subtypes of ACS: epidemic-intestinal type and endemic-diffuse-infiltrative type. Diet and environment are important factors for the epidemic form of ACS, which is associated with chronic atrophic gastritis and intestinal metaplasia of gastric mucosa. Genetic instability, inactivation of tumour suppressor genes, whereas activation of oncogenes, expression of growth factors, cytokines and angiogenic factors promote tumour progression and invasion[1-5].

Angiogenesis in tumours, as well as in a number of physiological (vasculogenesis, wound repair, *etc.*) and pathological (diabetic retinopathy, macular degeneration, rheumatoid arthritis, cancers and psoriasis) conditions, is induced by a number of factors, of which the most prevalent and only endothelium-specific one is vascular endothelial growth factor VEGF, also referred to as vascular permeability factor[6-9]. VEGF is a potent angiogenic mediator described in a wide variety of tumours, and it stimulates angiogenesis and increases vascular permeability[10]. It has been reported to be synthesized and secreted by gastro- intestinal tract adenocarcinomas. Recent studies have revealed a relationship between the increased expression of VEGF and tumour growth, distant metastasis, and the poor prognosis of patients with gastric carcinoma[11-13]. Experimentally, hypoxia and ischemia are known to induce angiogenesis in various cultured tumour cells by increasing VEGF[14-17]. Increased risk of malignancy is associated with chronic inflammation caused by chemical and physical agents[18], and autoimmune and inflammatory reactions of uncertain etiology[19]. Gastric cancer is a global health problem. Several factors are suspected to play a role in gastric carcinogenesis, including effects of diet, exogenous chemicals, intragastric synthesis of carcinogens, genetic factors, infectious agents and pathological conditions in the stomach (such as gastritis). Studies have shown that high intake of smoked, salted and nitrated foods and carbohydrates and low intake of fruits, vegetables and milk significantly increase the risk for gastric cancer[20,21]. Dietary factors, such as consumption of salted and nitrated food, are believed to be primarily responsible for the high incidence and mortality rates of gastric cancer in Turkey. Clinical and epidemiological studies have suggested a link between gastric cancer and concurrent or previous infection with a bacterium or virus. *Helicobacter pylori (H pylori)* is believed to play a role in about 60% of gastric cancer cases. Gastric carcinogenesis is a typical infection and inflammation-associated pathological alteration in which *H pylori* plays a critical role. Current knowledge of the detailed mechanisms underlying the interplay between biological modulators and lesions induced by *H pylori* is still incomplete[22]. Immune response to *H pylori* involves a complex network of inflammatory mediators including chemokines [*e.g.* interleukin (IL)-8], pro-inflammatory cytokines (*e.g.* IL-1, IL-6, tumor necrosis factor α) and immunosuppressive peptides (*e.g.* IL-10)[23]. It is believed that chronic infection with *H pylori* leads to alterations of the cell cycle, including increased epithelial

cell replication, increased rate of cell death (apoptosis) and production of oxidants. For instance, reactive oxygen species (ROS) could be elevated and cause oxidative DNA lesions in gastric epithelial cells during *H pylori*-elicited inflammation[24]. This, in combination with depletion of antioxidant defenses, may predispose to carcinogenesis by increasing the likelihood of DNA mutagenesis. Accumulation of mutations may then lead to metaplasia, dysplasia and gastric cancer. The level of oxidative DNA lesions was significantly higher in patients with chronic atrophic gastritis or gastric cancer than in normal gastric tissues, indicating that a progressive accumulation of oxidative DNA lesions could play a major role in gastric carcinogenesis[24-28]. Lipid peroxidation is initiated by free-radical attack of membrane lipids, generating large amounts of reactive products such as malonildialdehyde (MDA), which have been implicated in tumour initiation and promotion.

Cytokines have been proposed to play an important role in *H pylori*-associated gastric inflammation and carcinogenesis, but the exact mechanism remains unclear. Several studies have indicated that infection with *H pylori* induced the expression and production of various cytokines in gastric mucosa, epithelial cells, or macrophages[29,30]. IL-6, but not other cytokines, has recently been reported to be induced by *H pylori* infection in gastric epithelial cells[31]. In addition, IL-6 has a strong activity in stimulating the growth of human gastric cancer cell lines. These findings suggest that IL-6 may have a potential role in the pathogenesis of gastric cancer[32].

Recognized interactions and cytokine pathways mediated by surrounding stromal cells and between stromal cells and tumour play important roles in gastric carcinogenesis. VEGF and IL-6 are associated with the disease status of gastric carcinoma[33]. However, their relationship remains unclear. IL-6 produced in malignant tumours and inflammatory tissues has a stimulatory effect on tumour growth and a direct angiogenic activity[34]. Reactive oxygen species (ROS) and certain inflammatory cytokines always elevate during the human carcinogenic process. However, the biological significance of the interplay between ROS and inflammatory cytokines remains elusive. IL-6 is a pleotropic cytokine capable of not only inducing growth and differentiation but also modulating cellular apoptosis in many cell types[35-37].

In normal gastric mucosa, nitric oxide (NO) inhibits acid secretion, stimulates mucus and bicarbonate secretions, elevates mucosal blood flow and accelerates the healing of ulcers[38,39]. In some tumour tissues, NO has been found to enhance tumour angiogenesis and to induce vasodilatation, thus accelerating tumour growth[40]. NO may differentially affect tumour progression depending on the levels and timing of release. NO can also decrease adhesion molecule expression, increase vascular permeability and angiogenesis[41]. In addition to causing the initial mutagenic event leading to disease, NO has also been implicated, seemingly paradoxically, both in tumour reduction/prevention and in tumour promotion.

Chronic infection and inflammation have long been recognized as risk factors for a variety of human cancers. Procalcitonin (PCT), a 116 amino acid propeptide of calcitonin, has been proposed as a new diagnostic marker of severe infections. PCT is presumably synthesized in tissues other than thyroid C-cells, which are the source of calcitonin (CT) in normal physiology. At the same time, PCT is excreted by numerous cancers and might well be a useful biological marker for the follow-up of productive tumours. Enhanced production of calcitonin-like peptides was also seen in patients with different malignancies[42,43]. Another infection marker, C-reactive protein (CRP), is most widely used as a marker of ongoing infection in clinical practice. The use of CRP values to diagnose infection in cancer patients was often difficult, because the underlying malignancy also induced CRP production in hepatocytes[42,44,45]. Infections in cancer patients are milder than sepsis, and they are often associated with tumour necrosis and obstructions. Although the underlying cancer seems to disturb PCT and CRP, there may be quantitative differences and these markers did not help to identify infections and stage of cancer.

In this study, we investigated the circulating levels of VEGF and IL-6 which are markers directly related with tumour, and MDA and NO which are oxidative stress markers, and determined the correlation between these markers and infection markers (PCT and CRP) in cancer patients with abdominal pain, vomiting, malnutrition, weight loss, and increasing tendency of infection.

MATERIALS AND METHODS

Materials

Forty-two gastric cancer patients admitted to Firat University Hospital between 2001 and 2002 were included in the study. Serum VEGF, IL-6, PCT, CRP and plasma MDA, NO (nitrite/nitrate) levels were measured in 42 patients with gastric cancer, and 23 healthy subjects. The patients aged 46-78 years (average age 62). Nineteen were men, and 23 were women. Characteristics and demographic data of the study population are shown in Table 1. None of the patients received chemotherapy or radiation therapy before surgery. Each patient underwent the following procedures: chest radiography, stomach imaging (ultrasound or CT scan), endoscopy, other organ computed tomography (CT) scan, mammography, breast ultrasound, clinical diagnosis and hematological and biochemical profiles. The clinicopathological parameters were studied for prognostic values including age, tumour size, histological type, lymph node involvement, vascular involvement, distant metastasis, and serosal invasion. The pathologic diagnosis and classification were made according to the Union Internationale Contre le Cancer (UICC) TNM clinical classification for gastric cancer[46]. The histological diagnosis was based on morphological examination of hematoxylin and eosin-stained, routinely processed specimens. Tumour resection was carried out in all the patients (including 42 preoperative patients who subsequently underwent surgical resection for cure, and 4 patients with inoperable tumours). The control group consisted of 23 healthy controls (male: 11, female: 12, median age: 61 years (38-82 years)). ''Healthy'' was defined as being free from diabetes mellitus, arteriosclerosis and acute illness and without hospitalization for any illness during the previous 2 years.

Table 1 Characteristics of studied populations and demographic data

	No. of subjects	Median age (yr) (interquartile range)	Sex (M/F)
Healthy control	23	61 (38-82)	11/12
Gastric cancer	42	62 (46-76)	19/23
Histologic type			
Adeno carcinoma	34	61 (46-76)	18/16
Signet-ring cell carcinoma	4	51 (48-62)	3/1
Mucinous carcinoma	4	56 (51-58)	1/3
Stage			
I	12	60 (46-74)	7/5
II	16	56 (51-64)	8/8
III	10	65 (62-72)	4/6
IV[1]	4	70 (68-76)	2/2

M, male; F, female. [1]Distant metastatic sites: peritoneal (2), hepatic (1), multiple sites (1).

Peripheral venous blood samples were collected in routine biochemical test tubes for VEGF, IL-6, PCT and CRP analysis and in EDTA.K3 tubes for MDA and NO (nitrite/nitrate) determination. Plasma and serum tubes were centrifuged at 3 500 r/min for 10 min at 4 ℃. The serum and plasma were separated and stored at -70 ℃ until further processing.

Methods
Serum VEGF levels were determined by a quantitative sandwich enzyme immunoassay technique (Quantikine R&D Systems, Minneapolis, Minn.) according to the manufacturer's instructions. The system used a solid phase monoclonal antibody and an enzyme-linked polyclonal antibody rose against recombinant human VEGF. For each analysis 100 μL of serum was used. All the analyses and calibrations were performed in duplicate. The calibrations on each microtiter plate included recombinant human VEGF standards. Results were calculated from a standard curve generated by a four-parameter logistic curve-fit and expressed in pg/mL. The coefficient of variation of interassay determinations reported by the manufacturer varied from 6.2% to 8.8% when the VEGF concentrations ranged between 50 and 1 000 pg/mL. Human IL-6 levels were determined by enzyme linked immunosorbent assay (ELISA) kits (Bender MedSystems, MedSystems Diagnostics, Vienna, Austria) according to the manufacturer's guidelines.

Measurement of plasma MDA levels, MDA, the end product of lipid peroxidation, reacted with tiobarbutiric acid (TBA) to produce a fluorescence product, which was measured spectrophotometrically. Thus, plasma MDA levels were measured as an index of lipid peroxidation according to the TBA spectrophotometric method that was modified from the methods of Satoh and Yagi[47]. 1, 1, 3, 3, tetraetoxypropane was used as standard, and plasma MDA levels were expressed as nanomoles per milliliter.

The measurement of plasma NO was difficult because this radical was poorly soluble in water and had a short half-life in tissue (10-60 s), but its half-life might be as long as 4 min in the presence of oxygen. For these reasons, the determination of NO itself was difficult and required the handling of radioisotopes. In spite of this, the end products, nitrate and nitrite, were preferentially used in clinical biochemistry. Nitrite, a stable end-product of NO, was measured in plasma by using the spectrophotometric Greiss reaction[48]. One thousand μL experimental samples of deproteinised plasma was reacted with 500 μL N-naphthylethylenediamine, 10 g/L sulfanilamide for 45 min at room temperature and analyzed by spectrophotometry at 545 nm. Concentrations were determined by comparison with sodium nitrite. The lower limit of detection was 0.2 μmol/L.

The concentration of CRP in serum was determined by turbidimetric assay using Alfawassermann kits. Leukocyte counts were determined using a Beckman Coulter cell counter (Coulter Corporation, Miami, USA). Serum PCT concentrations were measured by immunoluminometric assay using Brahms kits, according to the manufacturer's protocol (LumiTest; Brahms Diagnostica, Berlin, Germany). PCT levels were found to be <0.08 ng/mL in plasma from 23 healthy controls.

Statistical analysis was carried out using the Statistical Package for the Social Sciences (SPSS). The results were expressed as mean±SE. Mann–Whitney *U*-test and Pearson's rank correlation test were used to compare levels of parameters among the patients. A *P* value <0.05 was considered statistically significant. Variables found to be significant at a level of *P*<0.05 were considered eligible for multivariate regression analysis.

RESULTS

Our findings on the assessed parameters in gastric cancer and healthy control subjects, and the differences between these parameters in infection and non-infection groups of cancer patients are shown in Table 2. Mean serum/plasma levels of IL-6, NO⋅, MDA, CRP and VEGF in patients with gastric cancer were significantly higher than those in the healthy

NS.: not significant.

controls. Serum VEGF levels in patients with gastric cancer were fairly higher than those in healthy controls, although it was not statistically significant compared between gastric cancer patients with and without infections.

As seen in Table 3, as the stage of the disease increased, slightly differences were observed in the levels of PCT and CRP. There were no differences in PCT levels among the 4 stages, whereas there was a statistically significant difference in CRP levels between stage 4 and stage 3 ($P<0.001$). There was a statistically significant correlation between PCT and CRP in gastric cancer patients with or without infection ($r=0.463$, $P<0.02$, Figure 1). IL-6 levels were significantly increased in stage 4 compared with stage 2 and stage 3. Levels of MDA and NO, the markers of oxidative stress, were increased in line with the stage of cancer. However, we had some problems in evaluation of the results in different cancer stage groups because of the small number of patients in stage 4 group. CRP, PCT, IL-6, NO and MDA levels were significantly higher in the cancer group with infection than in gastric cancer group without infection ($P<0.0001$). When the cancer group was classified based on their stages, VEGF levels were proportionally increased with the stage of cancer and there were statistically significant differences between the groups. Of the nineteen cancer patients with infection, 4 were in stage 1, 4 in stage 2, 6 in stage 3 and 5 in stage 4. Consequently, there was no significant difference among the stages of cancer patients with infection. Statistically significant correlations were determined in gastric cancer patients between each two of MDA, NO, VEGF, IL-6, except for the correlation between VEGF and IL-6 ($P>0.05$) (Table 4).

Figure 1 Correlations between serum PCT and CRP in gastric cancer group with and without infection.

DISCUSSION

Angiogenesis was required for tumour growth and progression and it was involved in metastasis[6,8]. The process could result from an imbalance between positive and negative angiogenic regulators released by both tumour cells and host cells[49]. Tumour vascularisation correlated directly with the prognosis of cancer patients in many carcinomas[1-4]. Gastric cancer is a major malignant disease. The development in new diagnostic techniques and mass screening have led to increased detection rates of patients with early-stage gastric cancer. However, even after curative resection of early gastric cancer, there are still various types of recurrences, and residual occult disease and distant micro metastasis. Gastric adenocarcinoma is associated with a high incidence of serosal invasion, direct invasion into the neighboring organs, peritoneal dissemination, lymph node metastasis, and liver metastasis. These lesions have led to a low resection rate and a poor prognosis, however a curative operation should be attempted to improve the 5-year survival rate[50]. Increased serum levels of VEGF in patients with various types of cancer and the relationship between tumour

development and these VEGF levels have been determined. In our study, we investigated the circulating levels of VEGF in gastric cancer patients as well as in healthy controls using a specific ELISA and found a statistically significant increase in VEGF levels directly proportional to the stage of cancer ($P<0.001$). Significantly higher VEGF levels were found in cancer patients than in healthy controls, but the increased VEGF levels were not related to infection ($P>0.05$). We concluded that VEGF was an important marker related with cancer.

IL-6 may play a role in tumour-related angiogenesis by inducing tumour cell proliferation and VEGF expression in tumour cells[51-54]. In the present study, plasma levels of IL-6 were significantly elevated in advanced gastric cancer patients. This result could be explained by IL-6 production in tumour cells and by inflammatory cytokines produced by stromal cells, which stimulated IL-6 production in various cells[52,53]. Serum IL-6 levels were significantly increased in cancer patients with infection than in those without infection ($P<0.001$). It has been reported to be an independent prognostic factor by multivariate analysis in patients with metastatic disease[55], and this result was confirmed by the present study, which found that plasma IL-6 was a predictor of metastasis and infection in patients with gastric cancer. Serum IL-6 levels in gastric carcinoma patients seemed to increase in a stage-related manner.

Infections are associated with elevated malondialdehyde in gastric mucosa which is a lipid peroxidation product. The infection of gastric mucosa stimulates influx of polymorphonuclear leukocytes, leading to the generation of reactive oxygen and nitrogen species. Cell membranes, rich in polyunsaturated fatty acids, are readily attacked by these compounds, producing fatty acid radicals and lipid hydroperoxides, which can decompose in complex ways, yielding species that are more radical and a wide range of compounds, notably aldehydes. Of these, MDA and 4-hydroxynonenal were most common[24,28,56]. MDA formed by the breakdown of prostaglandin endoperoxides[56], is a strongly genotoxic carbonyl compound that can react directly with DNA to produce a variety of adducts. Hypoxia generally takes place in tumours because of the increased oxygen requirement of proliferative cells and the increased tissue oncotic pressure. Hypoxia also induces VEGF and enhances lipid peroxidation and angiogenic potential of tumour cells. In our study, levels of MDA, the end product of lipid peroxidation, were higher both in patients with gastric cancer compared to healthy controls and in patients with infection compared to cancer patients without infection ($P<0.000$, $P<0.001$, respectively). Plasma MDA levels were also evaluated significantly when metastasis and invasion to other tissues occurred ($P<0.001$).

VEGF stimulates NO production by endothelial cells *in vitro* and *in vivo*. To date, experiments examining the role of NO in cancer initiation and progression showed that NO played a complex role. NO could be involved in initiating diseases by damaging DNA[39-41] and additionally, a much larger amount of NO released by cells in response to cytokines and endotoxins was synthesized by the inducible form of NOS and could mediate some of the cytotoxic and cytostatic effects of the immune system[57]. NO could also have a protective role. It was essential for the tumoricidal activity of immune cells[41,58-60]. Conversely, NO has been shown to have tumour-promoting effects[60]. In this study, we demonstrated that plasma NO levels were increased in patients with gastric cancer. In cancer patients, NO levels were significantly higher in infection group than in non-infection group and were higher in stage 4 compared with stages 1 and 2.

PCT was a specific marker of infection and CRP an acute-phase reactant that serves as a pattern recognition molecule in the innate immune system[42]. CRP has been traditionally thought as a bystander marker of vascular inflammation, which

did not play a direct role in the inflammatory process. However, recent evidences suggest that CRP may contribute directly to the proinflammatory state. CRP could stimulate monocyte release from inflammatory cytokines such as IL-1b, IL-6, and TNF-α and might directly act as a proinflammatory stimulus to phagocytic cells[44,45,61]. PCT and CRP levels were significantly increased in cancer patients with infection compared to gastric cancer patients without infection and were significantly higher in all gastric cancer groups compared to control group ($P<0.0001$). There was no statistically significant difference in PCT and CRP levels between different stages of cancer. PCT is an important determinant used in the diagnostic evaluation of fever and infections. Increased PCT levels in gastric cancer patients with infection can be used as a useful parameter for pre-diagnosis and follow-up. Therefore, CRP and PCT are two important markers for the diagnosis of infection in patients with cancer rather than for the diagnosis of cancer.

This study demonstrated that the plasma/serum levels of VEGF, IL-6, MDA and NO in patients with stage IV cancer were significantly higher than those in patients with stages I and II/III cancer, and that increased plasma levels of IL-6, MDA, NO and especially VEGF, might be useful in identifying metastatic gastric cancer patients, thus allowing more effective treatment strategies to be implemented. Moreover, our results support the existence of interactions between angiogenesis and the inflammatory system, which contributes to tumour metastasis and progression.

In conclusion, levels of MDA, IL-6, NO and especially VEGF can be used as important parameters for clinical diagnosis and follow up of cancer cases. CRP is a useful marker in the diagnosis of infections that frequently occur in cancer cases.

Abstract

AIM: To investigate the effect of transfected survivin antisense oligonucleotide (ASODN) on proliferation and apoptosis of gastric cancer cells.

METHODS: The authors designed ASODNs targeting different regions of survivin mRNA, including surviving ASODN1, ASODN2 and ASODN3. ASODNs were transfected into gastric cancer cell line SGC 7901, cell growth was detected by MTT assay. Cells exposed to the potent oligonucleotide were also examined for apoptosis induction by FCM and fluorescence microscopy. Semiquantitive RT-PCR and Western blot examinations were carried for expression of survivin mRNA and protein.

RESULTS: ASODN3 caused a statistically significant reduction of cell viability to 60.6% (±2.9%) ($P<0.01$), while ASODN1 and ASODN2 had no such changes ($P>0.05$). The cell growth was also significantly inhibited by ASODN3, compared with reversal and scrambled sequence. A significant loss of survivin mRNA was presented in ASODN3 treated cells and this was not seen in treatment with sense ODN or scramble ODN. Protein level was significantly decreased 48 h after survivin ASODN trasfected by approximately 2-fold decrease compared with untreated controls. However, ASODN3 did not induce significant apoptosis response until 48 h after transfection ($P>0.05$).

CONCLUSION: ASODN3, which targets translation initiation part, can be identified as a most potent antisense compound. Srvivin ASODN3 may provide a novel approach to therapy of gastric cancer.

INTRODUCTION

Disordered regulatory apoptosis plays an important role in tumorigenesis[1]. Several proteins that inhibit apoptosis have been identified, such as some members of bcl-2, HSP and IAP (inhibition of apoptosis). IAP gene family controls a downstream step in cell death by suppressing the activity of Caspases, the executers of cell death programs[2]. Survivin is a newly identified gene in IAP family, and it is characterized by a unique structure with a single, baculovirus IAP repeat and no zinc-binding domain known as Ring finger[3]. Its another characteristic is that it expresses in most human cancers but is essentially absent in normal tissues, which makes it an exciting potential therapeutic target in cancer treatment[4].

Gastric cancer is one of the leading causes of cancer deaths in China, and it still has poor prognosis in spite of some progresses in treatment. It has been demonstrated from immunohistochemicl analysis that about 34.5% of gastric cancers overexpress survivin, and are significantly associated with reduced apoptosis compared with survivin negative tumors[5]. Recently, manipulating apoptosis gene by antisense oligodeoxynucleotide (ASOND) might provide new therapeutic strategies in treating human diseases[6]. ASODN is a single-strand DNA which is complementary to specific regions of mRNA and capable of inhibiting the antiapoptotic gene, and it is noticeable that ASOND holds great promise as a pharmaceutical agent. Therefore, we investigated whether growth inhibition and induced apoptosis of gastric cancer cell line SGC7901 could be achieved by targeting survivin with ASODN.

MATERIALS AND METHODS

Cell culture
SGC7901 was maintained in RPMI 1640 and supplemented with 100 mL/L calf serum at 37 ℃ in humidified atmosphere containing 50 mL/L CO_2.

Immunohistochemistry
Cells were plated in 60 mm tissue culture dishes containing coverglasses overnight. The coverglasses were washed in phosphate-buffered saline (PBS), fixed for 30 min in 70 mL/L ethanol, washed twice in PBS. Quenching of the endogenous perixidase activity was obtained by treatment with 0.3 mL/L H_2O_2 in methanol. The sections were blocked with 10 mL/L goat serum in PBS and incubated with 3 µg anti -survivin polyclonal antibody (gift from Dr. Katsuya Shiraki, First Department of Internal Medicine, Mie University School of Medicine, Tsu, Japan) at 4 ℃ overnight, then incubated with HRP-conjuncted antibody for 30 min at room temperature. After three washes of 5 min in PBS, they were developed in a substrate solution of horseradish peroxidase. Negative control omitting survivin antibody was also performed to confirm the absence of non-specific reactions. Expression of survivin was classified into three levels: (-) no or weak staining, (+) less than 50% positive nuclei staining, and (++) greater than 50% positive nuclei staining of the total nuclei.

Oligodeoxynucleotide
ASODN1 and ASODN2 were designed by a computer program and could theoretically access survivin mRNA. ASODN3 was complementary to the initiation codon and 5 downstream

codons, and could empirically access survivin mRNA as shown in Table 1. In addition, the scramble sequence of survivin ASODN3 was as follows: 5' - GGA CCA CGC TAT CAG CCG- 3', and reverse anitsense (sense): 5' - ATG GGT GCC CCG ACG TTG- 3'. Phosphothioalate oligodexynucleotides were synthesized using an applied biosystems 3 900 DNA synthesizer (Shenggong, Shanghai, China). After the synthesis, ODNs were purified by use of high-pressure liquid chromatography system, dissolved with PBS, and frozen in aliquots at -20 ℃ until use.

Table 1 Sequence of ASODNS and their target site

Name	Sequence	Position
ASODN1	5' - GTT CTT GGA TGT AGA GAT GC-3'	102-121
ASODN2	5' - GCT TCT TGA CAG AAA GGA A-3'	305-323
ASODN3	5' - CAA CGT CGG GGC ACC CAT-3'	50-67

Transfection
According to the manufacture's instructions, ODNs were delivered into cells in the form of complexes with Lipofection regents (GIBCO, MD).

Measurement of cell growth
In vitro growth inhibitory effects of ODNs on SGC7901 were assessed by MTT assay performed according to the previously described protocol[7] with a slight modification. Two×10^4 cells were seeded in each well of 96-well micrometer plates and allowed to attach overnight. The cells were then treated with 400 nmol/L ODN-Lipofection complex for 24 h and incubated for another 48 h. Subsequently, 20 μL of MTT (5 g/L, Sigma) in PBS was added to each well, followed by incubation for 4 h at 37 ℃. Formazan crystals were dissolved in DMSO. Absorbance was determined with an enzyme-linked immunosorbent assay reader (model 318, Shanghai, China) at 540 nm. Each assay was performed nine times. The controls received medium alone. The results were expressed as mean±SE of controls with no ODN.

Reverse transcriptase-PCR (RT-PCR) analysis of survivin mRNA
Total RNA was extracted from SGC7901 cells by modification of guanidium-thiocyanate acid phenol method[8] and quantified based on the measured absorbance at 260 nm. cDNA was synthesized using 2 μg of RNA, 10^6 U/ L reverse transcripatase (GIBCO, Inc), 0.5 g/L Oligod T, in a total volume of 20 μL. Reaction was performed at 42 ℃ for 60 min, and terminated by heating at 99 ℃ for 5 min. The sequences of oligodexynucleotides primes for RT-PCR were as follows: survivin-S 5' -ATG GGT GCC CCG ACG TTG CC-3', survivin-A 5' -GCA GCT CCG GCC AGA GGC CT-3', β-actin-S 5' -GGC GGC ACC ACC TGT ACC CT-3' and β-actin-A 5' -AGG GGC CGG ACT CGT CAT ACT-3', respectively. For amplification of cDNA, 2 μL cDNA product was subjected to PCR-based technique using 2.5 U of Taq DNA Polymerase, 1 μL each of forward and reverse primers, and 200 μmol/L each of dNTPs. PCR consisted of 35 cycles at 94 ℃ for 1 min, at 62 ℃ for 1 min and at 72 ℃ for 1 min followed by a final extension at 72 ℃ for 5 min.

Western blot analysis
Cells were washed in ice-cold PBS and lysed in a buffer using standard methods. After centrifugation at 10 000 g for 10 min, the supernatants were stored at -70 ℃. Lysate equalized for protein content was separated in 150 g/L SDS-PAGE and transferred onto a PVDF membrane. The membranes were blocked for 1 h at room temperature in 10 g/L BSA, and incubated overnight at 4 ℃ with survivin antibody, followed by incubation with sheep anti-rabbit second antibody conjugated to horseradish peroxidase (Dako, Denmark) for 120 min. Finally

the membranes were developed with DAB and incubated until color developed sufficiently.

Measurement of apoptosis by flow cytometry and staining with Hchest 33342
In preparation of flow cytometry (FCM), SGC 7901 cells were centrifuged 72 h after transfection. The cells were washed with PBS, and fixed in 70 mL/L cold ethanol. Samples were treated with RNase (10 g/L), resuspended and stained with 10 g/L propidium iodine. After 30 min at room temperature in the dark, the cells were analyzed using a FCM scan flow cytometer. Apoptotic cells appeared in the cell cycle distribution as cells with DNA contents less than G_1 cells, and the percentage of apoptotic cells was calculated. In other experiments, transduced cells were cultivated for 24 h at 37 ℃ and assayed for nuclei staining. Both attached cells and detached cells were collected and resuspended. One drop of cell suspension was added to one drop of Hoechst 33 342 solution (10 mg/L in PBS), mixed gently on a slide, and immediately examined with Olympus fluorescence microscopy. Blue fluorescent condensed nuclei were interpreted as the number of apoptotic cells. Viable cells were interpreted as cells which exhibited green, diffusely stained intact nuclei. Cell ghosts with weak staining were not included in the cell count.

Statistical analysis
The data were expressed as mean±SE. The results were analyzed by ANOVA test. $P<0.05$ was considered statistically significant.

RESULTS
Expression of survivin in SGC7901
We examined the expression of survivin gene in SGC-7901 using immunohistochemistry. Expression of survivin was observed primarily in cytoplasm, and mild staining in nuclei (data not shown).

Cell proliferation assay
As shown in Figure 1, ASODN3 caused a statistically significant reduction of cell viability to 60.6±2.9% ($P<0.01$), while ASODN1 and ASODN2 had not such changes ($P>0.05$). We also investigated whether growth inhibition was changed by control sequences including reversal antisense (*i.e.* sense) and scrambled sequence with the same composition. As shown in Figure 2, neither had any changes in activity ($P>0.05$).

Figure 1 Cytotoxic effect of ASODN targeting different regions of survivin mRNA. Cells were cultured in plastic 96-well plates and quantitated using MTT assay as described in "Materials and Methods."

Induction of apoptosis by antisense oligodexynucleotide
Cells exposed to the oligonucleotides were examined for

apoptosis induction by FCM and fluorescence microscopy. As shown in Table 2, positive control 5-FU significantly induced apoptotic response, about $6.12\pm3.25\%$ for 24 h ($P<0.01$) and $11.35\pm1.50\%$ for 48 h ($P<0.01$). However, ASODN3 did not induce any significant apoptotic response until 48 h after transfection ($P>0.05$). Fluorescence microscopy also did not show any increase of condensed nuclei (data not shown).

Table 2 Apoptosis rates of each group 24 and 48 h after transfection (n=4)

	24 h (%)	48 h (%)
Untreated	1.98±0.40	3.74±0.19
survivin ASODN	2.27±0.48	4.57±0.61
5-FU	6.12±3.25	11.35±1.50

Changes of survivin mRNA expression after transfection

As shown in Figure 3, a significant loss of survivin mRNA was detected in antisense treated cells and this was not seen in either sense ODN treated or scramble ODN treated cells.

Changes of survivin protein expression after transfetion

We aimed to investigate whether survivin ASODN could downregulate survivin protein in SGC7901, and further determined whether it was in sequence-specific way. Figure 4 shows a typical change of survivin protein expression. Protein level was significantly decreased 48 h after survivin ASODN trasfection (by approximately 2-fold decrease compared with untreated control), whereas either sense ODN treated or scramble ODN treated cells did not modulate survivin expression levels. To sum up, these results provided strong evidence of sequence specific mechanism of survivin ASODN.

Figure 4 Survivin protein expression following incubation with surviivn, antisense, sense, scramble and no ODN control. Strong decrease of survivin protein could be detected in the ASODN group.

DISCUSSION

ASODN represents a useful experimental approach for manipulating gene expression, and recently some antisense compounds have shown anticancer efficacy in numerous preclinical studies[9-12]. Survivin was detectable in most types of cancer, and its presence was associated with a poor prognosis in many malignant tumors[13-16]. In this study, we chose survivin as the molecular target and designed ASODN to observe its influence on growth and apoptosis of gastric cancer cell line SGC7901. An immunohistochemical study showed that SGC7901 could positively express survivin, prior to ASODN transfection.

Then, it should be considered to design an optimal site for antisense blocking, which is the key factor of antisense research. Previous researches showed not all areas of a mRNA molecular were amenable to antisense hybridization. Therefore, among the possible ASODNs against a given target nucleic acid, only a small number of sequences seemed to give rise to satisfactorily strong inhibition of target gene expression. The reason is unclear and probably involves mRNA secondary structure. Therefore, computer program was used to design ASODN, but sometimes its usefulness was elusive[17]. On the other hand, empirically, ASODN targeting AUG starting site was most frequently used in antisense experiments[18], such as bcl-2 ASODN application in various cancer cell lines[19-23]. So far we still could not predict accurately the secondary structure of mRNA, and it is rather difficult to predict which is the best ASODN sequence unless through some screening experiments. In our experiment, ASODN1 and ASODN2 were designed by computer program and selected as candidate sequences. ASODN3 targeting the translation initiation codon region, was selected as another candidate sequence to screen the most potent sequence.

Survivin could regulate G2/M phase of the cell cycle by associating it with mitotic spindle microtubules[24,25], and its expression was positively correlated with proliferation of hepatic[26] and pancreatic[27] carcinoma cells. Therefore, we tried to determine which sequence was potent by observing cell growth as previous studies[7,28,29]. As a result, ASODN3 was able to suppress cell viability of approximate 40% decrease of the number of viable cells ($P<0.01$), while ASODN1 and ASODN2 did not affect cell viability significantly ($P>0.05$). On the other hand, the most widely recognized mechanism of ASODN involved RNase H mediated destruction of the target mRNA. Therefor, we also performed RT-PCR and Western blot to confirm the occurrence of antisense effect of ASODN3. As shown in Figures 3 and 4, ASODN3 caused a reduction in the mRNA and protein level 48 h after transduction. However, two different controls for ASODN3 did not modulate survivin mRNA and protein expression levels. Therefore, further evidences for sequence-specific antisense effect of ASODN3 were provided. The exact mechanism of ASODN3 is still unknown, and we suspect that the translation initiation codon region of survivin mRNA is probably a single strand.

In the present study, we identified that ASODN3 had a

potent sequence to inhibit cell growth, then we detected apoptosis by FCM and nuclei staining when survivin ASOND3 was transfected. However, it demonstrated that transfecting survivin ASODN solely was not sufficient to trigger apoptosis, indicating that decrease of cell viability was not due to apoptosis. Our results were different from the report by Olie RA[30]. It seemed plausible that the effects of ASODN varied depending on the expression profile of treated cells. It was also probably due to the complexity of apoptotic pathway in which other antiapoptotic genes might play more important roles in gastric cancer cell line SGC-7901.

In conclusion, ASODN3 can inhibit the growth of gastric cancer cell line but can not induce apoptosis by itself. From a clinical standpoint, anti-cancer therapy still relies heavily on cytotoxic agents, in spite of some advances in identifying molecular target by ASODN treatment[31]. So, it is meaningful to investigate further whether ASODN targeting survivin can enhance the sensitivity of chemotherapeutic drugs by decreasing apoptosis thresholds.

Abstract

AIM: To investigate the relationship between expression of p21^{WAF1} and p53 gene, and to evaluate the deletion and polymorphism of p21^{WAF1} gene in gastric carcinoma (GC).

METHODS: Expression of p21 and p53 proteins, and deletion and polymorphism of p21 gene in GC were examined by streptavidin-peroxidase conjugated method (SP) and polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) respectively.

RESULTS: The expression of p21 and p53 was found in 100% (20/20) and 0% (0/20) of normal gastric mucosae (NGM), 92.5% (37/40) and 15.0% (6/40) of dysplasia (DP) and 39.8% (43/108) and 56.5% (61/108) of GC, respectively. The positive rate of p21 in GC was lower than that in NGM and DP ($P<0.05$), while the positive rate of p53 in GC was higher than that in NGM and DP ($P<0.05$). p21 and p53 were significantly expressed in 63.3% (19/30) and 36.7% (11/30), 35.0% (14/40) and 77.5% (31/40), 26.7% (4/15) and 80.0% (12/15), 30.8% (4/13) and 30.8% (4/13), and 20.0% (2/10) and 30.0% (3/10) of well-differentiated, poorly-differentiated, undifferentiated carcinomas, mucoid carcinomas and signet ring cell carcinomas. The expression of p21 in well-differentiated carcinomas was significantly higher than that in poorly-differentiated, un-differentiated, mucoid carcinomas and signet ring cell carcinomas ($P<0.05$). Contrarily, The expression of p53 was increased from well-differentiated to poorly-differentiated and un-differentiated carcinomas ($P<0.05$). The expression of p21 and p53 in paired primary and metastatic GC (35.3% and 70.6%) was different from non-metastatic GC (62.5% and 42.5%) markedly ($P<0.05$). The expression of p21 in invasive superficial muscle (60.0%) was higher than that in invasive deep muscle or total layer (35.2%) ($P<0.05$) and was higher in TNM stages I (60.0%) and II (56.2%) than in stages III (27.9%) and IV (22.2%) ($P<0.05$), whereas the expression of p53 did not correlate to invasion depth or TNM staging ($P>0.05$). The exoression patterns of p53+/p21-, and of p53-/p21+ were found in 5.0% and 82.5% of DP. There was a significant correlation between expression of p21 and p53 ($P<0.05$). But there was no significant correlation between expression of both in GC ($P>0.05$). There was no deletion in exon 2 of p21 gene in 30 cases of GC and 45 cases of non-GC, but polymorphism of p21 gene at exon 2 was found in 26.7% (8/30) of GC and 8.9% (4/45) of non-

GC, a significant difference was found between GC and non-GC ($P<0.05$). There was no significant relation between p21 expression of polymorphism (37.5%, 3/8) and non-polymorphism (45.5%, 10/22) in GC ($P>0.05$).

CONCLUSION: The loss of p21 protein and abnormal expression of p53 are related to carcinogenesis, differentiation and metastasis of GC. The expression of p21 is related to invasion and clinical staging in GC intimately. The expression of p21 protein depends on p53 protein largely in NGM and DP, but not in GC. No deletion of p21 gene in exon 2 can be found in GC. The polymorphism of p21 gene might be involved in gastric carcinogenesis.There is no significant association between polymorphism of p21 gene and expression of p21 protein.

INTRODUCTION

Previous studies have shown that tumor suppressor genes play an important role in the progression of solid tumors. p21^{WAF1} is a recently identified gene. It encodes a nuclear protein of 21 ku, which inhibits cyclin-dependent kinase activity[1-3]. p21 protein has been reported to work as critical downstream effectors of p53 and a potential inhibitor of cyclin-dependent kinases. Thus, p21^{WAF1}gene is thought to play a central role in tumor suppression[4-9]. Alterations of p21 expression have been observed in a wide variety of human carcinomas by immunohistochemistry[10-15]. GC is common in China[16-27]. But the relationship between p21and p53 proteins expression and prognosis of GC is unclear.

In this study, expression of p21 and p53 proteins was detected by streptavidin- peroxidase conjugated method (SP). PCR and PCR-RFLP methods were used to analyze the deletion and polymorphism of p21^{WAF1} gene in GC. The correlation between the expression of p21^{WAF1} gene and carcinogenesis, differentiation, invasion and metastases, and the deletion and gene polymorphism of exon 2 in p21^{WAF1} gene in GC were investigated.

MATERIALS AND METHODS

Materials

One hundred and eight cases of GC and 20 cases of normal gastric mucosa (NGM) and 40 cases of dysplasia (DP) with gastric ulcer at the First Affiliated Hospital of Nanhua University, between April 1990 and December 1997 were used for this study, including 30 cases of well-differentiated, 40 cases of poorly-differentiated, 15 cases of undifferentiated GC, 13 cases of signet ring cell carcinoma and 10 cases of mucoid carcinoma. Eigty-one cases were men and 27 cases women, with a mean age of 58 years at diagnosis. Sixty-eight cases had lymph node metastasis and 40 cases had no lymph node metastasis.

Fifteen cases were stage I, 32 cases stage II, 43 cases stage III and 18 cases stage IV according to TNM staging. None of them had received any therapy before surgery. Freshly resected specimens including carcinoma, pericarcinoma tissues and normal mucosas located far from carcinoma, were cut into 2-4 blocks under sterile conditions. Each block was 1.5 mm×1.5 mm×1.0 mm and stored at -80 ℃ for PCR and PCR-RFLP analysis. The rest tissues were fixed in 100 mL/L neutral formalin, dehydrated, cleaned and paraffin-embedded. All paraffin embedded tissues were cut into 5 μm thick sequential slices and mounted onto glass slides previously processed by polylys.

Methods

Reagents and instruments Moues anti-human p21^{WAF1} and p53 monoclonal antibody, SP kit and DAB were all purchased from Maxim Company, USA. Protease K (Merk, USA), ALW261 agar gel, propylene acrylamide, N-N-sulmethyl bipropylene acrylamide, ammonium persulfate, xylene nitrile, and bromophenol blue were purchased from Shanghai Sangon Company. PCR primers were synthesized by Shanghai Sangon. Primer sequences of p21^{WAF1} gene at exon 2, Sense: 5' - CGGGATCCGGCGCCATGTCAGAACCGGC-3' , antisense: 5' - CCAGACAGGTCAGCCCTTGG-3' . The amplification fragment length was 536 bp, and 309 bp. Primer sequences of β-actin served as an internal control, Sense: 5' -TCCGTGGAGAAGAGC TACGA-3' , antisense: 5' -GTACTTGCGCTCAG-AAGGAG-3' . The amplification fragment length was 309 bp.

SP immunohistochemical staining All immunohistochemical analyses were performed on routinely processed, formalin- fixed, paraffin-embedded tissues using SP. Briefly, sections were dewaxed, rehydrated endogenous peroxidase was blocked, first antibody was added, then antibody bridge and enzyme labeled SP were added, colorized by DAB, stained by hematoxylin, dehydrated, cleaned and paraffin-embedded, observed under a microscope. According to Seta' standard with a slight modification[15], nuclei were considered positive when they showed a distinct brown color in the absence of background staining. A breast carcinoma with known positive immunostaining for p21 served as a positive control. Positive and negative control slides were included within each batch of slides. (+) indicates the cells were stained weakly or the number of stained cells was less than 25%, (++) indicates the cells were stained moderately or the stained cells were covered about 26-50%, (+++) indicates the cells were stained strongly or the number of stained cells was more than 50%.

Genomic DNA extraction High molecular weight DNA was isolated from tumors by standard protease K digestion and phenol-chloroform extraction. Frozen tissue of 0.5 g was put into liquid nitrogen and powdered immediately, 10×buffer (10 mmol/L Tris-HCl pH 8.0, 0.1 mol/L EDTA pH 8.0, 5 g/L SDS) was added and spanned in 37 ℃ water for 1 h at the same time. Protase K was added to the mixture at a final concentration of 100 mg/L in 50 ℃ water for 3 h and protease K was readjusted as possible reaction. After the mixture was lysed completely, 20 mg/L RNase reacted in 37 ℃ water for 1 h.Then saturated phony was put together and bugged slightly for 10 min, centrifuged and extracted. The supernant was transferred to a cleaned plastic tube, saturated phony was processed 3 times. 1/10 volume 3 mol/L NaAc and 2-2.5 times cold ethyl were added, DNA was precipitated by centrifugation. Ethyl was removed, DNA was washed by 700 mL/L ethyl, and centrifuged 3 times, dried, resolved with TE, A_{260}/A_{280}:1.8-1.9, and stored at 0 ℃ for use.

PCR amplification PCR was performed in 100 μL reactive volume containing 0.5 μg DNA template, 200 μmol/L each of dCTP, DATP, dGTP, dTTP, 0.25 μmol/L primer, PCR buffer (Tris- HCl 10 mmol/L, pH 8.3, MgCl₂ 1.5 μmol/L, KCl 50 mmol/L, gelatin 100 mg/L) pre-denatured at 95 ℃ for 5 min and 1.5 μL of Taq DNA polymerase and 75 μL of mineral oil were added. These samples were subjected to 30 cycles: at 95 ℃ for 1 min, at 68 ℃ for 1 min, at 72 ℃ for 1 min, and a final extention at 72 ℃ for 5 min. Five μL of PCR product and appropriate bromophenol blue were added to the sample point container and electrophoresed on 20 g/L agarose gel containing 0.5 mg/L ethidium bromide at a tank with 0.5×TBE liquid of electrophoresis, then they were observed and photographed with ultraviolet radiography.

PCR- RFLP A 50 μL PCR product was purified by ethanol, dissolved in 17 μL sterilized water, mixed with 2 μL 10×buffer and Alw261 2u, digested at 37 ℃ for 3 h. A 10 μL of the digested product and 10 μL loading buffer were added to the gel containing 80 g/L polypropylene acrylamide. Then it was vertically electrophoresed at 100 V for 4 h and gel was stained with silver in the following order: fixed in 100 mL/L alcohol for 10 min, oxidized in 100 g/L nitric acid for 3 min, washed in drip for 1 min with double distilled water, stained in 12 mmol/L silver nitric acid for 20 min, washed in drip for 1 min with double distilled water, colored in 0.028 mol/L anhydrous sodium carbonate and 0.19 g/L formaldehyde, ended by adding 100 mL/L glacial acetic acid, washed in drip with double distilled water and photographed.

Statistical analysis Statistical analysis was performed using Chiq-square test and analysis of variance. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Expression of 21^{WAF1} and p53 protein in gastric carcinoma

The positive expression rate of p21 and p53 protein was 100% (20/20) and 0% (0/20) in NGM, 92.5% (37/40) and 15.0% (6/40) in DP and 39.8% (43/108) and 56.5% (61/108) in GC, respectively (Figure1) (Table 1). p21 expression could only be seen in mucosal epithelial and adenoepithelial cells in NGM, no staining in matrix fibrocytes, lymphocytes and smooth myocytes was observed. The positive rate of p21 in GC was lower than that in NGM and DP (*P*<0.05), and positive expression of p53 in GC was higher than that in NGM and DP (*P*<0.05). But there was no significant difference between NGM and DP (*P*>0.05). Among the 108 cases of GC, the positive rate of p21 and p53 proteins was 63.3% (19/30) and 36.7% (11/30), 35.0% (14/40) and 77.5% (31/40), 26.7% (4/15) and 80.0% (12/15) , 30.8% (4/13) and 30.8% (4/13), and 20.0% (2/10) and 30.0% (30.0/100) in well-differentiated, poorly-differentiated, undifferentiated GC, mucoid carcinomas and signet ring cell carcinomas. The positive rate of p21 in well-differentiated GC was significantly higher than that in poorly- differentiated, undifferentiated, mucoid carcinomas and signet ring cell carcinomas (*P*<0.05). Contrarily, the expression of p53 was increased from well-differentiated to poorly-differentiated and undifferentiated GC (*P*<0.05). The positive rate of p21 and p53 in paired primary and lymph node metastatic GC (35.3% and 70.6%) was significantly different from that in non-metastasis carcinomas (62.5% and 42.5%) (*P*<0.05). The expression of p21 in invaded superficial muscle (60.0%) was higher than that in invaded deep muscle or total layer (35.2%) (*P*<0.05), and was higher in TNM stages I (60.0%) and II (56.2%) than that in stages III (27.9%) and IV (22.2%) (*P*<0.05). Whereas the expression of p53 did not correlate wth invasion depth and TNM stages (*P*>0.05). There was no association between age and sex and expression of p21 and p53 (*P*>0.05) (Table 2).
Relationship between expression of p21^{WAF1} and p53

Five precent cases had p53 positivity and p21 negativity simultaneously, whereas 82.5% cases had p53 negativity and p21 positivity simultaneously in 40 cases of DP. There was a significant correlation between expression of p21 and p53 proteins (*P*<0.05). Meanwhile, 32.4% of p21 negativity and p53 positivity and 15.7% of p21 positivity and loss of p53 protein were detected in GC, but there was no significant correlation between expression of p21 and p53 proteins in GC (*P*>0.05) (Table 3).

Table 1 Expression of p21 and p53 proteins in normal gastric mucosa, dysplasia and gastric carcinoma

Tissue type	Cases number	p21 Negativity (%)	p21 Positivity (%) +	++	+++	total	p53 Negativity (%)	p53 Positivity (%) +	++	+++	total
NGM	20	0 (0)	6	7	7	20 (100)	20 (100)	0	0	0	0 (0)
DP	40	3 (7.5)	8	11	18	37 (92.5)	34 (85.0)	1	3	2	6 (15.0)
GC	108	65 (60.2)	9	14	20	43 (39.8)	47 (43.5)	17	19	25	61 (56.5)

NGM: normal gastric mucosa; DP: dysplasia; GC: gastric carcinoma.

Figure 1 The results of immunohistochemical staining. A: p21 (left) and p53 (right) in NGM.×100, B: p21 (left) and p53 (right) in DP. ×100, C: p21 (left×200) and p53 (right×100) in GC.

Figure 2 PCR amplified products at exon 2 of p21[WAF1] gene. Lines 2, 4, 6, 8, 10: GC. Lines 1, 3, 5, 7, 9: tumor adjacent tissue. M: PCR marker.

Deletion and polymorphism of p21[WAF1] gene at exon 2 in gastric carcinoma
PCR amplification showed target products in all GC and NGM.

All experiments were performed three times. The results were identical (Figure 2). The 536-bp PCR amplified fragment at exon 2 of p21 gene was digested with the ALW261 restriction enzyme. Digestion of the wild type allele produced DNA fragments with a length of 124, 174, and 238 bp. The C→A polymorphism created an extra enzyme recognition site, resulting in ALW261 digested fragments of 76, 98, 124, and 238 bp in length[28] (Figure 3). There was no deletion at exon 2 of p21 gene in 30 cases of GC and 45 cases of non-GC, but polymorphism of p21gene at exon 2 was found in 26.7% (8/30) of GC and 8.9% (4/45) of non-GC. A significant difference was found between GC and non-GC ($P<0.05$). There was no significant relation between p21 expression of polymorphism (37.5%, 3/8) and non- polymorphism (45.5%, 10/22) in GC ($P>0.05$).

Figure 3 RFLP analysis of exon 2 of p21[WAF1] gene and ALW261 digestion analysis of codon 31. Digestion of a 536 bp polymerase chain reaction fragment containing wild type exon 2 yielded fragments of 124, 174, and 238 bp in length (lanes 2, 3). The C→A polymerase polymorphism created an extra recognition site resulting in DNA fragments of 76, 98, 124, 174, and 238 bp in the heterozygote 9 (Lanes 4, 5). M: PCR marker. Lane 1: undigested fragment.

Table 2 Association of p21 and p53 expression with clinico-pathologic parameters in gastric carcinoma

Parameters	Cases (n)	p21 positivity (%)	p53 positivity (%)
Age			
≤50	43	18 (41.9)	25 (58.1)
51-59	37	15 (40.5)	20 (54.1)
≥60	28	10 (35.7)	16 (57.1)
Sex

DISCUSSION

p21[WAF1] gene is localized at chromosome 6p21.2. It could play an important role in the regulation of cell cycle transitions in normal cells, inhibit several cyclin/ CDK complexes and block cell cycle progression[1-3]. Moreover, expression of p21 protein could be induced by p53. p21 protein is an important tumor suppressor and has been proposed as a tumor suppressor gene and a potential mediator of p53-associated tumorigenesis[4-9]. However, unlike p53-deficient mice, p21-deficient mice could undergo normal development with no exhibition early tumorigenesis. On the other hand, it has been shown that p21 expression could be mediated through p53- independent pathways. Even in the presence of p53 alterations, p21 expression could be maintained. p21 might represent an independent marker of tumor behaviors[29].

It was reported that p21 expression was limited to foveola epithelial cells. p53 expression was confined to only a few regenerative epithelial cells of the mucous neck region in NGM. Increased p21 expression was limited to surface DP epithelium and weak p53 expression was in full thickness of DP epithelium[30]. It was found p53 was stained negatively, while p21 was stained positively in each NGM[34]. In regard to expression of p21 and p53 in GC, Seo et al.[4], Okuyama et al.[7], Baldus et al.[33], Oya et al.[36], Kaye et al.[37] and Xiangming et al.[64] separately demonstrated various expression levels of 63.7% and 33.3%, 42.6% and 37.9%, 58% and 45%, 75% and 40%, 75% and 40%, and 90.2% and 28.9%. However, Zolota et al.[31], Liu et al.[32], Ogawa et al.[35] and Gomyo et al.[43] observed that the positive rates of p21 and p53 were 32% and 51%, 40.5% and 42.1%, 37.2% and 50%, 32% and 65%, respectively. Our study showed that expression of p21 and p53 was found in 100% (20/20) and 0% (0/20) of NGM, 92.5% (37/40) and 15.0% (6/40) of DP and 39.8% (43/108) and 56.5% (61/108) of GC, respectively. p21 expression could only be seen in mucosal epithelial and adenoepithelial cells in NGM. Expression of p21 and p53 in GC was remarkably different from that in DP and NGM (P<0.05). The results indicated that gastric carcinogenesis was probably related to the loss of p21 expression and mutation of p53. This finding is consistent with other reports[7,31,34,35,38,45]. It was found that the expression rate of p53 was 0% in LGAs, 9% in HGAs, 39% in IMCs and 43% in SMCs, and expression of p21 was present in 100% of LGAs, 74% of HGAs, 46% of IMCs and 4% of SMCs. Whereas p53+/p21- lesions were observed in 0% of LGAs, 4% of HGAs, 11% of IMCs and 26% of SMCs[36].

Clinicopathologic and prognostic significances of p21 and p53 expression have been reported in various carcinomas[10-15,48-52]. In GC, expression of p21 correlated with advanced stage, lymph node metastasis and survival[4,6,32-34]. Univariate and multi-variate survival analyses revealed that clinicopathological stage and expression status of p21 were independent prognostic factors[34]. But it was also reported that expression of p21 was not associated with clinicopathological features[64]. Expression of p53 correlated with depth of tumor invasion[4], lymph node metastasis[33] and poor prognosis[32]. However, no significant correlation could be observed between the status of p53 expression and survival[4]. Multivariate survival analysis revealed that TNM stage and lymph node state were independent prognostic factors[32]. In multivariate survival analyses, neither p21 nor p53 emerged as an independent prognostic factor[33]. There was no apparent correlation between the expression of p21 and p53 and tumor stage, depth of invasion or lymphnode metastases[31]. There were significant differences in the incidence of p53 expression, the loss of p21 expression, and the 5-year survival rate between Pen-A type and Super type in early GC[8]. Stratification of the carcinomas according to histological grade and growth pattern did not result in significant differences in p53 and p21 expression[38].

The present study found that the positive rate of p21 expression was 63.3% in well-differentiated carcinomas, which was significantly higher than that in poorly-differentiated (35.0%), undifferentiated GC (26.7%), mucoid carcinomas (30.8%) and signet ring cell carcinomas (20.0%) ($P<0.05$). Contrarily, expression of p53 was increased from well-differentiated (36.7%) to poorly-differentiated (77.5%) and undifferentiated GC (80.0%) ($P<0.05$). The positive rate of p21 and p53 in paired primary and metastatic GC (35.3% and 70.6%) was markedly different from that in non-metastasis GC (62.5% and 42.5%) ($P<0.05$). The expression of p21 in invaded superficial muscle (60.0%) was higher than that in invaded deep muscle or total layer (35.2%) ($P<0.05$). The expression of p21 in TNM stages I (60.0%) and II (56.2%) was higher than that in stages III (27.9%) and IV (22.2%) ($P<0.05$). Whereas the expression of p53 did not correlate with invasion depth and TNM stage ($P>0.05$). Our results indicated that loss of p21 expression and mutation of p53 were related to carcinogenesis, differentiation and metastasis, and loss of p21 expression was related intimately to invasion depth and TNM stage. It was suggested that combined examination of p21 and p53 expression was a reliable prognostic marker for GC.

Many investigations showed that the mutation of p53 gene was common in various human carcinomas. Mutated p53 can act as a dominant oncogene. The immunoreactivity of p53 protein is a general indicator of tumors with altered p53 function. p21 performs a part of p53 function through the induction of p21 by wild type p53. However, p21 could be transcriptionally induced by wild type but not mutated p53[14,54]. It was found that p21 gene expression level was high in wild type p53 human breast cancer cells, but low in mutated p53 human breast cancer cells, indicating p21 gene expression at mRNA and protein levels are associated with p53 phenotype[55]. However, the expression of p21 protein was suppressed in neoplastic tissues with and without p53 gene alterations[56]. Western blot analysis revealed increased expression of p21 protein after infection with AxCA-p53 in all the cell lines. It was suggested that the apoptotic pathway dominated the growth arrest pathway after infection with AxCA-p53[40]. The level of p21 mRNA was very low or undetectable in all cell lines containing mutated p53 gene. But cell lines with wild-type p53 gene could express, it and the level of p21 mRNA was high in 8 GC cell lines[45]. Qian *et al.* used Northern and Western blot to analyze the expression of p21 and found that p21 mRNA was expressed in 2 cases of 15 p53+ and all of the p53- cases, indicating inactivation of p53 was closely related with the unexpression of p21 mRNA in GC[47]. However, some investigators believed p21 protein expression was unrelated with p53 protein expression[4,35,37,39]. Accumulation of mutated p53 protein might suppress the expression of p21 protein in GC, and cancer cells with overexpression of p53 might have a high proliferative activity[5]. Combined analysis of p21 and p53 showed that p21+/p53- GC displayed less aggressive characteristics, better survival and no recurrence after curative resection than other groups of GC[4,7,35,41,64]. Evaluation of expressions of p53 and p21 might aid in predicting clinical prognosis for surgical treatment in GC[7,32,35,38,41]. The p21 expression of non-neoplastic mucosae was most likely related to cell senescence and/or terminal differentiation. Moreover, p53-independent induction of p21 expression apparently occurred in a considerable proportion of early GC. It was suggested that defects downstream of p21 might cause this apparent discrepancy[39]. In our studies, 5.0% cases were p53+/p21-, 82.5% cases were p53-/p21+ in totally 40 cases of DP. There was a significant correlation between expression of p21 and p53 ($P<0.05$). Meanwhile, 15.7% of p53-/p21+, 32.4% of p53+/p21-, 24.1% of p53+/p21+ and 27.8% of p53-/p21- were detected in GC, respectively. There was no significant correlation between p21 and P53 protein expression.

These findings suggested that p21 protein was expressed mostly in a p53-independent manner and in some other factors, such as platelet-derived growth factor (PDGF)[57].

Alterations in the integrity of human p21 gene were rare events in human tumors[58,59,61]. Mutation of p21 gene has not been detected[6]. The promoter of p21 gene was not methylated in GC[63]. However, recent reports have demonstrated an association of p21 gene polymorphisms with many carcinomas[28,60,61]. No abnormal bands of p21 gene were found in all of samples or cell lines, but three major variants at exons 2 and 3 of the gene were found to be consistent with the existence of two different DNA polymorphisms. Sequence analysis of the amplified products producing these three variants at each exon from normal DNAs confirmed the presence of polymorphisms in p21 gene. Mutation within the coding portion of p21 gene was undetectable in a large series of human tumors, many of which had a normal p53 gene. This suggested that p21 alterations were generally caused indirectly by p53 mutation rather than by intragenic mutation of p21 itself[58]. Two polymorphisms have previously been characterized in p21 gene: a C→A transversion at codon 31 (ser→arg) and a C→T transition at 20 nucleotides downstream from the 3' end of exon 3[28]. The two polymorphisms were found in 18 of 96 tumor samples lacking p53 alterations (18.8%). Nine of 54 prostate adenocarcinoma samples (16.7%) contained both p21 variants, whereas 9 of 42 squamous cell carcinomas of the head and neck (21.4%) displayed both polymorphisms. Of the 110 controls examined, 10 (9.1%) had both alterations. Both p21 polymorphisms occurred in all samples examined and there was no indication of mutation in the coding region of p21 gene[28]. We analysed the deletion of p21 gene at exon 2 with PCR and PCR-RFLP methods. No deletion of p21 gene was found in GC. The result suggested deletion at exon 2 of p21 gene was not the cause of loss expression of p21 gene. The induction of p21 was mediated by posttranscriptional mechanisms[62]. The polymorphism of p21 gene at exon 2 was found in 26.7% (8/30) of GC and 8.9% (4/45) of non-GC. A significant difference was found between GC and non-GC ($P<0.05$). The results in this study indicated that the polymorphism of p21 gene might be involved in gastric carcinogenesis. But There was no significant relation between p21 expression of polymorphism (37.5%, 3/8) and non-polymorphism (45.5%, 10/22) in GC ($P>0.05$). Its mechanism is still unclear. It was found that p21 gene was activated only by histone deacetylase inhibitors, suggesting that formation of the inactive chromatins through histone deacetylation seems to be a general mechanism for inactivation of p21 gene in GC cells[63].

Abstract

AIM: To study the effects of recombinant human growth hormone (rhGH) on growth of human gastric cancer cell line *in vitro*.

METHODS: Experiment was divided into control group, rhGH group, oxaliplatin (L-OHP) group and rhGH+L-OHP group. Cell inhibitory rate, cell cycle, cell proliferation index (PI) and DNA inhibitory rate of human gastric cancer line BGC823, at different concentrations of rhGH treatment were studied by cell culture, MTT assay and flow cytometry.

RESULTS: The distinctly accelerated effects of rhGH on multiplication of BGC823 cell line were not found *in vitro*. There was no statistical significance between rhGH group and control group, or between rhGH+L-OHP group and L-OHP group ($P>0.05$). The cell growth curve did not rise. Cell inhibitory rate and cells arrested in G_0-G_1 phase were obviously increased. Meanwhile, cells in S phase and PI were distinctly decreased and DNA inhibitory rate was obviously increased in rhGH+L-OHP group in comparison with control group and rhGH group, respectively ($P<0.01$). Cell inhibitory rate showed an increasing trend and PI showed a decreasing trend in rhGH+L-OHP group compared with L-OHP group.

CONCLUSION: *In vitro* rhGH does not accelerate the multiplication of human gastric cancer cells. It may increase the therapeutic efficacy when it is used in combination with anticancer drugs.

INTRODUCTION

Human growth hormone (rhGH) promotes protein synthesis and lipid mobilization and accelerates nitrogen balance. It is extensively applied in clinic for the adjustment of metabolic state in patients with severe trauma, burn or major operations. It was reported that recombinant human growth hormone (rhGH) was also applied in postoperative patients with tumor, but it is controversial whether rhGH accelerates the growth of tumor cells. In the present study we investigated the effects of rhGH on human gastric cancer cell line BGC823 *in vitro*, in order to clarify whether rhGH could be applied in postoperative patients with gastric cancer.

MATERIALS AND METHODS

Materials
Human gastric cancer cell line BGC823 was supplied by the cell bank of Shanghai Cell Biology Institute of Chinese Academy of Sciences. rhGH (Saizen) was supplied by Serono (Switzerland), one IU equals to 0.33 mg and the final concentration of rhGH was 50 ng/mL, 100 ng/mL, 200 ng/mL and 400 ng/mL respectively. Oxaliplatin (L-OHP) was selected as an anti-cancer drug supplied by Henrui Medical Company, Jiangsu, China, and its final concentration was 4 μg/ml. The main instruments were ELISA (EL340) and flow cytometer (EPICXU).

Methods
Experiment was divided into 4 groups: control group (I), anti-cancer drug group (II), rhGH group (III) and rhGH+anti-cancer drug group (IV) (Table 1).

Table 1 Experimental groups and concentrations of drugs

Groups	Names and concentrations of drugs
I	RPMI1640
II	L-OHP 4 μg/mL
III$_a$	rhGH 50 ng/mL
III$_b$	rhGH 100 ng/mL
III$_c$	rhGH 200 ng/mL
III$_d$	rhGH 400 ng/mL
IV$_a$	rhGH 50 ng/mL + L-OHP 4 μg/mL
IV$_b$	rhGH 100 ng/mL + L-OHP 4 μg/mL
IV$_c$	rhGH 200 ng/mL + L-OHP 4 μg/mL
IV$_d$	rhGH 400 ng/mL + L-OHP 4 μg/mL

BGC823 cells were placed in the medium containing 100 mL calf serum and RPMI1640, incubated at 37 ℃ in an atmosphere containing 50 mL CO_2 and 950 mL air. At logarithmic growth, the cells were digested by trypsin. Then the activity of the cells was examined (Via=99%) and the cells were counted in a hemocytometer using trypan blue exclusion. The density of single cell suspension was adjusted to 1×10^5/mL for use.

Single-cell suspension was added into a 96-well plate and 90 μL suspension was added to each well and there were 4 duplicate wells in each group. When the cells completely adhered to the wall of the well 4 h later, 10 μL test drugs was added into the wells (In rhGH+L-OHP group, the ratio of the volume of both drugs was 1:1). The cells were cultured for 1, 2, 3 and 4 d, respectively, at 37 ℃ in an atmosphere containing 50 mL CO_2 and 950 mL air. In addition, the cells were cultured as above for 48 h to examine cell inhibitory rates. A 10 μL

MTT (5 mg/mL) was added to each well 4 h prior to the ending of experiment. When the experiment ended, 100 μL triplicate liquid [100 g/L SDS-50 mL/L iso-butyl alcohol-0.012 mL/L HCL] was added into each well. Absorbent value of each well was examined at the wavelengths 570 nm and 630 nm by ELISA 12 h later.

A 10 mL cell suspension was placed and incubated in each well of 6-well plates and there were 3 duplicate wells in each group. When the cells completely adhered to the wall of wells 4 h later, the test drugs were added into each well as shown in Table 2.

Table 2 Scheme of drugs in each group

Group	I	II	III_a	III_b	III_c	III_d	IV_a	IV_b	IV_c	IV_d
L-OHP (μL)	/	50	/	/	/	/	50.0	50	50	50
rhGH (μL)	/	/	12.5	25	50	100	12.5	25	50	100
RPMI1640 (μL)	150	100	137.5	125	100	50	87.5	75	50	/

The cells were gathered after cultured for 48 h and washed with PBS. After fixed with 700 mL/L alcohol, the cells were kept at 4 ℃ overnight, then stained with fluorescence. Finally the cell cycle was examined at the wavelength 488 nm. Barlogie cell cycle assay was used[1].

Statistical analysis

Data were expressed as mean±SD and analyzed by variance analysis and *q* test. Statistical significance was considered at $P \leqslant 0.05$.

RESULTS

MTT colorimetric analysis

The inhibitory rate on gastric cancer cells was significantly higher in L-OHP group and rhGH+L-OHP group, compared with control group and rhGH group ($P<0.01$). The inhibitory rate was also higher in rhGH+L-OHP group than in L-OHP group, though the difference had no statistical significance ($P>0.05$). Between control group and rhGH group, the inhibitory rate did not change regularly with increase of the drug's dose (Table 3).

Table 3 Effects of rhGH and L-OHP on BGC823 cells (*n*=4, mean±SD)

Groups	OD values	Survival rate (%)	Inhibitory rate (%)
I	0.863±0.172	100.00	0
II	0.425±0.086[b]	49.25[b]	50.75[b]
III_a	0.947±0.142	109.73	-9.73
III_b	0.894±0.220	103.59	-3.59
III_c	0.848±0.346	98.26	1.74
III_d	0.844±0.196	97.79	2.21
IV_a	0.338±0.240[b]	39.17[b]	60.83[b]
IV_b	0.318±0.038[b]	36.85[b]	63.15[b]
IV_c	0.318±0.018[b]	36.85[b]	63.15[b]
IV_d	0.306±0.200[b]	35.46[b]	64.54[b]

[b]$P<0.01$ *vs* control group or rhGH group.

Cell growth curve

Cell growth curve shows no obvious change between rhGH group and control group or between rhGH+L-OHP group and L-OHP group (Figures 1-2).

But it dropped sharply when rhGH+L-OHP and L-OHP groups were compared with the control group.

Figure 1 BGC823 cell growth curve.

Figure 2 BGC823 cell growth curve.

Cell cycle

Cell cycle was obviously changed in L-OHP group and rhGH+L-OHP group. The number of cells in G_0-G_1 phase was obviously more in L-OHP group and rhGH+L-OHP group than in control group or rhGH group ($P<0.01$), but there was no significant difference in control group and rhGH group or in L-OHP group and rhGH+L-OHP group ($P>0.05$). The cells in S phase were fewer in L-OHP group and rhGH+L-OHP group than in control group and rhGH group ($P<0.01$), but there was no statistical significance between rhGH group and control group. The cells in G_2-M phase were significantly fewer in L-OHP group and rhGH+L-OHP group than those in control group or rhGH group ($P<0.01$). There was no statistical significance between L-OHP group and rhGH+L-OHP group or between control group and rhGH group. Further more, in S or G_2-M phase the cell number had no regular change in rhGH+L-OHP group (Table 4) (Figures 3-5).

Table 4 Percentages of BGC823 cells in various phases of cell cycle (*n*=3, mean±SD)

Group	G_0–G_1(%)	S (%)	G_2–M(%)
I	47.75±0.78	36.95±0.49	15.25±0.21
II	83.85±1.77[b]	7.85±0.64[b]	8.30±1.13[b]
III_a	53.03±4.31	32.17±7.47	14.73±3.40
III_b	52.33±4.55	32.63±6.19	14.73±1.88

**Figure 4** Percentage of cells in S phase (%).

Figure 5 Percentage of cell in G2-M phase (%).

Figure 6 Cell PI (%).

Proliferation Index (PI)

PI was obviously reduced in L-OHP group compared with rhGH group or control group ($P<0.01$), but there was no statistical significance between rhGH+L-OHP group and L-OHP group, or between rhGH group and control group ($P>0.05$). PI showed a decreasing trend in rhGH+L-OHP group compared with L-OHP group (Table 5, Figure 6).

DISCUSSION

L-OHP is a new platinum compound that has the similar effects to cisplatin and carboplatin. The main mechanism of L-OHP is that it makes DNA broken by inserting platinum atom between two neighboring guanines or between guanine and adenosine in DNA, thus, DNA can not replicate or transcript. It is not a cell circle-specific anticancer drug. We determined its concentration *in vitro*, by referring to the maximal concentration in human plasma when the drug was used in pharmacological doses, and according to Limburg and Heckman formula. On the basis of this concentration, we devised the concentration gradient, and found the IC$_{50}$ that L-OHP affected BGC823 cells was 4 µg/mL by sifting experiment of anti-cancer drugs *in vitro*. The majority of data reported that the concentration of rhGH *in vitro* was 50 ng/mL or 100 ng/mL[2]. Qi *et al*[3,4] devised the super-high concentration of 200 ng/mL according to its clinical

application. In addition, Estrov *et al*[5] suggested that rhGH could accelerate human leukemia cell proliferation at high concentrations (250-300 ng/mL), so we proposed this concentration. The duration of the drug treatment was 48 h according to the double proliferation time of BGC823 cells.

rhGH is secreted by pituitary gland, it can reverse many nutritional and metabolic abnormalities associated with severe catabolic states. It has been shown that rhGH can promote protein synthesis, improve nitrogen balance, accelerate wound healing[6-11], maintain host immune function and alleviate postoperation fatigue syndrome (POF)[12]. GH has become available for clinical use. It was reported that rhGH enhanced positive nitrogen balance in metabolic recuperation of postoperative patients with malignant tumor[13,14]. But it is still controversial whether rhGH should be used in postoperative tumor patients since hGH promotes the proliferation of normal cells, as well as tumor cells. Estrov *et al*[5] reported rhGH could increase the risk of human leukemia and solid tumor at a high concentration. Ogiliy-Stuart *et al*[15] thought rhGH was associated with the increasing risk for tumor, especially for colonic cancer, when it was used at a high concentration in patients with tumor. Akaza *et al*[16] found rhGH promoted carcinogenesis of chemically induced rat urinary bladder cancer. Ng *et al*[17] reported GH could increase the proportion of aneuploid cells in tumor-bearing rats. Some other studies showed that rhGH enhanced tumor growth[18-20]. However, Harrison[21] reported that rhGH did not prompt human pancreatic carcinoma growth. Tacke *et al*[22] thought that postoperative treatment with rhGH in a short term led to a faster recovery of the immune function, increased the activity of NK cells, helped clear away potential cancer cells, and inhibited the recurrence of tumor. Fiebig *et al*[23,24] also reported *in vitro* and *in vivo* rhGH did not promote tumor cells to proliferate. Bartlett *et al*[25] suggested GH inhibited tumor growth in protein-starved animals. Still, some other studies reported that rhGH did not increase tumor growth[26,27].

In the present study, the effects of rhGH on gastric tumor cells *in vitro* were investigated. The results showed that there was no apparent tumor growth stimulation. There were no distinct differences in survival rate, inhibitory rate, the number of cells in G_0-G_1 phase, S and G_2-M phase, PI and cell growth curve between rhGH group and control group or between rhGH+L-OHP group and L-OHP group ($P>0.05$). The results coincided with other clinical reports[26] and showed that it did not increase gastric cancer cell growth *in vitro* after rhGH was administered. In addition, the cell percentage in proliferation phase (S and G_2-M phase) was not obviously different between rhGH+L-OHP group and L-OHP group ($P>0.05$), demonstrating that rhGH did not stimulate tumor cell proliferation. The cell inhibitory rate was distinctly increased, the cell percentage of S and G_2-M phase and PI was decreased ($P<0.05$) and the cell growth curve was apparently dropped between rhGH+L-OHP group and control group, and between rhGH+L-OHP group and rhGH group. The cell inhibitory rate showed an increasing trend and PI showed a decreasing trend in rhGH+L-OHP group compared with L-OHP group ($P>0.05$). These results indicated rhGH could enhance L-OHP effect on tumor cells. It provides support for the practice that tumor patients should be treated by metabolic recuperation after operation or that in advanced cancer and inoperative patients the cachexia was improved, or in chemotherapeutic patients the adverse effect was alleviated by use of rhGH.

The mechanism of rhGH underlying tumor cell proliferation is unknown. Some reports showed GH could indirectly stimulate tumor cell proliferation by combining with IGF-1 receptors on the surface of tumor cells[28-32], but others showed that rhGH did not promote liver cancer cell proliferation because of reduced IGF-1 receptor expression[33,34]. Wennbo *et al*[35] found

that the activation of prolactin receptors but not mammary tumor induced by growth hormone receptors in transgenic mice. The exact mechanism of rhGH underlying gastrointestinal tumor cell proliferation is still unknown.

In conclusion rhGH does not promote gastric cancer cell proliferation and fission, on the contrary, it can enhance anti-cancer effects of drugs on gastric cancer cells *in vitro*.

Abstract

AIM: To report the results of radiofrequency ablation (RFA) of hepatocellular carcinoma (HCC) in cirrhotic patients and to describe the treatment related complications (mainly the rapid intrahepatic neoplastic progression).

METHODS: Eighty-seven consecutive cirrhotic patients with 104 HCC (mean diameter 3.9 cm, 1.3 SD) were submitted to RFA between January 1998 and June 2003. In all cases RFA was performed with percutaneous approach under ultrasound guidance using expandable electrode needles. Treatment efficacy (necrosis and recurrence) was estimated with dual phase computed tomography (CT) and alpha-fetoprotein (AFP) level.

RESULTS: Complete necrosis rate after single or multiple treatment was 100%, 87.7% and 57.1% in HCC smaller than 3 cm, between 3 and 5 cm and larger than 5 cm respectively (P=0.02). Seventeen lesions of 88(19.3%) developed local recurrence after complete necrosis during a mean follow up of 19.2 mo. There were no treatment-related deaths in 130 procedures and major complications occurred in 8 patients (6.1 %). In 4 patients, although complete local necrosis was achieved, we observed rapid intrahepatic neoplastic progression after treatment. Risk factors for rapid neoplastic progression were high preoperative AFP values and location of the tumor near segmental portal branches.

CONCLUSION: RFA is an effective treatment for hepatocellular carcinoma smaller than 5 cm with complete necrosis in more than 80% of lesions. Patients with elevated AFP levels and tumors located near the main portal branch are at risk for rapid neoplastic progression after RFA. Further studies are necessary to evaluate the incidence and pathogenesis of this underestimated complication.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent solid tumors with a worldwide incidence between 250 000 and 1 000 000 new cases per year[1,2].

Surgical therapies could be applied only in 10-20% of patients[3,4]. Liver resection is applicable in a small portion of patients because of advanced neoplastic stage or severity of liver diseases. Liver transplantation is available only in a small number of patients for shortage of donors[5].

The majority of patients, ineligible for surgical therapies, can be submitted to local ablative therapies like percutaneous ethanol injection (PEI) and radiofrequency ablation (RFA). These local ablative therapies were considered to be radical in small HCCs[6].

RFA showed good control of tumors with necrosis in more than 90% of HCC smaller than 5 cm[7-10]. In HCC larger than 5 cm results were unsatisfactory with complete necrosis in less than 30%[11].

Frequency of major complications related to the procedure was low, ranging from 5% to 15%[12,13]. Self-limiting intraperitoneal bleeding, liver abscess and right pleural effusions have been the most frequently reported complications[7,14].

Tumor seeding along the needle tract was also described but its incidence ranging from 0.6% to 12%, has been a matter of debate[15-18].

Rapid intrahepatic neoplastic progression after treatment was described in literature only in 1 case report after transcatheter arterial chemoembolization (TACE) and RFA[19].

To our knowledge no authors described this complication after RFA treatment.

The aim of this study was to describe the treatment related complications (mainly the rapid intrahepatic neoplastic progression) and the response rate of RFA of HCC in cirrhosis.

MATERIALS AND METHODS

From January 1st, 1998 to June 1st, 2003 patients submitted to RFA at the 1st Department of Surgery of Verona University Medical School were included in this study. Before treatment a detailed description of procedure was provided to patients and written informed consent was obtained from all cases. HCC was diagnosed on the basis of radiological criteria (2 coincident imaging techniques) or combined criteria [1 imaging technique associated with elevated alpha-fetoprotein (AFP) levels] according to Barcellona EASL Conference[6]. Fine needle biopsy was performed only in cases of uncertain diagnosis[6]. Before undergoing the procedure, patients underwent baseline clinical and laboratory evaluation of hepatic function, coagulation profile, blood cells and platelet count, hepatitis B and C virus serology and serum AFP level. Severity of cirrhosis was classified according to Child-Pugh classification and CLIP score[20,21]. Patients eligible for RFA with Child-Pugh B cirrhosis and/or multinodular tumors, and small number of patients with Child-Pugh A cirrhosis and single potentially resecable tumor were included in the study.

Exclusion criteria from study were extra-hepatic metastasis, more than 4 nodules, tumor diameter >7 cm, Child-Pugh C cirrhosis, severe ascites, severe coagulopathy (platelets count < 40 000/mmc and PT >1.5 INR) if not corrected with medical therapy and fresh-frozen plasma.

Antibiotic prophylaxis was administered in all patients before treatment. All patients were treated in operating room under general anesthesia. Treatment was conducted in all patients with percutaneous approach under ultrasound guidance using a radiofrequency generator (RITA medical system model 500 and 1 500, Mountain View, CA) through an expandable electrode needle as previously described[22]. Blood count and liver function tests were performed 12 and 24 h after RFA.

All patients were discharged after 1 d, unless complications necessitated a longer hospitalization.

Treatment results were estimated by dual-phase computed tomography (CT) and AFP level performed 30 d after the procedure. CT and serum AFP were performed every 3 mo for the first year and then every 6 mo.

At dual phase, CT complete necrosis was defined as the absence of pathologic enhancement within or at the periphery of the treated HCC after at least 2 consecutive CT examinations.

Incomplete necrosis or local recurrences of HCC detected during follow up were retreated with RFA or PEI.

Statistical analysis

Data were collected prospectively and analyzed with statistical software (SPSS inc., Chicago, IL). Comparisons between different categories were carried out with contingency tables, and significance was determined by χ^2. For all comparisons, significance was set at 0.05.

RESULTS

From January 1st, 1998 to June 1st, 2003, 87 patients with 104 HCCs and liver cirrhosis were submitted to RFA. Mean age was 67.9 years (range 41-88 years). Patient characteristics are described in Table 1. The mean follow up time was 19.2 mo. After the first treatment complete necrosis was achieved in 76 of 104 HCCs (73.1%). In 28 HCCs with incomplete necrosis RFA was repeated. After multiple treatments (range 2-4) 12 of 28 HCCs, with incomplete necrosis were completely ablated. Complete necrosis was achieved in HCC smaller than 3 cm, between 3 cm and 5 cm and bigger than 5 cm in 100%, 87.7% and 57.1%, respectively (P=0.02). The elevated AFP level before treatment was decreased to normal levels after complete necrosis. During the follow up 17 of 88 HCCs (19.3%) with complete necrosis showed local recurrence and 30 of 87 patients (34.4%) developed new intrahepatic tumors.

Treatment related complications

In 87 patients, 130 procedures were performed and treatment related complications occurred in 22 cases (16.9%) (Table 2). Minor complications occurred in 13 cases: fever >38 ℃ and moderate pain for 5-6 d in 10 cases, right pleural effusions in 2 cases, cutaneous burn in the insertion site of the neddle in 1 case. Major complications were observed in 8 patients: rapid tumor intrahepatic progression in 4 cases, bacterial endocarditis in 1 case, needle track seeding in 1 case, intraperitoneal bleeding in 1 case, hepatic decompensation in 1 case. All treatment related complications were managed with medical therapy. No treatment related mortality was observed.

Neoplastic seeding	1 (0.8)
Peritoneal bleeding	1 (0.8)
Hepatic decompensation	1 (0.8)

Rapid tumor progression

After treatment, CT examination showed tumor complete necrosis with a wide neoplastic spread to the adjacent liver segments (Figure 1). After 30 d, AFP values showed a rapid increase in 3 of 4 patients, from a pretreatment value of 119 kU/L, 560 kU/L and 1 313 kU/L to 4 997 kU/L, 2 500 kU/L

Table 3 Caracteristics of four patients with rapid tumor progression after RFA

Gender, age, etiology	Tumor size (cm)		Location	Differentiation
1. Male, 66 yr, alcohol	3.5	V segment	Near right portal trunk[a]	Poor
2. Male, 75 yr, HCV	3.8	VI segment	Near segmental portal branch[a]	Poor
3. Male, 59 yr, HBV, HCV	4.5	VII segment	Near cava vein	Poor
3. Male, 62 yr, HBV	4.5	IV segment	Near segmental portal branch[a]	Moderate

[a]: ≤1 cm from main or segmental portal branches.

and 5 282 kU/L, respectively. In the fourth patient, the baseline AFP value of 69 kU/L did not increase. Characteristics of patients and tumors are described in Table 3. We analyzed 10 variables in order to identify the risk factors for rapid tumor progression. The high AFP level and location of the tumor near the primary or secondary portal vein branches were more representative variables (Table 4). During the follow up 2 patients died after 2 and 3 mo for tumor progression, two patients were alive after 11 and 7 mo and they were submitted to transcatheter arterial chemoembolization (TACE).

DISCUSSION

More than 80% of patients with HCC could not be submitted to surgical treatment due to advanced tumor stage and poor hepatic function[3,4]. In selected patients ablative treatments could achieve good results, which were similar to those of surgical resection in small HCCs[23,24]. RFA could achieve complete necrosis in 90% of lesions smaller than 5 cm[7-10,22]. In our study local recurrence occurred in 19.3% of tumors with complete necrosis and it was related to tumor size. There were no local recurrences during the follow up for HCCs smaller than 3 cm. In early clinical results RFA showed low incidence of major complications (5-15%)[12,13,25]. Most frequent complications reported in literature were: capsular necrosis, intraperitoneal hemorrhage (usually self-limiting), subcapsular hematoma, cholecistitis, hepatic abscesses[7,14].

Needle track seeding after RFA was reported with low incidence (0.6-2.8%), but in a recent study in 32 patients Llovet *et al* reported an incidence of 12%[15-18]. The authors identified that tumors with poor differentiation, subcapsular location and high AFP levels were at risk for needle track seeding[15].

Another complication recently observed was the rapid tumor progression after local treatment[19]. This complication after RFA was described in only one case report in a patient who was previously submitted to TACE. In our experience 4 patients (4.5%) showed rapid intrahepatic spread of HCC after RFA without extrahepatic metastasis. To our knowledge this is the first report that describes this type of complication after RFA.

Seki *et al*, in their case report, suggested that aggressive biological behavior of the tumor might be involved in tumor progression[19]. Moreover the author suggested that neoplastic cell spreading might have been promoted by TACE with selection of highly malignant cells with low adhesive potential after partial necrosis.

Our paper describes the occurrence of rapid neoplastic spread after RFA and we have identified the possible risk factors for this complication. Assessment of tumor and patients characteristics showed that high AFP level and location of tumor near the portal vein branches were associated with this complication. Moreover 3 of 4 patients had a poor differentiation of the tumor.

In our opinion, mechanisms involved in the pathogenesis of neoplastic progression may be the following. a) Tumors with vascular invasion are characterized by elevated intratumoral pressure[26]. RFA during energy application may increase intratumoral pressure and favor intravascular spread of the tumor. b) Hooks delivering in "umbrella type" expandable needles may promote migration of neoplastic cells into portal vein branches. c) Creation of arterovenus fistula was reported after RFA[12, 27]. This alteration of hepatic vascularization may promote migration of neoplastic cells into portal vein circulation.

Definitive conclusions cannot be drawn because this complication is probably still underestimated. In our opinion, tumors with a high AFP level, location near the main portal branches and poor differentiation should be carefully evaluated before RFA treatment.

Abstract

AIM: Gp96, also known as Grp94, is a member of heat shock protein (HSP) family and binds repertoires of peptides thereof eliciting peptide-specific T cell immune responses. It predominantly locates inside the endoplasmic reticulum (ER) with some cell surface expression in certain cancerous cells. Previous studies have shown that gp96 expression level was up-regulated in tumor cells, including hepatocellular carcinoma (HCC). However, relationship between the extent of gp96 expression and disease progression especially HBV-induced chronic infection, cirrhosis and hepatocellular carcinoma, has not been addressed before. As primary HCC can be induced and progressed from chronic hepatitis B virus (HBV) infection and HBV-induced cirrhosis, we designed an immunohistochemical experiment to test the correlation between gp96 expression level and HBV-induced disease progression, from chronic HBV infection, cirrhosis to HCC.

METHODS: We chose liver samples from different patients of hepatitis B virus induced diseases, including chronic hepatitis B (77 patients), cirrhosis (27 patients) and primary HCC (30 patients), to test the expression level of gp96 in different affected groups. Formalin-fixed, and paraffin-embedded liver tissues taken from these patients were immuno-stained by using an anti-gp96 monoclonal antibody for the expression level of gp96 protein in the sections. In addition, Western blotting of whole cell lysates derived from established human embryonic liver cell lines and several human HCC cell lines (Huh7, HepG2, SSMC-7721) was compared with the expression of gp96.

RESULTS: We found that the extent of elevated gp96 expression was significantly correlated with the disease progression, and was the highest in HCC patients, lowest in chronic HBV infection and was that of the cirrhosis in the middle.

CONCLUSION: Increased expression of gp96 might be used as a diagnostic or prognostic bio-marker for the HBV infection and HBV-induced diseases.

INTRODUCTION

Heat shock protein (HSP) is a highly conserved group of cellular proteins and is up-expressed under hostile micro-environments, such as heat, hypoxia, acidosis, glucose deprivation, neoplasia and virus infection[1-3]. It functions mainly as molecular chaperones to facilitate protein folding, allowing the exposed cells to adapt to gradual alterations in micro-environments and to survive. Recent studies have shown that expression of HSPs in cancerous cells is up-regulated in general but down-regulated in some cases[4,5]. These have been used in some cases as disease-prognostic markers[6-9]. However the molecular basis for over- or lower- expressions of HSPs in tumors is not completely understood. Based on their regulatory roles in cell apoptosis, HSPs have been divided into two groups: pro-apoptotic or anti-apoptotic HSPs[10,11], *e.g.*, HSP27 and HSP70 are anti-apoptotic, whereas HSP10 and HSP60 are pro-apoptotic[10]. As such HSPs regulate cell apoptosis thereof, they modulate tumorigenicity and carcinogenesis.

Gp96 is a member of HSPs and shows anti-apoptotic effect in some tumor cells[12]. It also activates both innate and adaptive immunity and currently is being tested extensively as an autologous therapeutic vaccine for tumors[13-16]. Therefore it is a special member of the HSP family as a "Swiss-army knife" with multiple functions, both in immunity and tumorigenicity or carcinogenesis[14,16]. We previously reported the identification of an HBV-specific HLA class I specific peptide bound to gp96 in HCC patients[17,18], indicating its possible roles in immunity of HBV-induced HCC patients. At the same time, a Japanese group showed that gp96 expression level in HCC patients increased[19] and implied its effect on tumorigenicity.

It is estimated that 350-400 million people worldwide are persistently infected with HBV and some of these persistent infected patients develop into cirrhosis or HCC in later stage[20,21]. Therefore HBV is believed as one of the most successful human pathogens. Elucidation of the detailed pathogenesis mechanism of HBV infection, cirrhosis and HBV-induced HCC will shed light on virus-host interactions and ultimately lead to some prophylactic or therapeutic methods for the disease.

One previous report indicated that gp96 expression in HCC cells was highly up-regulated[19]. However relationship between the extent of gp96 expression and disease progression, especially HBV-induced chronic infection, cirrhosis and HCC, has not been addressed before. Therefore we addressed this problem in the current study and the results showed that there existed a significant correlation between the expression level of gp96 and the disease progression in HBV-induced diseases. The results imply that gp96 might act as an anti-apoptotic factor in HBV-induced disease progression, thus facilitating the tumorigenicity.

MATERIALS AND METHODS

Human liver tissue samples

Seventy-two patients with chronic hepatitis B, 27 patients with liver cirrhosis and 30 patients with HCC were enrolled in this study. The patients were hospitalized in You-An Hospital, Beijing, China, between January 1998 and August 2002. All patients studied were infected with HBV examined with ELISA and were HBeAg positive in serum. The final diagnoses were confirmed by histological evaluation of the liver specimens. Sixteen control normal liver tissues were obtained from patients who underwent gastrectomy with all serological HBV-viral markers tested negative. None of the patients received irradiation or chemotherapy at the time of surgery. The liver specimens from patients with chronic hepatitis were obtained by needle biopsy and primary HCC and adjacent non-tumorous liver tissues were obtained by autopsy. All liver specimens were stained with hematoxylin and eosin and also with Massons trichrome as well as Gordon Sweet's silver method for reticulin to confirm the histological diagnosis. In order to perform immunohistochemical study, liver specimens were fixed in 20% formalin and embedded in paraffin and cut into 5 μm thick sections. All these manipulations were approved by the Institutional Bioethics Committee and informed consent was given by all patients and participants.

Cell lines and cell culture

Three established human HCC cell lines (Huh7, HepG2 and SSMC 7721) obtained from Cell Bank of Chinese Academy of Sciences and a human embryonic liver (HEL) cell line from Cell Bank of Peking Union Medical College were subjected to this study. HepG2, Huh7 and SSMC 7721 cells were grown in DMEM medium (Life Technologies, Inc) supplemented with 2 mmol/L L- glutamine and 100 mL/L fetal bovine serum (FBS). HEL cells were grown in DMEM medium containing 200 mL/L FBS. Cells were incubated at 37 ℃ under 50 mL/L CO_2 in a humidified atmosphere and media were changed on alternate days.

Immunohistochemistry

Formalin-fixed, paraffin-embedded liver specimens were de-paraffinized in 3 times of of xylene change (5 min each) followed by 2 changes in 100 mL/L ethanol. Immunohistochemistry for gp96 was performed using the avidin-biotin-peroxidase complex method (ABC immunostaining method). Endogenous peroxidase activity was blocked with a 15 min incubation in 3 mL/L methanol hydrogen peroxide. For gp96 antigen processing, sections were rehydrated and treated with 0.1 mmol/L citrate solution at 92 ℃ for 10 min. After 3 times of phosphate-buffered saline (PBS) change, sections were treated with normal goat serum for 20 min to block non-specific bindings. Then, a rat-derived monoclonal antibody (McAb) against gp96 (1:400 dilution; Neomarkers, USA) was added to the sections and incubated at 4 ℃ overnight. On the next day, both sets of tissue sections were rinsed with PBS 3 times (5 min each), then incubated with biotinylated goat anti-rat immunoglobulin (1:150 dilution; Goldenbridge Co.) at 37 ℃ for 20 min. After three times of PBS change, sections were soaked in streptavidin-biotinylated peroxidase complex at 37 ℃ for 20 min. Rinsed with PBS 3 times, the sections were finally incubated with diaminobenzidine-hydrogen peroxide to visualize the reaction products.

Immunoblotting

Whole cell lysate without trypsin treatment was prepared from culture cells using CCR5 lysis buffer (Promega, USA). After centrifugation, aliquots of each cell extracts containing an equal amount (15 ug) was resolved by 100 g/L SDS-PAGE and electrophoretically transferred onto a nitrocellulose membrane.

Blots were probed with the anti-gp96 MAb (Neomarkers, USA). To verify that an equal amount of proteins was loaded onto the stocking gel, actin expression was simultaneously estimated in each example as the internal marker by Western blotting using anti-actin monoclonal antibody (Santa Cluz, USA). Protein concentration in the supernatants was measured using the Bradford assay (Bio-Rad laboratories Ltd, UK).

Gp96 expression and statistical analysis

For each tissue section, staining was assessed as negative, weakly positive or only focally positive (low-level expression), or strongly positive (high-level expression) and scored as 0, 1 and 2, respectively. When the stained cells accounted for ≥30% of the total, the tissue was evaluated as strongly positive (grade 2). If the frequency of stained cells was ≤5%, the tissue was evaluated as negative (grade 0). The samples, with 5-30% of stained cells, were classified as weakly positive (grade 1).

Statistical significance of the data was analyzed using the chi-square test and set at $P<0.05$.

RESULTS

Distribution of gp96 in normal, chronic hepatitis B, cirrhosis and HCC liver tissues

By using the ABC immunostaining method, we examined the presence of HSP gp96 in human liver parenchyma (Figure 1). Characteristically, HCC cells and normal hepatocytes were stained and the expressed styles could be diffusely cytoplasmic. In hepatitis liver tissues, the positive hepatocytes were often localized in peripotal areas when the positive immunostaining was weak or few (Figure 1B). When more positive cells were stained, they often diffusely localized in the liver lobule. Moreover, the positive hepatocytes were markedly increased in regenerative liver cells. Cytoplasmic gp96 staining was significantly higher in HCC cells than in adjacent non-tumor liver cells (Figure 1G). In addition, nuclear staining for gp96 was also detected in a small number of HCC cells (Figure 1F), but not found in non-tumorous liver cells or cells derived from hepatitis, cirrhosis. This was consistent with the observation that gp96 localized in the nuclear envelope[22]. Therefore the nuclear staining most likely reflected the outer nuclear membrane staining. It was observed that gp96 was detected not only in HCC cells and hepatocytes, but also expressed in lymphocytes (Figure 1H). Meanwhile, we observed specimens expressing gp96 in HCC with many leukocytes infiltrating tumour cells (Figure 1H). As a negative control, the second goat anti-rabbit antibody without prestaining of gp96 specific monoclonal antibody did not give any significant background staining, confirming the McAb specificity to gp96.

Table 1 Statistics of gp96 expression

Diagnosis	No	Negative	Weak	Strong	P-value[1]

HCC	30	0	9	21	<0.01

CON: control normal liver tissue; CH: chronic hepatitis; LC: liver cirrhosis; HCC: hepatocellular carcinoma. [1]Significance relative to control tissues.

Relations between histological findings and gp96 expression

To understand the association between intensity of gp96 staining and histological stages of chronic hepatitis, cirrhosis and primary HCC, semi-quantitative assessment of the gp96 expression level was performed according to the above criteria.

Typical staining grades (0, 1, 2) of the gp96 expression are shown in Figure 1 (1A, 1B and 1E respectively). As shown in Table 1, various staining patterns were observed for the gp96 expression. Of the specimens from 77 chronic hepatitis B and 27 liver cirrhosis, 62.3% and 85% were positive respectively. In 30 HCC tissues gp96 expression was positive (100%). These findings were statistically significant ($P<0.01$) with respect to the control normal tissues. As shown in Figure 2, the expression level of gp96 was indeed correlated positively with their corresponding histological stages, and was the highest in HCC patients, lowest in chronic HBV infection and that of the cirrhosis was in the middle. However, there was no significant association between gp96 expression and patient ages, gender or other clinic-

pathologic characteristics (data not shown) in this study.

Expression of gp96 in several HCC cell lines

We examined the gp96 expression by Western blot in three HCC cell lines available (Huh7, HepG2 and SSMC-7721) with variable phenotypes and a human embryonic liver cell line (HEL) established by Cell Bank of Peking Union Medical College. As expected, gp96 expression was observed in all three HCC cell lines. However, in HEL cell line, there was no visible band in the immunoblot of crude materials (Figure 3). Furthermore, immunocytochemistry analysis also showed gp96 protein expression in SSMC-7721 cells but did not in HEL cells (Figure 4).

Figure 1 Sections of immunoperoxidase staining for gp96 in chronic hepatitis liver, liver cirrhosis and HCC. Several representative liver tissues with A: gp96 negative in chronic hepatitis, B: gp96 weakly positive in chronic hepatitis, C: gp96 strongly positive in chronic hepatitis, D: gp96 strongly detected in liver cirrhosis, E: gp96 strongly positive in HCC, F: gp96 positive in the nuclear and cytoplasmic staining, G: Cytoplasmic gp96 staining significantly higher in HCC cells than in adjacent non-tumorous liver cells, and H: gp96 expression in HCC accompanied by lymphocyte infiltration (indicated by arrow).

Figure 2 Correlation of gp96 expression and the progression of hepatitis B virus induced diseases. For the definition of gp96 staining density (negative, weak and strong), please see Materials and Methods. X-axis, different stages of HBV infection; Y axis, the percentage of classified samples numbers in total numbers of each group samples. CON: control normal liver tissue; CH: chronic hepatitis; LC: liver cirrhosis; HCC: hepatocellular carcinoma.

Figure 3 Western blotting analysis of gp96 expression in HCC cell lines and human embryonic liver cells (HEL). Clearly shown in the figure are high-level expression of gp96 in the HCC cell lines but not in HEL. Actin expression level was used as SDS-PAGE loading control.

Figure 4 Immunocytochemical analysis of gp96 in HCC cell line SSMC-7721 (A) and HEL (B). High-level expression of gp96 was seen in SSMC-7721, but not in HEL.

DISCUSSION

In this study, the relationship between expression level of gp96 in liver tissues and the progression of HBV-induced diseases was quantitatively analyzed. It was clearly shown that there was a significant correlation. Gp96 expression increased as the HBV-induced disease progressed from chronic hepatitis to cirrhosis, then HCC. Elevated gp96 expression in tumour cells, including HCC (not quantitatively) and human colorectal cancers, was reported earlier[19,23], but its role in tumorigenicity is not clear. As the longevity of cirrhosis and HCC cells was observed compared to normal hepatocytes, it is plausible to propose that gp96 up-expression in these tumorous cells is closely related to the cell survival, thereof possibly preventing cell apoptosis. Some reports showed that gp96 might be a member of anti-apoptotic HSPs[12]. Our current observation seems to support this notion. However, it is not clear yet if the gp96 up-expression in cirrhosis or HCC is the cause or the outcome of the disease progression. This needs to be addressed in future studies.

This obvious correlation has also raised another possibility, *i.e.*, whether evaluation of gp96 expression level can be used as a prognostic marker of HBV-induced diseases. HBV infection is a serious problem worldwide, especially in China. A substantial number of HBV carriers develop into cirrhosis and HCC, but the mechanism underlying the different outcomes among patients is not clear. There is an urgent need for identification of molecular biomarkers for the evaluation of HBV-carriers' prognostic factors. Although some studies suggested that HBxAg could be used as a pathological prognostic factor in the progression of HBV-induced diseases, the expression patterns were often contradictory[24-26]. The expression level of other HSPs has been recognized as diagnostic or prognostic markers in certain tumours[6-9,27-31]. Nonetheless, use of gp96 expression in this purpose has not been addressed before. Gp96 was constitutively expressed at very low levels in ER of a variety of normal cell types[23] but the expression was dramatically enhanced by stressful conditions. Our data (Figure 4) are consistent with the previous observations as we did not detect any gp96 expression in HEL cell line but easily seen in HCC cell lines. Our results, combined with the earlier observation[19], suggested that immunohistochemical detection of increased gp96 expression in liver tissues was associated with an increased risk of HBV chronic infection development into cirrhosis or HCC. In other words, increased expression of gp96 in liver tissues might be a valuable diagnostic or prognostic marker for chronic HBV-infection patients though further work needs to be done for a conclusive implication.

Gp96 is not an oncofetal protein as HEL cells showed negative staining in this study. Gp96 expression was not associated with cell differentiation stages either but with cell malignancy. This finding was correlated with the data from tissue specimens in which enhanced expression occurred in tumor tissues rather than in (even neighbouring) normal tissues. The role of gp96 in HCC tumorigenicity is not clear, but some studies have suggested that high-level expression of gp96 could contribute to tumerigenicity of other tumours[23,32,33]. Gp96 expression was also reported to increase the immunity to tumours[34-38]. At least the complex preparation of gp96 and bound-peptides has been being successfully used as autologous tumour vaccines[13-16]. Our data however did not indicate a positive correlation of gp96 up-expression and host immunity against HBV-induced diseases as the high-level expression was associated with a worse clinical outcome. Why does not high expression level of gp96 in HCC or chronic HBV infection confer protection immunity on HCC or HBV-induced diseases? It is a complicated scenario. As to the other edge of the "Swiss-army-knife", the protection of gp96 against tumours was believed that gp96 could act as a chaperone to facilitate MHC class I peptide loading, therefore increasing the tumour peptides presented by MHC class I[16,39]. Because of the down-regulation of MHC class I on tumourous cell surfaces, cytotoxic T cells (CTL) were in general in a low density in chronic HBV infection or HCC[40], but exogenously introduced gp96-peptide complexes would help class I peptide loading through the up-taking of this complex by gp96 receptors on the cell surfaces, *e.g.* CD91[16]. Through this way CTL response could be induced and the

cellular tumour immunity was provoked. The high expression level of gp96 in cirrhosis and HCC was complicated by other factors because their effects could confer immunity on HCC.

In conclusion, there is a positive correlation between HSP gp96 expression in liver tissues and HBV-induced disease progression. Its mechanism and possible application in HBV-infection patients should be further studied.

Abstract

AIM: To investigate the influence of autologous cytokine-induced killer (CIK) cells on the phenotypes of CIK effector cells, peripheral T lymphocyte subsets and dendritic cell subsets in patients with primary hepatocellular carcinoma (HCC).

METHODS: Peripheral blood mononuclear cells (PBMC) were collected by a blood cell separator from 13 patients with HCC, then expanded by priming them with interferon-gamma (IFN-γ) followed by monoclonal antibody (mAb) against CD3 and interleukin-2 (IL-2) the next day. The phenotypic patterns of CIK cells were characterized by flow cytometry on d 0, 4, 7, 10, 13 and 15 of incubation, respectively. Then, 5 mL of venous blood was obtained from HCC patients before or 8-10 d after CIK cells were transfused into patients to assess the influence of CIK cells on the percentages of effector cells, and proportions of DC1 or DC2 in peripheral blood by flow cytometry.

RESULTS: After two weeks of *in vitro* incubation, the percentages of CD3$^+$CD8$^+$, CD3$^+$CD56$^+$, and CD25$^+$ cells increased significantly from 33.5±10.1%, 7.7±2.8%, and 12.3±4.5% to 36.6±9.0% ($P<0.05$), 18.9±6.9% ($P<0.01$), and 16.4±5.9% ($P<0.05$), respectively. However, the percentages of CD3$^+$CD4$^+$ and NK cells had no significant difference. The percentages of CD3$^+$ and CD3$^+$CD8$^+$ cells were kept at high levels during the whole incubation period, but those of CD25$^+$, and CD3$^+$CD56$^+$ cells began to decrease on d 7 and 13, respectively. The proportions of type I dendritic cell (DC1) and type II dendritic cell (DC2) subsets increased from 0.59±0.23% and 0.26±0.12% before CIK cell therapy to 0.85±0.27% and 0.43±0.19% (all $P<0.01$) after CIK cell transfusion, respectively. The symptoms and characteristics of HCC patients were relieved without major side effects.

CONCLUSION: Our results indicated that autologous CIK cells can efficiently improve the immunological status in HCC patients, and may provide a potent approach for HCC patients as the adoptive immunotherapy.

INTRODUCTION

Primary hepatocellular carcinoma (HCC) represents one of the most lethal neoplasms worldwide with a particularly high prevalence in China[1]. Chronic viral hepatitis patients, especially hepatitis B or C patients, often fall victims to liver cirrhosis and subsequent HCC[2,3]. The high percentage of chronicity may be due to the active combative mechanisms of the virus. In cirrhotic patients, the incidence of HCC annually has been reported to be between 2% and 7%. These findings indicate that prevention and early treatment of liver cancer, especially HCC, are an urgent and important issue.

HCC patients are often found to have functional deficiency in host adaptive immunity response and innate immunity response[4]. Current therapeutic regimens including surgery, chemotherapy and radiotherapy for HCC often have very limited efficacy, and tumors tend to relapse or metastasize easily. Combination therapy becomes the most important means for treating HCC patients. Antitumor immunity is mainly dependent on cellular immune response. Therefore, cellular immunity dysfunction is one of the reasons why tumors are incurable, and easy to relapse or metastasize. Cytokine-induced killer (CIK) cells are shown to be a heterogeneous population, and the major population expresses both the T cell marker CD3 and the NK cell marker CD56, and is termed NKT cells. Cells with this phenotype are rare (1% to 5%) in natural peripheral blood mononuclear cells (PBMC)[5]. CD3$^+$CD56$^+$ cells are able to expand nearly 1 000-fold when they are cultured with a cytokine cocktail comprising interferon-γ (IFN-γ), interleukin-2 (IL-2), mAbs against CD3, and interleukin-1α (IL-1α), and have a characteristic which is more effective in the treatment of tumors with a non-major histocompatibility complex (MHC)-restricted mechanism, and a most effective project[6]. We have previously reported that CIK cells could suppress the growth of tumor cells *in vitro* when HCC cells were transplanted in mice[7-10].

Dendritic cells (DCs) are specialized antigen-presenting cells (APC) in the immune system. They are critical for exerting T cell mediated immune responses, activating naïve T cells, and playing a critical role in innate immune response and adaptive immune response[11]. DCs capture tumor-associated antigens (TAA) efficiently in peripheral tissues, transport these TAA from peripheral sites to primary and secondary lymphoid organs, express high levels of MHC I and MHC II molecules that present the processed TAA epitope specific T cells, express high levels of costimulatory CD80 and CD86 which are required to activate naïve and memory T cells, and synthesize important immunomodulatory mediators such as, IL-12, IFN-α, tumor necrosis factor (TNF)-α. DC contains at least two major distinct subsets, DC1 or DC2, which have mutually exclusive phenotypes and functions. DC1 is APC, and DC2 has been identified as the principal producer of IFN-α, a key cytokine involved in clearance of viral infections. They play a critical role in antivirus or antitumor immune response[12,13]. We have recently reported that CIK cells could suppress the growth of HCC cells in animals or *ex vivo* effectively. In this study, we investigated the alterations of peripheral T lymphocyte subsets

and DC subsets in HCC patients for initial evaluation of autologous CIK therapy efficacy.

MATERIALS AND METHODS

Subjects

Thirteen patients (12 males and 1 female), mean age 46.8±7.3 (range, 30-53) years, with confirmed diagnosis of HCC were recruited based on biochemical analysis and imaging examinations, such as ultrasonography, computed tomography and angiography. The general clinical data of HCC patients are summarized in Table 1. All cases were patients with hepatocirrhosis with more than 20 years of chronic HBV infection. After written informed consent was obtained from each patient, the patients with HCC began to receive CIK cell therapy protocol, which was approved by the Department of Health of Chinese PLA.

Reagents

Serum-free AIM-V medium was purchased from Invitrogen Corporation (GIBCO, USA). Recombinant human IL-2 (rhIL-2) was purchased from Bejing Red United Cross Pharmaceutical Co., LTD (China). Anti-CD3Ab was purchased from CIMAB (Cuba). Recombinant human IFN-γ (rh IFN-γ) was obtained from Shanghai Clonbiotech Co., LTD (China). Human albumin was obtained from Brief Introduction To Sino-Foreign Joint Venture, Harbin Sequel Bio-Engineering Medicine Co., LTD (China).

Isolation and culture of CIK cells

By using a blood cell separator (Spectra v 6.1, Cobe, USA), $(2\text{-}4)\times10^9$ PBMC cells from each patient were obtained in a total volume of 50-60 mL. Cellular concentration was adjusted to 2×10^6/mL in fresh serum-free AIM-V medium, and incubated at 37 ℃ in a humidified atmosphere of 50 mL/L CO_2 in the Lifecell tissue culture flask (Nexell Therapeutics Inc., USA). To generate CIK cells, 2 000 U/mL rhIFN-γ was added on the initial day. After 24 h of incubation, 50 ng/mL mAb against CD3, and 1 000 U/mL rhIL-2 were added. Fresh IL-2 and fresh AIM-V media were replenished every 3 d. On d 0, 4, 7, 10, 13, and 15, cell densities were determined, and the phenotypes were identified by flow cytometry (Becton Dickinson, USA), respectively. Cells were transfused back into HCC patients on days 10, 13, 15, respectively.

Surface marker analysis of CIK cells in cultured or peripheral blood

Incubated CIK cells were collected, washed, and stained with mouse against human CD3 and CD25 (mAbs) coupled to FITC respectively, and mAbs against CD4, CD8, CD16, CD19, and CD56 coupled to PE (Becton Dickinson, San Jose, CA). Non-specific binding was determined using irrelevant mouse immunoglobulin isotypes IgG1-FITC, IgG2-FITC and IgG1 RD. Cells were incubated with Abs for 30 min at 4 ℃. Excess Ab was removed and the stained cells were washed and analyzed or sorted by flow cytometry.

Analysis of DC subsets or CIK effector cells in peripheral blood

Five millilitre venous blood was obtained from each subject before and after CIK cell transfusion, respectively, to analyze DC subsets or effector cell phenotypes by flow cytometry. Briefly, blood cells were incubated with a lineage (lin) cocktail (anti-CD3, CD4, CD16, CD19, CD20, CD56) conjugated with FITC, PE-conjugated anti-CD11c or -CD123, PerCP-conjugated anti-HLA-DR for 30 min, then treated with FACS lysing solution for less than 10 min, washed by PBS, fixed with 2% paraformaldehyde for 20 min at 4 ℃, and analyzed by flow cytometry[14]. Other blood cells were used as described in cultured CIK cells to analyze the phenotypes of effector cells in peripheral blood.

Preparation and transfusion of CIK cell supernatants

Incubated CIK cells were transfused back into HCC patients via vein 3 times on days 10, 13 and 15, respectively. One-third of all CIK cells each time were collected by centrifugation for 20 min at 1 500 r/min, and washed twice in saline water (containing 5 g/L human albumin and IL-2 at 100 U/mL). About $(3\text{-}5)\times10^9$ cells were resuspended in the same solution with 400-500 mL, then transfused back into patients intravenously.

Statistical analysis

The results were expressed as mean±SD. Results were analyzed by using SPSS software, and experiments were designed by self-pair. $P<0.05$ was considered statistically significant.

RESULTS

Phenotypes of CIK cells in various culture time

The percentages of all effector cells varied over time *in vitro* incubation. The percentage of CD3[+] T cells increased slowly, and kept a high level for a long time during the incubation period. The percentage of CD3[+]CD4[+] decreased slightly, but that of CD3[+]CD8[+] rose gradually. The percentage of CD3[+]CD56[+] remarkably increased after incubation, and reached a maximum level on day 13, then gradually decreased during the further generations. The percentage of CD25[+] increased rapidly after harvest, and reached a peak level on d 7, and then decreased rapidly (Figures 1 and 2).

Table 1 Clinical data of 13 hepatocellular carcinoma (HCC) patients

|	Male/ Female	Age (yr)	HBV history	HCC stage	HBV viral load (copies DNA/mL)	ALT (U/L)	AFP (μg/L)	TP (g/L)

Figure 1 Dynamic analysis of CIK cellular phenotypes by flow cytometry.

Lymphocyte phenotype analysis before or after CIK cell transfusion

Before and 10 d after CIK cell transfusion, PBMCs were obtained from the same patient and analyzed for phenotypes by flow cytometry. Ten days after CIK cell transfusion, the proportions of CD3+CD8+, CD3+CD56+ and CD25+ in peripheral blood increased significantly from 33.5%, 7.7% and 12.3% to 36.6% ($P<0.05$), 18.9% ($P<0.01$) and 16.4% ($P<0.05$), respectively.

However, the proportions of CD3+CD4+ or NK cells declined slightly, and there were no significant differences before and after CIK cell transfusion (Figure 3). The longest observation time for patients was 108 d after CIK cell transfusion, others were 20-90 d, and the percentage of lymphocyte subpopulations was the same 8-10 d after CIK cell transfusion, and had no significant difference. Therefore, the proportions of effector cells in peripheral blood might last for more than 108 d. All the patients were under follow-up observation.

Analysis of DC subset proportion before or after CIK cell transfusion

The frequencies of DC1 and DC2 increased from 0.59% and 0.26% before CIK cell transfusion to 0.85% and 0.43% after CIK cell transfusion, respectively, and had a significant difference ($P<0.01$). Therefore, CIK cell treatment could enhance the proportions of DC1 and DC1 in peripheral blood in HCC patients (Figure 4).

HBV viral load analysis before and after CIK cell transfusion

Before CIK cell therapy, the average HBV viral load in HCC patients was 1.85×10^6 copies of DNA/mL. After CIK cell transfusion, the average viral load was decreased to 8.75×10^5 copies of DNA/mL in one month, 1.44×10^5 copies of DNA/mL in 2 mo, and 1.41×10^5 copies of DNA/mL in 3 mo (Figure 5).

CIK cell therapy efficacy

After autologous CIK cell therapy, ameliorated symptoms, increased appetite, improved sleep and gained body weight were observed in most patients. The growth of tumors in all patients became slow down, the tumor volume was decreased in 3 patients. Most patients developed a fever 6 h after transfusion, and the body temperature was 37.5-40 ℃, which could last for 6-8 h. Most fever patients recovered without any treatment. No side effects on liver and kidney were found. Therefore, the autologous CIK cell treatment was a safe and efficacious approach.

DISCUSSION

Heterogenous CIK cells could be generated from PBMC with

stimulation of multiple cytokines. The major marker of CIK cells was CD3[+]CD56[+], termed NKT cells. It was thought that CIK cells which kill the tumor were non-MHC-restricted, but recently, NKT cells exerting efficient MHC-and non-MHC-restricted cytotoxicity against autologous tumor targets have been reported[15]. One reason why tumors are difficult to cure is that tumor escapes the host immune monitor. The human immune system against the tumor is mainly dependent on the cellular immunity. The host immune response in HCC patients was significantly suppressed. The cell number and cytotoxicity are necessary for efficient immunotherapy of tumors. Autologous CIK cell immunotherapy is the most efficient approach of neoplasms. Our present study indicated that autologous CIK cell transfusion was safe and efficient to cure liver neoplasms.

In healthy condition, cells with phenotype of CD3[+]CD56[+] were about 1-5% in peripheral blood[5]. CD3[+]CD56[+] cells could expand nearly 10-fold or even more than 100-fold under cytokine cocktail condition, and the cytotoxicity was greatly improved. The percentage of CD3[+]CD8[+], CD3[+]CD56[+] and CD25[+] before CIK cell transfusion increased from 33.5%, 7.7%, 12.3% to 36.6%, 18.9%, and 16.4% after CIK cell transfusion in peripheral blood, respectively. The level of CD3[+]CD8[+] could be kept as long as 100 d in vivo.

HBV chronic infection is the major pathogen of primary liver carcinoma. HCC patients had some immunity dysfunctions, including innate and adaptive immune responses[4]. The study showed that the number of DCs was decreased or DCs displayed low function[2,16,17]. DCs are considered unique APCs for their highly efficient capability of priming naï ve T cells via direct cell-cell interactions and cytokine production, stimulating the propagation of naï ve T cells, and playing a critical role in innate and adaptive immunity. They have been considered as one of the most potent regulators of the immunological mechanism[18-20]. DC1 is of myeloid origin and could express CD11c, induce Th1 type of T cell differentiation and immunity. On the other hand, DC2 is of lymphoid origin and could express CD123, induce Th2 type of T cell differentiation and was involved in the induction of immunogenic tolerance[21-23]. HBV patients exhibited a significant decrease in proportion of freshly isolated pDC1 to pDC2, and ex vivo generated DC1 function was impaired[24]. DCs function was also suppressed in patients with HCC with hepatitis B and C virus infections[25]. Decreased function of DCs might allow the development of tumor or the tumor itself might suppress the function of DCs[26,27]. Our results showed that the proportions of DC1 and DC2 in the peripheral blood in HCC patients increased from 0.59% and 0.26% to 0.85% and 0.43% (P<0.01) respectively after treatment with CIK cells. The reason was that some cytokines released by CIK cells, type I IFN for example, could promote the propagation or differentitation of DCs, enhancing the host immune response. Type I IFN can modulate DC activation/maturation and cytokine production in different ways depending on the experimental model and culture condition. The propagation of DC1 and DC2 could induce CTL against the tumor by producing more cytokines, and maintain the activity of CIK cells to kill the tumor efficiently[28,29]. The studies showed that interaction between dendritic cells and CIK cells could lead to activation of both populations[30]. This may provide a new approach in adoptive immunotherapy against tumors. Our data showed that HBV viral load decreased 3 mo after CIK cell therapy. The alpha-fetoprotein (AFP) in 6 cases significantly decreased. Serum alanine aminotransferase (sALT) decreased in 9 cases while enhanced in 2 cases. These results indicated that CIK cells played an essential role in anti-virus and anti-tumor treatment and improved the liver function. Our results also showed that CIK cell treatment efficacy was better when applied in combination with surgery or chemotherapy. For advanced HCC patients or those who were unfit for surgery or chemotherapy,

autologous CIK cell treatment could ameliorate symptoms, enhance quality of life and prolong the lives of patients.

In conclusion, autologous CIK therapy may greatly improve host immune responses. Therefore, CIK cells may have a major impact on immunotherapeutic protocols for patients with liver cancer.

Abstract

AIM: To assess the vascularity of hepatocellular carcinoma (HCC) before and after transcatheter arterial chemoembolization (TACE) with the quantitative parameters obtained by first pass perfusion weighted MR imaging (FP-MRI).

METHODS: Seventeen consecutive patients with one to three lesions in liver underwent FP-MRI before treatment. FP-MRI was also performed one, three, six, nine months, and one year after TACE. The baseline signal intensity (S0) of pre-TACE and one month after TACE was analyzed, the vascularity of HCC assessed by steepest slope of the signal intensity versus time curves (SS) was blindly correlated with their DSA feature and clinical outcome.

RESULT: No significant difference was found on baseline signal intensity (S0) between pre-TACE and one month after TACE ($F=0.309$, $P=0.583$), The SS (mean, 32% per second) of lesion one month after TACE was lower than that of pre-TACE (mean, 69% per second), but with no statistical significance ($F=3.067$, $P=0.092$). When local recurrence occurred, the time intensity curves became steeper. The vascularity of HCC before and after TACE graded by SS closely correlated with that by DSA ($K=0.453$, $P<0.05$).

CONCLUSION: FP-MRI is a useful criterion for selecting effective interventional treatment for patients with HCC in their initial treatment and during follow up.

INTRODUCTION

Transcatheter arterial chemoembolization (TACE) has been applied as an effective therapy to improve the survival rate in unresectable hepatocellular carcinoma (HCC) and to decrease the recurrence of resected HCC[1,2]. The efficacy of TACE usually depends on the vascularity (arterial blood supply) of HCC, that is, when HCC with hypervascularity, TACE is effective, otherwise, the efficacy of TACE is poor[3,4], other ablation methods such as percutaneous radiofrequency and percutaneous ethanol injection are needed[5-8]. Furthermore, since TACE is difficult to kill the entire tumor cells at one time, and it is generally used repeatedly or in combination with other ablation modalities. So it is essential to evaluate the tumor vascularity and its distribution before TACE and during follow up. Angiography is the golden standard to evaluate the tumor vascularity, but it is an invasive technique and is therefore not suitable for routine follow up. Generally, computed tomographic (CT) images could be considered as a routine modality to judge the efficacy of TACE depending upon the homogeneous and completely deposition of lipiodol within the lesion, but previous results indicated that even in lipiodol retention area there were viable tumor cells[9]. So it is difficult to access the viability and necrosis of the tumor correctly depending upon the deposition of lipiodol. On the other hand, viable tumors could be enhanced on CT contrast scanning[10,11], but the enhancement area within the lesions could also be affected by artifacts of the high concentrations of lipiodol, which could somewhat disturb the evaluation of vascularity during follow up. Although power Doppler ultrasonography was used to assess tumor vascularity, the detected velocities in the tumor were too slow to be detected, there were too many blooming artifacts associated with micro-bubble injection as well as artifacts resulted from respiration, and the duration of enhancement was short. So vascularity of tumors can not be evaluated in detail by power Doppler US[12,13].

T1 weighted FP-MRI with excellent temporal resolution (more than one imaging per second) has been used to assess tumor angiogenesis of uterine cervical carcinoma, and has a good correlation with microvessel density (MVD)[14]. The purpose of this study was to monitor the angiogenesis of HCC before and after TACE by FP-MRI compared with angiography and patient outcome, and to find out its feasibility and value in assessing vascularity of HCC.

MATERIALS AND METHODS

Between December 2000 and March 2002, patients with HCC included in this study fulfilled the following criteria, namely three or less HCC nodules and no portal thrombosis or extrahepatic metastasis. Seventeen patients (15 males, 2 females) were enrolled in this study. The age was 31-69 years, mean 48.5 years. The diagnosis of HCC was confirmed by fine needle biopsy.

Digital subtraction angiography (DSA) was performed through the celiac or hepatic artery, HCC were classified into the following 3 groups on the basis of vascularity by two angiographers independently who had no information on the current study: Grade A, tumors with more vascularity than nontumorous hepatic parenchyma; Grade B, tumors with vascularity similar to that of nontumorous hepatic parenchyma; and Grade C, tumors with less vascularity than Grade B tumors.

TACE was performed by injection of 8-10 mg mitomycin C mixed 30-50 mg doxorubicin and 10 mL of lipiodol (Guerbet,

Roissy, France) in either the right or left segmental branch of hepatic artery. Embolization was subsequently completed with gelform powder and a small amount of contrast medium under fluoroscopic guidance.

Before TACE and one, three, six, nine months, and one year after first TACE, patients with HCC underwent MR imaging by using a 1.5 T system (Magnetom Vision, Siemens Medical Systems) with a phased array coil, including T1WI (TR=525 ms, TE= 14 ms), T2WI (TR= 4.4 ms, TE=90 ms) and FP-MRI scanning. T1WI and T2WI were used to identify the satisfactory plan and section for perfusion study. For the FP-MRI, a strong T1-weighted, turbo-FLASH sequence was used with a high temporal resolution of 1.196 s per section, two axial or coronal images (TR=3.3 ms, TE=1.4 ms, TI=300 ms) were acquired sequentially with 65 repetitions. At the end of the 4th acquisition, a total dose of 0.1 mmol/kg body mass of gadopentetate dimeglumine (Bellona, Beijing, China) was administered intravenously; 10 mL of saline was immediately flushed to ensure completely delivery of the entire dose of gadopentetate dimeglumine.

To quantitative analysis of FP-MRI, four circular region of interesting (ROI) were drawn, signal intensity time curve was obtained over ROI, the baseline signal intensity (S0) of pre-TACE and one month after TACE (that is, the signal on FP-MRI without gadopentetate dimeglumine) and the steepest slope of the curve (SS) were calculated according to previous method[14]. When the nodules were similar to that of nontumorous hepatic parenchyma, they were classified into group II, while the nodules had larger or smaller SS than those of nontumorous hepatic parenchyma, and they were classified into group I or group III respectively.

All data were expressed as mean±SD, comparison was made by ANOVA, and the correlation between SS and DSA was assessed by Kappa statistic analysis. Significance was accepted when $P<0.05$.

RESULTS

Lesion signal intensity characteristics before and after TACE

MR studies were performed 53 times in 17 patients, twenty-nine lesions were evaluated, the mean size of which was 6 cm (range, 2-16 cm). Almost all the lesions assessed before TACE were hypo- to isointense relative to the surrounding liver parenchyma on T1-weighted images, and the most portion of tumors was iso- to hyperintense relative to the surrounding liver parenchyma on T2-weighted images, and the heterogeneous signal intensity was observed when liquefied necrosis or fat degeneration occurred. All the lesions demonstrated inhomogeneous enhancement on the FP-MRI. One month after TACE, all the lesions also demonstrated hypo- to isointense relative to the surrounding liver parenchyma on T1-weighted images. The signal intensity became higher on T2-weighted images compared to that of pre-TACE. No significant difference was found on S0 between pre-TACE and one month after TACE ($F=0.309$, $P=0.583$) (Table 1), only rim enhancement was found on FP-MRI in all the patients.

Quantitative analysis of HCC angiogenesis before and after TACE

Time intensity curves derived from ROIs drawn in the most-enhancing portion of the tumor before TACE showed different enhancement patterns: Type A (10 cases, 59%) showed a rapid initial increase in signal intensity followed by a plateau, representing hypervascularity. Type B (7cases, 41%), however, showed a slow initial increase in signal intensity followed by a plateau, indicating mild hypervascularity or hypovascularity of the tumor (Figure 1). The SS (mean, 40%) in three patients with arterioportal shunting associated with HCC was lower than the mean value of total patients (mean, 69% per second).

After TACE, Time intensity curves drawn in the rim-

enhancing portion of the tumor showed less steep (mean SS, 32% per second), and its central area demonstrated a horizontal line. No significant difference was found on SS obtained in rim-enhancing portion of the lesions between pre-TACE and post–TACE ($F=3.067$, $P=0.092$) (Table 1).When local recurrence occurred (2 cases), Time intensity curves became steeper than the previous ones (Figure 2). There was a good co1rrelation between SS and DSA in assessment of the vascularity of HCC ($K=0.453$, $P<0.05$) (Table 2).

Table 1 SS (% per second) and S0 of HCC before and after TACE

	cases	mean	minimum	maximum	*F*	*P*
SS						
Pre-TACE	17	69	37	101	3.067	0.092
After-TACE	15	32	11	52		
S0						
Pre-TACE	17	14.04	6.76	21.32	0.309	0.583
After-TACE	15	16.94	9.72	24.12

Figure 1 Signal intensity time curves of HCC in different groups before TACE. Type A represents hypervascularity, type B shows mild hypervascularity or hypovascularity of the tumor.
Figure 2 HCC before and after TACE. (A-B) FP-MRI and the signal intensity time curve derived from ROIs before TACE. (C-D) FP-MRI and the signal intensity time curve one month after TACE, the signal intensity time curve became steeper than that pre-TACE, indicating the remaining arterial blood supply of the lesion after TACE. (E) DSA before TACE and (F) DSA after TACE confirmed the FP-MRI finding. (G-H) one year after TACE, the lesion became larger and the signal intensity time curve became much steeper than that one month after TACE, suggesting the recurrence of the tumor. (I-J) T2 weighted image and enhanced T1 weighted image showing embolus in inferior vena cava and atrium dextrum.

DISCUSSION

Dynamic MR imaging with prior administration of gadopentetate dimeglumine has been used in a few studies to evaluate tumor angiogenesis[15-18]. Gadopentetate dimeglumine is rapidly distributed in the extra-vascular space during the signal acquisition, so the relative changes in signal intensity on dynamic MR imaging are not only correlated with MVD itself but also with perfusion rate, micro-vessel permeability, and the size of extra-cellular leakage space as well. Which of these pathophysiological mechanisms in HCC is the major contribution to the differences in the contrast media uptake is not clear. Because of high temporal resolution, FP-MRI can monitor the contrast medium first passing the microvessels,

the relative changes of signal intensity is significantly associated with MVD, and has been used to access tumor angiogenesis[14]. T1 weighted FP-MRI or T2* weighted FP-MRI may be obtained depending upon the different sequences used[14,19,20].

The time intensity curves derived from T1 weighted FP-MRI of HCC before TACE showed a rapid initial increase in signal intensity followed by a plateau corresponding to hypervascularity, while the time intensity curves showed a slow initial increase in signal intensity followed by a plateau representing mild hypervascularity or hypovascularity. Our study showed that there was a good correlation between SS derived from T1 weighted FP-MRI and DSA in assessment of

the vascularity of HCC. The different vascularity of HCC was due to its differentiation and size[4,21,22], which resulted in different uptake and deposition of lipiodol. HCC with hypervascularity often has homogeneous deposition of lipiodol, and leads to complete necrosis of tumor and a better prognosis. When HCC with hypovascularity it shows incomplete necrosis because of poor deposition of lipiodol and only other ablation techniques are effective. Otherwise, unnecessary repeated TACE may be offset by worsening liver function in patients with cirrhosis, so it is important to identify the angiogenesis of HCC before TACE.

After TACE, the center of the lesion demonstrated no vascularity. Although the time intensity curves drawn in the rim-enhancing portion of the tumor was less steep than before, no significant difference was found on SS of the lesions pre-TACE and post–TACE. This result indicated that vascularity existed even after TACE. The vascularity after TACE was mainly due to collateral blood supply after TACE[24,25]. Meanwhile, the expression of vascular endothelial growth factor (VEGF) of cancerous cells could be enhanced by TACE which might play an important role in reestablishing of blood supply to tumor after TACE[23]. In this study, the incomplete embolization (because of larger lesions, mean size, 6 cm. complete embolization is at the expense of liver function) might contribute to the remains of arterial blood supply. The arterial blood supply after TACE could offer nutrition and oxygen to the remaining viable tumor cells, resulting in partial or incomplete necrosis of the tumor, recurrence would occur sooner or later. When HCC recurred, the time intensity curves became steep again, and the SS increased (Figure 2). The angiogenesis after TACE is a challenge to TACE. Up to now, TNP-470, cyanoacrylate, Plcg-mitomycin-microsphere and bletilla have been shown to improve the therapeutic results[26-30]. On the other hand, how to correctly access the angiogenesis after TACE during follow up remains to be studied. The study presented here offers a noninvasive modality to evaluate the angiogenesis after TACE without artifact.

Our result also showed that there was no significant difference in the baseline signal intensity on FP-MRI pre-TACE and one month after TACE, indicating that the retention of lipiodol within the lesion did not influence the assessment of tumor vascularity after TACE. We encountered two patients with HCC who were treated with TACE in combination with percutaneous ethanol injection. Six months after the therapy, the patients were suspected of recurrence because of their increase of alpha-fetoprotein, although the lesion had high signal intensity on FP-MRI before administration of gadopentetate dimeglumine, the time intensity curves demonstrated the vascularity of the original lesion and intrahepatic metastatic lesions, which were confirmed by DSA.

The potential pitfall of the evaluation of HCC vascularity by using FP-MRI is that the arterioportal shunting (APS) coexists with HCC. APS breaks the equilibrium of normal dual blood supply to the liver tissue and affects the blood flow in tumors, the enhancement of tumors might be changed depending on the degree and location of the shunting[31-33]. Large HCC might be enhanced poorly, and the vascularity might be underestimated because of the limited amount of contrast material passed through the tumor bed. The SS in three patients with APS associated with HCC (mean, 40% per second) was lower than the mean value of the patients (mean, 69% per second). Nevertheless, when the APS coexisted with HCC, the vascularity of HCC evaluated by using FP-MRI should be with caution, only when the shunting disappeared after embolization, was the vascularity of HCC assessed correctly.

The discrepancy between SS and DSA in assessment of the HCC vascularity derived from T1 weighted FP-MRI was within group III and group I. When SS showed hypervascularity

in five lesions, DSA demonstrated hypovascularity. SS showed hypovascularity in two lesions, DSA, however, demonstrated hypervascularity. The differences between these two techniques were due to the pattern of contrast media administrated. The contrast media were administered through I.V. before MRI performance and through hepatic artery during DSA. As a result, the extrahepatic blood supply could not be revealed by DSA during arterial phase. This is the limitation of DSA in evaluation of HCC vascularity. On the other hand, the two sections of axial or coronal MR imaging not correlating with DSA point by point might contribute to their difference.

In summery, T1 weighted FP-MRI has been proved to be practical and noninvasive in assessment of the vascularity, and provides semi-quantitative criteria for the selection of patients to be treated with TACE or other ablation in their initial therapy and during follow up.

Abstract

AIM: To compare the accuracy of hydrocolonic sonography (HUS) in determining the depth of invasion (T stage) in colon and rectal cancer.

METHODS: A total of 1 000-2 000 mL of saline was instilled per rectum using a system for barium enemas, and then ultrasonography was conducted by a SSA-270A (Toshiba Co, Japan) sonolayer unit with a 3.75 MHz for 17 patients with colon cancer and 13 patients with rectal cancer before operation. After operation, T stage in HUS was compared with postoperative histological findings.

RESULTS: Overall, the accuracy of T stage was 70%. It was 88% in colon cancer and 46% in rectal cancer. In evaluating nodal state, the accuracy of HUS was low in both colon (71%) and rectal cancers (46%) compared with conventional CT or MRI. The overall accuracy of N staging was 60%.

CONCLUSION: HUS is valuable to evaluate the depth of invasion in colon cancer, but is less valuable in rectal cancer. Because HUS is low-cost, noninvasive, and readily available at any place, this technique seems to be useful to determine the preoperative staging in colon cancer, but not in rectal cancer.

INTRODUCTION

It is well recognized that the prognosis of colorectal cancer is very closely related to TNM stage[1,2]. In general, computed tomography (CT) or magnetic resonance imaging (MRI) has been widely used for the clinical staging before surgery. These modalities have shown a comparatively high accuracy, especially in evaluating N and M stages. But these modalities have shown some limitation in the depth of invasion[3-5]. Thus, to overcome this limitation, endoscopic ultrasonography (EUS) was developed, and has recently been widely performed[5-11]. However, this modality requires endoluminal access and expensive equipments available only at large medical institutes. Therefore, its application is limited.

Conventional ultrasonography (US) is a simple and safe method, most widely used for screening and diagnosis of abdominal diseases. But, it has limitations to evaluate the endoluminal surface and the depth of invasion of bowel wall[11,12], because of the inability of sonic waves to penetrate air. Over the last years, sonographic evaluation of gastrointestinal (GI) tract has been improved by the instillation of water into the endoluminal area. This procedure is called hydro-sonography (HUS), which allows us to visualize the endolunimal lesion and the depth of invasion of bowel wall in stomach or colon[13-23]. Because HUS is low-cost, non-invasive, and readily available in small medical institutes, it would be an acceptable modality for preoperative staging of colorectal cancer especially in evaluating the depth of invasion. The purpose of this prospective study was to compare the accuracy of HUS in T and N staging between colon and rectal cancer.

MATERIALS AND METHODS

Seventeen patients with colon cancer and 13 patients with rectal cancer, who visited Severance Hospital from 1997 to 2002, were enrolled. In all the cases, a barium enema was performed for detection of other lesions, and a colonoscopy with biopsy for histological confirmation was done as much as possible. They all underwent HUS before operation. Surgery was performed within 7 d after HUS, and we compared the histological stage with the preoperative stage by HUS. All the patients gave their written informed consent before treatment, and the study protocol was approved by the Ethical Committee for the Clinical Research of Institutional Review Board of Yonsei Medical Center in Korea.

For the preparation of bowel before HUS, all the patients took an oral laxative, magnesium sulfate 30 mg (Magrol 250 cc), and received two enemas using warm saline-soapy water suspension on the previous day of the examination. They did not eat anything overnight, and were given pre-medication, scopolamine-N-butyl bromide, 20 mg, intramuscularly just before examination for relaxation of the bowel and suppression of the sense of urgency for defecation. Eighteen Fr-Foley catheters were inserted through the anus and fixed to anal sphincter by ballooning. A total of 1 000-2 000 mL of warm saline water was instilled per rectum using a system, that was usually used for barium enemas (Pneumocolon; Barnes-Hind Barium Products) until the bowel wall was fully distended, and continuous sonography of the large intestine was conducted for adequate filling of water into the colon and rectum (Figure 1A). On occasion, the patients changed their position for optimal sonographic plane. We used a SSA-270A (Toshiba co, Japan) sonolayer unit with a 3.75 MHz convex type transducer, and lower frequency beams for proper penetration. The diagnosis of lesions was based on the sonographic evidence mentioned by Limberg[16]. The main criteria for malignancy were as follows: irregular thickening of the bowel wall with visible destruction of layer boundaries, infiltration into adjacent structures. The main criteria for enlarged regional lymph nodes were as follows: ⩾ 5 mm round hypoechoic mass to be delineated definitive

tumor margin around primary lesion because there were no accurate sonographic parameters to distinguish benign lymph node hyperplasia from malignant infiltration[9]. The first hyperechoic layer adjacent to the lumen corresponded to mucus, the second hypoechoic layer to the muscularis mucosa (MM), the third hyperechoic layer to the submucosa (SM), the fourth hypoechoic layer to the muscularis propria (PM), the fifth echogenic layer to serosa and the peri-colic fat tissues. The integration of mucus and MM layer was defined as mucosa layer (M)[16]. Normal images of colorectal wall architecture at each site were demonstrated in Figures 1B-F. A tumor was classified as T1 when the mass was confined to mucosal and submucosal layer of colon, as T2 when confined to the muscularis propria, as T3 when the tumor penetrated through muscularis propria layer (subserosa) and extended to the serosal layer (including pericolic fat infiltration), and as T4 when the tumor extended to the adjacent organs[24]. Additionally, we compared HUS with abdominal pelvic CT in accuracy. Statistical analysis was performed with nonparametric paired *t*-test, Mann-Whitney test. A two tailed *P* value less than 0.05 was considered statistically significant.

Figure 1 Normal images of five-layered colorectal wall architectures at each site. A: Distended rectum by instilling 1 000-2 000 mL warm saline inserted with a balloon catheter, B: rectum, C: sigmoid colon, D: descending colon, E: transverse colon, F: ascending colon. The first hyperechoic layer and the 2nd hypoechoic lesion were mucosa, the 3rd hyperechoic layer was submucosa, the 4th hypoechic lesion was muscularis propria, and the 5th outer echogenic layer was serosa (from inner to outer of the lumen).

RESULTS

Patient characteristics

The clinicopathological characteristics of the thirty patients are demonstrated in Table 1. There were no significant differences between colon and rectal cancer (*P*>0.05).

Table 1 Characteristics of the patients (*n*=30)

|	Colon cancer (*n*=17)	Rectal cancer (*n*=13)	*P* value
Sex			NS
Male	9	7	
Female	8	6	
Age			NS
Median (range)	52 (37-68)	56 (43-75)	
Size		NS	
Mean (range)	5.76 (3-9)	5.8 (3-9)	
Time intervals to operation day			NS
Median (range)	4 (3-7)	5 (3-9)	
Failure to passage of colonoscopy	7	1	NS
Shape			NS
Polypoid	4	3	
Ulcerative	2	2	
Ulcerofungating	4	4	
Ulceroinfiltrative	7	4	
Site			
Rectum	-	13	
Sigmoid colon	4	-	
Descending colon	1	-	
Transverse colon	6	-	
Ascending colon	6	-	

(*P*=0.05, Mann-Whitney test), NS: no significance.

Figure 2 Images of HUS corresponding with their histological stage A: A round mass originated from submucosal (SM) layer in the descending colon, its histological stage was SM (T1). B: A round mass with deformed PM layer (T2) in transverse colon, its histological stage was PM (T2). C: A large endoluminal polypoid mass penetrating the wall and extending to pericolic fat layer. HUS judged stage was T3, its histological stage was T3. D: A carcinoma with serosal infiltration extending into pericolic adjacent tissue in descending colon. HUS judged stage was T4, its histological stage was T4.

Figure 3 Images of HUS not corresponding with their histological stage. A: Sigmoid colon cancer; HUS judged as PM cancer (T2), but histology revealed pericolic fat infiltrated by tumor cells (T3). B: Transverse colon cancer; HUS judged as PM cancer (T2), but histology revealed intact PM layer and tumor cells infiltrated only SM layer (T1).

Detection for lesions

All the patients completed all the procedures successfully. Because we had acquired some information about the tumor location and shape before HUS by colonoscopy or barium enema, and the patients changed their position for optimal sonographic plane, no lesions were missed even though the tumor was located in the posterior wall opposite to the tranducer, or a site adjacent to the loops of small bowel or flexure.

Depth of invasion and T stage

HUS made a correct staging in 21 of the 30 colorectal cancers. Figure 2 demonstrates the preoperative HUS imaging corresponding to the postoperative histological staging, and Figure 3 demonstrates the discordant staging. The overall accuracy of HUS was 70%.

The accuracy of staging by HUS was favorable in colon cancer (88%), especially when the lesions were located in the descending or ascending colon and their depth was confined to pericolic fat infiltration (93 %) (Table 2). When the lesions were located in the sigmoid, transverse colon, and its flexure

and confined to the mucosal layer, the accuracy was relatively lower. Underestimated cases were relatively smaller than 2 cm and ulceroinfiltrating shaped masses, and overestimated cases were larger than 3 cm and fungating mass. But the differences were not statistically significant. In rectal cancer, however, the accuracy was unfavorable (46.1%) compared with colon cancer, at any site or of any shape (Table 2, $P = 0.038$). Table 3 demonstrates the accuracy of CT in staging of depth of invasion in colon and rectal cancers.

Nodal stage and N stage

The overall accuracy of HUS for N staging in colorectal cancer was 60%. The sensitivity and specificity were 55% and 67%, respectively. It showed 71% accuracy in colon cancer and 46% accuracy in rectal cancer, respectively. The accuracy of N staging by HUS was relatively lower than that by conventional CT or MRI in both colon and rectal cancers. In addition, the accuracy of N staging was affected by the size of the node. There was no statistically significant difference in the accuracy of N staging by HUS between colon and rectal cancers although

it was higher in colon cancer than in rectal cancer (Table 4). Table 5 demonstrates the accuracy of CT in staging of lymph node metastasis in colon and rectal cancers.

Table 2 Comparison of hydrocolonic sonography accuracy in depth of invasion between colon and rectal cancers (*P*=0.038)

Pathologic Diagnosis	Colon cancer				Accuracy (%)	Rectal cancer				Accuracy (%)
	T1	T2	T3	T4		T1	T2	T3	T4	
T1	1				1/1 (100)			1		0/1 (0.0)
T2	1				0/1 (0.0)		2	1		2/3 (66.7)
T3			1	14	14/15 (93)		3	4	1	4/8 (50.0)
T4					0/0				1	1/1 (100)
Total	2		1	14	15/17 (88)		5	6	2	6/13 (46.2)

Table 3 Comparison of the accuracy of CT in depth of invasion (*P*=0.048)

Pathologic Diagnosis	Colon cancer				Accuracy (%)	Rectal cancer				Accuracy (%)
	T1	T2	T3	T4		T1	T2	T3	T4	
T1		1			0/1 (0.0)			1		0/1 (0.0)

Pathologic Diagnosis	Colon cancer		Rectal cancer	
	n (-)	*n* (+)	*n* (-)	*n* (+)
N (-)	8	1	4	5
N (+)	4	4	2	2
Total	12	5	6	7
Accuracy (%)	12/17 (70.6)		6/13 (46.2)	

Table 5 Comparison of the accuracy of CT in lymph node metastasis (*P*=0.275)

Pathologic Diagnosis	Colon cancer		Rectal cancer	
	n (-)	*n* (+)	*n* (-)	*n* (+)
N (-)	8	1	5	4
N (+)	3	5	2	2
Total	12	5	7	6
Accuracy (%)	13/17 (76.5)		7/13 (53.8)	

(*P*=0.05, Mann-Whitney test), N (-): lymph node negative, N (+): lymph node positive.

DISCUSSION

Over the last years, sonographic evaluation of gastrointestinal (GI) tract has been improved by the instillation of water into the endoluminal area, named as HUS[13-24]. Allowing the sonographic differentiation of five layers of the colon wall, theoretically HUS was able to predict stage of colorectal cancer with a high sensitivity, specificity, and predictive value[16,18,22,23]. HUS also could diagnose a variety of colonic endoluminal lesions including polyp, inflammatory bowel disease, *etc*. with a high accuracy[14,15]. According to some reports, the accuracy of HUS was close to that of EUS in depth of invasion in colon cancer

(79-92%)[22]. However, the accuracy of HUS in rectal cancer was poor[22]. In the present study, we compared the accuracy of HUS in local staging between colon and rectal cancers, and observed under what condition the accuracy of HUS was relatively higher.

The accuracy of T staging by HUS was favorable in colon cancer (88%), especially when the lesions were located in the descending or ascending colon and their depth was confined to pericolic fat infiltration (93%). The result was similar to previous studies by Dux *et al*.[22]. The lower accuracy of HUS in T staging of rectal cancer was assumed to be caused by anatomical obstacle, that is, pubic symphysis, and incomplete removal of bowel gas[22]. Although the patient's position was changed to head-up or down position to avoid these obstacles, the limitation still occurred. In N staging, the accuracy of HUS was unfavorable in both colon and rectal cancers. The reasons might be that there were no accurate sonographic parameters to distinguish benign hyperplastic lymph node from malignant infiltration, and the nodes far away from the probe (N3) could not be traced sufficiently, and lymph node metastasis could occur without size enlargement[9,10]. However, in our study, the accuracy of N staging was affected by the size of the node.

Sigmoidoscopy has been widely accepted as an outpatient diagnostic procedure for colorectal cancer. But, in reality, 40% of colonic tumors occurred outside the sigmoid[25]. So, colonoscopy is required in order to detect the right side lesion. But incomplete studies were infrequent due to various reasons, such as lumen obstruction, poor preparation of the bowel, and anatomical problems, *etc*.[26]. Under such circumstances, a barium enema may be performed for detection of the right side or upper side lesion except for obstructive diseases. But it can not evaluate the depth of invasion. Besides, EUS cannot be always performed because it requires endoluminal access. Thus, HUS may be preferred.

Although we detected all lesions, some were difficult to detect and evaluate, such as the lesions in patients with obesity, located in the flexure and adjacent to the small bowel, with their size less than 2 cm.

In conclusion, HUS is valuable in evaluating the depth of invasion (T) of colon cancer at any site and of any shape. However it has limitations in rectal cancer. Because HUS is low-cost, noninvasive, and readily available at any place, this technique seems to be useful in local staging of colon cancer especially in cases where colonoscopy and EUS can not be performed.

Abstract

AIM: The prevention of recurrence of colon cancer (CC) after operation is very important for improvement of the prognosis of CC patients, especially those with micro-metastasis. The generation of fused cells between dendritic cells (DCs) and tumor cells maybe an effective approach for tumor antigen presentation in immunotherapy. In this study, we fused human colon caner SW480 cells and human peripheral blood - derived DCs to induce an antitumor activity against human CC.

METHODS: CC SW480 cells and human peripheral blood - derived DCs were fused with 500 mL/L polyethylene glycol (PEG).

RESULTS: The specific T cell responses activated by fusion cells (FCs), were observed. About 100 mL/L to 160 mL/L of the PEG-treated non-adherent cells with fluorescences were considered to be dendritomas that highly expressed the key molecules for antigen presentation in our five cases. *In vitro* studies showed that fusions effectively activated CD8+ T lymphocytes to secrete interferon-γ. The early apoptotic ratio of the colon cancer SW480 cells was higher than that of controls, which was affected by cytotoxic T lymphocytes (CTLs) stimulated by dendritomas.

CONCLUSION: The data indicate that fusion of tumor cells with DCs is an attractive strategy to induce tumor rejection.

INTRODUCTION

Colon cancer (CC) is one of the most common malignancies in the Western world. As diet custom has changed these years, the number of cases is increasing in the Eastern world. Although surgical resection is the first choice wordwide, an effective approach for the treatment of CC patients with metastasis and cancer recurrence postoperation has not yet been found.

Dendritic cells (DCs) are potent antigen-presenting cells (APCs) which are the prime naive T cells and initiate a prime immune response[1,2]. Various DC-based strategies, such as DCs pulsed with tumor-associated peptides or proteins, viral transduction of DCs with tumor-specific genes or transfection with liposomal DNA or RNA, have been developed to introduce tumor specific antigens into DCs and thereby to generate cytotoxic T lymphocyte (CTL) responses against malignant cells[3-9]. However, few tumor-specific antigens have been identified, and their immunogenicity is uncertain in most malignant tumors.

An attractive approach to the enhancement of antitumor activity is to generate the fusions between tumor cells and DCs[10]. Multiple tumor antigens, including those unidentified yet, are processed endogenously and presented to T lymphocytes by the MHC class I and II pathways in the context of costimulatory signals[11]. Some inspiring results have been reported *in vitro* and *in vivo* except that of human colon cancer due to the difficulty in isolating the tumor antigens from tumor tissues and the facility contaminated for primary culture[12-16].

In this study, we fused human colon caner SW480 cells and human peripheral blood - derived DCs to induce an antitumor activity against human CC, because they shared some common antigens between cells from tissue and cell line SW480.

MATERIALS AND METHODS

Colon cancer cell culture
Human SW480 colon cancer cells (ATCC#CCL-228) were grown in RPMI medium 1640 supplemented with 100 mL/L heat-inactivated FCS.

Preparation of DCs and CD8+ T cells
Peripheral blood mononuclear cells (PBMC) were isolated from patients with CC by Ficoll-Hypaque density-gradient centrifugation. The pure CD14+ PBMC and CD8+ T lymphocytes were isolated by MACS magnetic microbeads (Miltenyi, Germany) respectively according to the manufacturer's directions. CD14 PBMC were cultured for 1 wk in RPMI medium 1 640/10% human serum containing 1 000 U/mL granulocyte-macrophage colony-stimulating factor (GM-CSF) and 1 000 U/mL IL-4. CD8+ T lymphocytes were cultured in RPMI medium 1 640/10% human serum containing 20 u/mL IL-2.

Fluorescent staining and fusion
Tumor cells and DCs were stained red and green, respectively, using PKH26-GL and PKH67-GL kits (Sigma) according to the manufacture's directions. The tumor cells were irradiated at a dose of 30Gy before staining. Human DCs and tumor cells were fused together by mixing the two types at a ratio of 3:1 in a 15-mL conical centrifge tube. One milliliter of 500 mL/L polyethylene glycol (PEG) (Sigma) was added to the cells by drops for 1 min. Nine milliliters of serum-free RPMI medium 1640 was added to the mixture for 10 min. The cells were pelleted by centrifugation at 500 g for 5 min. The supernatant was removed and the cells were resuspended in 5 mL complete DC medium and plated in a T25 flask that was incubated at 37 ℃ in 50 mL/L carbon dioxide.

DCs and fusions assays

Fusion efficacy was evaluated by fluorescence microscopic analysis and flow cytometry analysis using Facsort (Becton Dickinson). DCs were washed with PBS and incubated with murine antibodies HLA-DR-APC, CD80-PE, CD86-FITC (PharMingen) for 15 min at 4 ℃. Fusions were washed with PBS and incubated with murine antibody HLA-DR-APC for 15 min at 4 ℃. Samples were then washed, fixed with 10 g/L paraformaldehyde, and subjected to flow cytometry analysis.

Scanning electron microscopy observation

Cells were fixed with 12 g/L glutaraldehyde in 0.1 mol/L PBS (pH7.4). Fixed cells were coated with 1 g/L poly-L-lysine, dehydrated in ascending concentrations of ethanol, treated with isoamyl acetate, and critical-point dried with liquid CO_2. Specimens were coated with vaccum-evaporated, iron-spattered gold and observed with a S-2250N scanning electron microscope (HITACHI).

Cytotoxic T lymphocyte generation

Dendritomas obtained by using 500 mL/L PEG were mixed with $CD8^+$ T lymphocytes at a ratio of 1:10. $CD8^+$ cells to be used were pelleted by centrifugation at 500 g for 5 min and resuspended in 1 mL medium containing RPMI-1640, 10% human serum, 5 ng/mL IL-12, and 20 U/mL IL-2. The mixture was incubated at 37 ℃ in 50 mL/L carbon dioxide for 8 d. As controls, homologous DCs were mixed with $CD8^+$ T cells at the same ratio.

Interferon-g assay

Each day CTL-generating cultures were refed. The supernatants of cultures were harvested and frozen at -20 ℃. Interferon-γ (IFN-γ) assay was performed on the supernatants by a commercially available ELISA kit (R&D). Each assay was performed according to the manufacturer's instructions. The lower detection limit was 4 pg/mL. All samples and standards were run in triplicate.

Cytotoxic T lymphocyte assay

To determine whether dendritomas stimulated a tumor cell-specific CTL response, cytotoxicity assay was performed using the cultured tumor cells as target cells. CTL effector cells and tumor cells were mixed in a 24-well tissue culture plate with a round-bottom at the concentration of 100:1 effectors-to-target cells. The mixtures were incubated at 37 ℃ in 50 mL carbon dioxide for 2 d. Tumor apoptosis was measured using an Annexin V-FITC/PI kit (Clontech) by FACS analysis after the mixtures were cultured for 24 h and 48 h respectively. The tumor cells were detached and incubated with Annexin V-FITC for 30 min at 4 ℃ after the unattached CTLs were removed by magnetic microbeads. The samples were washed 3 times with PBS and measured by FACS analysis. To determine whether the lysis was tumor cell –specific, mammary cancer cells SK-BR-3 (ATCC#HTB-30) and ovarian cancer cells SK-OV-3 (ATCC#HTB-77) were used as target cells in similar cytotoxicity assay.

RESULTS

Fusion identification and fusion efficacy assay

On scanning electron microscopy, SW480 cells had short processes on a plain cell surface and DCs had long denritic processes. Dendritomas were formed by fusions of the dendritic cells with CC cells (Figure 1). Fusion efficacy was about 16%. It was assessed by the analysis of fusions of SW480 cells stained with red fluorescent dye and DCs stained with green fluorescent dye using a fluorescent microscope (Figure 2) and flow cytometry repectively (Figure 3C).

Figure 1 A: Scanning electron micrographs of DC, B: Scanning electron micrographs of SW480 cell, C: Scanning electron micrographs of larg nonadherent cell, possibly a DC/SW480 fusion cell after treatment with 50%PEG.

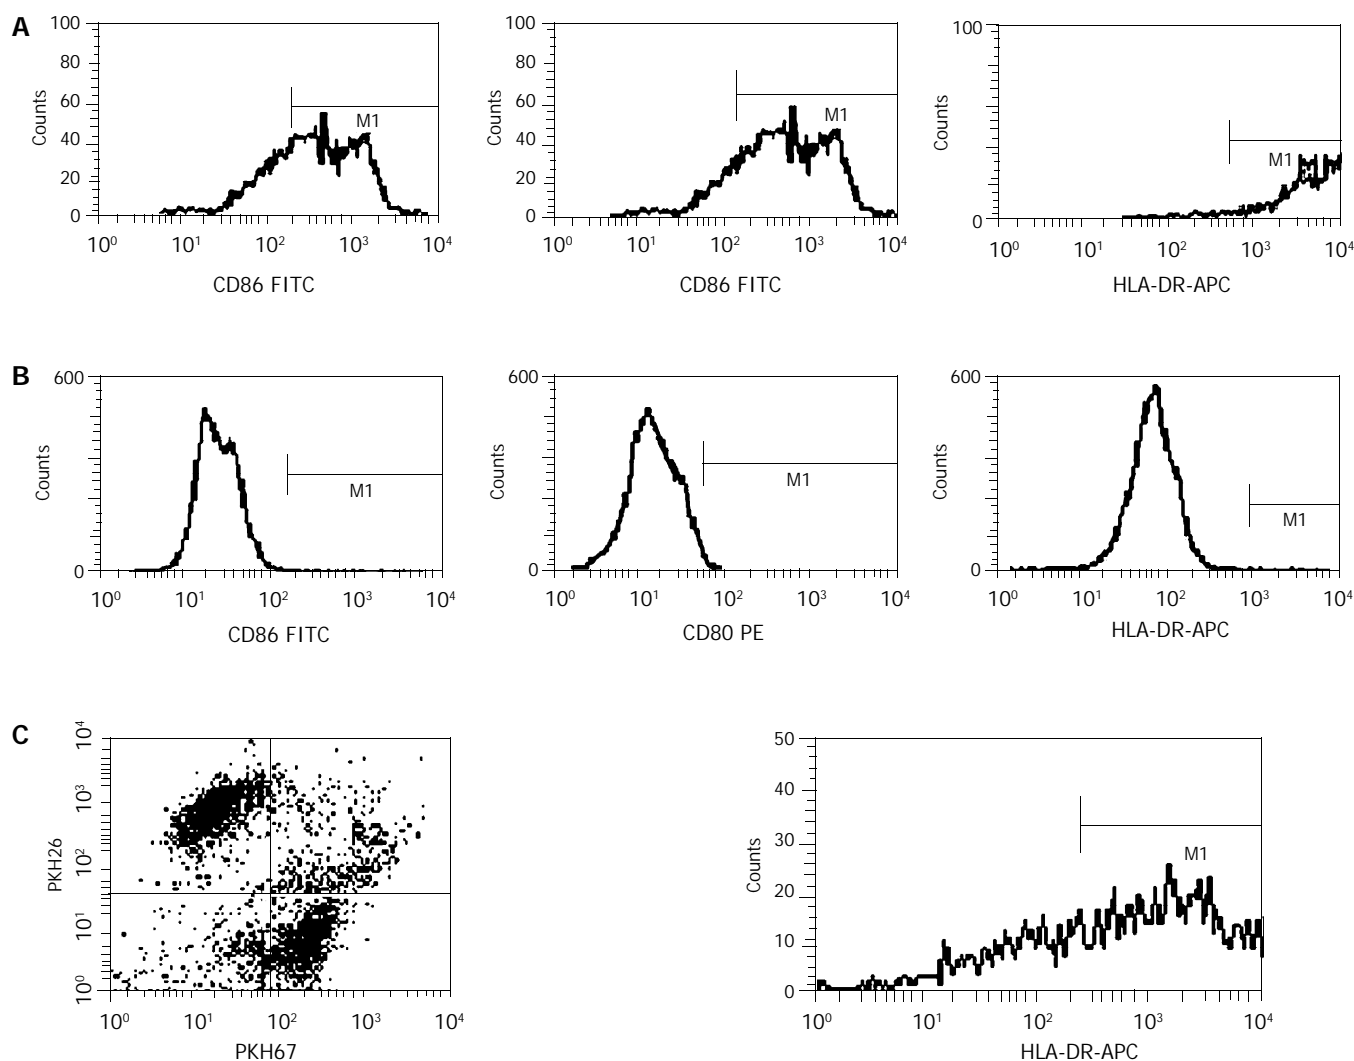
Figure 2 A: Fluorescent green staining of dendritic cells from peripheral blood mononuclear cells of patients using PKH67-GL. B: Fluorescent red staining of colon cancer cells SW480 using PKH26-GL. C: Fusion between PKH stained dendritic cells and tumor cells treated with PEG.


Figure 3 A: High expression of CD86, CD80 and HLA-DR by Dendritic cells, B: No expression of CD 86, CD80 and HLA-DR by SW480 cells, C: High expression of major molecule HLA-DR of DCs by dendritomas gated by dual red and fluorescent cells.

Characteristics of fusions of DCs and CC cells

To determine whether human DCs could be used in the generation of heterokaryons with tumor cells, DCs from PBMC of CC patients were prepared. Flow cytometry demonstrated that DCs highly expressed CD80, CD86 and HLA-DR, but SW480 cells did not. Dendritomas, which showed dual red and green fluorescence, highly expressed the major molecules HLA-DR of DCs (Figure 3).

Tumor cell-specific cytotoxic T lymphocytes stimulated by dendritomas

To determine whether dendritomas effectively presented tumor antigens to effective cells, CD8+ T lymphocytes were purified from autologous peripheral blood and cocultured with dendritomas at a ratio of 10:1. Trypan blue exclusion test showed that, 6 d after the stimulation, CTLs were activated to proliferate and the number of T cells increased (from 1.2×10^7 to 1.8×10^7). After activation, CTLs secreted high levels of IFN-γ, and the secretion of this cytokine induced by dendritomas was higher than that of controls (Figure 4).

Tumor cell apoptosis

To investigate whether the CTLs induced by dendritomas, had a tumor-specific response, CTLs and tumor cells were mixed in a 24-well tissue culture plate with a round-bottom at the concentration of 100:1 effectors-to-target cells. Tumor apoptosis was measured using an AnnexinV-FITC/PI kit by

FACS analysis after the mixtures were cultured for 24 h and 48 h respectively. The result indicated that the lysis was autologous tumor specific (Figure 5). The early apoptotic ratio of colon cancer SW480 cells was higher than that of controls, which was affected by cytotoxic T lymphocytes (CTL) that activated by denritomas after co-cultured for 24 h. Although there were no differences in the apoptotic ratios of tumor cells after co-cultured for 48 h, the necrotic fragments of colon cancer were higher than those of controls.

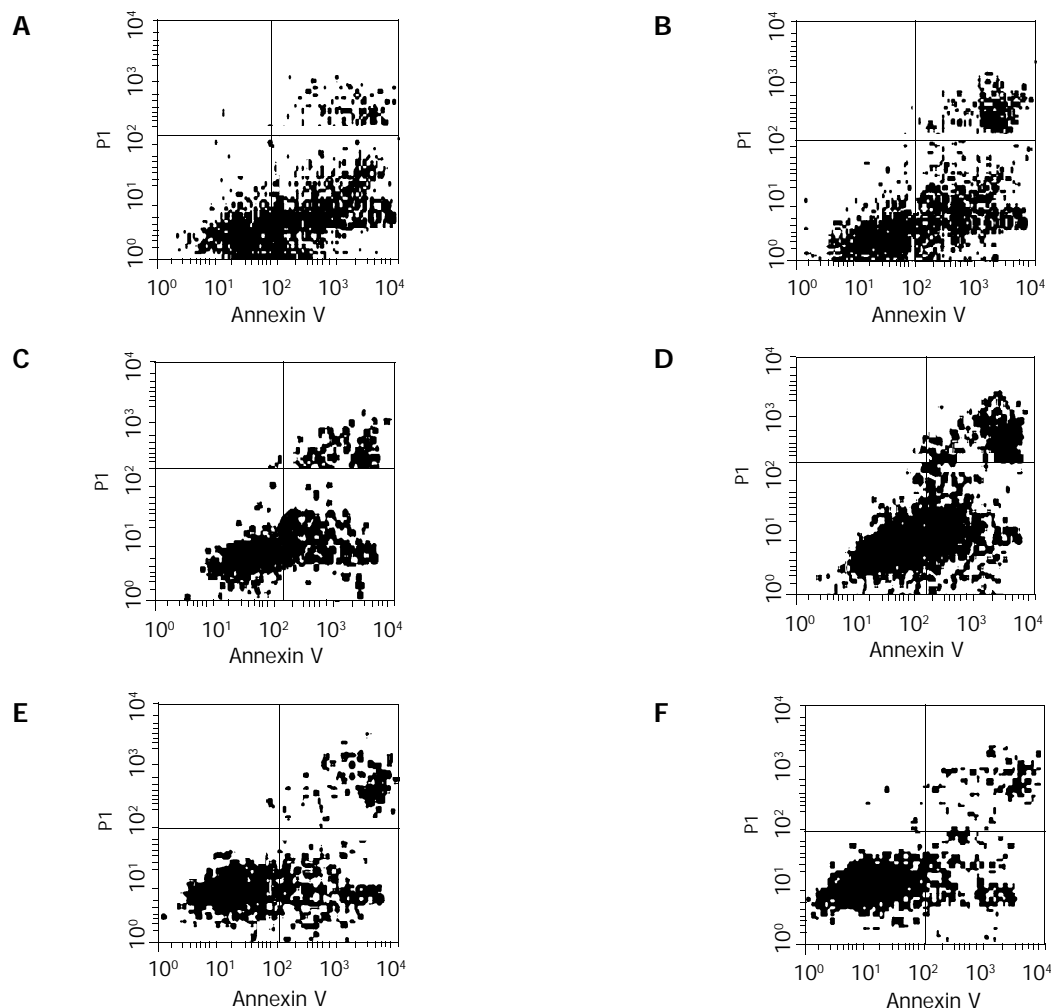
Figure 4 Interferon-γ expression by CTLs. Lane 1 represents IFN-γ expression by CD8+ T cells primed with dendritomas. Lane 2 represents IFN-γ expression by CD8+ T cells primed with DCs.


Figure 5 Early apoptosis (single Annexin V positive) of tumor cells measured by flow cytometry. The apoptotic ratios of SW480 cells affected by CTL induced dendritomas or physical mixture of SW480 cells and DCs without PEG, were about 38.25%(A) and 32.36% respectively (B). The apoptotic ratios of SK-BR-3 cells affected by CTL same as that in SW480, were about 25.64% (C) and 17.43%(D) respectively. The apoptotic ratios in SK-OV-3 were about 21.68% (E) and 17.43%(F).

DISCUSSION

Dendritic cells are professional antigen-presenting cells that play a vital role in stimulating immune responses. Not only can they activate naïve CD4+ T helper cells, but they also stimulate unprimed CD8+ cytotoxic T lymphocytes[1,17,18]. Many studies have shown that DCs, when effectively loaded with or expressing tumor antigens, can activate antitumor immune responses through cellular and humoral actions[19]. However, for those tumors whose tumor antigens have not been identified, especially for primary tumors from patients, fusion between DCs and tumor cells presented a promising alternative strategy. Because the process of isolating cells from primary tissues in gastrointestinal tumor was time-consuming and prone to contam- ination, these considerations have limited the clinical application of this approach. In this study, an attempt was made to fuse DCs with human colon cancer SW480 cells to induce a colon cancer-specific antitumor immune response, because there were some common antigens between primary tumor cells and homogenous cell line.

It is important to determine the fusion efficacy of DCs and tumor cells by treatment with PEG. Two-color FACS analysis showed that approximately 100 mL/L to 160 mL of PEG-treated non-adherent cells were positive for both PKH67-GL (DCs were fluorescently stained) and PKH26-GL (SW480 cells were fluorescently stained) in our 5 separate CC patients, which highly expressed the MHC of DCs for antigen presentation (Figure 3C). These results were consistent with those of the

landmark kidney cancer trial[20]. It is conceivable, therefore, that the fusions are able to present tumor antigen (s) to naive T cells by means of DC capability. Although exceptionally high fusion efficiencies sometimes have been reported using PEG, such reports might reflect an overlying optimistic interpretation of fluorescence-activated cell sorting data or nonrepresentative experiments[21]. Because fusions could generate not only tumor-DC hybrids but also tumor-tumor hybrids, DCs and tumor cells were fused at a ratio of 3:1 to decrease the tumor-tumor hybrids. Two types of aliphatic fluorescent dyes, PKH-67GL and PKH-26GL, have been widely used to label viable cells for *in vitro* and *in vivo* cell tracking[22,23]. In addition, researches have shown that there were no significant effects of the two dyes on cell viability, growth, or function[24,25].

To determine whether dendritomas effectively presented tumor antigens to immune cells and activated T lymphocytes, CD8+ T cells were isolated, and *in vitro* stimulation was performed. Then IFN-γ, a well-known marker of T-cell activation, was measured. Results showed that the secretion of CTLs activated by dendritomas was higher than that of controls after stimulation. Fusion hybrid vaccines might be more effective than other DC-based strategies because of superior antigen presentation[26]. Although DCs have a consistant capacity of processing exogenous antigens to achieve a major histocomp- atibility complex class II-restricted antigen presentation, the major histocompatibility complex I-restricted antigen presentation is often difficult to demonstrate

when DCs are pulsed with complex protein antigens rather than with synthetic 8-or 9-mer peptides. Tumor-DC fusion potentially confers not only DC functionality but also a continuing source of endogenous tumor antigens for major histocompatibility complex class I presentation[21].

In the early stages of apoptosis, which occurs at the cell surface, one of these plasma membrane alterations is the translocation of phosphatidylserine (PS) from the inner side of the plasma membrane to the outer layer, by which PS becomes exposed at the external surface of the cell. Annexin V is a Ca^{2+} dependent phospholipid-bind-ing protein with high affinity for PS. Hence this protein can be used as a sensitive probe for PS exposure upon the cell membrane. So Annexin V assay offers the possibility of detecting early phases of apoptosis before the loss of cell membrane integrity and permits measurements of the kinetic of apoptotic death in relation to the cell cycle. More extensive FCM allows discrimination between different cell subpopulations that may or may not be involved in the apoptotic process. In comparison with the traditional tests, Annexin V assay was sensitive and easy to perform[27]. To determine whether CTLs could lyse tumor cells, CTLs were harvested and apoptosis assay was performed using tumor cells as target cells. To confirm that the CTL activity was tumor cells specific, mammary cancer cells SK-BR-3 and ovarian cancer cells SK-OV-3 were used as target controls, in addition to colon cancer cells. The results indicated that the lysis was tumor cell specific (Figure 5). Similar results were obtained in the 5 cases.

Several preclinical studies have shown that vaccines consisting of such hybrids can provide effective active immunization against animal tumors and specific *in vitro* sensitization of human T cells to relevant tumor antigens[10,11]. Furthermore, in contrast to other vaccine strategies, the tumor-DC fusion strategy has already been met with resounding clinical success when applied to the treatment of patients with advanced renal cancer[20]. Immunization with fusions of DCs and human colon cancer cells may be a promising method for the prevention and treatment of micrometastasis and recurrence after operation of CC.

Abstract

AIM: To evaluate the feasibility of laparoscopic resection of rectal carcinoma and to compare the short-term outcome of laparoscopic procedure with conventional open surgery for rectal cancer.

METHODS: Thirty-eight patients with rectal cancer were included in a prospective non-randomized study. The patients were assigned to laparoscopic (n=18) or open (n=18) colorectal resection. Case selection, surgical technique, and clinical and pathological results were reviewed.

RESULTS: The operative time was longer in laparoscopic resection group (LAP) than in open resection group (189±18 min vs 146±22 min, P<0.05). Intraoperative blood loss and postoperative complications were less in LAP resection group than in open resection group. An earlier return of bowel motility was observed after laparoscopic surgery. The overall postoperative morbidity was 5.6% in the LAP resection group and 27.8% in open resection group (P<0.05). No anastomotic leakage was found in both groups. The pathologic examination showed that the length of the resected specimen, the mean number of harvested lymph nodes in laparoscopic resection group were comparable to those in open resection group.

CONCLUSION: Laparoscopic total mesorectal excision (TME) for rectal cancer is a feasible but technically demanding procedure. The present study demonstrates the safety of the procedure, while oncologic results are comparable to the open surgery, with a favorable short-term outcome.

INTRODUCTION

Since the first series of successful laparoscopic colon resections reported in 1991[1,2], the laparoscopic techniques for colorectal diseases have been accepted widely[3]. Although generally accepted for the treatment of benign diseases of the colon and rectum, the role of laparoscopic technique in cancer surgery remains controversial. Early reports of trocar site and wound recurrences of malignancies after laparoscopic procedures led to concerns over possible increased recurrences and the risk of peritoneal seeding from the pneumoperitoneum[4-6]. The ability to adhere to oncologic principles during laparoscopic surgical resection and the implications for long-term survival were also questioned.

The technical approach can significantly affect the outcome in colorectal cancer patients. The key principles including *en bloc* resection with removal of corresponding lymphatics, no-touch technique[7], and total mesorectal excision (TME) are often recommended in open surgery for colorectal cancer[8]. These oncologic principles are as important in laparoscopic surgery as in open surgery.

We presented our preliminary collected data on laparoscopic surgery for rectal carcinoma versus open resection in our university hospital to assess the safety and feasibility of laparoscopic resection of rectum with total mesorectal excision technique.

MATERIALS AND METHODS

Patients

Thirty-six patients (16 women, 20 men) undergoing anterior recto-sigmoidal and abdominoperineal resections for rectal carcinoma between April 2002 and May 2003 at the 1st Affiliated Hospital of Nanjing Medical University (Nanjing, Jiangsu, China) were entered into a database. Pre- and post-operative care was standardized for both laparoscopic and open resection groups. Preoperative assessment included physical examination, liver function and carcinoembryonic antigen (CEA) tests, liver ultrosonography, and colonoscopy with biopsy. Patients who had intestinal obstruction, emergency surgery, adjacent organ invasion diagnosed preoperatively, and history of colon surgery were excluded for laparoscopic operation.

In laparoscopic resection group eighteen patients (9 women and 9 men) undergoing laparoscopic operation for rectal carcinoma were reviewed. Inclusion in the laparoscopic or conventional treatment group was not randomized. All patients were operated on by 2 groups of surgeons, 1 group of surgeons who had experiences in advanced laparoscopic techniques used a laparoscopic approach, and the other group of surgeons performed conventional resections.

The patients were treated with mechanical and antibiotic bowel preparation preoperatively. Surgery was done under general anesthesia. All patients received antibiotics intravenously at the time of induction in the operating room.

Methods

Patients were placed in the modified lithotomy position to facilitate either transanal stapled anastomosis or peritoneal resection. All patients had an indwelling urinary catheter. For the laparoscopic resection group the pneumoperitoneum was established with an intra-abdominal pressure of 15 mmHg.

The laparoscope was sited at the umbilicus, 4 trocars were inserted. In brief, two 5-mm ports were placed in the right and left upper quadrants and a 10-mm trocar for the left iliac fossa. A further 12-mm trocar was inserted in the right iliac fossa for the endoscopic stapling device. Mobilization and dissection of sigmoid colon and rectum were achieved by using ultrasonic

scissors. The following procedures were required: left colon mobilization (including the splenic flexure if necessary), identification of the left ureter, and intracorporeal ligation of the inferior mesenteric vessels with clips or stapling devices. Rectum and mesorectum were mobilized through the avascular plane between the intact mesorectum anteriorly and Waldeyer's fascia posteriorly by sharp dissection and extended down to the level of the levator muscle. The ureters, hypogastric nerve, and pelvic parasympathetic plexus were protected. After intracorporeal transaction of the distal bowel with *endolineal staplers*, the bowel was drawn out through a left lower quadrant incision under wound protection and divided with appropriate proximal clearance. The proximal anvil was placed extra corporeally, and anastomosis was performed by double stapling technique.

For abdominoperineal resection, laparoscopic procedures were followed by perineal resection in the standard fashion. A terminal colostomy was created at the left lower abdomin port site. With the help of the perineal surgeon, the rectum and the whole mesorectum were fully mobilized and the specimen was retrieved through the perineum wound. The perineum wound was closed primarily with placement of a drain connected to a low-pressure suction, in the pelvic cavity.

In the conventional surgery group open procedures were performed according to the surgeon's established technique, conforming to standard rules for rectal cancer.

Outcomes

Characteristics of the patients, operative variables, and short-term outcomes were analyzed. The patient information including age, gender, premorbid conditions, and previous surgery was reviewed. Operative variables, and short-term outcomes including time to resumption of oral intake, first day to flatus, and duration of hospitalization were analyzed as clinical parameters for study. Pathology reports were reviewed to obtain lymph node harvest data, length of specimen, distance from the closest margin, and margin status. Intra- or post-operative complications were reviewed, and all results were compared with those of conventional rectal resections in the open group.

Statistical analysis

Statistical analysis was performed with Student's t-test and χ^2 test. Results are expressed as mean±SD. A P value less than 0.05 was considered statistically significant.

RESULTS

The patients' characteristics in laparoscopic or open resection group are summarized in Table 1. The two groups were comparable in terms of age, sex, American Society of Anesthesia score (ASA score), pathologic stage and type of resection.

The mean operating time was significantly longer in LAP resection group than in open resection group. The amount of operative blood loss was lower in LAP resection group than in conventional surgery group (Table 2). No patients needed conversion to open surgery in laparoscopic resection group. However, rectum injury was found in two cases with low anterior resection after colon-rectum anastomosis. This was managed by laparoscopic suture closure and pelvic drainage for one week without further sequela. In one patient with heavy smoking history, significantly increased $PaCO_2$ was found after two hours' pneumoperitoneum during the operation, and the patient recovered after deflation of pneumoperitoneum and hyperventilation for a short period of 20 min (Table 3).

Post-operative complications were more frequent in the open resection group than in LAP resection group (5.6% *vs* 27.8%; $P<0.05$).

The passage of flatus occurred earlier in laparoscopic resection group, and oral intake could be started earlier in the LAP resection group ($P<0.05$). Mean postoperative stay was shorter in LAP resection group than in open resection group, but the difference was not significant.

Table 1 Characteristics of patients in two groups

	LAP resection group (*n*=18)	Open resection group (*n*=18)	Difference (*P* value)

Surgical margins	clear	clear	

To assess the adequacy of oncological resection, several parameters were examined from pathology reports. Evaluation of the resected specimens is summarized in Table 4. The mean number of lymph nodes removed in LAP or open resection group was 7.8±1.7 (range, 4-13) and 8.2±2.3 (range, 3-15), respectively. No significant difference was found between the 2 groups. The average lengths of removed specimens with the two surgical procedures were also comparable. Tumor distances from the closest margin were similar too for the two procedures, and were adequate from an oncological standpoint of view. Histological examination revealed that proximal and distal margins were free of tumor in all surgical specimens in both groups.

DISCUSSION

Laparoscopic techniques for colonic resection were described in 1991[1,2], only 4 years after the introduction of laparoscopic cholecystectomy. Compared with conventional open surgery, laparoscopic surgery could offer a faster recovery, minimized postoperative ileums and pain, a shorter stay in hospital and a quicker return to normal activity[9,10]. However, the better appearance was secondary in importance compared with recurrence and survival. Port site metastasis and lack of long-term data in oncological outcome for patients with laparoscopic resection of colorectal cancer are controversial issues.

The main controversies have centered on the oncologic adequacy of laparoscopic resection in comparison with classic open surgery[11]. During laparoscopic resection, the colon and rectum can be mobilized by retraction of the bowel, using endoscopic graspers such as Bablocks, and the peritoneal attachments divided, using ultrasonic or electrocautery scissors. Our experiences show that the rectum can be excised with an intact mesorectal facial envelope all the way down to the level of the pelvic floor. The magnified views obtained deep in the pelvis at laparoscopy may facilitate accurate mesorectal dissection and vegetable nerve protection. Radical *en bloc* excision of the rectum and mesorectum, by low anterior resection or abdomino - perineal, has been the standard treatment for advanced rectal carcinoma[12,13].

Concerning with port-site recurrence, numerous experimental studies have been published since 1991. They have analyzed the possible role of pneumoperitoneum and carbon dioxide[14-20], the pathophysiology of minimally invasive techniques on tumor response and immunity[21,22]. In laparoscopic procedure, the tumor was removed through small incisions[23] in the abdominal wall or perineal, and this maneuver may theoretically lead to a risk of tumor contamination. To avoid port-site metastasis, Balli *et al*.[24] described a routine to follow in colorectal cancer resection: fixation of trocars to the abdominal wall, high vascular ligation, isolation of specimens before extraction from the abdominal cavity, and intraperitoneal and trocar site irrigation with a tumoricidai solution. With improved incision protection techniques, the reported port-site recurrence rate dropped rapidly. Zmora[25] reported a pot-site recurrence rate of 1% in a review of 1737 patients undergone laparoscopic colorectal resection for malignancy. Ramos *et al*.[26] reported abdominal wall metastases in only 3 of 208 patients with a minimum follow-up period of 1 year. All recurrences were in patients with Duke's C-stage carcinoma, and 2 of the 3 were found to have diffuse peritoneal carcinomatosis at the initial surgery. The port-site metastasis has not been a significant issue in the presence of adequate training and laparoscopic skills[27,28].

Moreover, laparoscopic surgery for rectal carcinoma should concern about the safety of the procedure, especially in low anterior resections for lower rectal carcinoma. The anastomotic leak rate reported in a larger series of laparoscopic anterior resection was consistently less than 10%, which was comparable to that of conventional open anterior resection[29,30]. In our present study, no anastamotic leak was found in laparoscopic resection group. However, the risks existed, especially in anterior resections for lower rectal carcinoma. For prevention of leakage, colorectal anastomosis must be tension-free and has a good blood supply. It was our routine to check the anastomosis for leaks in every case for laparoscopic low anterior resection. The pelvis was irrigated and filled with saline and the anastomosis was immersed. Then the rectum was insufflated with air, using a bulb syringe, for observing air bubbles. Pelvic drains were placed during all low anterior, abdominal perineal resections. Some authors have recommended protective ileostomy, and it might be used for low anterior resection in patients with borderline vascular status, malnutrition or neoadjuvant radiotherapy.

The stage I tumors (Duke's A) do not invade beyond the muscularis propria and have no lymph node metastasis. For this reason, stage I tumors have been considered to be the best indication for laparoscopic colectomy, with a very low rate of conversion to laparotomy (0-1%)[31], no port-site metastasis and no deaths were reported at long-term follow-up[32]. Adachi *et al*.[33] found that the mean size of stage I tumors was 2.86 cm and that most tumors <2 cm in size were free of both serosal invasion and lymph node metastasis. In such situations, because of the inability to palpate colonic tumors during laparoscopy, tumor localization must be precisely identified before resection is undertaken. On-table colonscopy at the time of surgery not only leads to prolonged operative time, but also makes further laparoscopic dissection impossible because of colonic distension. It is very helpful to use X-ray imaging at the time of preoperative colonoscopic examination to site small lesions accurately.

The rate of conversion to laparotomy ranged from 1.45% to 48% in literatures with a mean conversion rate of 15%[34,35]. Reasons for conversion to open surgery are difficulty to provide exposure or to identify anatomy because of the larger tumor size and relatively smaller pelvis. Abdominal obesity or presence of adhesions from previous surgery may compound this difficulty. The fixity of the tumor or invasion to adjacent organs at laparoscopy needed to convert to a formal laparotomy in order to complete the planned procedure[35,36]. The preoperative patient evaluation and surgeon's experience are important predictive factors as confirmed in our study.

Laparoscopic colorectal surgery invariably takes longer time than a corresponding open procedure. Again, operating time is reduced with increased laparoscopic experience. Our study also confirmed the low rate of postoperative complications after minimally invasive procedures. Postoperative ileum, urinary retention, and wound infections occurred less frequently than that in the open resection group. These advantages have also been confirmed by many authors[37,38].

Repeated evidences have indicated that a laparoscopic approach in colorectal cancer has several advantages including a shorter hospital stay, less pain, a better appearance and decreased postoperative analgesia requirements. In fact, laparoscopic surgery has been found to be associated with significantly decreased intraoperative blood loss and postoperative complications as well[39,40]. Furthermore, theoretic advantages of less physiologic trauma and immunologic suppression have recently received more attention in the literatures[38,41]. A less intensive inflammatory response has also been demonstrated after laparoscopic surgery compared with conventional open surgery. The results of the present study showed that laparoscopic approaches to rectal carcinoma did not compromise early postoperative recovery.

Advanced rectal tumors accounted for 83.3% of the cases in our study. However, no long-term follow-up has been available at this time. Cammpault[42] reported a 5-year survival rate of 60.7% in colorectal cancer patients with laparoscopic resection, with no difference compared with the open resection (62.5%). Recently, Franklin *et al*. reported the results of laparoscopic colectomy in 50 consecutive patients with stage III colorectal cancer, which was performed at a single hospital. The overall survival rates at 3 and 5 years were 54.5% and 38.5%, respectively, and the cancer-adjusted survival rates were 60.8% and 49%[43].

For low rectal lesions laparoscopy-assisted abdominoperineal resection (28.6% in our series) also allowed earlier postoperative recovery, with an equivalent tumor clearance, morbidity, mortality, disease-free interval, and duration of survival[10].

To date, all reported comparative nonrandomized studies and randomized studies have shown no difference in recurrence and survival rates with laparoscopic versus open colorectal resection, and a lower overall morbidity with laparoscopic procedure[10].

In conclusion, our results suggest that laparoscopic resection for rectal cancer can be performed safely and without compromising oncological principles. There are definitely perioperative advantages with laparoscopic surgery.

Abstract

AIM: To investigate the effects of autoantibodies against β_1-adrenoceptor in hepatitis virus myocarditis on action potential and L-type Ca²⁺ currents.

METHODS: Fifteen samples of autoantibodies against β_1-adrenoceptor positive sera of patients with hepatitis virus myocarditis were obtained and IgGs were purified by octanoic acid extraction. Binding of autoantibodies against β_1-adrenoceptor to guinea pig cardiac myocytes was examined by immunofluorescence. Using the patch clamp technique, the effects on the action potential and I_{Ca-L} of guinea pig cardiac myocytes caused by autoantibodies against β_1-adrenoceptor in the absence and presence of metoprolol were investigated. Cell toxicity was examined by observing cell morphology and permeability of cardiac myocytes to trypan blue.

RESULTS: The specific binding of autoantibodies against β_1-adrenoceptor to guinea pig cardiomyocytes was observed. Autoantibodies against β_1-adrenoceptor diluted at 1:80 prolonged APD_{20}, APD_{50} and APD_{90} by 39.2%, 29.1% and 15.2% respectively, and only by 7.2%, 5.3% and 4.1% correspondingly in the presence of 1 µmol/L metoprolol. Autoantibodies against β_1-adrenoceptor diluted at 1:80, 1:100 and 1:120 significantly increased the I_{Ca-L} peak current amplitude at 0 mV by 55.87±4.39%, 46.33±5.01% and 29.29±4.97% in a concentration-dependent manner. In contrast, after blocking of β_1-adrenoceptors (1 µmol/L metoprolol), autoantibodies against β_1-adrenoceptor diluted at 1:80 induced a slight increase of I_{Ca-L} peak amplitude only by 6.81±1.61%. A large number of cardiac myocytes exposed to high concentrations of autoantibodies against β_1-adrenoceptor (1:80 and 1:100) were turned into rounded cells highly permeable to trypan blue.

CONCLUSION: Autoantibodies against β_1-adrenoceptor may result in arrhythmias and/or impairment of myocardiums in HVM, which would be mediated by the enhancement of I_{Ca-L}.

INTRODUCTION

Viral hepatitis remains a worldwide public health problem[1-4] and is reported by the Chinese Ministry of Public Health as an infectious disease with the highest morbidity and mortality in China. Many complications are considered to be involved in viral hepatitis[5-17]. Hepatitis virus myocarditis (HVM) as a consequence of hepatitis virus infection, secondary to Coxackie virus myocarditis in morbidity in hepatitis virus predominated areas of China, displays severe cardiac manifestations in addition to liver impairment[18]. It was recently found that some cases of severe fulminant hepatitis virus myocarditis were accompanied by arrhythmias and/or cardiac injury. These cases were screened with a high prevalence of circulating autoantibodies against β_1-adrenoceptor (anti-β_1-receptor autoantibodies)[18], which have been recognized in idiopathic dilated cardiomyopathy (DCM) and Chagas' cardiomyopathy[19,20]. Using the patch clamp technique, we examined the effects of anti-β_1-receptor autoantibodies from patients with HVM on the electrophysiological properties of cardiomyocytes so as to find the possible clinical significance of the autoantibodies.

MATERIALS AND METHODS

Samples collection
A peptide was synthesized according to the sequence of β_1-adrenoceptor[21]: H-W-W-R-A-E-S-D-E-A-R-R-C-Y-N-D-P-K-C-C-D-F-V-T-N-R and was used as an antigen in ELISA as described by our laboratory[22] for screening of anti-β_1-receptor autoantibodies in serum samples of patients diagnosed as HVM according to the Chinese diagnostic criteria for adult acute myocarditis approved in 1999[23]. Fifteen serum samples were selected.

Antibody purification
As described by Seddik *et al*.[24], IgGs in anti-β_1-receptor autoantibodies-positive sera of patients with HVM were purified by octanoic acid extraction. The purity of IgGs was over 90%.

Cell preparation
Guinea pig ventricular myocytes were isolated essentially as described by Heubach *et al*[25] with a modification. An adult guinea pig weighing 200-300 g was anesthetized with sodium pentobarbitone (30 mg/kg i.p.), and the trachea was cannulated for artificial respiration. The chest was opened, and the aorta was cannulated *in situ*. The heart was dissected and retrograde perfused on a Langendorff perfusion system at 37 ℃. It was perfused first with Tyrode's solution for about 1 min at a

hydrostatic pressure of 70 cm, second with nominally Ca^{2+}-free Tyrode's solution for 3 min, and subsequently with 0.25 g/L collagenase type I, 0.20 g/L protease type XIV and 0.25 g/L bovine serum albumin for about 5 min. Finally the heart was washed with KB solution for 4 min and the ventricles were cut and teased into pieces in KB solution. All the solutions were bubbled with 1 000 mL/L oxygen. The dissociated cells were then kept in KB solution at room temperature for at least 1 h before the experiment.

Antibody binding

The binding of anti-β_1-receptor autoantibodies was examined by immunofluorescence. The isolated guinea pig cardiac myocytes were fixed by acetone at 4 ℃.The fixed cells were washed three times with cold PBS, incubated with anti-β_1-receptors autoantibody-positive or negative sera which were absorbed by the above peptide sequence (1:10) overnight at 4 ℃, and then washed 3 times in cold PBS, followed by incubation with goat anti-human IgG labeled with FITC (1:90) for 1 h at 37 ℃. After rinsed with PBS, the slides were mounted with cover slips for fluoscopy.

Electrophysiology

Cardiac myocytes were placed in Tyrode's solution and the Ca^{2+} resistant cells adhered to the coverslips of the recording chamber were selected for electrophsiological recording. Action potential and I_{Ca-L} were recorded using the whole-cell configuration of the patch-clamp technique. The cells were held in current-clamp mode or voltage-clamp mode using an Axopatch 200-A amplifier (Axon Instruments, USA). Action potential was elicited by constant current pulses of 1nA amplitude and a 6ms duration at a rate of 0.2 Hz.

In voltage-clamp experiments, the holding potential was set at –80 mV. Na^+ and T-type Ca^{2+} channels were inactivated by applying a 100-ms prepulse to –40 mV immediately before each test pulse. The time course of changes in Ca^{2+} conductance was monitored by applying a 300-ms test pulse to 0 mV once every 5 seconds. For analysis of I-V relationship, after a 100-ms voltage step to –40 mV, 300-ms depolarizing voltage steps from –40 mV to +60 mV in 10 mV increments were used to elicit currents. Data were acquired and analyzed using the ISO2 (MFK, Germany) analysis software package.

Cell toxicity

Cell toxicity was examined by observing cell morphology and the permeability of cardiac myocytes to 20 g/L trypan blue. The live cardiac myocytes were rod-shaped and excluded trypan blue, whereas the dead cells were rounded and permeable to trypan blue.

Reagents

Tyrode's solution contained (mmol/L) NaCl 135, KCl 5.4, $MgCl_2$ 1.0, NaH_2PO_4 0.33, $CaCl_2$ 1.8 ,HEPES 10 and glucose 10 (pH adjusted to 7.4 with NaOH). KB solution contained (mmol/L) $MgCl_2$ 5, KCl 40, KH_2PO_4 20, Taurine 20, Glutamicacid 50, EGTA 0.5, HEPES 10, glucose 10 (pH adjusted to 7.4 with KOH). All the chemicals for the electrophsiological experiment, enzymes and octanoic acid were purchased from Sigma Aldrich Company, USA. Metoprolol was a generous gift from AstraZeneca Company, USA. Goat anti-human IgG labeled with FITC was purchased from Wuhan Yafa Biotech Corp, China.

Statistical analysis

Data were expressed as mean±SEM and analysed using Student's t test. $P < 0.05$ was considered statistically significant.

RESULTS

Specific binding of anti-b_1-receptors autoantibodies to cardiac myocytes

Green fluorescence in rod-shaped cardiac myocytes only in slides incubated with anti-β_1-receptor autoantibodies-positive sera suggested the specific binding of anti-β_1-receptor autoantibodies to cardiac myocytes.

Figure 1 Specific binding of anti-β_1-receptor autoantibodies to guinea pig cardiac myocytes. Rod-shaped cardiac myocytes were stained by immunofluorescence (second IgG labeled with FITC), suggesting the specific binding of anti-β_1-receptor autoantibodies to cardiac myocytes.

Effects of anti-b_1-receptor autoantibodies on action potential in cardiac myocytes in the absence and presence of metoprolol

The effects of anti-β_1-receptor autoantibodies on action potential properties were tested in isolated cardiac myocytes in a current clamp mode of the patch clamp technique. After 5 min with stable action potentials, the antibodies diluted at 1:80 was superfused. The action potential duration (APD) was assessed as a duration to 20%, 50% and 90% repolarization (APD_{20}, APD_{50} and APD_{90}, respectively). Anti-β_1-receptor autoantibodies diluted at 1:80 prolonged the APD in all phases of repolarization, and the increase averaged 39.2%, 29.1% and 15.2% for APD_{20}, APD_{50} and APD_{90} vs control. Thus the plateau was markedly prolonged (Figure 2 and Table 1).

Table 1 Effects of anti-β_1-receptor autoantibodies diluted at 1:80 on action potential phases (n=6)

	Control	Anti-β_1-receptor autoantibodies
APD_{20}(mV)	67.3±1.8	93.7±3.6[b]
APD_{50}(mV)	148.8±5.4	192.1±6.7[b]
APD_{90}(mV)	195.6±8.2	225.3±11.5[b]

[b]$P<0.01$ vs control.

Whereas exposure of cells to anti-β_1-receptor autoantibodies diluted at 1:80 in the presence of 1 μmol/L metoprolol resulted in a slight prolongation of the APD. As in Table 2 shown, the increase averaged only 7.2%, 5.3% and 4.1% for APD_{20}, APD_{50} and APD_{90} vs control ($P<0.01$ vs anti-β_1-receptor autoantibodies diluted at 1:80).

Table 2 Effects of anti-β_1-receptor autoantibodies diluted at 1:80 on action potential phases in the presence of 1 μmol/L metoprolol (n=6)

|	Control	Anti-β_1-receptor autoantibodies and metoprolol
APD_{20}(mV)	65.8±1.1	70.5±2.3
APD_{50}(mV)	147.2±4.6	155.0±6.3
APD_{90}(mV)	196.2±5.1	204.3±9.4

Figure 2 AP recordings before and after superfusion with anti-β₁-receptor diluted at 1:80 in the absence and presence of 1 μmol/L metoprolol. A: effect of anti-β₁-receptor diluted an 1:80 on AP. ᵃrepresents AP before superfusion with 1:80 anti-β₁-receptor autoantibodies, ᵇrepresents AP after superfusion with 1:80 anti-β₁-receptor autoantibodies. B: no marked changes of AP after superfusion with 1:80 anti-β₁-receptor autoantibodies in the presence of 1 μmol/L metoprolol.

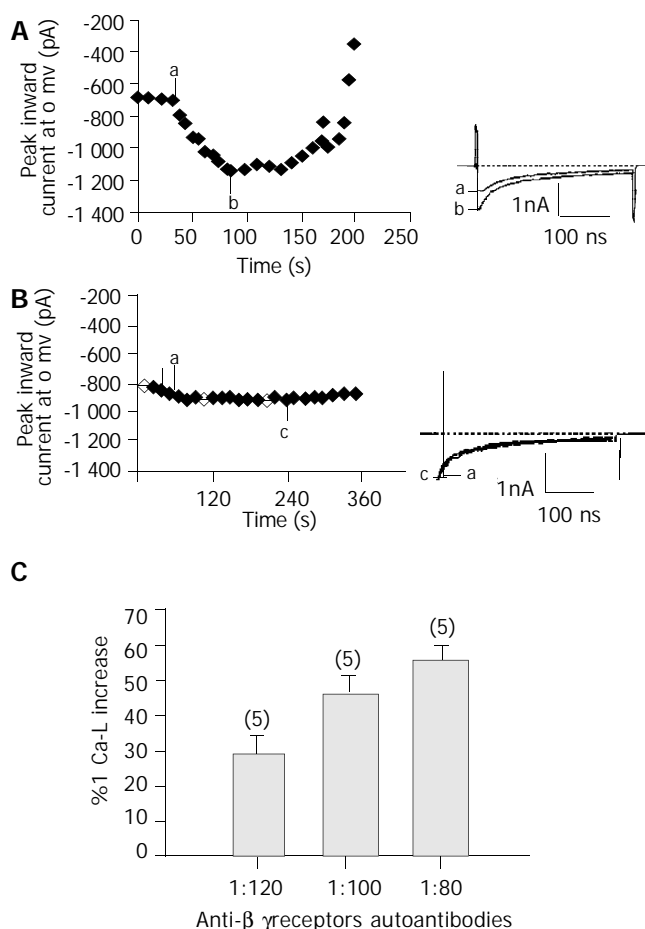

Figure 3 Effects of anti-β₁-receptor autoantibodies on peak current amplitude of I_{Ca-L} in the absence and presence of 1 μmol/L metoprolol. A and B (left): time-course changes of peak current amplitude of I_{Ca-L} before and after superfusion with anti-β₁-receptor autoantibodies diluted at 1:80 (A) or in the presence of 1 μmol/L metoprolol (B). A and B (right): traces of I_{Ca-L} before and after superfusion with anti-β₁-receptor autoantibodies diluted at 1:80 (A) or before and after superfusion with anti-β₁-receptor autoantibodies diluted an 1:80 in the presence of 1 μmol/L metoprolol (B). ᵃrepresents the maximal peak current amplitude of I_{Ca-L} before superfusion with anti-β₁-receptor autoantibodies diluted at 1:80, ᵇrepresents the maximal peak current amplitude of I_{Ca-L} after superfusion with anti-β₁-receptor autoantibodies diluted an 1:80. ᶜrepresents the maximal peak current amplitude of I_{Ca-L} after superfusion with anti-β₁-receptor autoantibodies diluted at 1:80 in the presence of 1 μmol/L metoprolol. C: concentration dependence of anti-β₁-receptor autoantibodies. The numbers in brackets indicate the number of cells studied at each concentration.

Effects of anti-*b*₁-receptor autoantibodies on I_{Ca-L} channels in the absence and presence of metoprolol

As described above, anti-β₁-receptor autoantibodies markedly prolonged the plateau, suggesting the antibodies might enhance I_{Ca-L}. We investigated the effect in the voltage clamp mode. Basal I_{Ca-L} was recorded 5-6 min after the cell membrane rupture, when I_{Ca-L} was stable. Exposure of cells to anti-β₁-receptors diluted at 1:80 led to a significant increase of the amplitude of I_{Ca-L}, as the time course of changes (Figure 3 A left) and the current traces of I_{Ca-L} (Figure 3 A right) illustrated. The enhancement of I_{Ca-L} was rapid, and generally 20-30 s were sufficient for the full effect of the antibodies to take place. The rapid run–down of I_{Ca-L} followed after around 1 min. In light microscopy, the clamped cells were observed contracting and deteriorating. Beyond this dilution, the potentiating effect of the antibodies on I_{Ca-L} was too large to make effective voltage control. In 5 cells, anti-β₁-receptor autoantibodies diluted at 1:80 caused an increase of 55.87±4.39% in the basal current ($P<0.01$ *vs* control), and the enhancement of I_{Ca-L} was in a concentration-dependent manner (Figure 3C).

I_{Ca-L} was recorded longer in cells exposed to anti-β₁-receptor autoantibodies diluted at 1:80 in the presence of 1 μmol/L metoprolol than that in the absence of metoprolol, with a slight increase of 6.81±1.61% ($P<0.01$ *vs* anti-β₁-receptor autoantibodies diluted at 1:80) (Figure 3B).

We also investigated the current-voltage (I-V) relationship by addition of anti-β₁-receptor autoantibodies in the absence and presence of metoprolol. Without shifting the *I*-V relationship, the antibodies caused a marked increase of current densities of I_{Ca-L}, whereas in the presence of 1 μmol/L metoprolol, a slight increase was found at positive and negative potentials (Figure 4).

Overall, these results indicated that anti-β₁-receptor autoantibodies could enhance I_{Ca-L} as agonists for β₁-adrenoceptors.

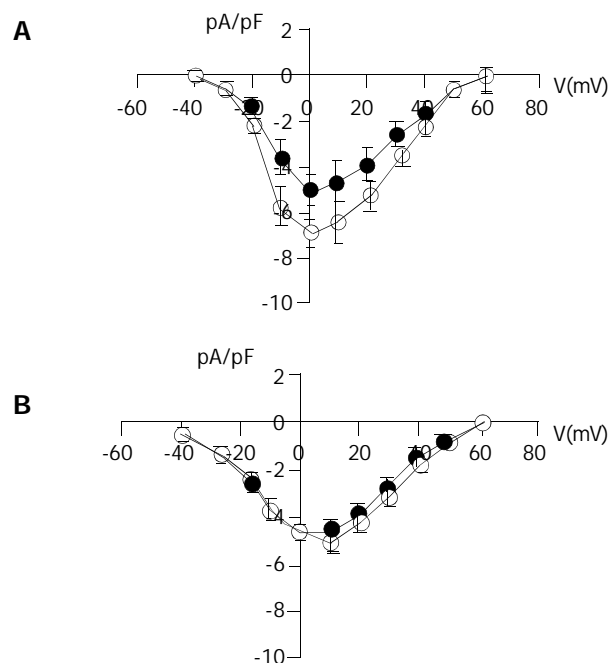

Figure 4 Effects of anti-β₁-receptor autoantibodies diluted at 1:100 on current-voltage (I-V) relationships normalized to cell membrane capacitance measured in 5 cells (mean±SEM) during voltage steps from –40 to +60 mV in the absence (A) and presence of 1 μmol/L metoprolol (B).

Cell toxicity effect

A large number of cardiac myocytes were exposed to high

concentrations (1:80 and 1:100) of anti-β_1-receptor autoantibodies. Approximately over 90% rod–shaped cells with regular striation excluding trypan blue were turned into rounded cells highly permeable to the dye within 2 min (Figure 5).

Figure 5 Cell toxicity effect of cardiac myocytes exposed to high concentrations of anti-β_1-receptors autoantibodies. A: rod-shaped cells excluding trypan blue. B: rounded cells permeable to trypan blue.

DISCUSSION

It was documented that there was a high homology between mouse hepatitis virus and β_1-adrenoceptors[26]. Therefore, autoimmune response directed against β_1- adrenoceptors can be initiated by cross reaction between these two molecules. In our clinical investigation, we found that the positive rate of hepatic virus antibodies and anti-β_1-receptor autoantibodies was highly consistent in patients with HVM[18]. Photomicrographs of guinea pig cardiac myocytes treated with anti-β_1-receptor autoantibodies before and after absorbed by the peptide sequence of β_1-adrenoceptor epitope and subsequently a fluorescently-tagged second antibody revealed the specific binding of autoantibodies in HVM to cardiac myocytes.

In heart diseases, interaction between catecholamine and β_1-receptors could result in various arrhythmias especially tachycardia and was the main cause of sudden death[27-29]. Based on our study, anti-β_1-receptor autoantibodies in HVM, as isoprenaline-like agonists for β_1-adrenoceptors were able to prolong the plateau of APD and enhance the Ca^{2+} permeability of cardiac myocytes via L-type Ca^{2+} channel, which triggers early after depolarization (EAD).

Ca^{2+} disorder was considered to be associated with myocarditis and cardiomyopathy[30]. It was reported anti-β_1-receptor autoantibodies in DCM could display a positive chronotropic effect on cultured neonatal rat ventricular cells without desensitization, thus increasing the metabolic pressure of myocardial cells[31], which was further demonstrated to be mediated by I_{ca-L}[32]. The time-course changes of I_{ca-L} in the presence of anti-β_1-receptor autoantibodies in HVM might reflect the process of the impairment of cardiac myocytes. About one minute after reaching the maximal peak value within 20-30s, I_{Ca-L} was observed running down and accompanied by

the clamped cells contracting and deteriorating in the presence of anti-β_1-receptor autoantibodies diluted at 1:80. Whereas I_{Ca-L} was recorded longer in cells exposed to anti-β_1-receptor autoantibodies diluted at 1:80 in the presence of 1 μmol/L metoprolol. Furthermore, cell toxicity was observed by cell morphology and the permeability of cells to trypan blue. Rod-shaped cardiac myocytes exposed to high concentrations (1:80 and 1:100) of the antibodies were turned into rounded cells highly permeable to trypan blue. The overall influx of I_{Ca-L} caused by anti-β_1-receptor autoantibodies in HVM triggered electrophysiological and biochemical changes of cardiac myocytes and β_1- adrenoceptor blocker (metoprolol) could inhibit these effects. These results may in fact contribute to the proper explanation of the findings in our clinical investigation. The clinical investigation indicated that myocardial injury of patients with positive anti-β_1-receptor autoantibodies was more severe than that of patients with negative anti-β_1-receptor autoantibodies. Some arrhythmias such as sinus tachycardia or ventricular arrhythmias were associated with anti-β_1-receptor autoantibodies. These patients benefited from the use of β_1- adrenoceptor blocker[18].

In conclusion, autoantibodies against β_1-adrenoceptors can result in arrhythmias and/or the impairment of myocardiums in HVM, which would be mediated by the enhancement of I_{Ca-L}. As a basic research, our investigation would help to give early diagnosis by examining the presence of autoantibodies against β_1-adrenoceptor and beneficial treatment by properly utilizing selective β_1- adrenoceptor blocker for hepatitis virus myocarditis.

Abstract

AIM: To study the inhibitory effect of oxymatrine on serum hepatitis B virus (HBV) DNA in HBV transgenic mice.

METHODS: HBV transgenic mice model was established by microinjection, and identified by HBV DNA integration and replication. Transgenic mice with replicating HBV were divided into 3 groups, and injected with normal saline (group A, $n=9$), 50 mg/kg (group B, $n=8$) and 100 mg/kg (group C, $n=9$) oxymatrine intraperitoneally once a day for 30 d, respectively. Quantitation of serum HBV DNA in HBV transgenic mice was performed by competitive polymerase chain reaction (PCR) in combination with DNA hybridization quantitative detection technique before and after treatment.

RESULTS: Compared with pre-treatment, the serum HBV DNA in group A ($F=1.04$, $P=0.9612$) and group B ($F=1.13$, $P=0.8739$) had no changes after treatment. However, in group C serum HBV DNA was significantly decreased ($F=13.97$, $P=0.0012$). The serum HBV DNA after treatment was lower in group C than in groups B and A ($F=8.65$, $P=0.0068$; $F=12.35$, $P=0.0018$; respectively). The serum HBV DNA after treatment was lower in group B than in group A, but there was no statistical significance ($F=1.43$, $P=0.652$).

CONCLUSION: Oxymatrine has inhibitory effects on serum HBV DNA in HBV transgenic mice.

INTRODUCTION

Hepatitis B virus (HBV) infection is a major cause of chronic hepatitis, cirrhosis, and hepatocellular cancer and accounts for 1 million deaths annually. Information on the virus load and the replicative activity of HBV is of paramount importance in the management of patients with chronic HBV infection, because of recent advances in medications which can effectively suppress HBV replication by using nucleoside analogues, interferon and other drugs[1-8]. Serological parameters include the levels of hepatitis B e antigen (HbeAg), DNA polymerase, HBV DNA measured by qualitative methods such as PCR or semi-quantitative dot blot hybridization, and HBV DNA quantitation by solution hybridization. The direct and quantitative nature of HBV DNA quantitation by solution hybridization makes it a useful clinical test to monitor serially the efficacy of antiviral therapy[9-15].

The aim of chronic hepatitis B treatment is to control infectivity, eradicate the virus and prevent the development of cirrhosis. However, permanent loss of HBeAg and HBV DNA is unusual and HBsAg persistently presents. For many years, alpha interferon was the only approved therapy for chronic HBV infection in most countries around the world. Interferon is effective in only 30-40% patients. It must be given by injection and is frequently associated with fever and flu-like symptoms[1-3]. Recently, lamivudine was approved for the treatment of chronic HBV infection in many regions of the world[1]. Although convenient and well-tolerated, lamivudine's efficacy is similar to that of interferon and prolonged administration of lamivudine is associated with development of resistance[6]. New agents, such as adefovir dipivoxil, offer promising effects when used either alone or in combination with lamivudine in the treatment of individuals who are ' treatment naï ve' or have developed lamivudine resistance[3,6]. Up to now, there is no specific therapy available for chronic hepatitis B. Therefore, the search continues for more efficacious treatments.

Many basic and clinical studies have revealed that oxymatrine has anti-hepatitis B virus effect, but the mechanism is unclear[16-20]. The hosts of HBV are very scarce, and *ex vivo* culture of HBV is very difficult, thus limiting the study on HBV and its related diseases. Since 1985, a variety of HBV transgenic mice have come out in succession, providing a new approach to study the mechanism and treatment methods of HBV and its related diseases[21-26]. Serum HBV DNA in transgenic mice was quantitated by competitive polymerase chain reaction (PCR) in combination with DNA hybridization technique in this study to assess the anti-HBV effect of oxymatrine, and to provide an important experimental basis for its clinical application.

MATERIALS AND METHODS

Plasmid P1.0 HBV was donated by Professor Xiang-Fu Wu (Institute of Biochemistry, Chinese Academy of Sciences). The complete genome (3.2 kb) of adr-type HBV was cloned at the *BamH1* site in PUC18 vector. ICR mice aged 8 wk were bought from Animal Center of Yangzhou University, raised in depurated animal rooms. Transgenic HBV mice obtained from Dr. Cheng Yong (Yangzhou University, Jiangsu Province) were used.

Detection of HBV integration in transgenic mice

Genomic DNA was extracted from the tails of HBV transgenic mice (about 1.0-1.5 cm) at age of 4 wk[25]. The sequences of PCR primers were 5' -AGAGTCTAGACTCGTGGTGGACTT-3' and 5' -TACGAACCACTGAACAAATGGCAC-3' . The amplified segment was in the region of 470 bp HBc DNA. PCR reaction mixture containing 5 µL 10×buffer (0.5 mol/L KCl, 0.1 mol/L

Tris-HCl pH8.3, 0.015 mol/L MgCl₂, 0.1 g/L glutin), 35 μL sterilized water, 5 μL 2 mmol/L dNTP, and 2 mL primers 1 and 2, was heated for 10 min at 95 ℃ to denature DNA. A 1 μL of Taq DNA polymerase was added to the mixture, which was overlaid with 50 μL of light mineral oil. The amplification reaction was run for 35 cycles as follows: denaturing at 93 ℃ for 60 s, annealing at 60 ℃ for 45 s, and extension at 72 ℃ for 1 min. A 5 μL amplification product was loaded into agarose gel for electrophoresis.

Identification of HBV expression in transgenic mice

The experimental procedures followed the instructions in the kit of Amplicor HBV monitor (Roche Diagnostic Systems, Inc.). Blood from positive HBV transgenic mice was collected and the serum was separated. Internal control was added to standard and samples. PCR was performed on HBV DNA extracted from serum. The sequences of primers were 5'-GTTGCCCGTTTGTCCTCTAC-3', and 5'-biotin-GATGATGTGGTATTGGGGGC-3'. The reaction mixture was heated for 5 min at 94 ℃ to denature DNA, then amplification was carried out 30 cycles: denaturing at 94 ℃ for 30 s, annealing at 57 ℃ for 30 s, and extension at 72 ℃ for 45 s, plus a final extension at 72 ℃ for 5 min. The amplification product was separated by agarose gel electrophoresis, identified and quantitateded by hybridization.

Quantitation by enzyme linked hybridization in microwell plate

The experiments were performed according to the instructions of the Amplicor HBV monitor kit.

The common probe (MXH2) was diluted with binding buffer. The sequence of the probe was 3'-AGCGTCCAGTCGTCGTTACAC-5' (500 nmol/L). A 50 μL of the diluted probe was added to each well in two DNA microwell plates and incubated at 37 ℃ for 2 h.

Pre-hybridization

The solution in the well was discarded, 50 μL wild segment capture probe diluted by 1×hybridization solution was added to each well of one plate. The sequence of the probe was 5' -TCGCAGGTCAGCAGCATGTGACATCAACTACCAGCACG-3' (500 nmol/L). Fifty μL mutation primer diluted by 1×hybridization solution was added to each well of the other plate. The sequence of the probe was 5' -GTTGCCCGTTTGTCCTCTACATCACACAAAGATCTACGTCGACGCAGGACCATGCAAGACCT-3' (500 nmol/L). The plate was incubated at 55 ℃ for 60 min, and then the solution was discarded. The plate was dried and washed twice with solution I.

Hybridization

The PCR products were diluted 10 times with distilled water, heated for 5 min at 100 ℃ to denature the DNA, then placed on ice immediately. One volume 2×hybridization solution was added to the product and 50 μL was added to the well. They were incubated at 48 ℃ for 60 min. The wells were washed three times with solution I at 48 ℃ for 3 min each. The solution was discarded and the plate was dried.

Signal assay

A 50 μL 1:1 000 diluted streptavidin-ALP complex was added to each well and incubated at 37 ℃ for 20 min. They were then washed four times for 4 min at 37 ℃ with solution II, dried, and stained with the substrate (p-nitrooheno-sodium phosphate). Absorbance was read at 405 nm after 2 h.

Effect of oxymatrine on HBV transgenic mice

Twenty-six transgenic mice aged 8-12 wk (either sexes) were divided into 3 groups, and injected with normal saline (group A, *n*=9), 50 mg/kg (group B, *n*=8) and 100 mg/kg (group C, *n*=9) oxymatrine intraperitoneally once a day for 30 d, respectively. Serum HBV DNA in HBV transgenic mice was detected by competitive polymerase chain reaction (PCR) in combination with DNA hybridization quantitative detection technique before and after treatment.

Statistical analysis

All the data were analyzed by SAS software. ANOVA was used to evaluate the significance of the quantity of serum HBV DNA. $P<0.05$ was considered statistically significant.

RESULTS

HBV DNA integration and replication in transgenic mice

Among the 396 transgenic mice, 137 had HBV DNA integration (34.59%), and 26 had HBV replication in serum (6.56%).

The results of HBV DNA quantitation in transgenic mice before and after oxymatrine treatment are summarized in Table 1.

The results showed that there was no significant difference in HBV DNA quantity before treatment among the three groups. Compared with before treatment, there was no change in HBV DNA quantity in group A (F=1.04, P=0.9612). HBV DNA quantity was decreased in group B (F=1.13, P=0.8739), and was significantly decreased in group C (F=13.97, P=0.0012) after treatment. The level of HBV DNA was significantly lower in group C than in groups A (F=12.35, P=0.0018) and B (F=8.65, P=0.0068). HBV DNA quantity of group B after treatment was lower than that of group A, but there was no statistical difference (F=1.43, P=0.652).

DISCUSSION

With the advent of embryo microinjection technology, it was clear that many questions related to HBV infection might be directly examined by introduction of a partial or complete copy of HBV genome into transgenic mice. Several lines of HBV-transgenic mice have been prepared by introducing either the full HBV genome, or a partial or selected portion of HBV genome into an inbred strain of mice. The successful estalishment of HBV-transgenic mice model and the expression of HBV gene products have shown that mice might be a host for the expression of HBV-related products. The characteristics of HBV infection in HBV transgenic mice have shown its potential utility as a model for study of anti-HBV drugs[22-24,27-35]. HBV transgenic mice were generated by microinjection, our results revealed that HBV genome was integrated in the genome of mice and expressed effectively. It proved that we could obtain mice bearing complete HBV genomes. In the 396 transgenic mice, 137 had HBV DNA integration (34.59%), and 26 had HBV replication in serum (6.56%). The existence of HBV DNA in serum demonstrated that there was HBV gene replication in mice[28,30,34,35].

Anti-HBV therapy of hepatitis B is still a difficult problem. Even the generally known drugs such as a-IFN and lamivudine have limitations such as low rate of HBV negativity, high price, side effects and virus variation. So it has become urgent to find new and effective anti--HBV drugs[1-3]. Oxymatrine has been found to be a kind of alkaloid extracted from a Chinese herb *Sophora alopecuraides L.*[20,36]. Basic and clinical researches have shown that oxymatrine has the following pharmacological effects: antivirus, protecting hepatocytes, antihepatic fibrosis, and immune regulation[37-41]. In particular, its inhibitory effect on hepatitis B virus (HBV) has attracted wide attention in recent years. Oxymatrine has been proven to have distinct anti-virus effects in the treatment of chronic hepatitis B (CHB)[16-20].

In vivo experiment indicated that oxymatrine could inhibit HBsAg and HBeAg secretion from HBV DNA transinfected cell strain 2.2.15. In a certain range, with increased concentration and reaction time, the inhibitory rate increased gradually. Given the same concentration and reaction time, the inhibitory rate on HBsAg appeared to be higher than that on HBeAg[42]. In an *in vivo* study on transgenic mice, the mice were injected intraperitoneally with 100 mg/kg, 200 mg/kg and 300 mg/kg oxymatrine everyday for 30 d. The amount of HBsAg and HBeAg decreased significantly compared with control group, and there was no difference among the treatment groups[19,42]. A clinical research suggested that when oxymatrine was applied to treat chronic hepatitis B, the normalization rates of serum ALT and TB, and the negative conversion rates of serum HBsAg and HBV DNA were similar to those with alpha interferon [42].

The amount of HBV DNA reflected the level of HBV replication directly. In this study we observed the effect of oxymatrine (50 mg/kg, 100 mg/kg) on HBV transgenic mice, and oxymatrine in both concentrations could inhibit the replication of HBV DNA. The results indicate that oxymatrine has inhibitory effects on the *in vivo* replication of HBV DNA. We still need to further explore how oxymatrine inhibits HBV DNA replication.

Abstract

AIM: The evidence for an association between *Helicobacter pylori* (*H pylori*) and gastroesophageal reflux disease, either in non- erosive (NERD) or erosive esophagitis (ERD) remains uncertain. The available data on the histological changes in NERD and the effect on *H pylori* infection on them are elusive. The aim of this study therefore was to prospectively evaluate the histological findings and the impact of *H pylori* infection on a group of symptomatic patients with NERD.

METHODS: Fifty consecutive patients were prospectively evaluated for symptoms compatible with GORD. In all cases, routine endoscopy and lugol directed biopsies were performed and assessed histologically in a blinded manner.

RESULTS: The overall prevalence of *H pylori* infection was 70%. Twenty-nine patients out of 50 (58%) were NERD patients. No statistical significance was observed between the *H pylori* status and NERD. The remaining 21 (42%) were diagnosed as follows: 13 (26%), 6 (12%), 2(4%) with esophagitis grade A, B and C respectively. A statistically significant correlation was observed between the *H pylori*+ and esophagitis grade A, as well as between *H pylori*- and grade B. Biopsies from 2 patients were not included because of insufficient materials. Histologically, a basal zone hyperplasia was found in 47 (97.91%) patients, alterations of glycogen content in 47 (97.91%), papillae elongation in 33 (68.75%), blood vessels dilatation in 35(72.91%), chronic inflammation in 21 (43.75%), infiltration with eosinophils, neutophils and T-lymphocytes in 4 (8.33%), 6 (12.5%) and 39 (81.25%) respectively. No correlation was observed between the *H pylori* status and the histological parameters studied either in NERD or GERD.

CONCLUSION: Histological assessment can not differentiate symptomatic patients with erosive versus non-erosive reflux disease. Moreover, *H pylori* infection may not act as an important factor in patients with NERD.

INTRODUCTION

Helicobacter pylori (*H pylori*) is a prevalent pathogenetic factor associated with ulceration, dyspepsia, and adenocarcinoma[1,2]. The role of *H pylori* in gastroesophageal reflux disease (GORD) has only recently received attention, with the evidence for an association between *H pylori* and GORD remaining uncertain[3]. Diminution of peptic ulcer disease and adenocarcinoma of the distal stomach have paralleled the decreasing prevalence of *H pylori* infections in the developed world. At the same time, there has been an increase in GORD, Barrett's esophagus, and adenocarcinoma of the distal esophagus and proximal stomach, suggesting that *H pylori* protects against these esophageal diseases[4,5].

Adequate assessment of reflux esophagitis has proved difficult to be assessed by endoscopy only, as the endoscopic appearance of the esophageal mucosa may be normal despite the presence of reflux symptoms[6,7]. Non-erosive gastroesophageal reflux disease (NERD) is the most common diagnosis in patients with reflux symptoms when organic diseases such as ulcers, esophageal erosions, and carcinomas, have been excluded by esophagogastroduodenoscopy[8].

Histological abnormalities have been described in GORD[6,8-11], and hence it seems reasonable to diagnose non-erosive reflux disease by simple esophageal biopsies during endoscopy. These mild histological findings are mainly basal zone thickening, elongated papillae, alterations in intracellular glycogen content, infiltration with neutrophils, eosinoiphils and T-lymphocytes, and submucosal blood vessel dilatation[6,8,9]. However, the available data on the diagnostic value of these histological criteria are contradictory[9]. This study therefore evaluated prospectively the histological findings and the impact of *H pylori* infection in a group of symptomatic patients with erosive and non- erosive reflux disease.

MATERIALS AND METHODS

Patients

Fifty patients (29 men, 21 women; mean age 49.9 years) were evaluated prospectively in our endoscopic unit for symptoms compatible with GORD, namely heartburn, acid regurgitation, and/or epigastric pain. A standardized questionnaire was completed for each patient during an interview with an experienced gastroenterologist. Demographic details of the GORD patients were recorded, including age, sex, smoking and drinking habits, tea and coffee consumption, and concurrent medical conditions including hypertension and diabetes mellitus. None of the patients included in this study had a

current or past history of peptic ulcer disease, previous gastric surgery or anti-*Helicobacter* therapy, or use of proton pump inhibitors, NSAIDs, steroids, or tetracycline during the past 4 wk. Ethics approval was obtained from the Ethics Committee of the University Hospital of Alexandroupolis, and patients gave their informed signed consent for biopsy specimens to be taken.

Methods

A routine endoscopy was performed by the same endoscopist on all patients using an (GIF-Q145) Olympus flexible endoscope. The distance between the esophagogastric junction and the incisor teeth was recorded. Reflux esophagitis was graded in accordance with the Los Angeles classification[12]. *H pylori* status was determined by the rapid urease test and histological examination of biopsies taken from the antrum and the corpus[13,14].

At least 4 biopsy specimens were taken 3 cm above the lower esophageal splinchter with Olympus biopsy forceps in a cross-fashion manner. In order to improve endoscopic visualization and provide biopsy orientation, 20 mL of 20 mg/L potassium iodine's solution (Lugol) was applied through a "spray" catheter[15-17]. To obtain sufficient material and to ensure an almost vertical pinch biopsy specimen, the opened forceps were withdrawn towards the tip of the scope, which was bent towards maximally, and hence the forceps were pressed vertically against the esophageal wall. Specimens were fixed in 40 g/L formaldehyde[8]. When all sections had been selected they were assessed histologicallly in a blinded manner (without endoscopic or clinical information). A standardized report completed by the histopathologist comprised an evaluation of the following histological parameters: basal zone hyperplasia, papillary length, dilatation of intraepithelial blood vessels, and semiquantitative cellular infiltration with T-lymphocytes, neutrophils, eosinophils. Alterations of glycogen content, erosion, ulceration and chronic inflammation were also assessed[6,8-11].

Statistical analysis

Statistical analysis was performed using SPSS (version 11.0 for Windows) on data from all 50 patients. The analysis was based on demographic characteristics, such as age, sex, and presence of *H pylori* infection, as well as endoscopic and histological findings. Differences in the distribution of the variables of interest between subgroups of patients were examined by Pearson chi-square test or Fisher's exact test (the latter when small frequencies were present). Comparison between proportions in 2 independent groups was performed with the z-test statistic. *P*-values less than 0.05 were considered significant.

RESULTS

The relationship between endoscopic findings and the presence (*H pylori*+) or absence (*H pylori*-) of *H pylori* infection is shown in Figure 1.

The overall prevalence of *H pylori*+ was 70% (35 out of 50 patients). A normal appearance of esophageal mucosa (non-erosive esophagitis) was observed in 29 out of 50 (58%) patients. No statistical significance was observed between *H pylori*+ and NERD patients [*H pylori* + in 20 out of 35 (57.1%) *vs H pylori* - in 9 out of 15 (60%) patients *P*>0.05]. The remaining 21 (42%) patients with erosive esophagitis were diagnosed as follows: 13 (26%), 6 (12%) and 2 (4%) with esophagitis grades A, B and C respectively. None of the patients in our series suffered from esophagitis grade D. A statistically significant correlation was observed between the *H pylori*+ and esophagitis grade A [*H pylori*+ in 11 out of 35 (31.4%) *vs H pylori*- in 2 out of 15 (13.3%) patients, *P*<0.05]. Similarly, a statistical difference was observed in the group of patients with esophagitis grade B [*H pylori*+ in 2 out of 35 (5.7%) *vs H pylori*- in 4 out of 15 (26.7%) patients, *P*<0.05].

Figure 2 summarizes the distribution of patients according to biopsy findings and the existence of *H pylori*. Biopsies from 2 patients were not included because of insufficient materials. No difference was observed between the 2 variables of interest. As expected, the majority of patients examined (46 of 48, 95.8%) were diagnosed histologically as having esophagitis, despite the esophageal mucosa appearing normal under endoscopy.

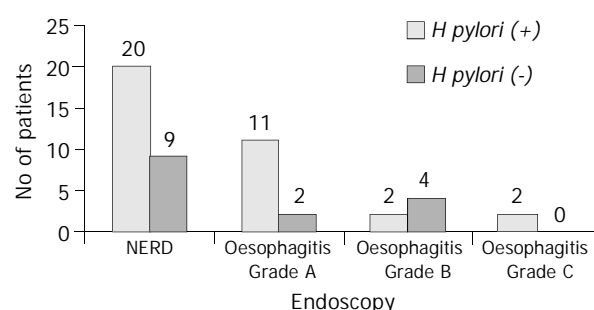

Figure 1 Findings at endoscopy. Note: *H pylori* (+): *Helicobacter pylori* positive patients; *H pylori* (-): *Helicobacter pylori* negative patients.

Figure 2 Findings at biopsy. *H pylori* (+): *Helicobacter pylori* positive patients, *H pylori* (-): *Helicobacter pylori* negative patients.

Table 1 Correlation of *H pylori* infection with the histological parameters esophagitis in NERD and GERD

Histological parameters	Total (*n*) of patients	NERD		ERD		*P*
		Patients (*n*) (%)	*H pylori* (+) (%)	Patients (*n*) (%)	*H pylori* (+) (%)	
Basal zone hyperplasia	47	28 (59.6)	19 (67.9)	19 (40.4)	14 (73.7)	0.462
Loss of glycogen	47	28 (59.6)	19 (67.9)	19 (40.4)	14 (73.7)	0.462
Papillae elongation	33	18 (54.4)	11 (61.1)	15 (45.6)	11 (73.3)	0.357
Blood vessels dilatation	35	20 (57.1)	15 (75.0)	15 (42.9)	12 (80.0)	0.527
Oesinophils infiltration	4	2 (50.0)	1 (50.0)	2 (50.0)	2 (100.0)	0.500
Neutrophils infiltration	6	2 (33.3)	1 (50.0)	4 (66.7)	3 (75.0)	0.600
T-lymphocytes infiltration	39	24 (61.5)	17 (70.8)	15 (38.5)	11 (73.3)	0.582
Chronic inflammation	21	13 (61.9)	10 (76.9)	8 (38.1)	5 (62.5)	0.410

Finally, Table 1 outlines the histological parameters of esophagitis with the presence or absence of erosions during endoscopy. We focused on patients with *H pylori* infection. No statistically significant difference was observed between *H pylori* (+) patients with erosive (ERD) and non-erosive esophagitis (NERD) for any of the histological parameters examined (*P* values refer to the numbers in italics).

DISCUSSION

This study investigated the impact of *H pylori* infection on the histological changes of non-erosive esophagitis. Our study was performed prospectively in a series of 50 patients with reflux symptoms. Esophageal erosions were found during endoscopy in 21 of these patients. The overall prevalence of *H pylori*+ was 70% (erosive: 15/21, 71.5%; non-erosive: 20/29, 68.9%). As expected, histological changes were noted in the majority of biopsies (95.8%) despite a normal appearance of esophageal mucosa under endoscopy in half of the cases.

In the group of patients with erosive esophagitis, *H pylori*+ was correlated with grade A esophagitis, whereas *H pylori*- was correlated with grade B disease. This probably indicates that *H pylori*- is a risk factor for ERD and aggravates the endoscopic appearance. This finding of a close association between *H pylori*+ and less serious endoscopic findings is consistent with other studies[14,18-21]. Some studies have found an inverse relation between *H pylori* and esophagitis, once *H pylori* has been eradicated[22,23]. In our series no patient had previously received eradication therapy. Furthermore, we confirmed previous findings that *H pylori* infection was not associated with positive or negative esophagitis findings in biopsies[24,25].

In the second group of patients (those with non-erosive esophagitis), no correlation was observed between the *H pylori*+ and the histological parameters studied. Little is known about the relationship between *H pylori* infection and the histological variables in non-erosive esophagitis. The fact that there appears to be no correlation between the *H pylori*+ and any of the aforementioned mild changes probably implies that these are provoked by mechanisms other than *H pylori* infection[26,27] (perhaps acid or bile reflux).

In conclusion, *H pylori* probably plays a statistically unimportant role in the histological changes seen in patients with non-erosive reflux disease, since similar histological alterations were detected in biopsies of both erosive and non-erosive esophagitis. Further research is required to identify other pathogenetic factors responsible for the histological parameters found in this group of patients.

Abstract

AIM: To construct a prokaryotic expression system of a *Helicobacter pylori* (*H pylori*) *cagA* gene fragment and establish enzyme-linked immunosorbent assays (ELISA) for detecting CagA and its antibody, so as to understand the manner in which the infection of CagA-expressing *H pylori* (CagA⁺ *H pylori*) isolates cause diseases.

METHODS: *H pylori* strains in gastric biopsy specimens from 156 patients with positive results in rapid urease test were isolated. PCR was used to detect the frequency of *cagA* gene in the 109 *H pylori* isolates and to amplify a 2 148-bp fragment (*cagA*1) of *cagA* gene from a clinical strain Y06. A prokaryotic expression system of *cagA*1 gene was constructed, and the expression of the target recombinant protein (rCagA1) was examined by SDS-PAGE. Western blotting and immunodiffusion assay were employed to determine the immunoreactivity and antigenicity of rCagA1, respectively. Two ELISAs were established to detect CagA expression in 109 *H pylori* isolates and the presence of CagA antibody in the corresponding patients' sera, and the correlations between infection with CagA⁺ *H pylori* and gastritis as well as peptic ulcer were analyzed.

RESULTS: Of all the clinical specimens obtained, 80.8% (126/156) were found to have *H pylori* isolates and 97.2% of the isolates (106/109) were positive for *cagA* gene. In comparison with the reported data, the cloned *cagA*1 fragment possessed 94.83% and 93.30% homologies with the nucleotide and putative amino acid sequences, respectively. The output of rCagA1 produced by the constructed recombinant prokaryotic expression system was approximately 30% of the total bacterial protein. rCagA1 was able to bind to the commercial antibody against the whole-cells of *H pylori* and to induce the immunized rabbits to produce antibody with an immunodiffusion titer of 1:4. A proportion as high as 92.6% of the *H pylori* isolates (101/109) expressed CagA and 88.1% of the patients' serum samples (96/109) were CagA antibody-positive. The percentage of

CagA⁺ *H pylori* strains (97.9%) isolated from the biopsy specimens of peptic ulcer appeared to be higher than that from gastritis (88.5%), but the difference was not statistically significant ($\chi^2=3.48$, $P>0.05$).

CONCLUSION: rCagA1 produced by the prokaryotic expression system constructed in this study possesses good immunoreactivity and antigenicity, and the established ELISAs can be used to detect CagA of *H pylori* and its antibody. *H pylori* isolates show high frequencies of *cagA* gene and CagA expression, but the infections by CagA⁺ *H pylori* strains are not the most decisive factors to cause gastric diseases.

INTRODUCTION

In China, gastritis and peptic ulcer are the most prevalent gastric diseases, and gastric cancer remains one of the most devastating malignant tumors with the highest morbidity[1-20]. *Helicobacter pylori* (*H pylori*) has been recognized as a human-specific gastric pathogen that colonizes in the stomach of at least half of the world's populations[21, 22]. Most infected individuals are asymptomatic, whereas in some cases, the infection causes acute, chronic gastritis or peptic ulceration, and plays an important role in the development of peptic ulcer and gastric adenocarcinoma, mucosa-associated lymphoid tissue (MALT) lymphoma and primary gastric non-Hodgkin's lymphoma[23-28].

So far, no evidence for the toxicity of the protein (CagA) expressed by cytotoxin-associated gene A (*cagA*) of *H pylori* has been presented[29,30]. However, previous studies demonstrated that CagA was closely associated with the pathogenicity of *H pylori* and severity of *H pylori*-related diseases[29-32]. Many epidemiological data indicated that the positive rate of *cagA* gene was significantly higher in the *H pylori* strains isolated from patients with peptic ulcer than in those with gastritis[33]. Patients infected with *cagA*⁺ *H pylori* had a higher risk of developing gastric cancers than those infected with *cagA*⁻ strains[34,35]. Approximately 60% to 70% of *H pylori* strains isolated from European and North American populations carried *cagA* gene[36-38], whereas over 90% of the isolates from Asia-Pacific populations were *cagA* gene-positive[39-42]. Strong antigenicity of CagA usually induces antibody in patients with *cagA*⁺ *H pylori* infection and this antibody has been considered as a possible specific clinical indicator of *H pylori* infection[43-45]. However, the data are scarce concerning the correlations between the presence of *cagA*, CagA expression and antibody production, CagA⁺ *H pylori* infection and types

of the resultant gastric diseases.

In the present study, a recombinant expression plasmid containing a relatively conserved *H pylori cagA* gene fragment 2 148 bp in length (*cagA*1) was constructed. *H pylori* strains in gastric biopsy specimens from patients with gastritis or peptic ulcer were isolated. The frequencies of *cagA* gene and expressions of *H pylori* isolates and CagA antibody in patients' sera were investigated. Furthermore, the correlations among CagA+ *H pylori* infection and types of the resulted gastric diseases were also analyzed for the purpose of understanding the pathogenic effect of CagA and the potential of CagA antibody detection in clinical diagnosis of *H pylori* infection.

MATERIALS AND METHODS

Materials

A typical *H pylori* strain named Y06 isolated clinically was used to amplify *cagA*1 fragment. Primers for PCR amplification were synthesized by BioAsia (Shanghai, China). *Taq*-plus high fidelity PCR kit and restriction endonucleases were purchased from TaKaRa (Dalian, China). T-A cloning kit and sequencing service were provided by BBST (Shanghai, China). Plasmid *pET32a* as the expression vector and *E.coli* BL21DE3 as the host cell were purchased from Novagen (Novagen, Madison, USA). Rabbit antiserum against the whole cell of *H pylori*, HRP-labeling sheep antisera against rabbit IgG and human IgG were purchased from DAKO (Glostrup, Denmark) and Jackson ImmunoResearch (West Grove, USA), respectively. Agents used for isolation and identification of *H pylori* were purchased from BioMérieux (Marcy I' Etoile, France).

Gastric biopsy specimens with positive urease for *H pylori* isolation and serum samples for CagA antibody detection were collected from 156 patients in 4 hospitals in Hangzhou during Nov. 2001 to Feb. 2003. None of the patients had received nonsteroidal anti-inflammatory drugs, antacids or antibiotics within two weeks prior to the study. From the 156 patients, 126 biopsy specimens of *H pylori* isolates were obtained and 109 of the isolates survived after -70 ℃ storage. In the 109 patients (including 76 males and 33 females, with a mean age of 40.2 years), 61 patients suffered from chronic gastritis (41 chronic superficial gastritis, 10 chronic active gastritis, 10 chronic atrophy gastritis), and 48 had gastroduodenal ulcer (12 gastric ulcer, 30 duodenal ulcer, 6 gastric and duodenal ulcer).

Methods

Isolation and identification of *H pylori* Each of the biopsy specimen was homogenized with a tissue grinder and then inoculated on Columbia agar plates supplemented with 80 mL/L sheep blood, 5 g/L cyclodextrin, 5 mg/L trimethoprim, 10 mg/L vancomycin, 2.5 mg/L amphotericin B and 2 500 U/L cefsoludin. The plates were incubated at 37 ℃ under microaerobic conditions (50 mL/L O_2, 100mL/L CO_2 and 850 mL/L N_2) for 3 to 5 d. A bacterial isolate was identified as *H pylori* according to typical Gram staining morphology, positive results of biochemical tests for urease and oxidase, and slide agglutination with the commercial rabbit antibody against whole cell of the bacterium.

Preparation of DNA template Genomic DNA from each of the *H pylori* strains was extracted by conventional phenol-chloroform method and DNase-free RNase treatment. Concentration and purity of the DNA preparations were determined by ultraviolet spectrophotometry[46].

Polymerase Chain reaction The primers were designed to amplify *cagA*1 fragment from *H pylori* strain Y06 *cagA* gene based on the published data in GenBank. The sequence of sense primer with an endonuclease site of *EcoR* V was 5' -GCCGAT ATCATGATCAATAATCTTCAAGTAGC-3' , and that of antisense primer with an endonuclease site of *Xho*I was 5' -

CGGCTCGAGTTATGAAAT CCATTCTGGATTG-3' . The total volume per PCR was 100 μL, containing 2.5 mol/L each of the dNTP, 250 nmol/L each of the two primers, 15 mol/L $MgCl_2$, 3.0 U *Taq*-plus polymerase, 100 ng DNA template and 1×PCR buffer (pH 8.3). The parameters for PCR were at 94 ℃ for 5 min, ×1; at 94 ℃ for 30 s, at 50 ℃ for 30 s, at 72 ℃ for 120 s, ×10; at 94 ℃ for 30 s, at 50 ℃ for 30 s, at 72 ℃ for 130 s (additional 10 s for each of the following cycles), ×20; at 72 ℃ for 10 min, ×1.

To increase the positive detection rate of *cagA* gene, two sets of primers derived from different regions of *cagA* gene were applied in PCR. The sequences of F1/B1 primers were 5' -GATAACAGGCAAGCTTTTGAGG-3' (sense), 5' - CTGCAAAAGATTGTTTGGCAGA-3' (antisense)[31]. The sequences of D008/R008 primers were 5' -ATAATGCTAAAT TAGACAACTTGAGCG-3' (sense), 5' -TTAGAATAATCAA CAAACATCACGCCA-3' (antisense)[36]. Except for the primers and DNA templates, all the other reagents and reaction volumes used in PCR for *cagA* detection were the same as in *cagA*1 amplification. The parameters for the two PCRs were at 94 ℃ for 5 min, ×1; at 94 ℃ for 30 s, at 55 ℃ for 1 min, at 72 ℃ for 90 s, ×35; at 72 ℃ for 7 min, ×1.

The results of PCR were observed under UV light after electrophoresis on 1.5% agarose gel pre-stained with ethidium bromide. The expected sizes of *cagA*1 amplification fragment and the two target amplification fragments for *cagA* gene detection were 2 172 bp (including ATG, TAA, and a 18-bp sequence containing endonuclease sites and protective nucleotide residuals), 349 bp and 298 bp, respectively.

Cloning and sequencing The *cagA*1 amplification fragment was cloned into plasmid vector *pUCm-T* (*pUCm-T-cagA*1) by using the T-A cloning kit according to the manufacturer' s instructions. The recombinant plasmid was amplified in *E.coli* DH5α and then extracted by Sambrook' s method[46]. A professional company (BBST) was responsible for nucleotide sequence analysis of the inserted fragment. Two plasmids *pUCm-T-cagA*1 and *pET32a* were extracted from two different strains of *E.coli* DH5α after amplification in LB medium and then digested with *EcoRV* and *Xho*I, respectively[46]. The fragments *cagA*1 and *pET32a* were recovered and ligated. The recombinant expression vector *pET32a-cagA*1 was transformed into *E.coli* BL21DE3, and the expression system designated as *pET32a-cagA*1-*E.coli* BL21DE3. The *cagA*1 fragment inserted in *pET32a* was sequenced again.

Expression and identification of target recombinant protein *pET32a-cagA*1-*E.coli* BL21DE3 was rotatively cultured in LB medium at 37 ℃ under induction with isopropylthio-β-D-galactoside (IPTG) at different concentrations of 1.0, 0.5 and 0.1 mmol/L, respectively. The supernatant and precipitate of the culture after incubation were separated by centrifugation and then the bacterial pallets were ultrasonically fragmented (300 V, 5 s×3). SDS-PAGE was used to measure the molecular mass and output of the target recombinant protein (rCagA1). Ni-NTA affinity chromatography was applied to collect rCagA1. The commercial rabbit antiserum against whole-cell *H pylori* and HRP-labeling sheep antiserum against rabbit IgG were used as the first and second antibodies to determine the immunoreactivity of rCagA1 by Western blotting, respectively. Rabbits were immunized with rCagA1 to prepare antisera. Immunodiffusion assay was performed to determine the antigenicity of rCagA1.

Enzyme-linked immunosorbent assay (ELISA) By using rCagA1 as the coating antigen at the concentration of 20 μg/mL, with the serum sample (1:400 dilution) from a patient as the first antibody and HRP-labeling sheep antibody against human IgG (1:4 000 dilution) as the second antibody, CagA antibody in the sera of the 126 *H pylori*-infected patients was detected. The result of ELISA for a patient' s serum sample was

considered positive if the value of optical density at 490 nm (OD_{490}) exceeded the mean plus 3 standard deviations of 6 different negative serum samples[47]. CagA expression in *H pylori* isolates was examined using ultrasonic supernatant of each of the *H pylori* isolates (50 μg/mL) as the coating antigen, self-prepared rabbit anti-rCagA1 serum (1:800 dilution) as the first antibody and HRP-labeling sheep antibody against rabbit IgG (1:3 000 dilution) as the second antibody. The result of ELISA for a *H pylori* ultrasonic supernatant sample was considered positive if its OD_{490} value was over the mean plus 3 standard deviations of 6 separated *E.coli* DH5α ultrasonic supernatant samples at the same protein concentration[47].

Analysis of correlation among *cagA* gene, CagA and its antibody and *H pylori*-related diseases According to the clinical data and the obtained results, the correlations among infection with *H pylori* carrying *cagA* gene and expressing CagA isolated from the patients' gastric biopsy specimens, and the type and severity of gastric diseases in the same patient were analyzed.

Statistical analysis

The nucleotide and putative amino acid sequences of the cloned *cagA*1 fragment were compared for homologies with the published corresponding sequences (GenBank accession No. AB015416). χ^2 test was applied to analyze the clinical data, PCR results for *cagA* detection and ELISA results for CagA detection.

RESULTS

Positivity rate of H pylori in clinical isolates

In the 156 gastric biopsy specimens with positive urease, *H pylori* was detectable in 126 specimens, with a positivity rate of 80.8%.

PCR results

Using the primer pairs F1/B1 and D008/R008 respectively, 82.6% and 78.9% of the tested *H pylori* isolates (90/109) were positive for *cagA* gene, and the total *cagA* gene positivity rate was 97.2%(106/109). The target amplification products of *cagA*1 from *H pylori* strain Y06 and two fragments for *cagA* gene detection from the isolates are shown in Figure 1.

Figure 1 Target amplification fragments of *cagA gene* amplified from *H pylori* isolates with different primers. Lane 1: 100 bp DNA marker; Lanes 2, 4 and 6: Target amplification fragments by using *cagA*1, F1/B1 and D008/R008 primers, respectively; Lanes 3, 5 and 7: Blank controls.

Nucleotide sequence analysis

The nucleotide sequences of *cagA*1 fragment in *pUCm-T-cagA*1 and *pET32a-cagA1* were completely the same. The nucleotide and putative amino acid sequences of the cloned *cagA*1 fragment showed 94.83% (Figure 2) and 93.30% (Figure 3) homologies with the published sequences from *H pylori* strain NCTC11637 (GenBank accession No.: AB015416), respectively.

Figure 3 Comparison of putative amino acid sequence homology of *cagA*1 fragment between different *H pylori* strains. (1): Corresponding putative amino acid sequence of *cagA*1 fragment from *H pylori* strain NCTC11637. (2): Putative amino acid sequence of *cagA*1 fragment from *H pylori* strain Y06. Underlined is the position of the primers.

Expression of target recombinant protein

IPTG at concentrations of 1.0, 0.5 and 0.1 mmol/L could efficiently induce the expression of rCagA1, which was detected mainly in the ultrasonic precipitate with an output of approximately 30% of the total bacterial proteins (Figure 4).

Figure 4 rCagA1 expression by *pET32a-cagA*1-*E.coli* BL21DE3 induced with IPTG. Lane 1: Protein marker; Lane 2: Blank control; Lane 3: Non-induced; Lanes 4-6: induced with 0.1, 0.5 and 1.0 mmol/L IPTG, respectively; Lanes 7 and 8: Bacterial supernatant and precipitate induced with 0.5 mmol/L IPTG, respectively.

Immunoreactivity and antigenicity of rCagA1

The commercial rabbit antibody against whole-cell *H pylori* could bind to rCagA1 as confirmed by Western blotting (Figure 5). Immunodiffusion assay demonstrated a titer of 1:4 between rCagA1 and rabbit anti-rCagA1 serum.

Figure 5 Western blotting of binding between rCagA1 and commercial rabbit antiserum against whole-cell *H pylori*. Lanes 1 and 2: 20 μL and 40 μL of rCagA1 extract, respectively; Lane 3: Blank control.

ELISA results

The mean A_{490} values (mean±SD) of the 6 negative serum samples was 0.37±0.03 in the detection of specific antibodies in sera of patients, and the positive reference value of 0.46 was consequently derived. According to the reference value, 88.1% (96/109) of the tested patients' serum samples were positive for the rCagA1 antibodies with an A_{490} value ranging from 0.56 to 1.05 (Table 1). From the mean A_{490} values of the 5 negative bacterial controls (0.27±0.09) in the detection of CagA1 in *H pylori* isolates, the positive reference value of 0.54 was

derived. According to the reference value, the epitope of rCagA1 with an A_{490} value ranging from 0.55% to 0.9792.6%(101/109) was detected in the tested *H pylori* isolates (Table 1).

Table 1 Detection of CagA expression in *H pylori* isolates and CagA antibody in infected patients' sera

Tested indicator	Tested cases	Positive cases	Negative cases	Positivity rate (%)
CagA gene	109	106	3	97.2
CagA protein	109	101	8	92.6
Anti-CagA	109	96	13	88.1

Correlation between CagA and gastric diseases

A high rate of 97.9% of *H pylori* isolated from the peptic ulcer specimens (47/48) and 88.5% from the gastritis specimens (54/61) was positive for CagA expression, showing no statistically significant difference between the two positive rates (χ^2=3.48, P>0.05). Of the 8 *H pylori* strains in which CagA expression failed to be detected, 1, 1 and 6 strains were isolated from the biopsy specimens of gastric ulcer, chronic active gastritis and chronic superficial gastritis, respectively, and this distribution did not show any statistically significant difference, either (χ^2=1.23, P>0.05).

DISCUSSION

CagA expressed by *H pylori* was demonstrated to induce cellular skeleton rearrangement and interleukin (IL)-8 secretion in gastric epithelial cells[31,32]. IL-8, recognized as an inflammatory cytokine, could cause inflammation by inducing gathering of neutrophilic cells[48,49]. Infection with *cagA*[+] *H pylori* may elevate the risks of atrophic gastritis, intestinal metaplasia and gastric adenocarcinoma[34,50,51], and CagA is therefore considered as the most important pathogenic factor of *H pylori*.

CagA gene had a single copy located at the terminal end of region I in cag pathogenic island (CPI)[31,52], and was prone to mutation, especially in the 3'-end by insertion of different numbers of repeated sequences, resulting in the great variation in its length ranging from 3 444 to 5 925 bp in different isolates[36,37]. According to the analysis of 37 *cagA* gene sequences from GenBank, a fragment with approximate 65 bp starting from the 5'-end of *cagA* gene of different *H pylori* isolates also exhibited frequent mutations such as replacement, insertion and deletion, *etc*. Therefore, a relatively conserved fragment of 2 148 bp from the 67th to 2 214th bp at 5'-end of *cagA* gene was selected for cloning, which was provisionally named as *cagA*1. In this study, homologies of the nucleotide and amino acid sequences of the cloned *cagA*1 fragment reached 94.83% and 93.30% respectively in comparison with the reported sequences in GenBank (accession No.AB015416). High output of rCagA1, approximately 30% of the total bacterial protein, expressed by the constructed recombinant prokaryotic expression system *pET32a-cagA1-E.coli* BL21DE3 was confirmed by SDS-PAGE. rCagA1 could be recognized by a commercial antibody against whole-cell *H pylori* and was able to induce rabbit to produce high-titer antibodies, indicating that rCagA1 with good immunoreactivity and antigenicity can be used in ELISA as a qualified antigen for detecting CagA antibody and for preparing animal antiserum to detect CagA.

Yang *et al* reported that all the *cagA*[+] *H pylori* isolates were capable of expressing CagA[41]. However, we found that 5 strains of *cagA*[+] *H pylori* (7.3%) failed to exhibit the expression. Considering the highly likely mutation in *cagA* genes from different *H pylori* isolates, this non-expression of CagA was probably due to sequence mutation or abnormal transcription

and translation[36,37]. In the present study, 88.1% of the serum samples from the *H pylori*-infected patients (96/109) were positive for CagA antibody, and the positive rate was only slightly lower than those of *cagA* gene (97.2%) and CagA (92.6%) of the isolates, suggesting that CagA possesses strong antigenicity and usually induces detectable specific antibody in *cagA*[+] *H pylori*-infected patients. However, we found in this study that 11.9% of the serum samples were negative for CagA antibody (13/109), including 3 cases (2.8%) of *cagA*[-] *H pylori* infection, 5(4.6%) of *cagA*[+] *H pylori* infection and 5(4.6%) of CagA[+] *H pylori* infection. In addition, previously published data and our results suggest that over 90% of the *H pylori* isolates from Asia-Pacific areas were *cagA* gene-positive[39-42], whereas 60% to 70% of the *H pylori* isolates from European and North American areas were positive[36-38], indicating that the presence of CagA antibody could be used as a reference indicator with only a small risk of error for detecting *H pylori* infection in individuals from Asia-Pacific areas, but not for those from European or North American areas. It should be noted that the positive rate of *cagA* gene in the *H pylori* isolates in this study was as low as 78.9% to 82.6%, as detected using a single pair of primers F1/B1 or D008/R008, indicating that using multiple pairs of primers in PCR may increase the positive rate for *cagA* gene detection.

Covacci *et al* and Figueiredo *et al* reported that *cagA*[+] *H pylori* infection could usually cause serious gastric diseases[37,38]. For example, 90% of *H pylori* isolates from peptic ulcer patients were *cagA* gene-positive, while only 50% to 60% of the isolates from superficial gastritis were positive. However, the reports from Asia-Pacific areas did not show a definite correlation between *cagA*[+] *H pylori* infection and severity of the diseases[39-42]. Although *cagA*[+] *H pylori* was isolated from chronic gastritis patients at a higher rate (97.9%) than from peptic ulcer patients (88.5%), the difference was not statistically significant (χ^2=3.48, P>0.05), probably due to the high rate of *cagA* gene-carrying *H pylori* (97.2%) and a relative small population tested in this study.

Abstract

AIM: rAAV mediated endostatin gene therapy has been examined as a new method for treating cancer. However, a sustained and high protein delivery is required to achieve the desired therapeutic effects. We evaluated the impact of topoisomerase inhibitors in rAAV delivered endostatin gene therapy in a liver tumor model.

METHODS: rAAV containing endostatin expression cassettes were transduced into hepatoma cell lines. To test whether the topoisomerase inhibitor pretreatment increased the expression of endostatin, Western blotting and ELISA were performed. The biologic activity of endostatin was confirmed by endothelial cell proliferation and tube formation assays. The anti-tumor effects of the rAAV-endostatin vector combined with a topoisomerase inhibitor, etoposide, were evaluated in a mouse liver tumor model.

RESULTS: Topoisomerase inhibitors, including camptothecin and etoposide, were found to increase the endostatin expression level *in vitro*. The over-expressed endostatin, as a result of pretreatment with a topoisomerase inhibitor, was also biologically active. In animal experiments, the combined therapy of topoisomerase inhibitor, etoposide with the rAAV-endostatin vector had the best tumor-suppressive effect and tumor foci were barely observed in livers of the treated mice. Pretreatment with an etoposide increased the level of endostatin in the liver and serum of rAAV-endostatin treated mice. Finally, the mice treated with rAAV-endostatin in combination with etoposide showed the longest survival among the experimental models.

CONCLUSION: rAAV delivered endostatin gene therapy in combination with a topoisomerase inhibitor pretreatment is an effective modality for anticancer gene therapy.

INTRODUCTION

Antiangiogenic therapy for cancer has emerged as an exciting new therapeutic modality because tumors are angiogenesis-dependent during growth and metastasis[1-6]. One of the most potent endogenous angiogenic inhibitors, endostatin, has been reported to inhibit endothelial proliferation and regression of solid tumors[7-10]. Although endostatin induces and sustaines the dormancy of tumor growth, large quantities of proteins are needed for prolonged periods[9]. Moreover, besides being difficulty to be purified, endostatin has a short half-life *in vivo*. In order to circumvent the obstacle presented by the pharmacokinetics of endostatin, delivery of the gene cassettes encoding endostatin has been attempted[11-19].

Recombinant adeno-associated virus (rAAV) vector is a good candidate for antiangiogenesis-based cancer gene therapy[20]. rAAV vector is derived from a nonpathogenic parvovirus that is capable of integrating into the host DNA, which allows the long-term expression. In addition, removal of the viral coding sequences minimizes immunogenicity. The rAAV vector has a broad host tropism and transducts in dividing and non-dividing cells. The liver is an important target for gene therapy, because of its large size, its protein synthesizing capacity and because it is easily accessible to vectors. Although the rAAV is a promising vector for liver-directed gene therapy, its potential for therapeutic use has been limited due to its inefficient transduction into the liver[21,22]. In order to achieve high serum levels of endostatin with a stable expression, the transduction of non-dividing cell populations is essential in liver-directed gene therapy. Some topoisomerase inhibitors, such as etoposide or camptothecin, increase the transduction efficiency of the rAAV in non-dividing cells as well as in dividing cells[23-25].

Therefore, this study investigated the potential of a rAAV vector-mediated endostatin gene therapy in combination with topoisomerase inhibitor in a liver tumor model. This paper demonstrates that a topoisomerase inhibitor in a rAAV delivered endostatin gene therapy enhances the antiangiogenic effects, and that this method has the potential to be used as a new strategy for cancer gene therapy.

MATERIALS AND METHODS

Cells culture

Hepa1c1c7 mouse hepatoma cell line (ATCC CRL 2026), S-180 murine sarcoma cell line (ATCC CCL-8) and 293-EBNA cells (transformed human embryonic kidney, ATCC R620-07) were grown in DMEM (Gibco BRL, Grand Island, NY) with 100 mL/L

heat inactivated (30 min at 56 ℃) fetal bovine serum, 2 mmol/L L-glutamine, 100 units/mL penicillin, and 100 mg/mL streptomycin at 37 ℃ in 50 mL/LCO$_2$. The 293-EBNA cell line was maintained in medium containing geneticin (G418, 250 µg/mL; Gibco BRL). Human umbilical vein endothelial cells (HUVEC) were isolated from the human umbilical vein (Institutional review board approved protocol with informed consent) using a collagenase type I (Sigma, St. Louis, MO) perfusion. The cells were then grown on gelatin-coated tissue culture plates in M199 medium (Sigma) supplemented with 100 ng/mL heparin (Gibco BRL), 200 mL/L FBS, 100 mg/mL streptomycin, 100 U/mL penicillin, 3 ng/mL bFGF (Upstate, Waltham, MA).

rAAV vector construction and production

pEndoSTHB vector was kindly provided by Dr K.K. Tanabe (Harvard Medical School, Boston, MA), which contained murine endostatin cDNA downstream of murine Ig κ-chain signal peptide and upstream of a *c-myc* epitope[26]. This plasmid was modified by site-directed mutagenesis (oligonucleotide primer 1: ACC-TCT-TTC-TCC-AAG-TAA-TGA-CTC-CAG-TGT-GGT-GGA, oligonucleotide primer 2: TCC-ACC-ACA-CTG-GAG-TCA-TTA-CTT-GGA-GAA-AGA-GGT), which mutated the sequence upstream of the c-myc epitope into stop codons to remove *c-myc* tag[27]. AAV-helper free system (Stratagene, La Jolla, CA) was used to produce rAAV. *Sal*I – *Xho*I fragment from modified pEndoSTHB was subcloned into the pCMV-MCS vector (Stratagene). Once this expression construct was verified, the NotI fragment, containing the expression cassette of endostatin, was cloned into the pAAV-LacZ viral expression vector (Stratagene). The parental vector rAAV-Lac Z was used as control. pAAV-endostatin containing the cytomegalovirus (CMV) promoter with a murine Ig κ-chain signal peptide was flanked by cDNA of murine endostatin. The rAAV vectors were produced using a standard triple-plasmid transfection method, and purified by a heparin sulfate column separation[28]. Briefly, the recombinant expression plasmid was co-transfected into 293-EBNA cells with pHelper (Stratagene) and pAAV-RC (Stratagene), which supply all the trans-acting factors required for AAV replication and packaging in 293-EBNA cells. rAAV stocks were subjected to 3 rounds of freezing and thawing. After cell debris was removed by centrifugation, the stocks were filtered using a low protein binding 5 µm syringe filter (Millipore, Bedford, MA), followed by a 0.8 µm syringe filter and subsequently by heparin agarose column (Sigma) separation. The viruses were finally concentrated in a millipore concentrator (100-ku cut off) and titrated by taking the average of three quantitative real time PCR using a LightCycler-FastStart DNA Master SYBR Green system (Roche Molecular Biochemicals, Mannheimn, Bermany) (forward primer: GGC-TAG-CCA-CCA-TGG-AGA-CAG-ACA, reverse primer: ACA-CTG-GAG-TCA-TTA-CTT-GGA-GAA, 10 min pre-incubation at 94 ℃ followed by 50 cycles at 94 ℃ for 15 s, at 60 ℃ for 5 s and at 72 ℃ for 10 s in a 7 700 Q-PCR machine, Applied Biosystems, Foster City, California).

Treatment with topoisomerase inhibitors

Stock solutions of etoposide (10 mmol/L) (Laboratories Lilly France, Fegersheim, France) and camptothecin (10 mmol/L) (Yakult Honsha, Tokyo, Japan) were stored at -20 ℃ and diluted into HBSS (Hanks' balanced salt solution, Gibco BRL) for use in experiments. Hepa1c1c7 cells were pretreated with either 3 µmol/L of etoposide or 10 µmol/L of camptothecin for 6 h, and then washed twice with L-DMEM (20 g/LFBS, 2 mmol/L L-glutamine in DMEM) prior to the rAAV addition. The vector was then added for transduction, and the plates were swirled gently at 30 min intervals during an incubation of 2 h. H-DMEM (180 g/LFBS, 2 mmol/L L-glutamine) was then added to each plate, and incubation was continued for 48 h at 37 ℃.

Western blot analysis

Western blot was performed on the protein from conditioned medium of rAAV transduced Hepa1c1c7 cells. The conditioned medium was concentrated in a Microcon YM-10 (millipore) and subjected to electrophoresis under reducing conditions on a 40-120 g/L NuPAGE gel (Invitrogen, San Diego, CA). The proteins obtained were transferred onto a nitrocellulose membrane (Invitrogen) and incubated overnight in 50 g/L nonfat milk in PBS at 4 ℃. After three 10-min washes in 19 g/L nonfat milk, 1 g/L Tween 20 in PBS, the membranes were incubated in monoclonal goat anti-mouse endostatin antibodies (R&D Systems, Minneapolis, MN) diluted 1:500. After washing, the membranes were incubated in horseradish peroxidase-conjugated donkey anti-goat immunoglobulin (Santa Cruz Biotechnology, Santa Cruz, CA) diluted 1:4 000 and the proteins were detected using an ECL plus kit (Amersham Pharmacia Biotechnology, Uppsala, Sweden).

Endostatin enzyme immunoassay

Endostatin levels in the conditioned medium of cultured cells or in the mouse serum were determined using a mouse endostatin immunoassay kit (Chemicon International, Temecula, CA, USA).

Endothelial cell proliferation assay

HUVECs were plated on 5×10^3 in 96-well gelatin-coated plates and allowed to attach in complete medium for 4 h. The medium was then replaced by the conditioned medium, where the endostatin concentration was measured by an ELISA assay. After 1 h, an equal volume of 2× complete medium was added, and the number of cells was quantified by a colorimetric MTT assay on the indicated days. The test was performed in triplicate.

Endothelial cell tube formation assay

Twenty-four well plates were coated with 50 µL of Matrigel (BD Biosciences, Bedford, MA) in an ice bath and then incubated at 37 ℃ for 1 h. HUVECs at a density of 5×10^4 cells in each well were seeded and cultured in the conditioned media. After 18-h incubation, the plates were photographed. All tests were performed in triplicate.

In vivo tumor model

Animal experiments were carried out in accordance with the policies of Animal Research Committee of the Yonsei University College of Medicine. Twenty-five 8-wk-old female ICR mice (Charles River Laboratories, Wilmington, MA) were randomly divided into 5 equal groups, namely no treatment and rAAV-LacZ treatment alone as the control, treated with rAAV-LacZ in combination with etoposide pretreatment, treated with rAAV-endostatin alone, and treated with rAAV-endostatin in combination with etoposide pretreatment. In the pretreatment group, etoposide (40 mg/kg) in 200 µL HBSS was administered 3 times for a week by an intraperitoneal injection beginning 7 d before rAAV injection. Hepatic tumors were induced by directly injecting 5×10^6 S -180 murine sarcoma cells into the liver. Simultaneously, 500 µL of rAAV-mEndostatin (1.5×10^{12} viral particles) was injected into the spleen in the endostatin treatment groups in order to deliver viral particles into the liver. The mice were sacrificed 7 d after tumor cell injections by a halothane overdose to examine hepatic tumors. The tumor volume (TV) was determined using the following formula: TV=(Length × width^2)/2. In order to evaluate the long-term survival, the experiment was repeated and the mice were followed up for 2 mo. The survival time was defined from the day of tumor injection to death. The mice that were alive at the end of the follow-up period were estimated as the censored observation.

Localization of endostatin expression in liver

The livers were harvested and 5 μm-thick sections of the formalin-fixed, paraffin-embedded specimens were deparaffinized in xylene and heated in a citrate buffer for 10 min. Endogenous peroxidase activity was blocked by incubation with 10 mL/L H_2O_2 and 10 g/L Triton X-100. Gout anti-mouse antibodies were applied at a dilution of 1:60 overnight at 4 ℃. Biotinylated rabbit anti-gout antibodies (Vector, Burlingame, CA) were then applied for 1 h at room temperature at a 1:200 dilution. After incubation with streptavidin conjugated to horseradish peroxidase, a substrate containing chromogen, 3,3' diaminobenzidine tetrahydrochloride, was added and the slides were counterstained with hematoxylin. All the slides were air-dried and kept in dark at 4 ℃ until evaluated.

Microvessel density (MVD) assessment

In order to analyze hepatic tumor microvessels, tissue sections (5 μm) of formalin-fixed, paraffin-embedded specimens were evaluated using rat anti-mouse CD34 antibodies (1:50; RAM34; Pharmingen, San Diego, CA) as the primary antibody and biotinylated rabbit anti-rat antibodies (Vector, Burlingame, CA) as the secondary antibody. After incubation of the tissue with streptavidin conjugated to horseradish peroxidase, the reactions were visualized by a substrate containing chromogen, 3,3' diaminobenzidine tetrahydrochloride. The slides were counterstained with hematoxylin. At least 5 thin slices were made from each tumor and used for MVD assessment. MVD was estimated by counting the number of CD34-positive vessels in the tumor area, which was representative of the highest MVD at ×200 magnification. The counts were typically made in 3-5 hot spots, and the highest MVD was used to characterize the tumor.

Statistical analysis

The data were expressed as mean±SD. Student's *t* test was used to analyze the statistical differences in endostatin levels in the conditioned medium of cultured cells or in mouse serum, endothelial cell proliferation, tumor size, or microvessel assessment among the groups. The Kaplan and Meier method was used to calculate the survival rate in the *in vivo* experiment and the survival differences between the groups were evaluated using the log-rank test. A *P*<0.05 was considered statistically significant.

RESULTS

Increased in vitro expression of endostatin molecules on rAAV-endostatin transduced hepatoma cells by pretreatment with topoisomerase inhibitors

Hepa1c1c7 mouse hepatoma cells in the 10 cm plate were incubated with either rAAV-endostatin or rAAV-LacZ vectors (1×10^4 viral particles/cell) for 48 h. In the pretreatment group, etoposide (3 μmol/L) or camptothecin (10 μmol/L) was administered 6 h prior to transduction. Conditioned media were concentrated 10 times and used in both Western blotting and ELISA. The *in vitro* expression of endostatin was detected by Western blot analysis. The recombinant endostatin was visualized in the supernatant of Hepa1c1c7 cells transduced with rAAV-endostatin, but not in the supernatant of Hepa1c1c7 transduced with rAAV-LacZ. The endostatin expression level was enhanced as a result of the pretreatment with either etoposide or camptothecin (Figure 1A). ELISA was performed to quantify the expression level. Hepa1c1c7 cells transduced with rAAV-endostatin expressed endostatin (19.0±3.0 ng/mL) compared with the vector control (0.3±0.3 ng/mL) and mock control (0.3±0.2 ng/mL), and topoisomerase inhibitors enhanced significantly the endostatin expression level (*P*<0.05) (Figure

1B). In the range of concentrations used in this study, etoposide or camptothecin had little effect on Hepa1c1c7 cell growth (data not shown). Etoposide increased the endostatin expression level more than camptothecin (43.3±5.1 *vs* 30.7±5.7 ng/mL, *P*<0.05). Consequently, etoposide was chosen as a combination therapy in the *in vivo* experiment.

Figure 1 Effects of topoisomerase inhibitors on rAAV mediated endostatin expression level. Hepa1c1c7 mouse hepatoma cells were transduced with 1×10^4 particles/cell of rAAV-endostatin or rAAV-LacZ. In pretreatment group, etoposide (3 μmol/L) or camptothecin (10 μmol/L) was administered 6 h before transduction. Fourty-eight hours later, the expression of endostatin was determined. A: Analysis of protein expression by NuPAGE electrophoresis, B: Concentration of endostatin measured by ELISA (*P*<0.05, rAAV-endostatin in combination with pretreatment groups versus other groups). Z: rAAV-LacZ without pretreatment, E: rAAV-endostatin without pretreatment, E/et: rAAV-endostatin pretreated with etoposide, E/cpt: rAAV-endostatin pretreated with camptothecin.

In vitro biological activities of endostatin produced by rAAV vectors and pretreatment with topoisomerase inhibitors

As expected, the conditioned media from Hepa1c1c7 cells transduced with the control rAAV-LacZ vector did not influence either endothelial cell proliferation or tube formation compared to the conditioned media from the non-treated control (data not shown). Etoposide and camptothecin had a minor effect on the growth of HUVECs, and recombinant endostatin actively reduced endothelial cell growth. However, the conditioned media from rAAV-enodstatin combined with etoposide group showed very strong inhibition (Figure 2A). Similarly, the recombinant endostatin suppressed tube formation of endothelial cells, and the rAAV-endostatin combined with etoposide group had the highest effect (Figure 2B).

Synergic effect of rAAV-endostatin with topoisomerase inhibitors in a mouse liver tumor model

Hepatic tumors were formed by injecting S-180 murine sarcoma cells directly into the predetermined site of the liver, and rAAV-Lac-Z treatment mice had similar hepatic tumors compared to non-treated mice (170.0±38.6 and 159.7±27.7 mm³, respectively). rAAV-LacZ in combination with etoposide and rAAV-endostatin reduced hepatic tumor burden (52.0±9.4 and 9.3±4.5 mm³, respectively) (*P*<0.05, treated group *vs* non-treated or rAAV-Lac-Z treatment group). Interestingly, tumor nodules were barely

observed in the rAAV-endostatin plus etoposide group (Figure 3). Serum endostatin was hardly shown in non-treatment group (30.4±20.8 ng/mL), rAAV-LacZ treatment alone (34.2±21.4 ng/mL) and rAAV-LacZ plus etoposide groups (25.8±19.9 ng/mL), although rAAV-endostatin induced detectable serum endostatin level (191.1±54.7 ng/mL, $P<0.05$, rAAV-endostatin group *vs* control groups). In contrast, rAAV-endostatin plus etoposide induced the highest endostatin level (321.5±54.3 ng/mL, $P<0.05$, rAAV-endostatin plus etoposide group *vs* other groups) (Figure 4). The *in vivo* expression of endostatin was detected immunohistochemically. Staining with anti-endostatin antibodies revealed positive cells in vessels of the liver sections from the rAAV-endostatin treatment group, whereas the control sections were negative, and a dramatic increase was observed in rAAV-endostatin plus etoposide treatment mice (Figure 5). Moreover, endostatin was stained in hepatocytes of rAAV-endostatin plus etoposide treatment mice. The microvessel densities in tumor were estimated by CD34 staining, which were found to be decreased in the rAAV treatment group (19.3±4.5, $P<0.05$, rAAV treatment group *vs* control groups) compared with the mock control (97.7±15.2) and the vector control (105.2±17.6). As expected, the rAAV-endostatin plus etoposide treatment mice had the lowest microvessel density (7.6±1.5) (Table 1). All the non-treated or rAAV-lacZ treated mice died within 30 d. rAAV-LacZ plus etoposide treatment barely affected the survival and rAAV-endostatin extended the survival time. However, the rAAV-endostatin plus etoposide treatment mice had the longest survival (Figure 6). In addition, significant endostatin expressions were detected in the surviving mice of rAAV-endostatin plus etoposide treatment group even after 2 mo (data not shown).

Table 1 Microvessel assessment of S-180 murine sarcoma tumors

Group	Microvessel density
No treatment	97.7±15.2
rAAV-LacZ alone	105.2±17.6
rAAV-LacZ plus etoposide	52.0±9.4
rAAV-endostatin alone	19.3±4.5
rAAV-endostatin plus etoposide	7.6±1.5[a]

The microvessel density was measured with a light microscope in the tumor representative of the highest microvessel density at magnification ×200 ("hot spot"). [a]$P<0.05$, rAAV-endostatin plus etoposide group against other groups.

Figure 2 *In vitro* biological activities of expressed endostatin. A: 5×10³ HUVECs in a 96-well were cultured in the conditioned media from Hepa1c1c7 mouse hepatoma cells without pre-treatment (Z), those from the cells pretreated with etoposide (Z/et) or camptothecin (Z/cpt), those from the rAAV-endostatin transduced cells without pretreatment (E), those from rAAV-endostatin transduced cells pretreated with etoposide (E/et) or camptothecin (E/cpt). The number of cells was then calculated by a MTT assay. Each value represents mean±SD of 3 independent experiments ($P<0.05$, rAAV-endostatin in combination with pretreatment groups versus other groups). B: Impact on tube formation of endothelial cells. HUVECs were seeded into 24-well plates coated with Matrigel at a density of 5×10⁴ cells in each well and cultured in the conditioned media. After 18 h incubation, the level of cell growth and differentiation was observed. All tests were performed in triplicate.
endostatin vector were injected into the spleen simultaneously with tumor cell inoculation (5×10^6 S-180 cells) into the liver. The tumor volume was determined 7 d after injecting murine sarcoma cells ($P < 0.05$, rAAV plus etoposide group versus other groups). *Tumor volume = (Length×width²)/2.*

Figure 4 Mouse endostatin levels determined in sera of mice inoculated with murine sarcoma cells. S-180 murine sarcoma cells were inoculated into liver. Seven days later, ELISA determined the endostatin concentration and the results were expressed as mean±SD of 5 animals ($P < 0.05$, rAAV-endostatin plus etoposide group versus other groups).

Figure 3 Effect of rAAV-endostatin in combination with etoposide on murine sarcoma bearing mice. Twenty five mice bearing S-180 murine sarcoma cells were randomly divided into 5 groups, namely no treatment, rAAV-LacZ alone, rAAV-LaZ plus etoposide pretreatment, rAAV-endostatin alone, and rAAV-endostatin plus etoposide pretreatment. In the pretreatment group, etoposide (40 mg/kg) was administered 3 times for one week by an intraperitoneal injection beginning 7 d prior to rAAV injection, and 1.5×10^{12} viral particles of rAAV-
Figure 5 Detection of endostatin in livers of tumor-bearing mice. Hepatic tumors were induced by injecting murine sarcoma cells into the liver. After 7 d, the livers were harvested from the mice of different groups and analyzed by immuno-histochemical staining for endostatin. Livers without treatment, rAAV-LacZ alone and rAAV-LacZ plus etoposide pretreatment did not express endostatin. The vessels of livers treated with rAAV-endostatin were stained with anti-endostatin antibodies and a significant increase was observed in the rAAV-endostatin plus etoposide treatment group (arrow). Endostatin was also detected in hepatocytes of the rAAV-endostatin plus etoposide treatment group (arrow head).

Figure 6 Survival time of sarcoma-bearing mice. Twenty-five mice were randomly divided into 5 groups: no treatment, rAAV-LacZ alone, rAAV-LacZ plus etoposide, rAAV-endostatin alone, or rAAV-endostatin plus etoposide. The tumor-bearing mice treated with rAAV-endostatin in combination with etoposide had a significantly longer survival than those in other groups ($P<0.05$).

DISCUSSION

The transduction of non-dividing cell populations is an attractive goal of gene therapy, especially in terms of antiangiogenesis against cancer. rAAV vectors could transfer a foreign gene into non-dividing cells, but the gene transfer efficiency was too low[29]. The transduction of non-dividing cells by AAV vectors was increased by DNA-damaging agents, such as γ- and UV-irradiation and cisplatinum, which were toxic to normal cells at the concentrations needed to increase transduction[30]. In contrast, pretreatment with topoisomerase inhibitors increased AAV vector mediated transduction of non-dividing cells with a lower cytotoxicity[23]. It was found in this study that topoisomerase inhibitors in rAAV mediated endostatin gene therapy increased endostatin expression level. Etoposide more effectively enhanced the expression of target molecules than camptothecin. This rAAV-endostatin plus etoposide treatment induced anti-angiogenic effects to a significantly larger extent than rAAV treatment only, and endostatin expression levels were found to correlate well with the antiangiogenic effects.

rAAV with a CMV promoter used in this study, proved stable and strongly expressed endostatin. Etoposide could irreversibly inhibit CMV replication and suppress viral DNA and late viral-protein synthesis[31]. It is unclear whether or not etoposide inhibits the function of CMV promoter. This study did not evaluate the effect of etoposide on CMV promoter. However, topoisomerase inhibitor increased the overall endostatin expression level.

This study examined the *in vivo* antitumor effects of combined therapy with rAAV-endostatin and etoposide. In this mouse model of a hepatic tumor, etoposide had little antitumor effect, and rAAV-endostatin alone was insufficient to control a hepatic tumor. However, the combined modality significantly enhanced the tumor response. Interestingly, endostatin expression was immunohistochemically detected in hepatocytes and was significantly increased around vessels in the liver of the rAAV-endostatin plus etoposide treatment group compared with those of the rAAV-endostatin alone group. The topoisomerase inhibitor increased the transduction efficiency of AAV in both S-phase and non S-phase cells, and hepatocytes were much more efficiently transduced than other cells[24]. Overall, rAAV-endostatin in combination with etoposide increased the endostatin expression level in hepatocytes of mice, and induced sufficient control in the hepatic tumor model. One potential obstacle to the clinical application of rAAV-mediated anti-angiogenesis gene therapy is that it maintains high levels of the target molecules over a long-term. rAAV vector-mediated cancer gene therapy protocols combined with topoisomerase inhibitor pretreatment might be a solution to this problem.

Abstract

AIM: Hepatic ischemia/reperfusion injury may cause acute inflammatory, significant organ damage or dysfunction, and remains an important problem for liver transplantation. Our previous *in vivo* and *in vitro* studies demonstrated that Yisheng injection (YS), a traditional Chinese medicine, had protective effect on ischemia/reperfusion injury. In this study, we examined whether YS had protective effect for hepatic ischemia/reperfusion injury and explored its protective mechanism.

METHODS: Hepatic warm ischemia/reperfusion was induced in mice. YS at different doses (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. The hepatocellular injury, oxidative stress, neutrophil recruitment, proinflammatory mediators and adhesion molecules associated with hepatic ischemia/reperfusion injury were assayed by enzyme-linked immunosorbent assay (ELISA), immunohistochemical assay and reverse transcription polymerase chain reaction (RT-PCR).

RESULTS: Undergoing 90 min of ischemia and 6 h of reperfusion caused dramatical injuries in mouse livers. Administration of YS at doses of 5, 10 and 20 mg/kg effectively reduced serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH), from 3 670±463 U/L, 2 362±323 U/L and 12 752±1 455 U/L in I/R group to 1 172±257 U/L, 845±193 U/L and 2 866±427 U/L in YS (20 mg/kg) treated group, respectively (*P*<0.01). The liver myeloperoxidase (MPO) and malondialdehyde (MDA) contents were decreased from 1.1±0.2 (U/mg protein) and 9.1±0.7 (nmol/mg protein) in I/R group to 0.4±0.1 (U/mg protein) and 5.5±0.9 (nmol/mg protein) in YS (20 mg/kg) treated group, respectively (*P*<0.01). Moreover, the serum levels of tumor necrosis factor-alpha (TNF-α) were reduced from 55±9.9 (pg/mL) in I/R group to 16±4.2 (pg/mL) (*P*<0.01). Furthermore, the over-expressions of TNF-α and intercellular adhesion molecule-1 (ICAM-1) were suppressed by YS treatment in a dose-dependent manner.

CONCLUSION: YS attenuates hepatic warm ischemia/

reperfusion injury by reducing oxidative stress and suppressing the over-expression of proinflammatory mediators and adhesion molecules.

INTRODUCTION

Clinical and experimental evidences suggest that an initial insult to organ allografts may influence both early and late functional survival. This injury may be either immunologic or antigen independent[1].

Hepatic ischemia/reperfusion injury is an important nonimmunologic factor and remains a significant problem and limitation of liver transplantation and may result in liver failure, remote organ failure, and even death[2,3].

During the initial phase of hepatic ischemia-reperfusion injury, Kupffer cells are activated and release reactive oxygen species (ROS)[4] and proinflammatory cytokines[5], especially tumor necrosis factor-alpha (TNF-α)[6,7]. The enhanced production of TNF-α plays an important role in the initiation of a cascade of events that causes significant liver injury mediated by neutrophils. One of the main functions of TNF-α is to up-regulate the expression of adhesion molecules, especially intercellular adhesion molecule-1 (ICAM-1), and then mediate the recruitment of neutrophils into the liver resulting in further hepatic injury[8,9].

Ischemia-reperfusion injury becomes significant through rapid up-regulation and surface expression of adhesion molecules, and activation of circulating host leukocytes and their binding to the vascular endothelium[10]. In addition, the insult from ischemia/reperfusion surrounding engraftment may trigger alloresponsiveness in the host, making it potentially more prone to rejection[11]. Furthermore, the initial acute rejection injury predisposes to chronic graft dysfunction early injuries may also affect later events. For this reason, the protection of liver against ischemia-reperfusion injury (IRI) remains one of the major nonimmunologic problems of liver transplantation[12].

Our previous studies demonstrate that Yisheng injection (YS), a herbal preparation developed from traditional Chinese medicine, can effectively protect endothelial cells against hypoxia/reoxygenation injury[13,14]; decrease the blood viscosity in hypostasis rats[15]; attenuate the sclerosis of transplanted abdominal aorta in rats by reducing the generation of free radicals and down-regulating the expression of TGF-β[16]; protect isolated testes against cold preservation/reperfusion injury through reducing lipid peroxidation, calcium supercharge and damage to mitochondrial function[17]; and protect kidney against ischemia/reperfusion injury in pigs by reducing serum levels of TNF-α (unpublished results). In this study, we examined whether YS had protective effect for hepatic ischemia/reperfusion injury and explored its protective mechanism.

MATERIALS AND METHODS

Yisheng injection

Yisheng injection (YS, 20 mg/mL) was provided by Chengdu Huayi Drug Co (Chengdu, China). Its effective ingredients are alkaloids extracted from *Corydalis thalictrifolia Franch*. and *Schnabelia oligophylla Hand.-Mazz*. In this study, YS was diluted with sterile saline.

Animals

Male C57BL/6 mice weighing 22 to 25 g were purchased from Vital River Co, Beijing, China. All mice were provided with standard laboratory chow and water and housed in accordance with institutional animal care policies.

Experimental design

The mice were randomly assigned into five experimental groups as follows: (1) sham operation group, (2) I/R group (treated with saline), (3) small-dose (5 mg/kg of YS) treated group, (4) middle-dose (10 mg/kg of YS) treated group, (5) large-dose (20 mg/kg of YS) treated group.

The model of partial hepatic ischemia and reperfusion was performed with published method[18]. Briefly, 24 h and 1 h before the induction of ischemia, the mice received intraperitoneally two times either sterile saline or YS (5, 10 or 20 mg/kg). They were anesthetized with sodium pentobarbital (60 mg/kg intraperitoneally), then a midline laparotomy was performed and an atraumatic clip was used to interrupt the arterial and the portal venous blood supply to the left lob of the liver. After 90 min of partial hepatic ischemia, the mice again received either sterile saline or YS (5, 10 or 20 mg/kg) via the lateral tail vein, and the clip was removed initiating hepatic reperfusion. Sham control mice underwent the same protocol, but without vascular occlusion. Abdomen was sutured by two layers with 4.0 suture.

In order to determine the proper reperfusion time point, we assayed the alanine transaminase (ALT) levels in the blood samples obtained at different time points of 2, 4, 6, 10 and 24 h of reperfusion following 90 min of ischemia, and found that the blood ALT level reached the peak at the end of 6 h of reperfusion (data not shown). So the time point of 6 h of reperfusion was chosen in this study. Mice were killed after 6 h of reperfusion following 90 min of ischemia, and liver tissue (from the ischemic lob) and blood samples were taken for analysis.

Blood assay

Blood was obtained at the time of sacrifice. The plasma concentrations of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) were measured in a clinical laboratory as markers of hepatic damage. The serum levels of TNF-α were determined by using an ELISA Kit (Jingmei Biotech Co, Shengzheng, China) according to the maneufactors' instructions.

Liver edema

The extent of liver edema was measured by tissue wet-to-dry weight ratios. After dissection, liver samples were weighed and then placed in a drying oven at 55 ℃ until a constant weight was obtained[18]. In this determination, liver edema was represented by an increase in the wet-to-dry weight ratios.

Myeloperoxidase, superoxide dismutase and malondialdehyde assay

Liver samples were homogenized in 100 mmol/L Tris-HCl buffer and centrifuged at 10 000 g for 20 min, and then liver myeloperoxidase (MPO), superoxide dismutase (SOD) and malondialdehyde (MDA) contents were assayed by using assay kits (Jiancheng Biotech Ltd, Nanjing, China), and the protein contents were assayed by using assay kits (Bio-Rad, USA)

according to the maneufactors' instructions.

Immunohistochemic assay

Tissue samples were fixed in 40 mg/L buffered formaldehyde and embedded in paraffin. For immunohistologic analysis, 5 μmsections of paraffin-embedded liver tissues were cut, and stained with primary anti-mouse mAbs against TNF-α (diluted, 1:500, Santa Cruz Biotech Co, Santa Cruz, CA) or ICAM-1 (diluted, 1:400, Santa Cruz Biotech Co, Santa Cruz, CA). After incubation, the sections were incubated with peroxidase-conjugated goat anti-mouse IgG. The bound peroxidase was detected using 3,3' -diaminobenzidine.

Reverse transcription-polymerase chain reaction

Total RNA was extracted from liver tissue using SV Total RNA Isolation System (Promega Co, Madison, WI, USA), according to the manufacturer's instructions, and was quantified by UV spectrophotometer. RNA (1 μg) was reverse transcribed and amplified using TaKaRa One-Step RT-PCR Kit (TaKaRa Biotech Co, Dalian, China) at following RT-PCR conditions: 50 ℃ for 30 min; 30 cycles at 95 ℃ for 1 min, 59 ℃ for 90 s, and 72 ℃ for 2 min. Primers used in PCR reactions were as follows[18]: TNF-α sense (5' -AGCCCACGTAGCAAACCACCAA-3') and antisense (5' -ACACCCATTCCCTTCACAGAGCAAT-3'), to give a 446-bp product; ICAM-1 sense (5' -TGGAACTGCACGTGCTGTAT-3') and antisense (5' -ACCATTCTGTTCAAAAGCAG-3'), to give a 513-bp product; and β-actin sense (5' -CTGAAGTACCCCATTGAACATGGC-3') and antisense (5' -CAGAGCAGTAATCTCCTTCTGCAT-3'), to give a 672-bp product. PCR products were stained with SYBR green dye, electrophoresed in a 20 g/L agarose gel, and photographed. Digital photographs were assessed with image-analysis software (Image-Pro Plus System, Media Cybernetics Co, USA) and mRNA expressions were evaluated by the band intensity ratios of TNF-α and ICAM-1 to β-actin and presented as percentage of β-actin.

Statistical analysis

All data were expressed as mean±SD. Statistical analysis was performed by analysis of variance (ANOVA), and Student's *t* test was used to compare individual group means. *P* values less than 0.05 were considered statistically significant.

RESULTS

YS suppressed hepatic injury

Hepatic injury was assessed by measuring serum levels of ALT, AST and LDH. Undergoing 90 min of hepatic ischemia and 6 h of reperfusion caused dramatical increases in serum ALT levels compared with sham controls, from 157±60 U/L to 3670±463 U/L (Figure 1A). Administration of YS at a dose of either 5, 10 or 20 mg/kg reduced the serum ALT levels by about 6.6%, 51.6% and 68.1% respectively, and YS at middle and large doses (10 and 20 mg/kg) showed significant effects (Figure 1A). Measurement of AST and LDH values reflected similar differences among the groups (Figure 1A, B), further demonstrating the dose-dependent protective effects of YS.

YS suppressed hepatic neutrophil recruitment and liver edema

Hepatic neutrophil recruitment was determined by liver MPO content and liver edema was determined by tissue wet-to-dry weight ratio. Hepatic ischemia and 6 h of reperfusion caused marked increases in liver MPO content compared with sham controls (Figure 2A). In the presence of YS (5, 10, 20 mg/kg), liver MPO content was significantly reduced by about 49.1%, 52.7% and 63.6% respectively (Figure 2A). In addition, administration of YS also reduced the liver edema in a dose-dependent manner (Figure 2B).
Figure 1 Effects of YS on hepatocellular injury induced by hepatic ischemia and reperfusion. After 90 min of ischemia and 6 h of reperfusion, serum levels of ALT, AST (A) and LDH (B) were determined. YS at different doses (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. For all groups, n=8. [b]P<0.01 compared with sham group; [d]P<0.01 compared with I/R group.

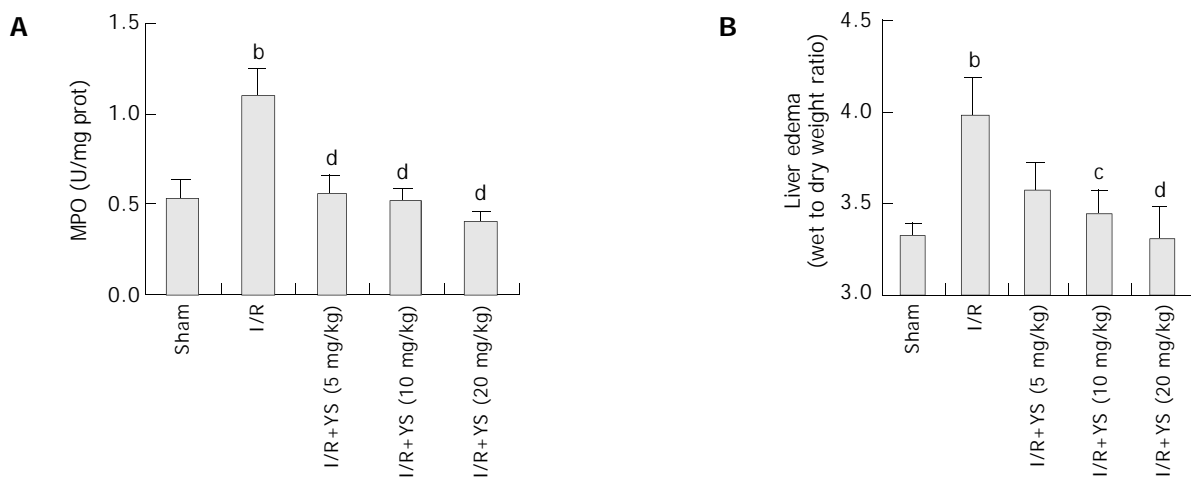

Figure 2 Effects of YS on neutrophil recruitment (A) and liver edema (B) induced by 90 min of ischemia and 6 h of reperfusion. MPO contents in liver tissues were analyzed as the index of neutrophil recruitment. Liver edema was determined by tissue wet-to-dry weight ratio. YS at different doses (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. For all groups, n=8. [b]P<0.01 compared with sham group; [c]P<0.05, [d]P<0.01 compared with I/R group.

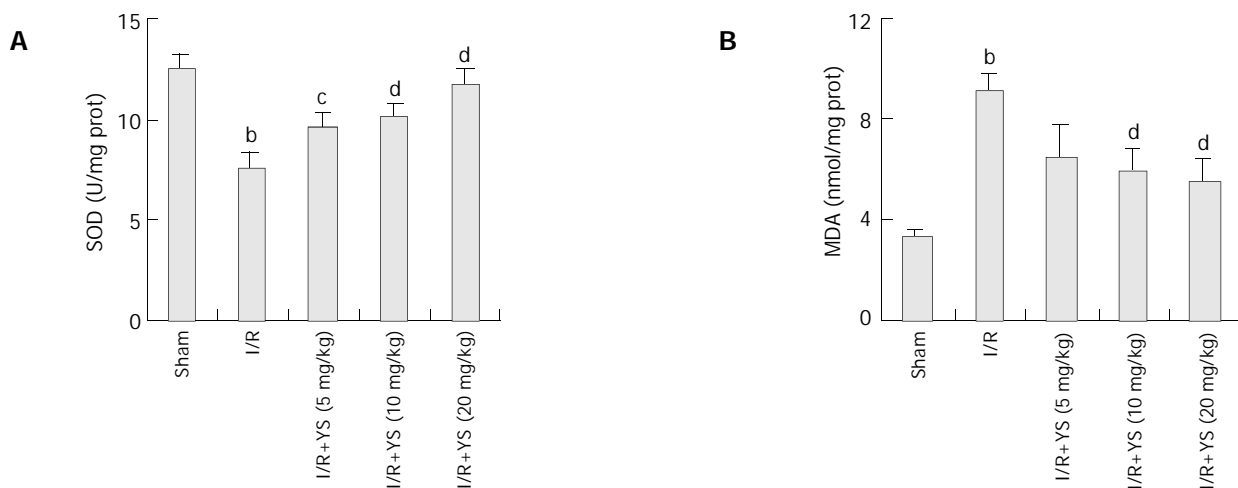

Figure 3 Effects of YS on SOD (A) and MDA (B) levels in liver tissues. After 90 min of ischemia and 6 h of reperfusion, liver tissues were homogenized and assayed for SOD and MDA levels as the index of hepatic oxidative stress. YS with different dose (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. For all groups, n=8. [b]P<0.01 compared with sham group; [c]P<0.05, [d]P<0.01 compared with I/R group.

YS reduced oxidative stress

Hepatic ischemia and 6 h of reperfusion caused marked decrease in liver SOD activity (Figure3A) and resulted in remarkable increases in liver MDA content compared with sham controls (Figure 3B). In the presence of YS at doses of 5, 10 and 20 mg/kg, the liver SOD activities were elevated by about 26.6%, 33.6% and 54.8% respectively, and liver MDA content reduced by 28.6%, 35.2% and 39.6% respectively, both in a dose-dependent manner.

Figure 4 Effects of YS on serum levels of TNF-α analyzed by enzyme-linked immunosorbent assay. Mice were subjected to 90 min of ischemia and 6 h of reperfusion. Saline or YS with different dose (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. For all groups, n=8. ^{b}P<0.01 compared with sham group; ^{c}P<0.05, ^{d}P<0.01 compared with I/R group.

YS reduced TNF-α in serum and ICAM-1 on liver tissues

Hepatic ischemia and 6 h of reperfusion markedly increased the levels of TNF-α in sera (Figure 4). Administration of YS at different doses of 5, 10 and 20 mg/kg significantly reduced the serum levels of TNF-α by about 48.2%, 57.3% and 70.9% respectively (Figure 4). The over-expressions of TNF-α and ICAM-1 on liver tissues after I/R were demonstrated by immunohistochemical assay (Figure 5A, B; Figure 6A, B). In the presence of YS (20 mg/kg), hepatic ischemia/reperfusion-induced increases in TNF-alpha and ICAM-1 expression were dramatically suppressed (Figure 5C; Figure 6C).

YS reduced hepatic mRNA expression of TNF-α and ICAM-1

To determine the expressions of proinflammatory mediators and adhesion molecules, mRNA transcripts for TNF-α and ICAM-1 were assessed. RNA extracts from livers undergoing 90 min of ischemia and 6 h of reperfusion were analyzed by reverse transcription PCR. Furthermore, the band intensity ratios of TNF-α and ICAM-1 to β-actin were evaluated and presented as percentage of β-actin, and were compared among sham, I/R and YS-treated groups. Hepatic ischemia and reperfusion remarkably increased mRNA expression of TNF-α (Figure 7A) and ICAM-1 (Figure 7B), respectively. Administration of YS at doses of 5, 10 and 20 mg/kg significantly abrogated hepatic ischemia/reperfusion-induced increases in TNF-α and ICAM-1 mRNA expression (Figure 7A, B). The comparison of band intensity ratios of TNF-α and ICAM-1 to β-actin in sham, I/R and YS-treated groups demonstrated that YS treatment at doses of 5,10 and 20 mg/kg effectively suppressed the evaluation of TNF-α and ICAM-1 mRNA expression in a dose-dependent manner (Figure 7C, D).

Figure 5 Immunohistochemical assay of TNF-α on liver tissue. Compared with sham control (A), the expression of TNF-α was highly up-regulated by 90 min of ischemia and 6 h of reperfusion (B), and the up-regulation of TNF-α expression was markedly inhibited by YS (20 mg/kg) (C). Original magnification: ×400.

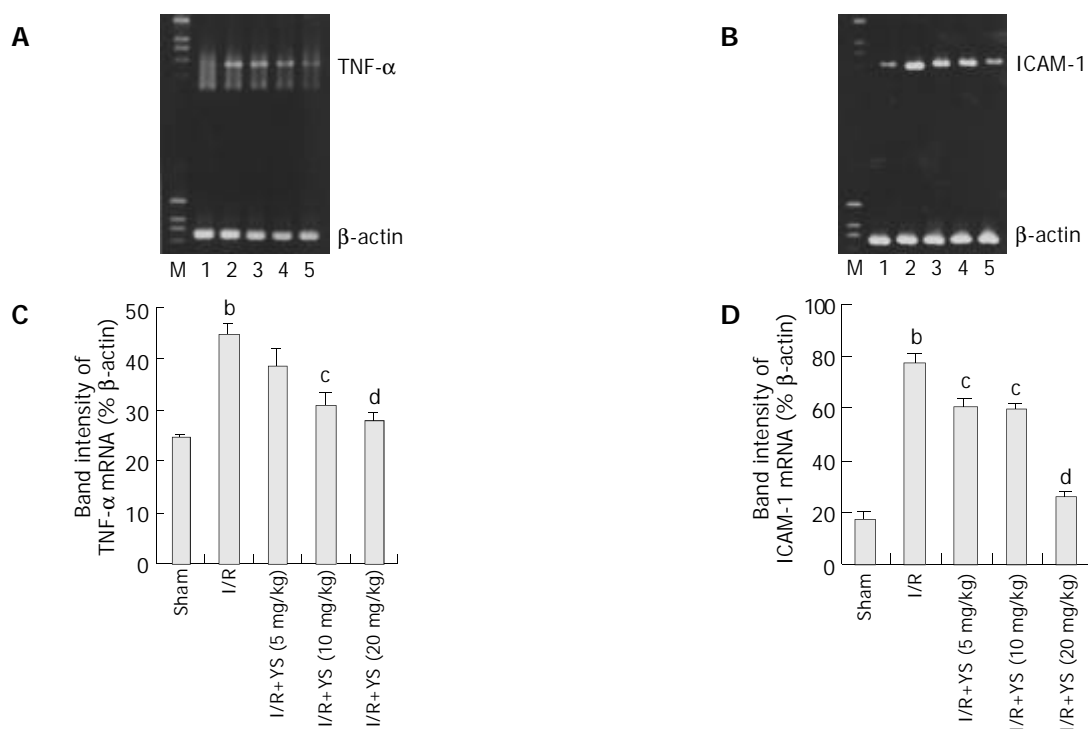
Figure 6 Immunohistochemical assay of ICAM-1 on liver tissue. Compared with sham control (A), the expression of ICAM-1 was highly up-regulated by 90 min of ischemia and 6 h of reperfusion (B), and the increase of ICAM-1 expression was dramatically inhibited by YS (20 mg/kg) (C). Original magnification: ×400.


Figure 7 RT-PCR analysis of TNF-α (A) and ICAM-1 (B) mRNA expression in the liver tissues. β-actin was used as control. Mice were subjected to 90 min of ischemia and 6 h of reperfusion. Saline or YS with different dose (5, 10, 20 mg/kg) was injected intraperitoneally 24 h and 1 h before ischemia and a third dose was injected intravenously just before reperfusion. Liver RNA extracts were analyzed by reverse transcription PCR and stained with SYBR green dye. M: marker; *Lain* 1: sham control; *Lain* 2: I/R group; *Lain* 3-5: 5, 10 and 20 mg/kg of YS treated groups. The band intensities of TNF-α (C) and ICAM-1 (D) in sham, I/R and YS-treated groups were compared. One representative experiment from three performed is shown. [b]$P<0.01$ compared with sham group; [c]$P<0.05$, [d]$P<0.01$ compared with I/R group.

DISCUSSION

Ischemia-reperfusion (I/R) is an unavoidable process in liver transplantation. A major disadvantage of this event is an acute inflammatory response that may cause significant organ damage or dysfunction. Inflammatory organ injury is a primary concern after liver transplantation[18]. Previous studies have identified many of the mediators involved in the pathogenesis of hepatic ischemia/reperfusion injury[4-8]. Among them, ROS, TNF-α, ICAM-1 and neutrophil are central to this process[6,19].

After warm ischemia, ROS produced at the moment of reperfusion activated and promoted the adhesion of leukocytes to microvascular endothelium[20]. Previous studies suggest that free radicals formed during reperfusion are involved in the mechanism of graft failure following liver transplantation in the rat[21]. Moreover, oxidative stress is found to have sustained for a long time after clinical liver transplantation[22], and linked with primary graft nonfunction[23]. Furthermore, studies of lung[24] and renal[25] transplant recipients have suggested that oxidative stress may predispose grafts to acute and chronic rejection. On the other hand, treatment of ROS-scavenging enzymes, such as SOD, can prevent the large increase in MPO activity (an index of tissue neutrophil count) associated with ischemia-reperfusion[26], reduce hepatic oxidative stress, and effectively protect liver against ischemia-reperfusion injury and transplanted liver failure[27,28].

Results in this study showed that treatment of YS at different doses of 5, 10 and 20 mg/kg elevated the liver SOD activities and reduced the hepatic MDA contents in a dose-dependent manner (Figure 3A, B), demonstrating YS' effects to reduce the oxidative stress caused by hepatic warm ischemia/reperfusion and attenuate subsequent organ damages (Figure 1A,B).

TNF-α produced by activated Kupffer cells is thought to play a central role in the initial phase of ischemia/reperfusion injury[7]. Previous studies have showed that TNF-α caused overexpression of adhesion molecules on both endothelial cells and leukocytes[29];

had multiple effects on neutrophil activity, including increased ROS generation[30]; increased neutrophil aggregation and adhesion to endothelial cells[31]; and resulted in hepatocyte necrosis[32] or apoptosis[33,34]. On the other hand, recent studies have demonstrated that neutralization with specific monoclonal antibodies against TNF-α before ischemia induction can ameliorate apoptosis and attenuate postischemic hepatic injury[35].

Administration of YS significantly reduced the serum levels of TNF-α (Figure 4) and the TNF-α expression on liver tissues (Figure 5), and this effect was confirmed by RT-PCR analysis on TNF-α mRNA in liver tissues (Figure 7A, C). This means YS treatment can effectively reduce the release of TNF-α through suppressing the overexpression of TNF-α mRNA caused by hepatic ischemia/reperfusion, and attenuate subsequent insult events mediated by overexpression of TNF-α, such as up-regulation of adhesion molecules and neutrophil recruitment.

Normally, ICAM-1 is weekly expressed on portal and hepatic endothelium, but in acute rejection and ischemia/reperfusion there is over-expression of ICAM-1 on bile ducts, endothelium, and perivenular hepatocytes[19,20]. ICAM-1 is found to be a potent specific indicator of rejection and may be useful in predicting which patient will progress to irreversible rejection[19].

It has been found that TNF-α can directly up-regulate the expression of ICAM-1 in both lung and liver after hepatic ischemia/reperfusion injury[7], and the over-expression of ICAM-1 may result in the adhesion and transmigration of neutrophils from the vascular lumen into tissue parenchyma[36], ultimately leading to tissue injury and organ dysfunction[18]. Furthermore, blockade of TNF-α decreases hepatic expression of the adhesion molecule ICAM-1 as well as liver neutrophil recruitment[7].

Treatment with YS effectively suppressed the overexpression of ICAM-1 on liver tissue (Figure 6) and abrogated hepatic ischemia/reperfusion-induced increase in ICAM-1 mRNA expression (Figure 7B). As a result, the neutrophil recruitment

was effectively reduced by YS treatment (Figure 2A) and the liver edema was attenuated as well (Figure 2B).

In summary, YS treatment significantly reduced the oxidative stress, the overexpression of TNF-α and ICAM-1, and the neutrophil recruitment associated with hepatic ischemia/ reperfusion, and finally effectively protected liver against ischemia/ reperfusion injury. This drug would be a useful tool for preventing liver dysfunction or failure caused by hepatic ischemia/reperfusion injury in liver surgery and liver transplantation.

Abstract

AIM: CT virtual endoscopy has been used in the study of various organs of body including the biliary tract, however, CT virtual endoseopy in diagnosis of gallbladder polyps has not yet been reported. This study was to evaluate the diagnostic value of CT virtual endoscopy in polyps of the gallbladder.

METHODS: Thirty-two cases of gallbladder polyps were examined by CT virtual endoscopy, ultrasound, CT scan with oral biliary contrast separately and confirmed by operation and pathology. CT biliary cystoscopic findings were analyzed and compared with those of ultrasound and CT scan with oral biliary contrast, and evaluated in comparison with operative and pathologic findings in all cases.

RESULTS: The detection rate of gallbladder polyps was 93.8%(90/96), 96.9%(93/96) and 79.2%(76/96) for CT cystoscopy, ultrasound and CT scan with oral contrast, respectively. CT biliary cystoscopy corresponded well with ultrasound as well as pathology in demonstrating the location, size and configuration of polyps. CT endoscopy was superior to ultrasound in viewing the polyps in a more precise way, 3 dimensionally from any angle in space, and showing the surface in details. CT biliary cystoscopy was also superior to CT scan with oral biliary contrast in terms of observation of the base of polyps for the presence of a pedicle, detection rates as well as image quality. The smallest polyp detected by CT biliary cystoscopy was measured 1.5 mm×2.2 mm×2.5 mm.

CONCLUSION: CT biliary cystoscopy is a non-invasive and accurate technique for diagnosis and management of gallbladder polyps.

INTRODUCTION

Since Klein *et al.*[1] in 1993 reported the computed tomographic cholangiography using spiral scanning and 3D image processing, many lesions of the biliary tract have been studied[2-14]. In 1994 CT virtual endoscopy (CTVE) was introduced, its application in obtaining organ images has been described extensively[15-28]. However, we have not seen any report concerning CTVE in the diagnosis of polyps of the gallbladder. In the current paper we reported the CTVE findings of gallbladder polyps in 32 patients.

MATERIALS AND METHODS

From January 1999 to the present study, 32 patients with gallbladder polyps confirmed by operation and pathology underwent CT biliary cystoscopy (CT virtual endoscope of the gallbladder, CTVEGB). There were 18 males and 14 females (age range, 28-47 years, mean age, 35.8 years). Eight patients had vague pain in the right upper abdomen, 4 patients had colicky pain, and the remaining 20 patients were asymptomatic. All patients had normal serum bilirubin and alkaline phosphatase levels. On the day of CTVEGB, abdominal ultrasonographic studies were done for all patients.

The CT scanner was Somatom plus 4 power helical CT (Siemens, Germany) with a Virtuoso workstation (WS). The sonographic equipment was color Doppler ultrasound HDL 5 000 (ATL USA). Sixteen hours prior to CT study, each patient took 4.5 g of iopanoic acids orally and the gastrointestinal tract was properly prepared. CT scanning parameters were: 120 kV, 200-220 mA, slice thickness 2-3 mm, pitch 1-1.2 or 1.5-2.0; image reconstruction interval: 0.8-1.2 mm or 1.5-2.0 mm, FOV 214-263 mm; scan time 25-32 s, scan speed 0.75 s per 360° revolution.

Image post processing was done by Dr. Hu. The reconstructed image was transferred to virtuoso WS. "Fly" software was used to obtain 3D stereo image of the gallbladder and surrounding structures, then virtual endoscopic image of the gallbladder was proceeded simply by double click on the mouse, threshold value was adjusted so that the normal gallbladder mucosa was displayed clearly (Figure 1). The threshold value ranged from -178-251HU. Color encoding was performed using green color (color of the bile). Endoscopy was carried out from any viewpoint in the gallbladder with varying views, size, speed and angle, and detailed scrutiny was performed. It took 1 h to complete CTVEGB. All axial source CT images were interpreted as spiral CT with oral biliary contrast (OCCT) and 3D stereo images using fly software as CTVEGB, which were done by two radiologists, who were unaware of the clinical and ultrasonographic information. Another two radiologists did ultrasonographic study. All radiologists worded together in evaluating the number, size, configuration, location, surface and base of polyps of the gallbladder. A professional statistician performed all statistical analyses by using a commercially available statistical software package (SAS Institute, Cary, Nc). The results of CTVEGB, OCCT, ultrasound and pathology were compared with each other by means of the chi-square test.

RESULTS

On OCCT, the gallbladder was clearly visualized in 32 cases. The 3D stereo view clearly displayed the gallbladder and its surrounding structures such as the liver, ribs and spine on maximum intensity projection (MIP) protocol. CTVEGB images were obtained from all patients. No procedure-related adverse reaction was observed in all 32 cases.

Correlation of CTVEGB with ultrasound

The 3D image, CTVEGB image (Figure 1A) and axial source

image could be displayed simultaneously on Virtuoso WS. CTVEGB could be manipulated flexibly from multiple views and various angles so that the location, size, configuration, surface and base of the polyps could be clearly shown better on CTVEGB than on ultrasound images. Among the 32 cases with gallbladder polyps, the detection rate of polyps was 96.9(93/96) by ultrasound and 93.8%(90/96) by CTVEGB. Comparison of ultrasound and CTVEGB with operative and pathologic findings is shown in Table 1. The smallest polyp detected by CTVEGB measured 1.5 mm×2.2 mm×2.5 mm (Figure 1B). One polyp with cauliflower appearance (Figure 1C) and another butterfly-like one were detected by CTVEGB, which were in accordance with ultrasound (Figure 1D) and operative findings. Pathologically both were confirmed to be inflammatory polyps of the gallbladder (Figure 1E).

Comparison between CTVEGB and OCCT

On OCCT, the gallbladder filled with contrast medium was well visualized, the polyps appeared as filling detects of various sizes and numbers. Among the 96 polyps, OCCT detected 76 while CTVEGB detected 90, the detection rate was 79.2% and 93.8% respectively. The correlation with operative and pathologic findings is shown in Table 2. CTVEGB missed 3 polyps with a diameter <3 mm, while OCCT missed 20 polyps with a diameter <5 mm. The difference was statistically significant ($P<0.01$, a=0.05).

CTVEGB and pathological classification

The incidence of polyps was related to the pathologic type. Of the 90 polyps detected by CTVEGB, 60 were cholesterol polyps, in which 12(20%) were single cholesterol polyps (Figure 1B) and 48(80%) were multiple cholesterol polyps (Figure 1D). Among the 30 inflammatory polyps, 15(50%) were single polyps (Figure 1F) and 15 were multiple types (Figure 1C). The size of gallbladder polyps was related to pathologic types. Among the 90 polyps detected by CTVEGB, 60 were cholesterol polyps, in which 38(63%) had the greatest diameter ≤5 mm, 22 (37%) had a diameter of 5-10 mm and 0(0%) had a diameter of ≥10 mm. There were 30 inflammatory polyps, 10(33%) were ≤5 mm, 8(27%) were 5-10 mm and 12(40%) were ≥10 mm. The configuration of polyps was related to pathologic types. Among the 60 cholesterol polyps, 52(87%) had a spherical configuration, 7(11%) were papillary and 1(2%) irregular in outline. Of the 30 inflammatory polyps, 23(77%) were spherical and 7(23%) were irregular and none was papillary in form. The location of gallbladder polyps was

Figure 1 CTVEGB detection of gallbladder polyps. A: Surface detail of gallbladder displayed by CTVEGB in a 47-year old normal man. B: Smallest single cholesterol polyp (arrow head) detected by CTVEGB in a 28-year-old man. C: Multiple gallbladder polyps in a 30- year-old man. (1) Multiple polyps of cauliflower appearance and small polyps (arrow head). (2) Color ultrasonography found multiple polyps of cauliflower appearance and small polyps (arrow head). (3) Multiple polyps were inflammatory polyps on pathology (HE×20). D: Multiple cholesterol gallbladder polyps in a 30-year-old woman. Two cholesterol polyps (arrow head) were proved by pathology (HE×20). E: Single inflammatory gallbladder polyps in a 29-year-old woman. An irregular inflammatory polyp was proved by pathology (HE×20).

Table 1 Comparison of ultrasound and CTVEGB in 96 gallbladder polyps

Modality	Polyps (n)	Diameter (mm)			Location (n)			Configuration (n)					Base (n) peduncle	
		<5	5-10	10-	Neck	Body	Base	Spherical	Papillary	Irregular	Butterfly	Cauliflower	(-)	(+)

Table 2 Comparison of OCCT and CTVEGB in 96 gallbladder polyps

Modality	Polyps	Diameter (mm)			Location (n)			Configuration (n)					Base (n) peduncle	
		<5	5-10	10-	Neck	Body	Base	Spherical	Papillary	Irregular	Butterfly	Cauliflower	(-)	(+)
Pathology	96	54	30	12	24	64	8	81	7	6	1	1	58	38
OCCT	76	34	30	12	24	44	8	61	7	6	1	1	52	24
CTVEGB	90	48	30	12	24	58	8	75	7	6	1	1	52	38
χ^2	7.518	8.561				8.157		7.743					14.797	
P value	<0.01	<0.01				<0.01		<0.01					<0.01	

1. Statistical difference between ultrasound and CTVEGB findings ($P<0.01$, a=0.05); 2. CTVEGB is abbreviation of CT virtual endoscopy of the gall bladder; 3. OCCT is abbreviation of spiral CT with oral biliary contrast.

related to pathologic types. Of the cholesterol polyps, 40(67%) were located in the body of gallbladder, 19(31%) in the neck and 1(2%) in the base. Of the 30 inflammatory polyps, 18(60%) were located in the body of gallbladder, 5(17%) in the neck and 7(23%) in the base. The presence or absence of a pedicle was related to pathologic type. There were 36(60%) cholesterol polyps with a pedicle and 24(40%) devoid of a pedicle. Two (7%) inflammatory polyps were pedunculated and 28(93%) not.

DISCUSSION

A lot of techniques have been developed for studying the biliary tract. Ultrasonography, the technique of choice for studying the gallbladder, is of limited value in the evaluation of polyps of gallbladder, depending on the operator's skill. Intravenous cholangiography is a safe technique, but does not adequately opacify the polyps of gallbladder. Conventional computed tomography (CT) is inadequate for detection of low-density lesions of the gallbladder. ERCP and PTC can provide excellent delineation of biliary anatomy and pathology, but both are invasive and associated with risks and complications. MR cholangiography is a popular noninvasive technique and has been shown to be both sensitive to and specific for visualization of various conditions of the biliary tract. Although it is safe, the technique is contraindicated in patients with aneurysm clips or cardiac pacemakers. In addition, MR cholangiography may not be suitable for patients with claustrophobia or those with multiple metallic clips, which may cause artifacts. There are few alternatives to the invasive techniques, and additional noninvasive techniques are in demand.

Spiral CT allows imaging of a volume of tissue during a single breath-hold. Axial CT data could be reconstructed into two-dimensional multi-planar or three-dimensional (3D) volume-rendered images using workstations and image-rendering software[1]. This CT technology combined with the administration of IV cholangiographic contrast agents could produce diagnostic images of the biliary tract[2-7,9,10,14], and has been used for diagnosis of obstructive biliary disease, choledochocele, choledocholithiasis and aberrance bile ducts. The main limitation of this technique is that the rate of allergic reactions and renal or hepatic toxicity (or both) are relatively

high due to by these contrast agents.

Oral cholangiographic contrast agents are a potential alternative to IV contrast agents. Unlike the later, these contrast agents had few side effects, such as diarrhea, loose stools, nausea and stinging on urination[8]. Because the patients ingested 6 g iopanoic acid before CT examination[8,11,13], the contrast agents were decreased to 4.5 g iopanoic acid. No side effect was found in our study. CT cholangiography was used to assess choledoch variants and describe choledocholithiasis[8,11,13]. To our knowledge, there have been few studies or reports in which IV cholangiograhpic contrast agents were used to diagnose gallbladder polyps[10]. It has not yet been established whether these oral contrast agents can reliably demonstrate gallbladder polyps on CTVEGB.

Some factors could influence the image quality of CTVEGB, which is important for precise diagnostic information. Usually 16 h after oral administration of 4.5 g iopanoic acid, CTVEGB could yield the image of gallbladder with a good quality. With a dose of 3.0 g, visualization of the gallbladder would be inadequate. Inadequate control of respiratory motion has adverse impact on image quality, resulting in failure to detect small lesions or ragged distortion of large lesions. Optimal image quality is achieved by single breath hold. Higher reconstruction rates such as 0.8-1.2 mm are more helpful in displaying minute lesions and the details. Higher pitch (1.5-2.0) may produce artifact-mimicking polyps or miss small lesions. Pitch 1.0-1.2 is a good choice. FOV is related to the displayed area of the surrounding structures but not to observation of the polyps. However, adequate FOV can clearly demonstrate the stereo relation of gallbladder and surrounding structures. The threshold value seriously affects effective observation of polyps. Variation of the threshold value leads to marked change in visualization of the size and appearance of polyps, therefore selecting appropriate threshold value is critical to avoid image distortion. Generally, a threshold value is selected so that the normal gallbladder mucosa is shown clearly.

Based on our clinical experience in diagnosing gallbladder polyps by CTVEGB, TVEGB can clearly display the normal anatomy of the interior of gallbladder. CTVEGB can clearly show the size, configuration, location, surface and base of gallbladder polyps in accordance with color ultrasound,

operative and pathologic findings. The smallest polyp reported in this article was 1.5 mm×2.2 mm×2.5 mm. Localization of the polyps was accurate. Good depiction of polyp configuration could be obtained. In this series 12 polyps with irregular appearance were proved to be inflammatory in nature with adhesions. Detailed observation of the base of polyps to confirm the presence of a pedicle by CTVEGB was possible by viewing from different angles and in this respect, CTVEGB was superior to color ultrasound. Among the 96 polyps, CTVEGB missed 6 polyps with the diameter less than 3 mm. Color ultrasound missed 3 polyps because of adhesion with surrounding tissues. The difference, however, was not statistically significant (*P*>0.05). The correspondence was good. OCTT, being a safe, simple and efficient method[1-7], is capable of detecting biliary calculus, tumor, anomaly and dilatation of the biliary tract and protruding lesions with a bigger size. However, limited by the concentration of contrast medium, small polypous lesions are easily obscured and thus escaping detection by OCCT. In this series, 20 polyps with a diameter less than 5 mm were missed. OCCT is also inferior to CTVEGB in terms of observation of the base of polyps for the presence of a pedicle, detection rate as well as image quality.

In comparison of the findings of CTVEGB with pathological changes, in cholesterol polyps, multiple polyps were far more frequently seen than single polyps (80% *vs* 20%). While in inflammatory polyps, the incidence was 50% for each, indicating that most cholesterol polyps were multiple, while single polyp and multiple ones were equally common in inflammatory polyps. Among the cholesterol polyps, 63% were ≤5 mm, 37% were between 5-10 mm, none was ≥10 mm. While in inflammatory polyps, 33% were ≤5 mm, 27% was between 5-10 mm, 40% were ≥10 mm, indicating that smaller polyps (≤5 mm) were common in cholesterol polyps and bigger ones (≥10 mm) were common in inflammatory polyps. Among cholesterol polyps, spherical type was most common (87%), followed by papillary type (11%), then irregular type (2%). For inflammatory polyps, 77% were spherical type, 23% irregular type. There was no papillary inflammatory polyp in this series. For cholesterol polyps, 67% occurred in the body of gallbladder, 31% in the neck and 2% in the base. Whereas for inflammatory polyps, they were 60%, 23% and 17% in the body, base and neck respectively. Cholesterol polyps usually occurred in the body and neck of the gallbladder, while for inflammatory polyps usually in the body and base. Sixty percent of the cholesterol polyps were pedunculated and 40% were devoid of a pedicle. Most of the inflammatory polyps (93%) were non-pedunculated.

Abstract

AIM: To investigate whether hepatic progenitor cells (HPC), that reveal the features of oval cells in rodents and small epithelial cells (SEC) in certain human liver disease, were also found in human liver cirrhosis (HLC).

METHODS: Surgical liver specimens from 20 cases of hepatitis B virus-positive HLC (15 cases containing hepatocellular carcinoma) were investigated by light microscopic immunohistochemistry (LM-IHC). Among them specimens from 15 cases were investigated by electron microscopy (EM) and those from 5 cases by immunofluorencence confocal laser scanning microscopy (ICLSM). Antibodies against cytokeratin 7 and albumin were used and single and/or double labelling were performed respectively.

RESULTS: LM-IHC showed that at the margins of regenerating nodules and in the fibrous septae, a small number of cells in the proliferating bile ductules were positive for CK7 and albumin. At the EM level these HPC were morphologically similar to the SEC described previously, and also similar to the oval cells seen in experimental hepatocarcinogenesis. They were characterized by their small size, oval shape, a high nucleus/cytoplasm ratio, a low organelle content in cytoplasm, and existence of tonofilaments and intercellular junctions. ICLSM revealed that HPC expressed both cytokeratin 7 and albumin.

CONCLUSION: HPC with ultrastructural and immunophenotypical features of oval cells, *i.e.*, hepatic stem cell-like cells as noted in other liver diseases, were found in HLC. These findings further support the hypothesis that bipotent hepatic stem cells, that may give rise to biliary epithelial cells and hepatocytes, exist in human livers.

INTRODUCTION

In rodents, administration of hepatocarcinogens could lead to proliferation of oval cells that are capable of differentiating towards both hepatocytes and bile duct epithelium. These oval cells are thought to be hepatic progenitor cells or stem cells[1-4]. In contrast to the situation in rodents, it is still controversial, however, whether hepatic progenitor cells also exist in human livers. Recently, we described a population of cells with the morphological and immunophenotypical features of oval cells in hepatoblastoma (HB) that we termed small epithelial cells (SEC)[5-6]. In further studies we also observed similar cells in livers of patients with hepatocellular carcinoma (HCC)[7], extrahepatic biliary atresia (EBA)[8] and HLC[9].

SEC reveal certain morphological features, such as a small size, a high nucleus to cytoplasm ratio, intercellular junctions and tonofilaments. Under immunoelectron microscopy, SEC were found to express both cytokeratin 7 (a marker of biliary differentiation), and albumin (a marker of hepatocytic differentiation)[5-9]. Thus SEC exhibit morphological and immunophenotypical features of oval cells in rodents. This study was undertaken to further verify that SEC did occur in hepatitis B virus (HBV)-positive HLC and that such cells played a key role in the pathogenesis of the disease. The findings further support the hypothesis of the existence of human hepatic stem cells.

MATERIALS AND METHODS

Fifteen surgical specimens of cirrhotic liver tissue adjacent to HCC were investigated. All patients were HBV-positive. As controls, 5 specimens of HBV-positive cirrhotic liver tissue from patients without liver tumour and 5 specimens of normal liver tissue were investigated.

For routine histological and immunohistological investigation, the tissue was fixed in 40 g/L buffered formaldehyde and embedded in paraffin. Immunohistochemical investigations were performed on all specimens using an undiluted monoclonal mouse antibody against cytokeratin 7 and a polyclonal antibody against albumin (both from DAKO, Glostrup, Dennmark) diluted 1:1 000. Single labelling with each antibody separately, and double labelling using both antibodies on the same section, were carried out.

For conventional transmission electron-microscopic (TEM) investigation, the tissue was fixed in 40 g/L glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.3). TEM investigations as described elsewhere[5-9] were performed on 10 cases of HLC with associated HCC. In order to distinguish labelling of the 2 antigens (cytokeratin 7 and albumin) in the double labelling procedure, goat anti-mouse IgG, goat anti-rabbit IgG as secondary antibodies and DAB (brown), NBT (green) as chromogen were used respectively.

For ICLSM investigation the specimens from 5 cases of HLC with associated HCC, 2 cases without HCC and 2 specimens of normal liver tissue were fixed in 40 g/L buffered formaldehyde and embedded in paraffin for immunohistochemical investigations.

Paraffined sections were prepared for immunofluorescent labelling. Briefly, primary antibodies against cytokeratin 7 (undiluted) and albumin (1:1 000 diluted in phosphate-buffered saline with 5 g/L bovine serum albumin and 1 g/L gelatine) and secondary antibodies (goat anti-mouse IgG and goat anti- rabbit IgG) conjugated with FITC or Cy3 (Sigma) were used. Double labelling using both antibodies on the same section was performed. Primary antibodies and secondary antibodies were incubated for 1 h at room temperature. Nuclear staining was carried out with DAPI (Sigma) in PBS. Slides were stored at 4 ℃ and analysed within 24 h. As a control, the primary antibody was omitted.

Immunofluorescence was observed with Zeiss LSM 510 (Zeiss; Jena, Germany). We used an argon laser at 488 nm in combination with a helium neon laser at 543 nm to excite the green (CK7) and red (albumin) fluorochromes simultaneously. Emitted fluorescence was detected with a 505-530 nm bandpass filter for the green signal, a 560 nm longpass filter for the red signal and 633 nm filter for the blue signal.

RESULTS

In all the investigated cases of HLC, micronodular and/or macronodular cirrhosis was a basic morphologic feature. In fibrous septae, proliferating bile ductules and lymphocytic infiltrates were found at a varying extent. Hepatic progenitor cells (HPC) with a histological picture morphologically similar to oval cells of rodents were found in all cases studied (Figure 1). HPC were numerous in proliferating bile ductules or noted as discretely scattered cells at the edge of regenerating nodules and in fibrous septae (Figure 1). The number of HPC varied from 2 to 10 in 40 high power fields. Their number was larger in cases exhibiting signs of active regeneration, but no differences were seen between cases with and without associated HCC. HPC, however, were not observed in normal livers. Immunohistochemical investigations showed that HPC could express both cytokeratin 7 and albumin (Figures 2-4). In the normal liver, hepatocytes were immunoreactive for albumin and biliary epithelial cells for cytokeratin 7. No double staining of albumin and cytokeratin 7 could be found in hepatocytes or biliary epithelial cells in normal livers.

Figure 1 HLC. Several proliferating bile ductules are seen at the edge of a regenerating nodule. There is a dense, mostly lymphocytic inflammatory infiltrate. Haematoxylin and eosin ×200.

At electron microscopic level, a very small number of cells with ultrastructural features typical of the SEC found in HB[5,6], EBA[8] and HCC[7] were noted in all cases of HLC. As noted by light microscopy, HPC were mainly located in ductules that were composed of 2-8 cells, and they were also seen in the fibrous septae and at the periphery of nodules. They were characterized by their small size (8 to 18 μm), oval shape, scanty cytoplasm with a high nucleus/cytoplasm ratio, tonofilament bundles, tight junctions or desmosome-like junctions, and an

oval, electron-dense nucleus in which heterochromatin was seen as small clumps dispersed in the nucleoplasm with peripheral condensation. Junctions were found both between HPC and hepatocytes and between HPC and epithelial cells of small bile ductules (Figures 5 and 6).

Figure 2 HLC. Immunohistochemical staining shows that cells of proliferated bile ductules are strongly positive for CK7. Anti-CK7, ×200.

**Figure 3** HLC. Some small hepatic progenitor cells, immunoreactive with albumin are seen at the edge of regenerated nodule. Anti-albumin ×200.

Figure 4 HLC. Double labelling immunohistochemistry shows that cells of proliferated bile ductules are positive for CK7 (brown), hepatocytes are positive for albumin (green) and a few HPC are stained with both CK7 and albumin (brown-green). Anti-albumin and CK7, ×200.

The number of organelles in HPC varied. Some contained numerous free ribosomes, and others contained free ribosomes and rough endoplasmic reticulum. As in EBA and hepatoblastoma[8], HPC with ultrastructural features of differentiation towards biliary epithelial cells or hepatocytes were also found in HLC. These differentiated cells were mainly located in proliferating bile ductules. HPC with signs of biliary differentiation contained a higher number of tonofilament bundles than undifferentiated HPC and sometimes exhibited small surface microvilli and

formed bile canaliculi with neighboring hepatocytes[9]. Some HPC were partly surrounded by a basement membrane. HPC with signs of hepatocytic differentiation exhibited more cytoplasm, more mitochondria and fewer tonofilament bundles than undifferentiated HLC. Intercellular junctions between HPC and adjacent biliary epithelial cells were noted not only in undifferentiated HLC but also in HLC with signs of biliary and hepatocytic differentiation (Figures 5 and 6).

Figure 5 HLC. Under electron microscopy, two HPC characterized by small size (approximately 10 μm), oval shape, and high nucleo/cytoplasm ratio, are seen. They are adjacent to hepatocytes (H) on one side and to HPC on the other side. ×5 000.

Figure 6 HLC. At higher magnification, cytoplasm of HPC is seen to contain tonofilaments (thin arrow) and intercellular junctions (thick arrows) between HPC and hepatocytes. ×16 000.

Figure 7 HLC. Immunofluorencence confocal laser scanning microscopy (ICLSM) indicates at edge of regenerating nodules, proliferating bile ductules in which not only bile epithelia cells (anit CK7, green), but also HPC (anti CK7 and albumin, orange) are noted. ×1 800.

ICLSM investigation revealed labelling of HPC for both cytokeratin 7 and albumin. HPC with double labelling of both cytokeratin 7 and albumin were observed, as noted under light microscopy, at margins of regenerating nodules, in fibrous septae, and especially in proliferating bile ductules

that were composed of 2-8 cells. Although we could not see the accurate location of a labelling for cytokeratin 7 (as seen with immunoelectron microscopy, this was associated mainly with tonofilament bundles) and for albumin (this was cytoplasmic and diffuse), but the double labelling in HPC was rarely noted from this method. Some HPC (with signs of biliary differentiation) exhibited a stronger labelling for cytokeratin 7 and a weaker labelling for albumin. In comparison, those cells with signs of hepatocytic differentiation exhibited a stronger labelling for albumin and a weaker labelling for cytokeratin 7 (Figures 7 and 8).

Figure 8 HLC. Immunofluorencence confocal laser scanning microscopy (ICLSM) shows that two proliferating bile ductules are composed only of bile epithelial cells (anit CK7, green), but one proliferating bile ductule contains HPC (anti CK7 and albumin, orange). ×1 000.

DISCUSSION

In rodents, administration of hepatocarcinogens could lead to proliferation of oval cells, which are characterized by certain morphological features, such as a small size, an oval shape and a high nucleus/cytoplasm ratio[1-4]. These cells express both biliary and hepatocytic markers, and are able to differentiate into biliary epithelial cells and hepatocytes. It has been widely accepted that oval cells represent hepatic stem cells in rodent livers, or are at least closely related to them[2].

Whether bipotent hepatic stem cells that give rise to both biliary epithelial cells and hepatocytes exist in human livers, however, is still a matter of controversy[2]. Cells with the morphologic features of oval cells in rodents have been recently, described in various liver diseases[11-13]. In previous studies we demonstrated that cells with the morphological and immunophenotypical features of oval cells of rodents, that we termed SEC, existed in human livers under pathological conditions such as in HB[5,6], HCC[7], EBA[8] and HLC[9] but not in normal livers[5-9]. In this study, we further demonstrated with immunohistochemistry, ICLSM and electron microscopic technique, that HPC did occur in HLC due to HBV infection in cases with and without associated HCC.

As in HB, HCC and EBA, HPC in HLC exhibit several important features that closely resemble those of oval cells of rodents. (1) They are often characterized by an oval shape and an oval nucleus, a high nucleus/cytoplasm ratio and a small size with 8-18 μm average diameter. (2) The ultrastructural features of HPC closely resemble those of oval cells as described in rodents[10], i.e., HPC represent desmosome-like or tight junctions, tonofilaments, microvillous interdigitations and basement membrane. (3) They exhibit corresponding immunophenotypes to oval cells as shown by immunohistochemistry and ICLSM. These cells are verified to express both albumin (a marker of hepatocytic differentiation) and cytokeratin 7 (in the liver a marker of biliary differentiation). (4) A positive correlation exists between the number of HPC

and the activity of cirrhosis. (5) HPC are located in bile ductules that contain 2-8 cells.

On the basis of our findings in HLC, as described in HB, EBA and HCC, it seems likely that HPC represent potential bipotent stem cells in human livers that by difinition, give rise to biliary epithelial cells and hepatocytes.

There is a likeness of HLC to other liver diseases in that an association exists between the activity or severity of cirrhosis and the number of HPC. This has led us to advance the hypothesis that oval cell proliferation might not be disease-specific but occurs in response to progressive liver injury and fibrosis.

HPC mainly occurred in proliferating bile ductules that were found both in experimental animal models[2] and in various human neoplastic and non-neoplastic liver diseases[11-14]. As to the origin of proliferating ductules, the hypothesis of proliferation of pre-existing bile duct epithelium or a metaplasia of periportal hepatocytes has been reported[2,3,15]. However, there is now increasing evidence that, at least in some cases, proliferating bile ductules arose directly from hepatic progenitor cells not only in rodents[1-4], but also in various human liver diseases[11-14]. This study indicated again that oval-like cells did appear in proliferating bile ductules in human livers and that these ductules might indeed arise from proliferation and differentiation of hepatic progenitor cells.

HPC have been recently demonstrated only in pathological liver specimens but not in normal livers. It can rationally be speculated that as in rodent livers, the activation and proliferation of putative stem cell pool in human livers took place only if the replicative capacity of hepatocytes was severely impaired after some endogenous or exogenous toxic injury or stimuli[10,13,16]. Several studies indicated that HPC activation in rodent livers was regulated by or associated with various factors, such as tumour necrosis factor-α (TNF-α), transforming factor-α (TGF-α), epidermal growth factor (EGF), hepatocyte growth factor (HGF), *etc.*[10,13,16]. Some non-hepatocytes such as Kupffer cells and Ito cells have also been reported to participate in HPC activation[3]. These findings await to be verified in human liver diseases.

In conclusion, HLC caused by HBV-infection contain HPC. The findings further support the hypothesis that human hepatic progenitor cells may play a role in the course of liver diseases.

Abstract

AIM: Considerable controversy surrounds the adoption of endoscopic sphincterotomy (ES) to facilitate the placement of 10F plastic stents (PS) and to reduce the risk of pancreatitis The aim of the study was to assess the possible advantages of ES before PS placement.

METHODS: From 3/1996 to 6/2001, 172 consecutive patients, who underwent placement of a single 10F- polyethylene stent for inoperable malignant strictures of the common bile duct, were randomly assigned to 2 groups. In group A (96 patients), a ES was performed before PS placement In Group B, 96 patients had PS directly. Early complications (within 30 d) and late effects (from 30 d to stent replacement) were assessed. Patency interval was defined as the period between PS placement and obstruction or death. The success of stent replacement in the 2 groups was evaluated.

RESULTS: Stent insertion was successful in 95.8%(92/96) of the pts in group A and in 93.7%(90/96) of the patients in group B (*P*>0.05).Early complications were more frequent in patients who underwent ES (6.5% *vs* 4.4%) but the data were not significant (*P*>0.05). In group A pancreatitis developed in two patients and bleeding in three; whereas pancreatitis occurred in 2 patients in group B. Complications were managed conservatively. No procedure related mortality occurred. All late complications were acute cholangitis due to stent occlusion. We performed a stent replacement in 87 patients that was successful in 84 cases without differences between groups.

CONCLUSION: Sphincterotomy does not seem to be necessary for placement of 10F-PS in patients with malignant common bile duct obstruction.

INTRODUCTION

Endoscopic insertion of biliary stents is the preferred method of palliation for inoperable malignant biliary obstruction[1-3]. It efficiently relieves jaundice and improve quality of life in patients with malignant obstructive biliary disease. The endoscopic approach is more cost-effective than the operative approach.

The use of plastic stents (PS) is nowadays raccomended in patients with poor prognosis (less than 5-6 mo)[4-6]. Initial endoscopic placement of a metal stent is a cost-saving strategy only in patients expected to survive longer than six months.

Controversy exists regarding the use of endoscopic sphincterotomy (ES) before placing 10F stents. Endoscopists who preferred to perform ES pointed out that it was easier to place stents and substitute. Also ES would decrease also post-procedure pancreatitis. Antagonist to ES aim to eliminate risks of complications due to ES. The purpose of this study was to evaluate the potential advantages for ES before PS placement.

MATERIALS AND METHODS

From March 1996 to June 2001 172 consecutive patients who underwent placement of a single 10F polyethylene stent (Cotton Leung biliary stent) for inoperable malignant stricture of the common bile duct, were randomly assigned to two groups (Table 1). In group A (96 patients) an ES was performed before PS was placed.

Group B (96 patients) received PS placement without ES.

The following patients were excluded namely those who had already had ES, precut papillotomy or stent placements, those with previous Billroth II resection and, also, those suffering from coagulopathy. Those with ampullary tumours were not included, either.

The diagnosis and poor prognosis of the patients were estabilished by various imaging methods (US, EUS, TAC, MRC) and on the basis of age.

Patients were randomised by using sealed opaque envelopes. Randomitation was done only after diagnostic cholangiography had been performed.

This study reviewed and approved by the ethics committee of our hospital, was carried out in accordance with the Helsinki Declaration as revised in 1989. All patients were included after they had given their written informed consent on ethics committee forms.

All patients underwent operative endoscopic retrograde cholangiopancreatography (ERCP) with a duodenoscope (JF 140 Olympus) performed by 2 experienced endoscopists. A standard 0.035 –inch guidewire to perform deep cannulation of the biliary tree and to pass through the strictures.

Occasionally a hydrophilic guidewire was used. In every patient we also aimed to visualize the pancreatic duct.

The success the technique was evaluated as a correct placement of the stent with good drainage of bile from the bile duct into the duodenum as visualized endoscopically. Early complications (occurring within 30 d) and late effects (from 30 d to stent replacement or death) were assessed. Complications of papillotomy were considered according to the criteria of Cotton[7] Stents were not replaced routinely and patients were treated if occlusion of the stent or cholangitis

developed.

Occlusion was considered in patients with jaundice.

Patency interval was defined as the period between PS placement and obstruction.

Analysis of data was performed with the statistical package SPSS/PC version 4.0 (M.J. Norusis Chicago, Ill). Rate differences were tested by using the χ^2 analysis with Yates' correction and Fisher's exact test, when appropriate. The Mann whitney *U* test was used to compare maedian values of variables between the two groups. Values of *P*<0.05 were regarded as statistically significant.

RESULTS

Patient characteristicts did not differ between groups (Table 1). A histological diagnosis was obtained in 104 patients (54.1%) using biliary brushing and biopsies, and FNA-US. In the other cases we presume diagnosis using morphologic criteria.

A similar mean stents length among groups indicated a similar localization of biliary strictures.

Results of endoscopic treatment are shown in Table 2. The mean follow up time was 115±95 d (mean±SD).

Table 1 Patients characteristics

	Group A With ES	Group B w/o ES	Total
Patients	96	96	192
Median Age (±SD)	72±6	75±6	73±7
Gender (M/F)	51/35	47/39	98/74
Bilirubine (mg/dL)	13.5	11.9	12.7
Stent lenght(cm)	6.78	6.76	6.79
Visualization of pancreatic duct	77	79	156
Pancreatic cancer	64 (66.6 %)	67 (69.8 %)	131 (68.2%)
Cholangiocarcinoma	31 (32.3 %)	28 (29.1 %)	59 (30.7 %)
Metastatic lymph nodes	1 (1.1%)	1 (1.1%)	2 (1.1 %)

Table 2 Endoscopic tecnique results

	Group A With ES (%)	Group B w/o ES (%)	P
Successful stent insertion	92/96 (95.8)	90/96 (93.7)	0.745
Early complications	6/92 (6.5)	4/90 (4.4)	0.772
Pancreatitis	2/92 (2.2)	2/90 (2.2)	0.629
Bleeding	3/92 (3.7)	0/90	0.252
Clogging	1/92 (1.2)	2/90	0.985
Procedure related mortality	0	0	
Late complications	16/92 (17.4)	15/90 (16.6)	0.946
Migration	3/92 (3.2)	3/90 (3.3)	0.698

Four cases of pancreatitis were treated successfully with conservative therapy.

In all the 3 cases bleeding stopped after papillar needle infiltration with adrenaline solution.

In three cases we have early clogging of the prostheses and we performed an urgent stent replacement. No procedure related mortality occurred. In 6 cases (6.5%) stents migrated proximally. 86 patients died before stent occlusion (8 during the first month but non related to endoscopic therapy). Nine patients did not come for follow-up after the first period of 30 d.

Late complications in all cases were acute cholangitis due to stent occlusion.

Eighty-seven patients (47.8%) needed a stent replacement which was successful in 95.4% of the cases (Table 3).

Table 3 Stents replacement

	Group A with ES	Group B w/o ES	P
Patients (*n*)	41	46	
Successful stent replacement	39/41	45/46	0.919
Patency (median±SD)	109±15	110±18	0.765

DISCUSSION

Our data showed no differences between two groups in regard to success of stent insertion, incidence of early and late complications and patency. Our data were similar to those of literature[8-9] limited to common bile duct obstructions.

In a retrospective study, Margulies[10] considered the effect of sphincterotomy on acute and chronic complications of 10F stent therapy in 130 patients. The incidence of acute complications was higher in patients undergoing sphincterotomy 8.3% *vs* 1.2% *P*=0.04). A gastrointestinal bleeding was seen in 3 cases (6.2%) in whom ES was performed. There were no inclusive criteria reported in this study, therefore we do not know whether patients with coagulopathy were considered.

In our experience the incidence of bleeding was lower. We had three cases of bleeding in the ES group (3.1%) which were treated successfully with endoscopic therapy.

Coagulopathy has been found to be an indipendent risk factor for hemorrhage after ES[11] and its incidence increases in cholestasis[12,13].

In a retrospective study, Tarnasky[14], found that the rate of pancreatitis following transpapillary stenting without ES increased in patients with a proximal biliary stenosis because this kind of lesion worked as a fulcrum leading to a distal deflection of the stent and a consequential compression of the pancreatic orifice. Patients with proximal biliary strictures were at significantly increased risk for postprocedure pancreatitis (4 of 24) versus those with distal or no stricture (0 of 59) (*P*=0.006).

In our study the incidence of pancreatitis was not significantly different between the two groups (Group with ES: 2/92, Group without ES 2/90), probably because our patients did not have proximal stenosis.

Johanson[15] examined multiple risk factors associated with stent migration such as stent diameter and length.In his study the odds ratio of proximal migration in patients with ES was 3.9, and 0.3 in patients without ES.

The association between sphyncterotomy and proximal migration was not statistically significant, but the authors concluded if ES was not performed the risk of proximal migration might decrease.

Lahoti[16] examined retrospectively 2 993 procedures for insertion of biliary or pancreatic duct stents. Thirty-three proximally migrated duct stents and twenty-six proximally migrated pancreatic duct stents were identified. All patients except one had a sphincterotomy.

Margulies[10], on the other hand, found an increased incidence of migration in patients who had stents placed without ES. Stent migration was seen in 8.5% of patients in the no ES group.

In our experience,the incidence of proximal or distal migration was not so high and we didn't find differences between the groups.

Stent replacement was possible in 97.8% (45/46) of the patients who had not undergone ES, probably owing to the persistent dilation of the papilla caused by the presence of the stent.

In conclusion, according to our prospective study, placement of a 10 F biliary stent for common bile duct stenosis without ES is safe and has the same success rate of the ES technique.

No ES can avoid the risk of perforation and bleeding. ES must not be performed in patients with coagulation problems which are frequent in patients with cholestasis due to neoplastic biliary obstruction. If we consider long term complications of sphincterotomy whose range was 5.8-24%[17-18] ES should not be performed in patients with non neoplastic pathology (bile leaks , non malignant strictures). We did not find any difference in stent replacement between patients with ES and those without.

Abstract

AIM: To investigate the efficacy and tolerability of albendazole and metranidazole treatment in giardiasis.

METHODS: The open comparative randomized trial was carried out prospectively from December 1999 to July 2001 in Duzce City of Turkey. The diagnosis was based on the presence of signs and symptoms compatible with giardiasis including a positive stool examination of giardia cysts or trophozoite. Metranidazole group consisted of 29 patients and was given metranidazole 500 mg, three times a day for 5 d and albendazole group was consisted of 28 patients and was given albendazole 400 mg/d for 5 d.

RESULTS: There were no significant differences in demographical and therapeutical effects and patient's compliance between both groups. But side effects were seen more in metranidazole group than in albendazole group.

CONCLUSION: Albendazole is as effective as metranidazole in adults' giardiasis. Albendazole has less side effect potentials than metranidazole in the treatment of giardiasis.

INTRODUCTION

Giardia intestinalis is a protozoan parasite in the small intestine that causes extensive morbidity worldwide. Giardiasis is a hyperendemic disease in households lacking municipal sewer and water in the developing countries[1]. The life cycle of *G. intestinalis* has 2 forms: the trophozoite and the cyst. As few as 10 cysts may establish infection[2,3]. Giardiasis is currently treated with metronidazole, tinidazole and quinacrine[3]. The adverse effects and treatment failures to some of the currently recommended drugs (particularly 5-nitroimidazoles) for giardia infection have given rise to the need for alternative antigiardial agents. Albendazole is an important alternative drug for treament of giardiasis. *In vitro* Albendazole inhibits the growth of trophozoites of *G.intestinalis* and their adhesion to cultured intestinal epithelial cells and disturbs the activity of microtubules and microribbons in the trophozoite's adhesive disk. The results of giardiasis treatment with albendazole have been confused. A lot of trials were carried out for gairdiasis treatment with albendazole in pediatric groups. Albendazole was found to be effective for pediatric giardiasis patients. Albendazole at a dose of 400 mg per day for 5 d, cured 97 percent of infections in children in Bangladesh[4]. A few studies were about the effects of albendazole on adult intestinal giardiasis. It was ineffective in a study of adult travelers returning from tropical areas[3,5]. In this study we aimed to investigate effect of albendazol on adult giardiasis compared with metronidazole treatment.

MATERIALS AND METHODS

Subjects

Adults with diarrhea at the outpatient clinic of the Department of Infectious Diseases of Social Security Hospital in Duzce/ Turkey were screened for enrollment in the study. After informed consent was obtained, a detailed medical history was taken from each patient and physical examination was performed. For the demonstration of trophozoites or cysts in the stool, 3 stool samples were obtained. Patients with diarrhea and *G.intestinalis* cysts or trophozoites in a sample were eligible for enrollment in the study. Diarrhea was defined as more than 4 times of unformed stools per day. Giardia cysts were identified in fresh faecal material by direct faecal microscopic examination. A stool culture was carried out to identify bacterial causes of diarrhea. Patients with a positive coproculture for bacterial causes of diarrhea were excluded from analysis. All patients had a clinical response, recorded on d 7, 15, and a parasitological response recorded on the basis of examination of 2 stool samples between d 7 and 15 after initation of treatment.

Study medication

Patients were randomized to receive albendazole 400 mg/d for 5 d or metronidazole 500 mg thrice daily for 5 d.

Treatment methods

Of the original 67 (38 female and 29 male) patients who were selected, 57 (24 males and 33 females) completed this study in the follow-up period (Figure 1). Twenty-nine patients who received metronidazole (Falgyl® 500 mg 3 times daily for 5 d. Twenty-eight patients received albendazole (Andazol® 400 mg /d for 5 d.

Assessment of compliance

All patients were investigated for compliance to treatment, and one of the following requirements should be fulfilled in order to define a case as noncompliance to treatment, namely, failure to attend the controls, not use one or a few of the medicines at the instructed dose and the duration, not use the drug without taking the consent of the doctor.

Ethics

The study protocol was approved by the locally ethics committee. All patients were informed and agreed to participate in the study.

Table 1 Demographical and clinical findings of treatment groups (mean±SD)

Parameter	Metranidazol Group (n=29)	Albendazol Group (n=28)	P
Female /Male	18/11	15/13	#
Age (yr)	38±14	41±12	#
Hemoglobin	13.2±1.5	12.7±1.5	#
Leukocyte count	7 996±2 668	8 225±3 016	#
Faecal examination positive for cysts or trophozoits on d 7	0	0	NA
Faecal examination positive for cysts or trophozoits on d 15	0	1	NA
Metal taste	9	0	NA
Anorexia +/-	18	2	0.0001
Abdominal pain	3	1	#
After starting treatment healing of symptoms (h)	83±39	80±28	#
Advers effects other than anorexia	8	6	#
Non-compliance to treatment	7	5	#

#: *P*>0.05, NA: Not applicable.

Statistical analysis

Gender, age, mean hemoglobin concentration and leukocyte counts were compared between the 2 groups using non-parametric test (Mann-Whitney U test). Difference between the 2 groups was analyzed using chi-square test. We used Epi-info 6.0 (Centers for Disease Control, Atlanta) to perform the analysis and considered *P*<0.05 as statistically significant.
Criteria for exclusion

Patients receiving or having received antiparasitic drugs during the 10-d prior to commencing the study, patients with fever, pregnant women, mothers who were breast feeding, patients with known hypersensitivity to either albendazole or metronidazole, patients for whom any of the treatments used in the study were contraindicated.

Figure 1 Flow chart of patients studied.

RESULTS

The clinical and demographic findings in the albendazole group and metronidazole group are presented in Table 1.

No positive giardia cyst was found in the stool samples of both albendozole and metronidazole groups on d 7. But on d 15 one patient in of albendazole group was found to be positive for giardia cyst, while none of the patients in metranidozole group was positive for giardia cyst. Abdominal pain was found in 3 patients of metronidazole group and 1 patient of albendazole group (*P*>0.05). Vomiting was seen in 1 patient of metronidazole group and none in albendazole group. Noncompliance to treatment was found in 7 patients of metronidazole group and in 5 patients in albendazole group (*P*>0.05). Anorexia was found in 18 patients of metronidazole group and in 2 patients of albendazole group (*P*<0.001). Metal taste was determined in nine patients of metronidazole group and none in albendazole group. Records associated with other (headache, abdominal pain, dazedness) adverse effects except anorexia and metal taste were not found to be significantly different between the 2 groups (*P*>0.05).

DISCUSSION

Infections with parasitic helminths and protozoa are important causes of morbidity and mortality worldwide. The protozoan parasite *Giardia intestinalis* (synonyms: *Giardia duodenalis* and *Giardia lamblia*) is recognized as a major cause of diarrheal illness in humans and livestock. It is one of the most important non-viral infectious agents causing diarrheal illness, the infection may be asymptomatic or present with a variety of symptoms such as diarrhea, weight loss, abdominal cramps and failure to thrive. *G.intestinalis* may attach to small bowel wall but not invade it. Trophozoites may be encysted and shed in faeces for future ingestion by other hosts. Whereas the organism can cause diarrhea and abdominal pain. Some people experienced only a mild self-limiting illness, while others developed a chronic illness lasting for several months. Furthermore, people might be infected without any symptoms, and it has even been suggested that some people could benefit from their carrier state[6,7].

Although Giardia infections resolve spontaneously in 85% of patients within 6 wk, all patients with symptomatic giardiasis should be treated. Metronidazole and quinacrine are the first-line treatment options and are more than 90% effective. Tinidazole, furazolidone, paromomycin, mebendazole, and albendazole have been used as alternative anti-giardial drugs[8]. Cedillo -Rivera *et al*.[9] investigated the susceptibility of a strain of *Giardia lamblia* to benzimidazole carbamates, 5-nitroimidazoles, nitrofurans and other drugs. They found that albendazole was the most active compound among the 5-nitroimidazoles tested, ornidazole was the most effective, and

tinidazole, metronidazole, secnidazole were less active.

Various reports have published the effect of albendazole on gairdiasis. Albendazole was found to be very effective on giardiasis[10]. Misra *et al*.[10] studied the effect of albendazole and metranidozole on giardiasis in 64 children aged 2-12 years. They concluded that albendazole was proved as effective as metronidazole in the treatment of giardia infection in children with the absence of anorexia. Similarly, another study found albendazole at dose of 400 mg /d for 5 d cured 97% of infections in children in Bangladesh[4]. But, Escobedo *et al*. investigated in a comparative trial. One hundred and sixty-five Cuban children with confirmed giardiasis were randomized to receive albendazole (400 mg/d for 5 d), chloroquine (10 mg/kg twice daily for 5 d) or tinidazole (50 mg/kg, as a single dose). They found that tinidazole and chloroquine appeared equally effective, curing 91% and 86% of the children treated, respectively, and were significantly better than albendazole, which only cured 62% of the children[11].

In this study we investigated the effect of albendazole and metronidazole on symptomatic adult giardiasis. We did not find any significant difference in demographical properties (gender, age), mean hemoglobins, and mean leukocytes between the 2 groups. Giardia cysts were not found in faecal examination both groups on d 7. But on d 15 after starting treatment, one patient was found to be positive for giardia in albendazole group and none in metronidazole group. We thought that this patient might be reinfected. After starting treatment, 9 patients complained of metal taste in metronidazole group and no patient in albendazole group. Anorexia was found in 18 patients of metronidazole group but only 2 patients complained of anorexia in albendazole group ($P<0.01$). In terms of adverse effects, albendazole was found superior to metronidazole. Patients' compliance was found to be similar in both groups ($P>0.05$). We thought that it might be due to a short treatment period (five days). Similarly, chan Del Pino *et al*.[12] investigated the efficacy and tolerance of albendazol compared with metranidazol, furazolidone, tinidazol and secnidazol in the treatment of giardiasis in 79 children. They concluded that albendazol was as effective as metronidazol, furazolidone, tinidazol and secnidazol, but faster in eradicating *Giardia lambila* in children and had a better tolerance than metranidazol, furazolidone and tinidazol.

The drug resistance was not an important problem for giardiasis[13-15]. In our country cost of both drugs is similarly. We thought that both drugs can be used in the treatment of giardiasis, because according to our results albendazole is as effective as metronidazole in adult's giardiasis and albendazole treatment has also less side effects than metronidazole.

Abstract

AIM: Non-bioartificial liver has been applied to clinic for quite a long time, but the reported efficacy has been very different. The aim of this study was to compare the efficacy and safety of hemoperfusion adsorption, plasma exchange and plasma exchange plus hemoperfusion adsorption in treatment of severe viral hepatitis.

METHODS: Seventy-five patients with severe viral hepatitis were treated with hemoperfusion adsorption therapy (24 cases), plasma exchange therapy (17 cases) and plasma exchange plus hemoperfusion adsorption therapy (34 cases). The data of liver function, renal function, blood routine test, prothrombin time (PT) and prothrombin activity (PTa) pre- and post-therapy were analyzed.

RESULTS: Clinical symptoms of patients improved after treatment. The levels of aminotransferase, total bilirubin, direct bilirubin decreased significantly after 3 therapies ($P<0.05$ or $P<0.01$). PT, the level of total serum protein decreased significantly and PTa increased significantly after plasma exchange therapy and plasma exchange plus hemoperfusion adsorption therapy ($P<0.05$ or $P<0.01$). The side effects were few and mild in all patients.

CONCLUSION: Three therapies were effective in the treatment of severe viral hepatitis. Plasma exchange therapy and plasma exchange plus hemoperfusion adsorption therapy are better than hemoperfusion adsorption therapy.

INTRODUCTION

The treatment of severe viral hepatitis is always intractable in clinic. The previous non-bioartificial liver has widely been applied to clinic treatment[1-16], but its reported efficacy is various. In order to make an objective evaluation and comparison of the effects of non-bioartificial liver in the treatment of severe viral hepatitis, we chose three therapies of hemoperfusion adsorption, plasma exchange and plasma exchange plus hemoperfusion adsorption and compared their efficacy and safety.

MATERIALS AND METHODS

Materials

Sixty-four males and 11 females aged from 23 to 66 (41.3 on average) years with severe viral hepatitis were hospitalized in our section from January 1998 to February 2002. The diagnosis of 75 patients meeting the criteria for severe viral hepatitis established in National Viral Hepatitis Symposium[17], was all severe chronic hepatitis. The conditions of 75 patients were 4 at the early stage, 31 at the middle stage, 40 at the late stage of liver failure. Among them, there were 56 with simple hepatitis B virus (HBV) infection, 8 with HBV combined with hepatitis D virus (HDV) infection, 3 with HBV combined with hepatitis A virus (HAV) infection, 1 with HBV combined with hepatitis E virus (HEV) infection, 2 with hepatitis C virus (HCV) infection and 5 with all hepatitis virus markers negative. Before treatment, 41 had occurred hepatoencephalopathy, 9 hepatorenal syndrome, 20 spontaneous peritonitis, 5 septic shock and 3 gastrointestinal hemorrhage. Seventy-five patients were divided into 3 groups, respectively receiving hemoperfusion adsorption therapy (24 cases), plasma exchange therapy (17 cases) and plasma exchange plus hemoperfusion adsorption therapy (34 cases). There was no significant difference between three groups in clinical classification, pathogen, complications and clinical data of liver function, renal function, blood routine tests, PT, PTa ($P>0.05$).

Methods

Hemoperfusion adsorption therapy In the computer-controlled system of Type HSZ2000 artificial liver device, we chose the program of hemoperfusion adsorption therapy. The blood was pumped out of the body with the flow velocity of 60-80 mL/min and into a new type of activated charcoal column for adsorption and then backed into the body with 100 mL saline through deferens. Meanwhile, the same quantity of protamine was infused to neutralize heparin so that coagulation time (CT) could become normalized. Each patient received hemoperfusion adsorption for 1 to 4 times and all patients received 52 times in total, averaging 2.2 times per person.
Plasma exchange therapy In the computer-controlled system of Type HSZ2000 artificial liver device, we chose the program of plasma exchange therapy. The blood was pumped out of the body with the flow velocity of 60-80 mL/min and into a plasma exchange filter to discard the plasma and then mixed up with fresh frozen plasma (FFP) with flow velocity of 30-50 mL/min to be reperfused back into the body with 50 mL 200 g/L albumin solution and 100 mL saline through deferens. The balance of output and input should be controlled closely. Meanwhile, the same quantity of protamine was infused to neutralize heparin so that coagulation time (CT) could get normalized. Each patient received plasma exchange for 1 to 4 times and all patients received 36 times in total, averaging 2.1 times per person.
Plasma exchange plus hemoperfusion adsorption therapy In the computer-controlled system of Type HSZ2000 artificial liver

device, we chose the program of plasma exchange plus hemoperfusion adsorption therapy. The blood was pumped out of the body with the flow velocity of 60-80 mL/min and into a plasma exchange filter to discard the plasma and then through activated charcoal column for adsorption and then mixed up with fresh frozen plasma (FFP) with flow velocity of 30-50 mL/min to be reperfused back into the body with 50 mL 200 g/L albumin solution and 100 mL saline through deferens. The balance of output and input should be controlled closely. Meanwhile, the same quantity of protamine was infused to neutralize heparin so that coagulation time (CT) could get normalized. Each patient received plasma exchange plus hemoperfusion adsorption from 1 to 4 times and all patients received 65 times in total, averaging 1.91 times per person. This process could last for one and a half to three hours and the exchanged plasma volume was up to 2 500-3 000 mL.

Experimental tests The blood samples were collected before and after each treatment to check the liver function, renal function, PT and for blood routine test.

Clinical therapeutic efficacy The standard to evaluate the clinical curative effect refers to the references[18,19].

Statistical analysis

All data were shown as mean±SD. *t* test was used to compare the data before and after treatment.

RESULTS

The effect of hemoperfusion adsorption therapy

Liver function improved significantly after treatment (Table 1). The levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TB) and direct bilirubin (DB) were decreased significantly ($P<0.05$ or 0.01). Total serum protein (TSP) level was decreased but not significantly ($P>0.05$). Coagulation function improved after treatment. Prothrombin time decreased from 24.4 s to 21.31 s ($t=1.268$, $P>0.1$) and prothrombin activity was increased from 28.61% to 33.14% ($t=1.216$, $P>0.1$), but no significant difference was presented on statistical analysis.

Table 1 Comparison of liver function between pre- and post-therapy of hemoperfusion adsorption

	Pre-therapy	Post-therapy	*t*	*P*
ALT (IU/L)	80.3±52.9	40.4±15.2	2.628	<0.01
AST (IU/L)	123.6±57.8	79.9±42.6	2.249	<0.05
TB (μmol/L)	619.0±193.9	403.3±132.7	3.376	<0.01
DB (μmol/L)	345.1±125.4	233.6±94.9	2.622	<0.01
TSP (g/L)	63.9±8.8	57.9±8.7	1.359	>0.05

ALT: alanine aminotransferase, AST: aspartate aminotransferase, TB: total bilirubin, DB: direct bilirubin, TSP: total serum proteins.

The effect of plasma exchange therapy

Liver function improved greatly after treatment (Table 2). The levels of ALT, AST, TB, DB and TSP were decreased and significant difference was presented ($P<0.05$ or 0.01). Coagulation function improved greatly after plasma exchange. Prothrombin time decreased from 29.46 s to 23.74 s ($t=1.713$, $P<0.05$) and prothrombin activity was increased from 23.73% to 32.15% ($t=2.338$, $P<0.05$). Both showed significant differences on statistical analysis.

The effect of plasma exchange plus hemoperfusion adsorption therapy

Liver function improved immensely after treatment (Table 3).

The levels of ALT, AST, TB, DB and TSP were decreased and significant difference was presented ($P<0.05$ or 0.01). Coagulation function improved greatly. Prothrombin time decreased from 28.0 s to 22.9 s ($P<0.05$) and prothrombin activity was increased from 25.8% to 30.9% ($P<0.05$). Both showed significant differences on statistical analysis.

Table 2 Comparison of liver function pre- and post-therapy of plasma exchange

	Pre-therapy	Post-therapy	*t*	*P*
ALT (IU/L)	122.8±115.5	70.8±86.8	2.040	<0.05
AST (IU/L)	147.7±106.6	95.3±81.6	2.214	<0.05
TB (μmol/L)	488.3±189.9	300.6±135.9	4.596	<0.01
DB (μmol/L)	244.4±100.0	153.7±73.6	4.152	<0.01
TSP (g/L)	65.1±9.2	57.7±9.8	3.168	<0.01

Table 3 Comparison of liver function pre- and post-therapy of plasma exchange plus hemoperfusion adsorption

	Pre-therapy	Post-therapy	*t*	*P*
ALT (IU/L)	109.45±102.06	61.52±74.19	2.594	<0.02
AST (IU/L)	140.16±94.71	90.59±72.32	2.844	<0.01
TB (μmol/L)	528.75±200.57	332.16±142.91	5.459	<0.01

The data of renal function and blood routine test pre- and post-therapy

Renal electrolytes showed no obvious changes and the levels of urea nitrogen and creatinine were shown no significant difference pre- and post-therapy ($P>0.01$ or 0.05).

There was no significant difference in the levels of white blood cells (WBC), red blood cells (RBC), hemoglobin (Hgb) and platelet (PLT) pre- and post-therapy ($P>0.01$ or 0.05).

Side effects

In the group with hemoperfusion adsorption therapy, 2 patients had side effects twice, skin itch and rash once, pyrogen reaction once. In the group with plasma exchange therapy, 3 patients experienced side effects 3 times, skin itch and rash once, hemolytic reaction once and transfusion reaction once. In the group with plasma exchange plus hemoperfusion adsorption therapy, 10 patients had side effects thirteen times, skin itch and rash once, numbed face and 4 limbs 4 times, blood pressure fluctuation once and hypothermia once, hemolytic reaction once, transfusion reaction once, pyrogen reaction once. All side effects were relieved after treatment and had no influence on the whole therapeutic process.

DISCUSSION

It has been proven that hemoperfusion adsorption plays a role in removal of bilirubin and intermediate molecular substances. Previously owing to the poor technique of activated charcoal filter, there were obvious side effects in application of hemoperfusion adsorption therapy. Especially some severe side effects such as serious hemorrhage following platelet destruction and hemolysis following erythrocyte destruction once made the clinical application and basic research of artificial liver support system home and abroad go to a standstill for a long period of time. In the past few years, because the advance of technique of activated charcoal filter and the particles of charcoal became smaller and their surface was processed, the chance of platelet destruction and erythrocyte destruction was

much less when the blood flowed through activated charcoal filter, biocompatibility of activated charcoal improved[20]. Therefore, the therapy of hemoperfusion adsorption has again been applied to clinic to treat the liver failure patients[21-23]. That 24 patients had an improvement in clinical symptoms temporarily and in liver function indicates hemoperfusion adsorption therapy has a temporary supportive effect on liver failure caused by severe viral hepatitis.

The mechanism of severe viral hepatitis is the cooperation of immunopathological lesion caused by hepatitis virus and the secondary lesion of liver cells that results from the great deal of cytokine such as tumor necrosis factor-alpha (TNF-α), interleukin-1β (IL1-β), interleukin-10(IL10) released by intrahepatic and extrahepatic mononuclear macrophages due to the enteroendotoxemia following the impairment of hepatic barrier function. In this process, the secondary lesion plays an important role[24-28]. Cytokine can induce hepatocyte apoptosis[29]. Cytokine and endotoxin removal can relieve hepatic lesion, reduce leucocyte emigration and platelet aggregation and maintain the intracellular stablization so as to delay or reverse the disease progress and improve the prognosis.

Hemoperfusion adsorption therapy can eliminate endotoxin and cytokine nonspecifically and play an important role in supporting treatment of liver failure[30].

Plasma exchange separated and discarded plasma of liver failure patients to remove the toxic substances (especially those binding with proteins) and compensated with normal fresh frozen plasma to supplement some essential substances such as coagulation factors, albumin, immunoglobin so as to ameliorate the microenvironment of liver and accelerate the liver regeneration and the liver function recovery[31,32]. The therapeutic effects of 17 acute liver failure patients who received plasma exchange therapy were similar to those reported abroad[32,33], but quite different from those reported home[22]. This may be related to the severity of the patients in our series who are all in the intermediate or late stages of liver failure caused by severe chronic hepatitis[18,19] and in addition, the times of plasma exchange should be taken into consideration. Though the prognosis of patients receiving plasma exchange therapy did not live up to our expectation, the clinical symptoms of patients after treatment showed temporary relief and liver function and coagulation function improved obviously. So plasma exchange therapy has temporary supportive effects on liver failure caused by severe viral hepatitis.

Plasma exchange plus hemoperfusion adsorption therapy is a combination of plasma exchange and hemoperfusion adsorption, so it is more beneficial to the liver microenvironmental amelioration and liver regeneration and recovery of liver function. The therapeutic effects of 34 patients receiving plasma exchange plus hemoperfusion adsorption therapy showed coincidence with those receiving plasma exchange plus hemoperfusion adsorption therapy abroad[33,34]. That the patients' clinical symptoms after treatment showed temporary relief and liver function and coagulation function improved obviously indicates this therapy has temporary supportive effects on liver failure caused by severe viral hepatitis.

In comparison among three groups pre- and post-therapy, the coagulation function amelioration and plasma protein decrease by plasma exchange therapy and plasma exchange plus hemoperfusion adsorption therapy were more obvious than those by hemoperfusion adsorption therapy.

The main advantages of hemoperfusion adsorption therapy are low cost and less protein loss. Theoretically, plasma exchange therapy is a relatively complete liver substitutive therapy and its effects have been proven, but a large supply of plasma, high cost, and easy infection of blood-transmitted diseases fail them and plasma exchange deprives patients of

hepatocyte growth substances. Consequently it may do harm to liver regeneration and long-term therapeutic effects. The concentrations of plasma proteins will decrease if plasma is not compensated enough after a great loss.

Through the liver failure rat model which received total blood exchange, Eguchi[35] found that the hepatocyte regeneration was suppressed. In the fresh frozen plasma for exchange, there are a great deal of citrates which can increase the incidence of side effects after infused into the body and can do harm to hepatocyte energy metabolism and hepatocyte regeneration. How to advance various therapies and combine them with bioartificial liver support system in order to get good effects and reduce the side effects await further study[36-41].

Abstract

AIM: To explore how to trigger an HLAI-restricted CD8+ T cell response to exogenously synthesized polypeptides *in vivo*.

METHODS: Three mimetic therapeutic polypeptides based on the immunodominant CTL epitope of HBcAg, the B- epitope of HBV PreS$_2$ region and a common T helper sequence of tetanus toxoid were designed and synthesized with Merrifield′s solid-phase peptide synthesis method. Their immunological properties of inducing T$_{H1}$ polarization, CD8+ HBV-specific CTL expansion and CD8+ T cell mediated cytotoxicity were investigated in HLA-A2 transgenic mice.

RESULTS: Results demonstrated that the mimetic polypeptides comprised of the immunodominant CTL, B-, and T helper epitopes could trigger specifically and effectively vigorous CD8+ HBV-specific CTL-mediated cytotoxicity and T$_{H1}$ polarization of T cells in HLA-A2 transgenic mice.

CONCLUSION: A designed universal T helper plus B-epitopes with short and flexible linkers could dramatically improve the immunogenicity of CTL epitopes *in vivo*. And that the mimetic therapeutic peptides based on the reasonable match of the above CTL, B- and T helper epitopes could be a promising therapeutic peptide vaccine candidate against HBV infection.

INTRODUCTION

At present, the commercial vaccines against HBV infection are mainly based on humoral responses which can prevent the virus infection, but can rarely interrupt the intracellular infection or lead to the infected cell clearance. As in other infections with noncytopathic viruses, an MHC class I-restricted cytotoxic T lymphocytes (CTLs) response to endogenous HBV antigens is believed to be the major determinant for infected cell clearance, and HBV-specific CTL-mediated cytotoxicity plays the key role in controlling HBV infection and in the clearance of infected cells[1-8].

Natural HBV antigens contain generally inappropriate epitopes which could elicit T$_{H1}$/T$_{H2}$ disequilibrium, immune deviation or immune deficiency, and the conserved amino acid sequences might also interfere with intercellular communication. Thereby some viruses may evade the immune defence and present consistently in hepatocytes, and result in chronic hepatitis, liver cirrhosis, and even hepatocellular carcinoma[9-19]. Thus new generations of therapeutic vaccines should induce CTL responses different from that induced by natural virus infection, and at the same time hold the specificity of HBV antigens. According to reports in recent years, effective protection relys on the appropriate match of a set of epitopes[19,20]. Thus, natural antigens should be redesigned or modified on the basis of immunodominant epitopes.

In this study, we chose the immunodominant CTL epitope of HBcAg and the B cell epitope of HBV PreS$_2$ region, and introduced them into the common T helper epitope of tetanus toxoid to strengthen the Th response. Three mimetic peptides based on the above epitopes were initially designed and synthesized, and their immunological functions of inducing T$_{H1}$ polarization, CD8+ HBV-specific CTL expansion and CD8+ HBV-specific CTL-mediated cytotoxicity were investigated in HLA-A2 transgenic mice. We aimed to explore how to trigger an HLAI-restricted CD8+ T cell response to exogenously synthesized polypeptides *in vivo*, and to find a rational strategy of stimulating the HBV specific CTL response *in vivo* and to break to some extent the immune tolerance to HBV antigens.

MATERIALS AND METHODS

Materials

Inbred male and female HLA-A2 transgenic mice (H-2K^b) aging 6-8 wk were purchased from Jackson Laboratory, USA. Amino acids used for peptide synthesis were purchased from PE & ACT companies. Na$_2{}^{51}$GrO$_4$ for target cell labeling in standard ^{51}Gr release assay was from New England Nuclear (NEN^{TM}), Boston, USA. There were also materials used in this study as the following: RPMI1640 medium (Gibco), fetal calf serum (FCS) (HyClone), chimeric HLA-A2K^b tetramer kit (ProImmune, UK) and murine IFN-γ ELISpot kit (Diaclone, France).

Methods

Preparation of mimetic therapeutic polypeptides The immunodominant B- and CTL epitopes of HBV pre-S2 and HBcAg were identified on the basis of the HLA-A2.1 binding motifs[21]. Mimetic polypeptides were calculated and sieved using computerized molecular design methods. Peptide1 was determined as the immunodominant HBcAg$_{18-27}$ CTL epitope peptide (FLPSDFFPSV), to the N-termini of which linked the common T helper sequence of tetanus toxoid with a linker of "-Gly-Gly-Gly-" as peptide2 (QYIKANSKFIGITE GGG FLPSDFFPSV). The common T helper epitope of tetanus

toxoid and the Pre-S2 B-epitope were linked to the N- and C-termini of the HBcAg$_{18-27}$ sequence respectively with the linker of"-Ala-Ala-Ala-" and "-Gly-Gly-Gly-" as peptide3 (QYIKANSKFIGITEAAAFLPSDFFPSVGGGDPRVRGLYFPA). Melanoma associated MART-1$_{27-35}$ CTL epitope peptide (AAGIGILTV) was used as irrelevant control.

The above peptide antigens were synthesized with the Merrifield's solid-phase peptide synthesis method (PE431A synthesizer), purified by RP-HPLC (WATERS 600) and analyzed by MS/MS (API 2000). All peptides with a purity over 95% were disolved in DMSO with the concentration of 10 mg/mL and preserved at -70 ℃.

Immunization of mice Mimetic polypeptides in DMSO were diluted with 0.02 mol/L, pH 7.2 phosphate buffered saline (PBS) and emulsified respectively with complete Freund's adjuvants (CFA) and incomplete Freund's adjuvants (IFA). HLA-A2 transgenic mice were separated into 5 groups with 3 in each. The mice were injected subcutaneously in the 2 flanks and in the hind footpads first with peptide1, 2, 3 and then irrelevant control peptide in CFA at 500 μg/kg dosage respectively. Two weeks later, the mice were immunized weekly with the same antigens at IFA in 250 μg/kg dosage for 4 times. The mice injected with PBS alone were used as negative controls.

Two weeks after the last time of immunization, the mice were killed, the splenocytes were separated and suspended in RPMI1640 medium supplemented with 100 mL/L FCS and used as fresh samples[19].

T$_{H1}$ polarization assay For the assay of T$_{H1}$ polarization induced by mimetic peptides, mouse IFN-γ ELISPOT kit was used. Briefly[19,22], 96-well PVDF membrane-bottomed plates were coated with capture anti-mouse IFN-γ mAb at 4 ℃ overnight. Fresh splenocytes were added to triplicated wells at 5×10^3/well in the presence of 10 μg/mL relative mimetic antigens and the plates were incubated for 15 h at 37 ℃ in 50 mL/L CO$_2$. At the end of incubation, cells were washed off and a second biotinylated anti-IFN-γ mAb was added, followed by streptavidin-alkaline phosphatase conjugate and substrates. After the plates were washed with tap water and dried overnight, spots were counted under a stereomicroscope. The number of T$_{H1}$ polarized cells (peptide-specific CD8$^+$ T cells), expressed as IFN-γ secreting cells(ISC) /10^6 lymphocytes, was calculated after subtracting negative control values. Results of samples were considered as positive if above the mean by three standard deviations and with a cut off of 50 ISC/10^6 lymphocytes above mean background.

Cytotoxicity assay Peptide-specific CTL lines were primed as follows: The fresh splenocytes were plated at a concentration of 2×10^5/mL in 24-well microplates (2 mL/well) in PRMI1640 medium supplemented with 100 mL/L FCS and 30 U/mL murine IL-2 and in the presence of 10 μg/mL corresponding mimetic peptides respectively, with an exception of the lymphocytes from negative controls which were just cultivated in medium supplemented with 100 mL/L FCS and 30 U/mL murine IL-2. Five days after stimulation, cells were harvested, and used as fresh effectors.

CTL-mediated cytotoxicity was detected by a standard 4 h ^{51}Cr release assay[18,19,23,24]. P815 cells were used as targets and preincubated with HBcAg$_{18-27}$ peptide 2 h before use. The 1×10^6 target cells were labeled with 3.7×10^6 Bq Na$_2$^{51}GrO$_4$ in 0.8 mL RPMI1640 medium supplemented with 150 mL/L FCS for 60 min at 37 ℃, and then washed 3 times before the addition of effectors. Various concentrations of effector cells were mixed with 1×10^4 targets at effector/target(E/T) ratios of 12.5, 25, 50 and 100 in 200 μL of culture medium in 96-well V-bottomed microplate in triplicates. The microplate was centrifuged for 3 min at 500 r/min, and then incubated for 4 h at 37 ℃ in 50 mL/L CO$_2$. After the incubation terminated, 100 μL/well

of supernatants was harvested and counted on a γ-counter. Percentage of target cell specific lysis was determined as: [(average sample counts - average spontaneous counts)/ (average maximum counts - average spontaneous counts)] ×100%. Maximum and spontaneous counts were measured using supernatants from wells receiving 1 mol/L HCl or culture medium alone, respectively. In all experiments, spontaneous counts should be less than 30% of maximum counts. CTL responses were considered positive if exceeded the mean of specific lysis caused by irrelevant mimetic antigen (MART-1$_{27-35}$) by 3 standard deviations and by 10%.

HBcAg$_{18-27}$ specific CD8$^+$ CTL detection

Chimeric HLA-A2K^b tetramer binding kit was used to quantify the HBcAg$_{18-27}$-specific CD8$^+$ T cells[24-26]. A part of the fresh splenocytes separated from mice killed were washed with PBS, counted, suspended in PBS and separated equally into different tubes in 1.0 mL of each. The cells were stained with 25 ng/μL of tetramers for 20 min at 37 ℃, and then washed and stained with anti-mouse CD8 mAb for 20 min at room temperature. All samples were collected, washed twice, dissolved into 300 μL of PBS and FACS-sorted on a FACstar (Beckton-Dicknson) with Cell Quest software. Results were expressed as percentages of tetramer-binding cells in the murine CD8$^+$ T cell population. A total of 5×10^5 events were acquired in each analysis. Results were considered as positive for tetramer-binding cells when above the mean caused by irrelevant mimetic antigen (MART-1$_{27-35}$) and above 0.1% CD8$^+$ T cells.

Statistical analysis

All data were expressed as mean±SD. Statistical analysis was performed using a two-tailed Student's *t* test.

RESULTS

T$_{H1}$ polarization induced by mimetic peptides

When the immunization terminated, the mice were killed and the spleen lymphocytes were used for T$_{H1}$ polarization assay with an IFN-γ ELISPOT method. Spots of IFN-γ secreting cells generated could be observed in each of the mimetic peptides immunized groups. The negative control values of peptide-specific CD8$^+$ T cells were on average 250±138 ISC/10^6 lymphocytes. The most vigorous peptide-specific CD8$^+$ T cells magnification was produced in peptide3 immunized mice with approximately 8 050±1 233.8 ISC/10^6 lymphocytes generated. In peptide1 and 2 immunization groups, the peptide-specific CD8$^+$ T cells induced were 1 150±236.7 and 1 367±231 ISC/10^6 lymphocytes respectively. And also 1 135±312 ISC/10^6 lymphocytes were generated in MART-1$_{27-35}$ CTL epitope peptide immunized mice (Table 1).

Cytotoxicity assay

When the mice were killed, the fresh splenocytes were separated and peptide-specific CTL lines were generated *ex vivo*. The CTL-mediated cytotoxicity induced was tested by standard 4 h ^{51}Cr release assay against HBcAg$_{18-27}$ peptide preincubated P815 targets. Data demonstrated that all the three mimetic polypeptides based on HBcAg$_{18-27}$ CTL epitope could induce positive HBV-specific CTL response, among which peptide3 induced the most vigorous CTL activity, and as high as (55.3±10.1)% targets lysis was observed at E/T=100. The percentages of targets lysed in peptide1 and 2 immunization groups were dramatically lower than in peptide 3 group (*P*<0.01) and showed statistically no difference between. The spleen lymphocytes from irrelevant peptide control and negative control mice showed no specific target cell lysis activity (Table 2).

Table 1 T_{H1} polarization assay with an IFN-γ ELISPOT method. (mean±SD, n=18)

	Peptide1	Peptide2	Peptide3	MART-1$_{27-35}$	Negative controls

[d]$P<0.01$ vs negative control; [b]$P<0.01$ vs peptide1 and 2 groups.

Figure 1 Detection of the HBcAg$_{18-27}$-specific CD8$^+$ T cells produced with chimeric A2K^b/HBcAg$_{18-27}$ tetramer-binding assay. A: murine splenocytes from negative control mice, B: murine splenocytes from MART-1$_{27-35}$ irrelevant peptide immunized mice, C: murine splenocytes from peptide1 immunized mice, D: murine splenocytes from peptide2 immunized mice, E: murine splenocytes from peptide3 immunized mice.

HBcAg$_{18-27}$-specific CD8$^+$ CTL detection

After the immunization terminated, the HBcAg$_{18-27}$-specific CD8$^+$ T cells induced in vivo were quantified using chimeric A2K^b/HBcAg$_{18-27}$ tetramer-binding assay. No HBcAg$_{18-27}$-positive CD8$^+$ T cells could be detected in the spleen lymphocytes from the negative control mice and the mice immunized with MART-1$_{27-39}$ peptide, and the tetramer staining was lower than background (0.02%). In splenocytes from the mice immunized with peptide1, 2 and 3, the frequencies of A2K^b/HBcAg$_{18-27}$· CD8 positive T cells were respectively 0.36% (3 600/10^6 lymphocytes), 0.39% (3 900/10^6 lymphocytes), and 1.01% (10 100/10^6 lymphocytes). It showed no statistical difference between the effects induced by peptide1 and peptide2, and the immunogenicity of them was dramatically weaker than that of peptide3 (Figure 1).

DISCUSSION

HBV-specific CD8$^+$ cytotoxic T cells play a critical role in viral clearance. Low HBV-specific CTL responses in chronic HBV infection may favor the persistence of virus, whereas stimulation and expansion of HBV-specific CTL activity may assist elimination of HBV infection[1-8]. Natural HBV antigens contain some inappropriate epitopes and conserved amino acid sequences which might induce inappropriate immune responses and result in hepatic pathology and lesions. Hence new generations of therapeutic vaccines should be designed on the basis of immunodominant epitopes which could induce CTL responses different from that induced by natural virus infection, and at the same time hold the specificity of HBV antigens. As in other infections with noncytopathic viruses, helper T cells control the intensity of CD8$^+$ T-cell responses and helper T-cell responses might be compromised in chronic carriers of HBV[27-32]. In this paper, we chose the immunodominant B cell epitope of HBV PreS$_2$ region and the CTL epitope of HBcAg, and introduced them into the common T helper epitope of tetanus toxoid to strengthen the Th response. Three mimetic peptides based on the above epitopes were initially designed and synthesized, and their immunological properties of inducing T_{H1} polarization, CD8$^+$ T-cell expansion and CTL-mediated cytotoxicity were primarily investigated in HLA-A2 transgenic mice.

After immunization, the mice were killed and the splenocytes were separated, a direct tetramer-binding assay was used to detect the frequencies of HBcAg$_{18-27}$-specific CD8$^+$ T cells, the results varied according to the peptides used. The highest frequency was from peptide3 immunized mice splenocytes. No statistical difference was observed between the frequencies of HBcAg$_{18-27}$-specific CD8$^+$ T cells augmented in peptide1 and peptide2 mice groups, which indicated that the immunogenicity of short CTL epitope peptides *in vivo* could not be improved dramatically simply by introduction of a universal T helper epitope, and that by our reasonable match of the above immunodominant CTL, B-, T helper epitopes and linkers, the immunogenicity of HBcAg$_{18-27}$ CTL epitope of inducing HBV-specific CD8$^+$ T cell expansion *in vivo* was dramatically improved.

The tetramer-binding assay detects only the number of T cells with an appropriate TCR but not their function[24,33], so a chronium release assay and IFN-γ ELISpot assay were used to detect the immune functions of the mimetic antigens designed. And a highly significant correlation was found between the frequencies of HBcAg$_{18-27}$-specific CD8$^+$ T cells and the functions of responding splenocytes from the mice. The three mimetic polypeptides designed could induce T$_{H1}$ polarization of spleen lymphocytes and generate cytotoxicity in mice, among which peptide3 with the immunodominant B-, CTL and T helper epitopes was the most potent, peptide 1 and 2 could also produce the above immune functions but not as efficiently. After introducing T helper epitope into HBcAg$_{18-27}$, the CD8$^+$ CTL frequency was not remarkably improved, and cytotoxic activity remained low, suggesting that the help provided by this conformation was not sufficient to drive proliferation of CTL, and their differentiation into mature killer cells. The comparatively higher immunogenicity of peptide3 might rely on its molecular structure: the introduction of T helper and B-epitopes, the design of short linkers "Ala-Ala-Ala" and "Gly-Gly-Gly", and the reasonable match. The designed linker was proved to be highly flexible and might act as "hinges". We surmise that the peptide be recognized by MHC-I and II restricted molecules, and be presented to CD4$^+$ T cells and CD8$^+$ T cells, and ultimately T helper and Tc cells be activated and functioned interactively. It indicated that introducing short and flexible "hinges" and "Th+B" epitopes into short CTL epitope peptides might dramatically improve the peptide's immunogenicity and the ability of being presented to APCs *in vivo*. The results also demonstrated that designed peptide3 was highly immunogenic and HBV-specific *in vivo*, and might be a potential candidate for the therapeutic vaccine designed against hepatitis B.

Little knowledge is known so far on the molecular mechanisms of the *in vitro* and *in vivo* functions of the peptides[33-38]. In our opinion, *in vivo* induction of cytotoxic activity relys on the efficient presentation by APCs, and the crucial point is how to improve the antigenicity of short peptides so to meet the needs for efficient antigen presentation *in vivo*. Thus to redesign or modify the linear short peptides on the basis of immunodominant epitopes, change their molecular properties to meet the needs of antigen presentation, and stimulate the direct recognition of the peptides by T$_H$/Tc cells may be a promising approach to this problem.

Abstract

AIM: The pathophysiology underlying gastrointestinal
complications of long-standing diabetes is poorly understood.
Recent evidence suggests an important role of intestitial
cells of cajal in controlling gastrointestinal motility. The aim
of this study was to clarify the changes of ultrastructural
characteristics of interstitial cells of cajal in stomach of
diabetic gastro-electric dysrhythmic rats.

METHODS: Rats were randomly divided into diabetic group
and control group, the model of diabetic rats was established
by peritoneally injection of streptozotocin. Electrogastrograms
were recorded and intestitial cells of cajal in antrum were
observed by electrictelescopy after diabetic model rat was
established for 3 mo.

RESULTS: In the rats of diabetic group, the gastro-electric
dysrhythmia was increased compared with control group,
the abnormal rhythm index and the cofficient of variation
of slow wave frequency were significantly higher than those
of normal rats. The number of the gap junctions of interstitial
cells of cajal in antrum of diabetic rats was significantly
decreased, and the remaining structures were damaged.
The organelles were also damaged, and vacuoles were
formed.

CONCLUSION: It is possible that changes in ultrastructural
characteristics of interstitial cells of cajal in stomach are
one of the mechanisms underlying gastro-electric dysrhythm
in diabetic rats.

INTRODUCTION

Gastric motility abnormity occurs in up to 30- 50% of patients
with long-standing diabetes. Symptoms of diabetic gastropathy
can range from mild dyspepsia to recurrent vomiting and
abdominal pain and may progress to irreversible end-stage
gastric failure known as gastroparesis. Gastroparesis seriously
affects quality of life. There is deterioration in glycemic control
and incapacitating symptoms such as malnutrition, water and
electrolyte imbalance, and aspiration may occur. However, the
pathophysiology of diabetic gastropathy and gastroparesis,
including impaired fundic and pyloric relaxation and impaired
electrical pacemaking, is still not delineated[1-2]. It is generally
considered that diabetic gastropathy and gastroparesis may
be due to visceral autonomic neuropathy, hyperglucose and
smooth muscle degeneration.

Interstitial cells of cajal (ICCs) are a unique class of cells
dispersed in gastrointestinal tracts of mammals. In the region
of gastric corpus and antrum, multipolar interstitial cells of cajal
form two dimensional networks, and have been mistaken for
neurons, glial cells, smooth muscle cells, macrophages and
fibroblasts. In fact they are mesenchymal in origin. As interstitial
cells of cajal develop, they assume major gastrointestinal
motility. Interstitial cells of cajal are the pacemaker cells
responsible both for initating slow wave activity in
gastrointestinal muscles and for active propagation of electrical
slow wave. These cells also mediate motor inputs from the
enteric nervous system.

Studies have also suggested that many gastrointestinal motor
disorders have changes of number and/or structure of
interstitial cells of cajal[3-9]. In this study, we established the
model of diabetic rats by peritoneal injection of streptozotocin,
and intended to investigate the reason of gastric-electrical
dysrhythmias by recording the gastric electrical activity and
characterizing the ultrastructural features of interstitial cells of
cajal in the antrum.

MATERIALS AND METHODS

Animals

Fifty 2-mo-old healthy Wistar rats (weighing 100-160 g) of either
sex were obtained from Animal Center of Third Military Medical
Univisity and were divided randomly into control group (n=20)
and diabetic group (n=30). After fasted overnight, diabetic
group rats were injected intraperitoneally with streptozotocin
(60 mg/kg) and control group rats were injected intraperitoneally
with saline. Blood glucose concentration, weight, appetite and
urine volume were measureed every two weeks. In this test,
diabetic group animals were considered as diabetic if blood
glucose levels exceeded 16.9 mmol/L and were eliminated if
blood glucose levels remained <16.9 mmol/L.

Gastric-electrical activity recorded

Gastric-electrical activities of control and diabetic group rats
were recorded afte 3 mo. After fasted over 12 h, rats were operated
under anaesthesia with 3% soluble pentobarbitone (30 mg/kg)
intraperitoneally. A pair of stainless platinum wires was
implanted in deep muscular plexus of antrum. The wires were
arranged in an arching line along the greater curvature about
0.5 cm apart from pylorus. The distance between electrodes
was about 0.3 cm apart. The electrodes were affixed to the
serosa by nonabsorbable sutures in the seromuscular layer of
stomach. Teflon-insulated wires were brought out from nape
through the anterior abdominal wall percutaneously. After
surgery, the rats were transferred to a recovery cage for a week.
After fasted overnight, rats underwent anaesthesia with 3%
soluble pentobarbitone (30 mg/kg) intraperitoneally. Wires were
connected with a gastro-electrical activity amplifier, and
recorded parameters were adjusted. All recorded signals were

displayed and simultaneously recorded on computer. Gastric-electrical activity recorded lasting for 60 min. All recorded signals were analyzed by computer. In this study, the frequency of normal rat gastric slow wave was 4.41±0.91/min and its normal range was 2.63-6.19/min. Gastric slow wave was defined as bradygastria if its frequency was lower than 2.63/min and had a duration of longer than 1 min and form of slow wave was ruled and rhythm was in good order. Gastric slow wave was defined as tachygastria if its freguency was greater than 6.19/min and had a duration of longer than 1 min and form of slow wave was ruled and rhythm was in good order. Gastric slow wave was defined as dysrhythmias if its form of slow wave was not ruled and rhythm was in bad order and had a duration of longer than 1 min.

Morphological studies

After gastric–electrical activity was recorded, the abdomen was opened immediately and antrum was removed (antrum was cut apart 0.5 cm from pylorus) and fixed containing 3% glutaraldehyde and 4% paraformaldehyde. The specimens were rinsed twice in 0.2 mol/L saccharum-phosphate buffer and post-fixed in 10 g/L osmium tetroxide for 2 h at 4 ℃. The specimens were then rinsed in distilled water, block-stained with saturated uranyl acetate solution for 3 h, dehydrated in a grade series of acetone and embedded in epoxy resin 618. Ultrathin sections were cut and double-stained with uranyl acetate and lead citromalic for observation under JEOL-2000EX electron microscope.

Statisitical analysis

Values in the text were expressed as mean±SE. Statistically significant differences were tested using an analysis of variance. A P value <0.05 was taken as statistically significant.

RESULTS

Gastric-electrical activity

Slowform of normal rats was regular (Figure1), the mean frequency of control rats was 4.41±0.91 cpm (range: 2.63-6.19 cpm), the abnormal rhythm index was 18.00±4.96% and the cofficient of variation of slow wave frequency was 10.00±6.46%. Compared with normal rats, diabetic rats had less chance of normal rhythm, the mean frequency was 4.03±1.23 cpm (range: 1.62-6.44 cpm), its slowform was irregular (Figure 2). The abnormal rhythm index was 30.62±7.38% and the cofficient of variation of slow wave frequency was 23.50±2.98%. Both of them were significantly higher than those of normal rats (P<0.01).

**Figure 1** Electrgastrogram of normal rats.

Figure 2 Electrgastrogram of diabetic rats.

Ultrastructural features of interstitial cells of cajal in rat antrum

In the normal rat antrum (Figure 3), interstitial cells of cajal were located within the circular muscle layer (ICC-CM) and in the myenteric region (ICC-AP) and were in closely associated with small nerve bundles. These cells were interconnected with each other and neighboring smooth muscle cells via a number of

large gap junctions. Interstitial cells of cajal in rat stomach were characterized by abundant mitochondria. Numerous caveolae were observed on cell membranes. The nucle were big and irregular, heterochromatins were often observed on the nuclear membrane and its strucure was clear. Their cytoplasm was usually less, and one or more processes were observed. Intermediate filaments, golgi apparatus, rough (RER) and smooth (RER) endoplasmic reticulum were abundant. Variation in the ultrastructural features of the intestial cells of cajal in different regions was also observed. ICC-CM was characterized by dense cytoplasm, no basal lamina could be clearly identified. ICC-AP was characterized by numerous caveolae and a distinct basal lamina. In the antrum of diabetic rats (Figure 4), interstitial cells of cajal were fewer. The number of the gap junctions between interstitial cells of cajal and neuron cells, between interstitial cells of cajal and smooth muscle cells, and between themselves were decreased significantly. The remaining structures of those gap junctions were also damaged. Basal lamina was discontinuous and not distinct, some were apart from cell membrane and formed cavum. The organelles-mitochondria and ribosome, for example, were also significantly decreased. Mitochondria were swollen, vacuoles and cytoplasm were dissolved, vacuole and myelin figures were formed. Endoplasmic reticulum was dilated, cytoplasm was dissolving, vacuoles were formed and distributed along plasma membrane, perinuclear space was broadened.

DISCUSSION

Despite reports of diabetic gastroparesis without autonomic neuropath, this disease, and, particularly, impaired electrical pacemaking, are usually considered to be the result of systemic and/or enteric neuropathies. Recent studies in spontaneously diabetic BioBreeding/Worcester rats and in streptozotocin-diabetic rats have demonstrated decreased nitric oxide synthase expression and reduced nitrergic motor inputs to the stomach, as well as impaired intracellular signaling in response to excitatory neurotransmitters in gastric smooth muscle. Clearly,

these defects may contribute to the many abnormal features of diabetic gastropathy. However, it is unclear how impaired neural inputs (especially impaired inhibitory inputs) or impaired smooth muscle response to cholinergic stimulation could result in the loss of slow-wave activity, which has been observed in both humans and animals with diabetes.

Interstitial cells of Cajal were originally described in the gut more than hundred years ago by Ramón y cajal[5]. He characterized "interstitinal neurons" as "primitive accessory components that perhaps modify smooth muscle contraction, subject themselves to regulation from principal neurones". Cajal provided us with detailed pictures of methylene blue-stained networks of interstitial cells of cajal, which were described as spindle shaped or stellate cells with long, ramified cell processes and large, oval, nuclei with sparse perinuclear cytoplasm, and intercalated between autonomic nerve endings and smooth muscle cells. Interstitial cells of cajal were found within discrete locations within the *tunica muscularis* throught the gastrointestinal tract and classified into five types according to different locations, *i.e.*, ICC-AP (Auerbach's myenteric plexus) located between the circular and longitudinal muscle layers, ICC-DMP (deep muscular plexus) located between the inner thin and outer thick sublayers of the circular smooth muscle, ICC-SMP (submuscular plexus) located at the submucosal border, ICC-CM located within the outer thick circular muscle layer; and ICC-LM located within the longitudinal muscle layer.

Many studies have indicated that each organ manifests a unique pattern of distribution of interstitial cells of cajal. In the stomach of rats, we observed interstitial cells of cajal located in close association with small nerve bundles within the circular muscle layer (ICC-CM) and in the myenteric region (ICC-AP), no interstitial cells of cajal were found at the most inner region of the circular muscle layer, submucosal border and deep muscular plexus.

Though there are a large number of methods for indentification of interstitial cells of cajal, such as methylene blue staining, zinc-iodide osmic acid (ZIO)-staining and immunohistochemistry using antibodies against kit proteink. The "gold-standard" for indentification of interstitial cells of cajal is still a combination of structural features in transmission electron microscopy. Although some structural varations have been described to be between species and between various regions of the gastrointestinal tract, the Interstitial cells of cajal ultrastructure are characterized by a combination of the following features: numerouly large and often elongated mitochrondrial profiles, large bundles of intermediate filaments, absence of thick filaments, presence of surface caveoli variably developed basal lamina, synapse-liked contacts between Interstitial cells of cajal and tertiary nerve bundles, well-developed smooth endoplasmic reticulum and often also rough endoplasmic reticulum, close apposition or gap junction contact with smooth muscle cells.

Interstitial cells of cajal have ultrastructural distinction from fibroblasts or smooth muscle cells. Some interstitial cells of cajal may have muscle-like ultrastructural features, such as a basal lamina, caveolae, subsurface cistern and gap junctions. For this reason, some interstitial cells of cajal have been considered as modified or specialized smooth muscle cells. Howerer, the interstitial cells of cajal do not contain the well-organized contractile apparatus characteristic of muscle cells. Some interstitial cells of cajal may have an appearance similar to fibroblasts and lack clear muscle-like features. However, even in these cases, they are distinguishable from fibroblast-like cells by a combination of features including a characteristic electron density of cytoplasm, large gap junctions, abundant intermediate filaments, numerous mitochondria, well-developed SER and flattened cisterns of RER. Furthermore, a great number

of collagen fibers often distribute around fibrobalst cells.

Morphological observations have led to a number of hypotheses on the possible physiological roles of interstitial cells of cajal[10-18]. (1) These cells may be the source of slow electrical waves in gastrointestinal tract. (2) They participate in conduction of electrical currents, and (3) They mediate neural signals between enteric nerves and muscles. These hypotheses have been tested by experiments. (1) Slow electrical waves in gastrointestinal muscle strips were absent when interstitial cells of cajal were removed by dissection or lesioned by cytotoxic chemicals. (2) Electrophysiological experiments on isolate cells confirmed that interstitial cells of cajal could generate rhythmic electrical activity and also respond to messenger molecules known to be released from enteric nerves. (3) In Ws/Ws mutant rats, or in mice treated with antibody against the protein c-kit, slow wave activity was impaired. (4) Slow wave passively decayed as a function of distance from the pacemaker appeared. (5) After removal of interstitial cells of cajal, smooth muscle cells continued to be excitable, but in the absence of interstitial cells of cajal, smooth muscle produced action potentials rather than slow wave-like activity. Studies have also suggested that many diseases of gastrointestinal motor disorders have changes in number and/or structure of Interstitial cells of cajal[3-9]. In infants with hypertrophic pyloric stenosis, there was a significant decrease in the number of interstitial cells of cajal, this decrease was prominent in the ICC-AP. In some patients with pseudo-obstruction, there was a marked decrase in the number of interstitial cells of cajal. Constipation was a very prevalent motility problem, but its underlying mechanisms were obscure. Studies found that the volume of interstitial cells of cajal in the colon of patients with slow transit constipation was significantly decreased compared with normal controls.

Normal gastric emptying requires the proper function of the gastric electrical pacemaker system. Gastroparesis has been associated with electrical abnormalities, and deviations from normal slow-wave rhythm (dysrhythmias) have been reported to result in delayed gastric emptying. In this study, we established the model of diabetic rats by peritoneally injection of streptozotocin, and recorded the gastro-electrical activity after 3 mo. We discovered that in the rats of diabetic group, the gastro-electric dysrhythmia was increased compared with control group, the number of interstitial cells of cajal in antrum of diabetic rats was significantly decreased and the number of the gap junctions of interstitial cells of cajal also was significantly decreased, and the remaining structures were damaged. The organelles-mitochondria and ribosome, for example, were also significantly decreased. Mitochondria were swollen, myelin figures were formed. Endoplasmic reticulum was dilated, cytoplasm was dissolved, vacuoles were formed and distributed along plasma membrane, perinuclear space broadened. This shows that degeneration of interstitial cells of cajal is responsible for gastro-electrical dysrhythmias of diabetic rats, the identification of abnormalities in interstitial cells of cajal in diabetic gastro-electric dysrhythm offers a potential future therapeurapy.

Amebiasis is one of the three most common causes of death from parasitic disease, and *Entamoeba histolytica* is the most widely distributed parasites in the world. Particularly, *Entamoeba histolytica* infection in the developing countries is a significant health problem in amebiasis-endemic areas with a significant impact on infant mortality[1]. In recent years a world wide increase in the number of patients with amebiasis has refocused attention on this important infection. On the other hand, improving the quality of parasitological methods and widespread use of accurate tecniques have improved our knowledge about the disease.

We read with interest the publication by Ustun *et al.*[2] and would like to comment on both the differentiation of *E. histolytica/Entamoeba dispar* and therapeutic approach to amebiasis in inflammatory bowel disease (IBD) cases. We strongly agree that IBD sometimes can co-exist with amebiasis. This infrequent phenomenon may also arise from inaccurate diagnosis, however before the specific anti-inflammatory treatment initiation for IBD, empirical anti-amebic treatment is usually suggested in the hyper-endemic regions. We think that those prevalences (54% and 69%) from other Turkish studies reported on the discussion section seem to be very high, and suggest the possibility of overdiagnosis. The current data given on subjects with IBD and controls clearly showed that the disease not only diminishing in Turkey but also accurate diagnosis of amebiasis with permanent staining technique maximized obtaining more valid results, as authors stated in their articles.

We also would like to note another recent article about climatic pattern of amebiasis in Turkey, published by Erdem *et al*[3], in a similar point of view for the accuracy of the diagnosis. Single microscopic examination is not a recommended diagnostic tool for accurate diagnosis of luminal amebiasis. Microscopy (also not clear in the article[3] whether permanently stained smears such as trichrome staining was used or not) is one of the most difficult and insensitive techniques to interpret. In some cases, false positive results might be due to identification of human white blood cells as amoebae[4-6]. Also, it did not allow to differentiate *E. histolytica* from *E. dispar* by using only trichrome staining method because both had similar morphological features as stated[2]. Numerous studies have demonstrated the insufficiencies of microscopic examination in the diagnosis of *E. histolytica*[4]. After the re-classification

of *Entamoeba* genus, it is essentially important to distinguish the 2 morphologically identical but biologically and immunogenetically different species: *E. histolytica* and *E. dispar*[1,7,8]. In addition to this, *E. dispar* is the more prevalent strain than *E. histolytica* allover the world. Morphologically, the presence of ingested red blood cells in trophozoites is not adequate for the diagnosis of *E. histolytica* since Haque *et al*[9] have demonstrated that some *E. dispar* trophozoites might also contain ingested erythrocytes. So that, microscopy had a low sensitivity and could easily mislead the clinicians. At present, among the traditional and conventional approaches to the diagnosis of amebic colitis and liver abscess, serological testing remains an important instrument. In addition to this, for a decade there has been a reliable stool antigen detection using ELISA, which has a very high sensitivity and a good clinical correlation. Another important point to remember, if there is a high prevalence of intestinal amebiasis in a certain geographical area, then it should have been a large number of cases with extra-intestinal involvement and a high prevalence rate of specific antibody. So far, these indirect indicators have a very low percentage in Turkey.

The diagnosis and treatment of IBS in patients without appropriate diagnosis of intestinal amebiasis are a great challenge. The clinical presentations are very similar, and inaccurate laboratory methods could be misleading and even endoscopic examination might not solve the diagnostic dilemma. It is more realistic to start empirical anti-amebic treatment, preferably with metronidazol derivates despite the fact that it would postpone the treatment for IBD as stated in classical medical literature.

In summary, since microscopy is neither sufficiently sensitive nor specific for the diagnosis of *E. histolytica* infection, it is essential to perform an antigen detection using ELISA[9] or PCR analyses for accurate the diagnosis of intraluminal amebiasis to provide a more reliable comment on the epidemiological pattern and clinical impact of the disease.
