Akagi[32] examined the relationship between expression of VEGF-C in 99 primary tumors and 18 metastatic lymph nodes from colorectal cancer and clinicopathological features by semi-quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) and immumohistochemistry. The results showed that the expression of VEGF-C was correlated with lymphatic involvement, lymph node metastasis, and depth of invasion. To study the correlation between lymphogenous metastasis in early gastric carcinoma (EGC) and the expression of VEGF-C, Kabashima[33] selected 35 cases of lymph node metastasis-positive [n(+)] EGC and 70 cases of lymph node metastasis-negative [n(-)] EGC. Clinicopathologically, there were significant differences in median size, lymphatic invasion, and venous invasion between the two groups, the incidence of positive-expression of VEGF-C in n(+) EGC was significantly higher than that in n(-) EGC. In breast cancer, the expression of VEGF-C was correlated with lymphatic vessel invasion, the 5-year disease free survival rate of the VEGF-C positive group was significantly poorer than that of the VEGF-C negative group[34]. The expression of VEGF-C in breast cancer cells could increase intratumoral lymphangiogenesis, resulting in significantly enhanced metastasis to regional lymph nodes and lungs, and the degree of tumor lymphangiogenesis was highly correlated with the extent of lymph node and lung metastases[35].

Most of the studies demonstrated that VEGF-C was mainly produced by cancer cells, and VEGFR-3/FLT-4 by endothelial cells of the stromal lymphatic vessels, the incidence of VEGF-C was closely correlated with VEGFR-3/FLT-4 expression in the primary tumors. VEGF-C produced by cancer cells might induce the expression of VEGFR-3/FLT-4 on lymphatic endothelial cells, consequently, the activation of VEGF-C/FLT-4 paracrine loop induced the lymphangiogenesis[36].

However, the study by Gumingham[37] obtained opposite results, in which a significant correlation was found between expression of VEGF-C and VEGFR-3/FLT-4 in breast cancer, but no significant difference in VEGF-C expression between normal and neoplastic breast tissues and no association between VEGF-C and either lymph node status or number of involved nodes, patient age, tumor size, estrogen receptor status, or tumor grade were found.

We studied the correlation between VEGF-C and VEGFR-3/FLT-4 expression in 80 primary gastric cancers and adjacent normal tissues by semi-quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) and immumohistochemistry. The results showed that there was a significant difference in VEGF-C expression between primary tumor and adjacent normal tissue samples, and a significant correlation between expression of VEGF-C and VEGFR-3/FLT-4 in tumor tissues. The present study also clearly demonstrated that expression of VEGF-C and VEGFR-3/FLT-4 was closely related to the histological type of tumors and lymph node metastasis. Expressions of VEGF-C and VEGFR-3/FLT-4 were detected both in primary gastric cancer and in adjacent normal tissues. However, the former was significantly higher than the latter. Meanwhile, VEGFR-3/FLT-4 expression was detected in endothelial cells of stromal blood vessels and lymphatic vessels.

Tumor cell metastasis to regional lymph nodes is an early event in tumor spread, and this index is frequently used to predict disease prognosis[38]. VEGF-C is the first growth factor related to lymphangiogenesis, and the study of lymphangiogenesis of tumors is only at its beginning. Its mechanisms and mediators await further studies.

Abstract

AIM: To investigate the mechanism and significance of NF-κB activation regulated by hepatitis B virus X protein (HBx) in hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC).

METHODS: The expression levels of HBx, p65, IκB-α and ubiquitin were detected by immunohistochemistry in HCC tissue microarrays (TMA) respectively, and IκB-α was detected by Western blot in HCC and corresponding liver tissues.

RESULTS: The percentage of informative TMA samples was 98.8% in 186 cases with a total of 367 samples. Compared with corresponding liver tissues (60.0%), the HBx expression was obviously decreased in HBV-associated HCC (47.9%, $u=2.24$, $P<0.05$). On the contrary, the expressions of p65 (20.6% *vs* 45.3%, $u=4.85$, $P<0.01$) and ubiquitin (8.9% *vs* 59.0%, $u=9.68$, $P<0.01$) were notably elevated in HCC. In addition, IκB-α had a tendency to go up. Importantly, positive relativity was observed between HBx and p65 ($\chi^2=10.26$, $P<0.01$), p65 and IκB-α ($\chi^2=16.86$, $P<0.01$), IκB-α and ubiquitin ($\chi^2=8.90$, $P<0.01$) in HCC, respectively.

CONCLUSION: Both active and non-active forms of NF-κB are increased in HBV-associated HCC. Variant HBx is the major cause of the enhancement of NF-κB activity. The activation always proceeds in nucleus and the proteasome complexes play an important role in the activation.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a malignant tumor with a poor prognosis. Hepatitis B virus (HBV) has been shown to be linked epidemiologically to the HCC development and about eighty percent of the tumors in China are induced by HBV. As a unique non-structure protein, hepatitis B virus X protein (HBx) performs a variety of biological functions, such as gene transactivation[1], interaction with p53[2], interference with host DNA repair[3], repression of physiological proteolysis[4], modulation of cell proliferation and apoptosis[5,6], induction of malignant cell migration[7,8]. These functions may play an important role in the initiation and development of HCC associated with HBV infection. NF-κB, a crucial transcriptor, takes part in almost all aspects of cell regulation, including immune cell activation, stress response, proliferation, apoptosis, differentiation and oncogenic transformation. Currently, more attentions have been paid to the carcinogenesis of HBx transactivating NF-κB[9]. However, the active state of NF-κB in HCC has been seldom studied. As a new high-throughput technology introduced in 1999, tissue microarray (TMA) is worthy of popularization. In our study, the expression levels of HBx, p65, IκB-α and ubiquitin were detected by immunohistochemistry on TMA respectively, as well as IκB-α was detected by Western blot, in order to investigate the mechanism and significance of HBx activating NF-κB.

MATERIALS AND METHODS

Tissue samples

Paraffin specimens were prepared from operatively-resected HCC and non-HCC counterparts between 1997 and 2000, including 171 cases of serum HBV-positive HCC, 10 cases of serum HBV-negative HCC and their corresponding liver tissues, 5 cases of normal control liver tissues (Table 1). In addition, 24 couples of fresh HCC and its corresponding liver tissues were collected between March and October in 2001, stored at -80 ℃ until experiment.

Tissue microarray construction

All formalin-fixed and paraffin-embedded HCC tissues used in this study were sectioned and stained with hematoxylin-eosin (H&E). The H&E-stained sections were carefully diagnosed, and the representative regions of the tumor and its corresponding liver tissue for microarray were defined as well. HCC TMA was constructed according to the procedure described by Kononen *et al*[10]. Briefly, core tissue specimens, 0.6 mm in diameter, were taken from selected regions of individual donor blocks and precisely arrayed into recipient paraffin blocks (45 mm×22 mm) using a tissue-arraying instrument (Beecher Instruments, Silver Spring, MD, USA). After construction, the recipient paraffin block was incubated at 37 ℃ for one hour and the surface of the block was smoothed. Five-micrometer consecutive sections of this TMA block were cut with a microtome. The presence and morphology of tumor and liver tissues on arrayed samples were identified by H&E stained sections.

Immunohistochemistry

TMA section was deparaffinized through xylene and dehydrated with graded alcohol. Endogenous peroxidase was then blocked with 0.3% H_2O_2 diluted in methanol for 30 min at room temperature. Antigen retrieval was performed by treating the slide in citrate buffer in a microwave for 10 min. The slide was incubated in a moist chamber with HBx mouse monoclonal

antibody (1:100; Chemicon, USA), p65 mouse monoclonal antibody (Santa Cruz, USA), IκB-α rabbit polyclonal antibody (Santa Cruz, USA) and ubiquitin rabbit polyclonal antibody (Neomarkers, USA) at 4 ℃ overnight respectively. After a brief wash in PBS, the slide was treated with goat anti-mouse antibody and goat anti-rabbit antibody (EnVision™ +Kits, DAKO, Denmark), respectively, for 45 min at 37 ℃. After a brief wash in PBS, the slide was developed in 0.05% freshly prepared diaminobenzedine solution (DAB, Sigma, St. Louis, MO) for 8 min, and then counterstained with hematoxylin. More than 5% cells stained were identified as a positive result.

Western blot

Western blot was carried out based on the protocol of *molecular clone*[11]. Briefly, frozen tissues were lysed in a single eradicator buffer (150 mmol/L NaCl, 50 mmol/L pH 8.0 Tris-HCl, 0.02% natriumazid, 1 ug/ml aprotinin, 100 ug/ml PMSF, 1% Triton X-100) and quantified by BCA method. The samples were boiled, loaded, separated on 12% SDS gel electrophoresis, transferred to nitrocellulose membrane, and reacted with IκB-α rabbit polyclonal antibody (1:1 000, Santa Cruz, USA). At last, the membrane was exposed several minutes after ECL substrate incubation.

Statistical analysis

HBx, p65, IκB-α, ubiquitin expression differences between HBV-associated HCC and corresponding liver tissues were analyzed statistically using u test. The relativity between HBx, IκB-α, p65, ubiquitin was analyzed statistically using χ^2 test or adjusted χ^2 test.

RESULTS

Tissue microarray

In this study, two HCC TMA blocks were constructed which

contained a total of 181 cases with 367 samples. One thousand four hundred fifty-one informative samples were totally detected by immunohistochemistry on arrays and the observed ratio was up to 98.8% (1 451/1 468 samples). HE-stained sections showed that the morphology of tissues and cells could be seen clearly. The HCC array HE-stained sections and several types of the tumor are shown in Figure 1.

Figure 2 Expressions and locations of HBx, p65, IκB-α and ubiquitin in HCC detected by immunohistochemistry, EnVision ×200. A: HBx expression in cytoplasm, B: p65 immunostaining in cytoplasm and nuclei, C: IκB-α distribution in cytoplasm and nuclei, D: ubiquitin location in nuclei.

Expression differences of four proteins in HCC and corresponding liver tissues

The expression of HBx was restricted exclusively to cytoplasmic location in both HCC and liver tissues. The positive immunostainings of p65 and IκB-α were seen only in cytoplasm of liver tissues, but in both cytoplasm and nuclei of HCC. The positive signal of ubiquitin was distributed predominantly in cytoplasm of liver tissues and in nuclei of HCC (Figure 2).

In serum HBV-positive cases, the HBx expressions in HCC (81/169, 47.9%) were significantly decreased as compared with the corresponding liver tissues (102/170, 60.0%, $P<0.05$). On the contrary, the expressions of p65 and ubiquitin were notably elevated in HCC (45.3%, 59.0% respectively) as compared with corresponding liver tissues (20.6%, 8.9% respectively, $P<0.01$). The positive rate of immunostaining reaction of IκB-α in HCC and corresponding liver tissues was 72.9% and 67% respectively. The difference was not significant, though the staining in HCC was more intense (Table 2).

In serum HBV-negative cases, the expressions of HBx, p65, IκB-α, ubiquitin in HCC were detected in 2/10 cases, 5/9 cases, 7/9 cases and 5/10 cases respectively. In corresponding liver tissues, their expressions were detected in 2/10 cases, 2/9 cases, 7/9 cases and 2/10 cases respectively.

In five normal liver tissues, all expressions of HBx, p65 and ubiquitin were negative, whereas, IκB-α was demonstrated to be weakly positive.

Western blot of IκB-α

Compared with corresponding liver tissues, elevated levels of IκB-α were detected in 10 HCC cases, decreased in 1 case. In the other 13 couples of HCC and corresponding liver tissues, no obvious difference of expression was detected (Figure 3).

Figure 3 IκB-α expression levels detected by Western blot. IκB-α levels were elevated in 3 cases of HCC compared with their corresponding liver tissues.

Relativity analysis between HBx, IκB-α, p65 and ubiquitin

χ^2 test showed that no relativity existed between HBx, IκB-α, p65 and ubiquitin in corresponding liver tissues, but a positive relativity was observed between HBx and p65, p65 and IκB-α, IκB-α and ubiquitin in HCC (Table 3).

DISCUSSION

TMA is a new technology first introduced in 1999. It contains hundreds or even thousands of small tissue samples arranged into a grid for rapid, cost efficient and high-throughput analysis. TMA has been used widely in gene or protein expression analysis, antibody screening, tissue specificity detection of proteins, phenotype versus genotype analysis, RNA or DNA *in situ*-hybridization[10,12,13]. Based on TMA, we studied the expressions of HBx, NF-κB, IκB-α, ubiquitin and their interrelationship in HCC.

The result of HBx expression detection in HBV-associated HCC showed that HBx expression was reduced in cancer tissue as compared with the corresponding liver tissue. The result might be ascribed to the existing form of HBV in tumor tissue. Many researches indicated that integration was the major form of HBV in HCC, so the viral copies were far less than that in non-tumor tissues where free virus prevails[14]. The expression of HBx in samples with serum HBV-negative implicated quite a few patients were once infected with HBV. Moreover, the cytoplasmic location of HBx was consistent with the previous reports[15].

NF-κB plays a vital role in almost all aspects of cell regulation such as immune cell activation, proliferation, apoptosis, stress response, differentiation and oncogenic transformation. Activated NF-κB can mediate the expression of a large (more than 150) and diverse set of inflammatory and immune response mediators. It has been considered as a central regulator of cellular responses and played a pivotal

role both at the stage of initiation and perpetuation of chronic inflammation[16-19]. NF-κB is sequestered in the cytosol of unstimulated cells via non-covalent interactions with a class of inhibitor proteins, called IκBs. Signals that induce NF-κB activity cause the phosphorylation of IκBs, their dissociation and subsequent ubiquitination and degradation in 26S proteasome complex, allowing NF-κB proteins to enter the nucleus and induce gene expression by binding κB site in DNA. As one of the NF-κB activation products, IκB-α could induce NF-κB export from the nucleus by reuniting NF-κB and terminating associated gene activation. The negative feedback loop could keep NF-κB sensitivity to signals by returning rapidly to baseline activity[20-22].

Because p65 is one of the most common members in NF-κB family, and IκB-α is the most important inhibitor, detection of p65 and IκB-α expression can reflect the state of NF-κB metabolism. In our test, low expression rate of p65 and weakly positive expression of IκB-α represented the nonactive state of NF-κB in non-cancerous tissues, but the activation enhancement of NF-κB in HCC was in accord with the previous reports[23,24]. The expression of IκB-α in HCC and its corresponding liver tissue has not been reported yet. In our study, no statistical difference was found in positive rates between HCC and its corresponding liver tissue, the discrimination of immunostaining intensity was scented. Furthermore, Western blot validated the concentration augmentation of IκB-α in HCC, while in the meantime, molecular weight alteration was not observed. The results illustrated that IκB-α regulation gave priority to quantity change in HCC. The location of p65 and IκB-α represented the activation or non-activation form of NF-κB. Quite a few cytoplasm locations of p65 and IκB-α observed in our test accounted for the non-activated NF-κB increase in HCC, which contradicted with cytoplasm decrease of p65 and IκB-α observed *in vivo* system[25]. We ascribed the contradiction of NF-κB metabolism to the persistence in HCC and the transience *in vivo* system. The lasting activation of NF-κB can automatically regulate the production of IκB-α and possibly even p65 or p50. A great deal of non-activated NF-κB repertory is in favor of lasting activation of NF-κB.

IκB-α proteolysis is by the ubiquitin-proteasome pathway, but the exact locality is still not clear. Birbach *et al* expatiated IκB-α shuttle mechanism between cytoplasm and nucleus[26]. It is recognized now that besides IκB-α, up-stream kinases such as NIK and MAPKK can shuttle between cytoplasm and nucleus. The present study is the first to show the distribution and expression of ubiquitin in HCC. The results of nuclear location of ubiquitin and its relativity with IκB-α indicated the proteolysis of IκB-α was processed in tumor cell nuclei. Of course, another likelihood was that transcription of ubiquitin would be promoted after NF-κB activation[27]. There is no relativity between ubiquitin and HBx, so whether the proteolysis of HBx passes through non-ubiquitin pathway or not remains to be determined.

Positive relativity between HBx and p65 in HCC indicated that HBx existed in tumor tissues was one cause of inducing NF-κB activation. It has been found in some studies that HBx mutation was common in HCC compared with corresponding liver tissues[28]. Frequent types of HBx mutation were COOH-terminal truncation and hotspot mutations in certain amino acids[29-31]. COOH-terminally truncated HBx is encoded by truncated X gene, which usually derives from HBV integrated into host genome. Base mutation and frame-shift are the other causes. Usually, it was considered that HBx activated NF-κB relied on its transactivation domains, and COOH-terminal transactivation domain was important to its transactivation function[32,33]. In our study, NF-κB activation was elevated in HCC with a low HBx expression compared with corresponding liver tissues. Therefore, the results implied that HBx might

activate NF-κB by other unknown mechanisms but not its transactivation ability. One likeness was that C-terminally truncated HBx lost its ability to suppress proteasome complex and facilitated IκB-α degradation and NF-κB activation[4]. The high percentage of ubiquitin expressions in HCC (59.0%) from our results in part supports the opinion. The detailed mechanism of NF-κB activation in HBV-associated hepatocellular carcinoma remains to be further studied.

In conclusion, NF-κB activation induced by HBx could not only facilitate infected cell survival and HBV escape from immune clearance, but also promote liver cell malignant transformation and tumor cell advantageous growth[34]. Variant HBx plays an important role in potentiating NF-κB activation.

Abstract

AIM: To purify the heat shock protein (HSP) 70-associated tumor peptides and to observe its non-MHC-I molecule restrictive antitumor effect.

METHODS: By ConA-sepharose affinity chromatography, ADP-agarose affinity chromatography, and DEAE anion exchange chromatography, we were able to purify HSP70-associated peptides from mouse hepatoma (HCaF) cells treated in heat shock at 42 ℃. Specific active immunization and adoptive cellular immunization assay were adopted to observe the immunoprotective effect elicited by HSP70-associated peptide complexes isolated from HcaF.

RESULTS: The finally purified HSP-associated peptides had a very high purity and specificity found by SDS-PAGE and Western blot. Mice immunized with HSP70-associated peptide complexes purified from HCaF cells were protected from HCaF living cell challenge. This effect was dose dependent. Adoptive immunization of immune spleen cells of mice immunized with HSP70-associated peptide complexes could elicit immunity against HCaF challenge, and the tumor-free mice could resist repeated challenges. This effect could be continuously enhanced by repeated challenge with HCaF living cells. The tumor-free mice could tolerate the challenge for as high as 1×10^7 HCaF cells. The mice immunized once with spleen cells pulsed with HSP70-associated peptide complexes *in vitro* could also result in a certain adoptive immunity against HCaF.

CONCLUSION: High purity and specificity of HSP70-associated peptides could be achieved from tumor cells by the low-pressure affinity chromatography method used in this study. HSP70-associated peptide complexes derived from the HCaF can elicit non-MHC-I molecule restrictive immunoprotective effect against HCaF. This effect can be transferred by adoptive immunization to mice and enhanced by repeated challenge with HCaF live cells.

INTRODUCTION

Heat shock proteins (HSPs) are molecular chaperones which are emerging as biochemical regulators of cell growth, apoptosis, protein homeostasis and cellular targets of peptides. Numerous studies have demonstrated that HSP70 preparations derived from a tumor can elicit cancer-specific immunity against the same tumor by virtue of their ability to bind tumor-specific peptides[1-7]. Further studies indicated that tumor immunity elicited by immunization with HSP peptide complexes, including HSP70 and gp96 family, is mediated by CD8+ T lymphocytes, and its mechanism involves MHC-I class molecule restricted response which is required to channel the peptides into class I presentation pathway[8-10]. In this study, we isolated successfully HSP70-associated peptides from mouse hepatoma HCaF by low-pressure chromatography system and investigated the non-MHC-I class molecule restrictive anti-tumor immunity elicited by purified HSP70 associated peptide complexes.

MATERIALS AND METHODS

Materials

Animals and tumor strain BALB/c mice (H-2^d), weighing 18-20 g, were purchased from Xipuerbikai Experimental Animal Ltd, Shanghai, China. Mouse hepatoma HCaF(non-MHC-I class molecule expression) was obtained from Cancer Institute, Dalian Medical University, China.
Reagents ConA-sepharose was purchased from Pharmacia Inc. ADP, ADP-agarose from Sigma Corp. Macro-Pre DEAE support, Macro-Prep High Q from Bio-Rad Corp. Low-molecule weight standard protein and IgG of goat anti-mouse labeled with horseradish peroxidase from B.M Corp, RPMI1640 and new born bovine serum from GIBCO Corp, and anti-HSP70 McAb(mouse anti-mouse) from Wuhan Boster Corp. All other reagents used were of analytic grade.

Methods

Purification of HSP70-associated peptides The ascites of mice which had been inoculated intraperitoneally with HCaF cells for 6-7 days were used. HCaF cells were washed three times in PBS, and then suspended in RPMI1640 complete medium with water immersion at 42 ℃ for 12 hours. The HCaF cell pellets harvested were homogenized in hypotonic buffer (10 mM NaHCO$_3$, 0.5 mM PMSF, pH7.1) and centrifuged at 100 000×g for 90 min at 4 ℃, and the supernatant was collected. The supernatant concentrated by PEG(MW600) was applied to a ConA-sepharose column in the presence of ConA-sepharose bound buffer C (20 mM Tris-acetate, pH 7.5, 0.5 mM NaCl, 2 mM CaCl$_2$, 2 mM MgCl$_2$, 15 mM 2 ME, 0.5 mM PMSF), and fluid was collected at a flow rate of 12 ml /h, that was the

ConA-sepharose unbound protein. The fraction was dialyzed against buffer D (20 mM Tris-acetate, pH7.5, 20 mM NaCl, 3 mM MgCl$_2$, 15 mM 2ME, 0.5 mM PMSF) overnight at 4 ℃. The sample was applied to an ADP-agarose column equilibrated previously with buffer D at a flow rate of 12 ml/h. The proteins were eluted by buffer D containing 0.5M NaCl and buffer D until the protein was not detected by Bradford method. The column was eluted by 25 ml buffer D containing 3 mM ADP. The harvested elute was concentrated and dialyzed against DEAE ion-exchange buffer A (20 mM Na$_3$PO$_4$, 20 mM NaCl, pH7.2). The sample was applied on a DEAE column equilibrated with buffer A at a flow rate of 10 ml/h. After buffer A equilibrium for 30 min, the target protein was eluted at a linear gradient of 20 mM-1 000 mM NaCl in buffer A (20 mM Na$_3$PO$_4$, 1M NaCl, pH7.0, ranging from 0%-100%). Various fractions harvested were detected with SDS-PAGE and silver staining. The fractions of HSP70 protein were collected, pooled and dried with freeze-drying, and stored at -20 ℃ until further use.

Identification of HSP70-associated tumor peptides HSP70 proteins were resolved on 10% SDS-PAG, subjected to electrophoresis, detected by silver staining, and blotted using mAb specific for HSP70. Manipulation of SDS-PAGE and Western blot were performed according to the method described by Sambrook et al[11]. The protein content was determined by Bradford standard curve method[12].

Active immunization assays BALB/c mice were immunized subcutaneouly with HSP70-associated peptide complexes, supernatant from homogenate of HCaF cells treated with heat shock (S-HCaF), supernatant from homogenate of liver cells treated with heat shock (S-HC), and PBS twice at weekly intervals separately and challenged by subcutaneous injection of the indicated number of HCaF living cells (5×10^4 cells in 100 μl PBS) one week after the last immunization.

Adoptive immunoprotection experiment BALB/c mice were immunized with tail vein injection of immune spleen cells (ISC, 1×10^7 cells in 200 μl PBS) of mice immunized with HSP70-associated peptides and free of tumor, twice at 5 days intervals, and challenged subcutaneouly by 5×10^4 HCaF living cells in 100 μl PBS 3 days after the last immunization. The mice with complete protection were challenged by 1×10^5 HCaF living cells again 50 days after the first challenge. The mice which tolerated the second HCaF challenge, were challenged by 1×10^7 HCaF living cells again. In another experiment, the mice were immunized by tail vein injection of spleen cells (1×10^7 cells in 200 μl PBS) pulsed with HSP70-associated peptides *in vitro* and challenged subcutaneouly by 5×10^4 HCaF living cells in 100 μl PBS 3 days after immunization. Corresponding control groups were set in above experiment.

Statistical analysis
Values were expressed as mean±SD or percent (%). The data were analyzed with SPSS 8.0 software package. The results were considered statistically significant when $P<0.05$.

RESULTS

Purity and specificity of HSP70-associated peptides
Purified HSP70-associated peptides showed one was bond on SDS-PAGE (Figure 1). Western blotting showed that molecular weight of HSP70-associated peptides purified from HCaF was about 70KD, which was consistent with the expected maker (Figure 2). The results indicated that HSP70-associated peptide complexes isolated from HCaF had a very high purity and specificity.

Active immunoprotective effect of HSP70-associated peptides derived from HCaF
As shown in Figure 3 and Table 1, different degrees of

immunoprotection against HCaF challenge could be elicited by immunization with HCaF-70 associated peptide complexes derived from HCaF. The effect on female groups was much better than that on male groups. This effect was dose-dependent. In the female groups, mice immunized with 600 μg/kg HSP70-associated peptides showed better protection than those immunized with 300 μg/kg HSP70-associated peptides. The survival rate of the two groups was 83.3% and 60%, respectively. The female mice immunized with S-HCaF also could result in a certain extent of protective effect against HCaF challenge, and the survival rate and mean survival time of tumor-bearing mice had significant differences from S-HC and PBS control groups ($P<0.01$).

Figure 1 SDS-PAGE analysis of HSP70-tumor peptide complexes (silver staining). M: protein molecular weight marker, 1: protein eluted with 250-350 mmol/L NaCl buffer, after ADP-agarose chromatography (eluted with 0.5 mol/L NaCl buffer, PH7.5, containing 20 mmol/L Tris-acetate) and DEAE-ion exchange, 2-4: protein eluted with 250-350 mmol/L NaCl buffer, after ADP-agarose chromatography (eluted with 3 mmol ADP/L buffer, pH7.5, containing 20 mmol/L Tris-acetate) and DEAE-ion exchange.

Figure 2 Western blot identification of HSP70-tumor peptide complexes purified from HCaF cells. The notes are the same with Figure 1.

Table 4 Adoptive immunoprotective effect against HCaF challenge elicited by ISC transfer

Group	Survival rate (%) (No. of death/No. of mice challenged)	Survival days of tumor-bearing mice (mean±SD)	Extended survival rate (%)	Tumor wt. (g) (mean±SD)	Spleen wt.(g) (mean±SD)
ISC	75 (2/8)[a]	50.5±9.2[b]	71.0[b]	14.92±0.42[bc]	0.39±0.01[bc]
SC	0 (8/8)	36.8±12.9	24.6	7.73±2.14	0.18±0.05
Chal. control	0 (8/8)	29.5±3.9	0	7.35±1.16	0.21±0.05

[a]$P<0.05$, *vs* chal. Control; [b]$P<0.01$, *vs* chal. Control; [c]$P<0.01$, *vs* SC.

On the 10th day and 15th day after HCaF challenge, the tumor volume of tumor-bearing mice in both HSP70-associated peptides and S-HCaF groups was apparently smaller than that in S-HC and PBS groups (Table 2). In females, tumor weight and spleen weight of dead mice in both HSP70-associated peptides and S-HCaF groups were significantly larger than those in S-HC and PBS groups (Table 3).

Adoptive immunprotective effect

Adoptively transferred immune spleen cells of mice, which had been immunized with HSP70-associated peptides and were free of tumor, could provoke immunoprotection against HCaF challenge. The survival rate of ISC-immunized mice was 75%, and the mean survival time of tumor-bearing mice was significantly prolonged compared with both non-immune spleen cells (SC) group and challenge control (Table 4).

The mice which tolerated HCaF challenge were challenged by 1×10^5 HCaF living cells, and the survival rate was 83.3%, while all of the challenge controls died within 27.5 days. The mice which tolerated the second challenge could tolerate repeated challenges for as high as 1×10^7 HCaF living cells, while all the challenge controls died within 22 days (Figure 4).

The mice immunized once with spleen cells pulsed with HSP70-associated peptides *in vitro* could lead to a certain extent of protection against HCaF challenge. Although the survival rate of mice was only 20%, the mean survival time of tumor-bearing mice was 42 days, all the mice treated with S-HCaF, S-HC, SC or PBS died within 33 days.

Figure 4 Protective effect of transferred immune spleen cells against repeated challenges with HCaF. – ▲-▲ ×-× First, second, and third challenge controls. ●-● Transferred immune spleen cell group.

DISCUSSION

Intracellular HSP70 is very low in content of cells and makes up approximately 0.01% of the cell wet weight. At present, ConA-sepharose affinity chromatography or ADP-agarose affinity chromatography in combination with fast protein liquid chromatography[13,14] has been the typical method for purifying HSP70. The recovery of HSP70 isolated by the above methods was lower than 50 mg /L cell pellet[4]. The purification protocol used in our experiment resulted in a relatively high recovery compared with the traditional method of HSP70 purification, being for 50-100 mg /L wet weight of cell pellet. This purification method might be used as a universal technique due to its easy and reproducible isolation of antigenic HSP from other tissues of different sources.

Numerous investigations have shown that HSP itself had no antigenicity and its immunogenicity has been attributed to the peptide chaperoned carried by itself[1-4]. In this experiment, tumor rejection assay demonstrated that HSP70 purified from HCaF could elicit tumor immunity. We therefore conclude that purified HSP70 identified by both SDS-PAGE and Western

blot should be regarded as HSP70-associated tumor peptides.

Our experiment indicated that HSP70-associated peptides derived from HCaF could elicit anti-tumor immunity. Mice immunized with 600 µg/kg HSP70-associated peptides showed better protection than those immunized with 300 µg/kg. This effect was dose-dependent, and was consistent with other reports[4]. In this study, we found the transferred immune spleen cells of mice immunized with HSP70-associated peptide complexes could elicit immunity against HCaF challenge, and the tumor-free mice could resist repeated HCaF challenges. This effect could be continuously enhanced by repeated challenges with HCaF living cells. The mice so treated could tolerate a challenge for as high as 1×10^7 HCaF cells. Our results demonstrated that adoptively transferred immune spleen cells immunized with HSP70-associated tumor peptides could result in immunoprotection against the same tumor. This evidence indicates that anti-tumor immunity elicited by HSP70-associated peptides has a considerable stability of immunoprotection and specific immunologic memory.

It has been generally believed that tumor immunity elicited by immunization with exogenous HSP70-peptide complexes is mediated by antigen-presenting cells and presented by MHC class I molecules[15-24]. It is worth pointing out that the tumor model of HCaF used in our experiment did not express MHC class I molecule protein. Therefore, the tumor immunity elicited by HSP70-associated peptides derived from HCaF might not be mediated by CD8+ CTL. Several studies have shown that HSP70-associated peptides could directly activate γ δ +T lymphocytes or nature killer cells as superantigen without being dependent on the stimulation of MHC-Ia and I b class molecules[25-30]. It is possible that HSP70-associated peptides derived from HCaF can elicit antitumor immunity in a similar manner.

In addition, we found that the supernatants of HCaF cell homogenate could also result in a certain tumor immunity. This effect might be related to the expression of HSP in HCaF cells induced by heat shock.

Compared spleen weight of tumor-bearing mice in various groups, the mean spleen weight of tumor-bearing mice in HSP70-associated peptide complexes group was significantly higher than that in the controls. Our results further showed that adoptively transferred spleen cells pulsed with purified HSP70-associated peptides could also provoke a certain protection against HCaF challenge. These results indicated that spleen cells might play an important role in tumor immunity mediated by HSP70-associated peptides.

It is of great interest to note that the protective effect in the female mice immunized with HSP70-associated peptide complexes was significantly better than that in the male group. The difference may be associated with estrogens, its mechanisms remain to be explored further.

Abstract

AIM: To evaluate the inhibitory effect of antisense phosphorothioate oligonucleotide (asON) complementary to the initiator of human telomerase catalytic subunit (hTERT) on the growth of hepatoma cells.

METHODS: The as-hTERT was synthesized by using a DNA synthesizer. HepG2.2.15 cells were treated with as-hTERT at the concentration of 10 μmol/L. After 72 h, these cells were obtained for detecting growth inhibition, telomerase activity using the methods of MTT, TRAP-PCR-ELISA, respectively. BALB/c(nu/nu) mice were injected HepG2.2.15 cells and a human-nude mice model was obtained. There were three groups for anti-tumor activity study. Once tumors were established, these animals in the first group were administered as-hTERT and saline. Apoptosis of tumor cells was detected by FCM. In the 2nd group, the animals were injected HepG2.2.15 cells together with as-hTERT. In the third group, the animals were given as-hTERT 24 hours postinjection of HepG2.2.15 cells. The anti-HBV effects were assayed with ELISA *in vitro* and *in vivo*.

RESULTS: Growth inhibition was observed in cells treated with as-hTERT *in vitro*. A significant different in the value of A_{570}-A_{630} was found between cells treated with as-hTERT and control ($P<0.01$) by MTT method. The telomerase activity of tumor cells treated with as-hTERT was reduced, the value of A_{450} nm was 0.42 compared to control (1.49) with TRAP-PCR-ELISA. The peak of apoptosis in tumor cells given as-hTERT was 21.12%, but not seen in saline-treated control. A prolonged period of carcinogenesis was observed in the second and third group animals. There was inhibitory effect on the expression of HBsAg and HBeAg *in vivo* and *in vitro*.

CONCLUSION: As-hTERT has an anti-tumor activity, which may be useful for gene therapy of tumors.

INTRODUCTION

Human hepatocellular carcinoma (HCC) is a critical disease threatening human health. It is one of the most common malignant tumors worldwide, however there is no effective treatment at present. It is very necessary to explore new methods for the therapy of HCC. The developments in molecular biochemistry have afforded the possibility for this purpose.

Telomerase, a ribonucleoprotein enzyme that synthesizes telomeric DNA, is thought to be necessary for cellular immortality and carcinogenesis[1,2], and consists of human telomerase RNA component (hTERC), human telomerase protein 1(hTEP1), and human telomerase reverse transcriptase (hTERT). Among them, only the expression of hTERT mRNA is correlated with telomerase[3], and mainly regulates the expression of human telomerase enzymatic activity[4-6]. hTERT is a useful marker for telomerase activation[7,8]. It is associated with the majority of malignant human cancers. Therefore, telomerase is the target of anti-tumor drugs research. For example, many scientists declared that ribozyme which cleavaged telomerase mRNA and PS-ODNs complementary to the repeat sequence of the mammalian telomere (5' TTAGGG3') could arrest tumor cells [9-13] in cell lines. In this study, we observed the inhibitory effect of as-hTERT both *in vivo* and *in vitro*.

In HCC, the activity of telomerase played a very important role during the occurrence of HCC and cirrhotic livers[14]. The positive hTERT mRNA was 89.47% in HCC tissues[15]. Though many factors were related to hepatocarcinogenesis[16], infection of HBV and HCV[17] was the most important. Tahara *et al*[18], discovered that telomerase activity was 100% in HCC tissues with HBV positivity. These studies indicated that there might be a close relationship between HBV infection and telomerase activity during hepatocarcinogenesis. Therefore, in this study, HepG2.2.15 cells, a cell line in which HBV genome was integrated into the chromosome, were the target cells and as-hTERT complementary to hTERT promoter was added to these cells, and the anti-tumor effects and inhibitory action on HBV gene expression of as-hTERT were studied *in vitro* and *in vivo*.

MATERIALS AND METHODS

Materials

The oligomers used in this study were prepared by Shenggong Co. The solutions were suspended in sterile phosphate-buffered saline(PBS) and filtered into 1.5 ml sterile Eppendorf tube, and stored at 4 ℃ until use. AsON used in this study targeted at the promoter area of human hTERT with the sequence 5' GCC ACG TGG GAA GCG 3' (-192--176 site). In this area, there is a potential binding site of upstream stimulating factors, such as pro-oncogene c-myc. The random sequence (5' TTG CCG AGC GGG GTA 3') was used as control. HepG2.2.15 was used as targeted cells. This cell line was purchased from Beijing Institute of Medical Biology. Fetal calf serum (FCS) and G418 were purchased from GIBCO and Sigma respectively. The quantitative detection kit of telomerase (PCR-ELISA) was purchased from Roche Molecular Biochemicals, Germany.

Cell culture

The experimental protocols were similar to those as previously described[19,20]. HepG2.2.15 was a hepatoma cell line which was integrated with HBV genome, and could replicate intact HBV DNA and extract HBsAg and HBeAg. The cells were grown *in vitro* in a 25 ml flask at a concentration of 5×10^4 cells per milliliter in MEM media supplemented with 10% fetal bovine serum containing 380 µg/ml G418[21,22]. The cells were tested for HBsAg and HBeAg and found to replicate HBV DNA. When the cells grew to 75% confluence, they were digested and used for the *in vitro* and *in vivo* studies.

MTT assay

The cells were cultured in 60 mm² dishes with 2×10^5 cells per dish. The next day as-hTERT and control sequence were added at a concentration of 10 µM. After 72 h incubation, these cells were added 20 µL of MTT per dish. Four hours later, the cells were given 100 µL of DMSO per dish and the absorbance of the sample was measured at 570 nm and 630 nm using an ELISA microtiter plate reader. The value of absorbance at 570 nm and 630 nm was named A_{570} and A_{630}.

Determination of telomerase activity

Telomerase activity assay was performed according to a polymerase chain reaction-based telomeric repeat amplification protocol as described previously[23-26] using a kit from Roche (Germany). The cells (10^5-10^6 per dish) were harvested after 72 h incubation with as-hTERT and control sequence.

Preparation of extracts from cells The cells were put in a 1.5 ml Eppendorf tube and pelleted at 3 000×g for 10 min in a refrigerated centrifuge at 4 ℃. Then these cells were washed once in cold PBS. For one tube, 200 µl pre-cooled lysis reagent was added and incubated on ice for 30 min and centrifuged at 10 000×g for 20 min at 4 ℃. A total of 175 µl supernatant was carefully transferred to a fresh Eppendorf tube. These cell extracts were used for the tolemerase assay using the telomerase PCR-ELISA procedure.

Telomeric repeat amplification protocol (TRAP reaction) For each sample, 25 µl reaction mixture was transferred into a PCR tube. Three µl cell extract and sterile water were transferred to a final volume of 50 µl. Then a combined primer elongation reaction was performed according to the following protocol (Table 1).

Table 1 Protocol of TRAP reaction

Step	Time	Temperature	Cycle number
Primer elongation	30 min	25 ℃	1
Telomerase inactivation	5 min	94 ℃	2
Amplification			3-32
Denaturation	30 s	94 ℃	
Annealing	30 s	50 ℃	
Polymerization	90 s	72 ℃	
	10 min	72 ℃	33

Hybridization and ELISA procedure The product of PCR was aliquoted, denatured, bound to a streptavidin-coated 96 well plate, and hybridized to a DIG-labelled telomeric-repeat specific probe. An antibody to DIG conjugated to peroxidase was subsequently bound to DIG. Then tetramethyl benzidine (TMB) was metabolized, the substrates of the enzyme was added to produce a colored reaction product. The absorbance of the sample was measured at 450 nm using an ELISA microtiter plate reader within 30 min after adding the stop reagent. The value of absorbance at 450 nm was named A_{450}.

Animal studies

BALB/c (*nu/nu*) mice (weighing approximately 18-20 g) were purchased from the Experimental Animals Center of Chinese Academy of Sciences. The mice were divided into eight teams randomly. These animals were placed into fresh cages with free access to sterile water. All the solutions were filtered into sterile bottles. In order to compare the different curative effects of as-hTERT by different administration routes, the study was divided into three study groups.

Group I: Each mouse was injected subcutaneously 5×10^6 cells at the left axilla and tumor progression was measured daily. Two weeks postinjection, the mice with tumors about 0.5 cm in diameter were selected, and as-hTERT and control sequencewere injected into the tumors subcutaneously. These animals were divided into two teams, one team (*n*=12) was injected as-hTERT 100 µg/mouse/day, the other (*n*=6) was treated with saline 100 µl/mouse/day. Five days postinjection, the mice were killed by removing the eyeballs and the tumor tissues were removed, and stored in 10% formalin for FCM. These tumor samples were also embedded in paraffin, and sectioned into slices about 5 µm in thickness. The sections were stained with hematoxylin and eosin for histological examination. In this group, the serum were harvested and stored at -20 ℃ for detecting HBsAg and HBeAg.

Group II: Each mouse was injected subcutaneously 5×10^6 cells at the left axilla and as-hTERT 100 µg/mouse (*n*=7) simultaneously, the controls with saline 100 µl/mouse (*n*=6) and random controls with as-hTERT 100 µg/mouse (*n*=6), and tumor progression was measured daily.

Group III: Each mouse was injected subcutaneously 5×10^6 cells at the left axilla. One day postinjection, each mouse was injected as-hTERT 100 µg/mouse (*n*=12), saline 100 µl/mouse (*n*=8) and random controls with as-hTERT 100 µg/mouse (*n*=8) at the same axilla. Three weeks postinjection, no tumors were detected in 10 animals treated with as-hTERT. These mice were divided further into another two teams: one team (*n*=6) was injected subcutaneously as-hTERT at the dosage of 30 µg/mouse at the same place as the first time, the other (*n*=4) was given saline.

In each group, tumor progression was measured, and observations on animal behavior were recorded daily during the study period.

HBV antigen detection

According to the protocol of antigen detection kit (Lizhu Co. Shenzhen, China), the concentrations of HBsAg and HBeAg in the supernatant were detected using an ELISA microtiter plate reader. The results were illustrated with P/N value (P/N=sample A/negative control A. A stands for the amount of light absorbance).

Statistical analysis

All the data were expressed as the mean ± standard error of the mean (SE). The *P* values were calculated by ANOVA or exact probability method. A *P* value less than 0.05 was considered statistically significant.

RESULTS

as-hTERT on activity of telomerase

The results were shown with the value of A_{450}nm. A_{450}nm of as-hTERT treated cells, random sequence control, positive control were 0.42, 1.49 and 1.51 respectively (Figure 1). That of the negative control was 0.08. Telomerase activity was inhibited with the addition of 17-base as-hTERT at a concentration of 10 uM.

Antiproliferation effect of as-hTERT on HepG2.2.15 cells

Seventy-two hours after incubation with the drugs, as-hTERT caused significant (F=251.13, P=0.0001) inhibition of cell growth as shown in Figure 1, but not in random sequence controls and saline controls.

Figure 1 Inhibition effects on HepG2.2.15 cells of as-hTERT *in vitro*. A, B and C: Growth inhibition by MTT method. a, b, and c: Inhibitory effects on telomerase activity by PCR-ELISA. A and a: as-hTERT treated cells, B and b: Random sequence treated cells, C and c: Saline treated cells.

Growth arrest of human hepatocarcinoma in vivo

The drugs were injected into the tumors. After seven days, the peaks of apoptosis of tumor cells treated with as-hTERT, saline control were 21.12% and 7.92% respectively (Figure 2). Inflammation was observed in tissues treated with as-hTERT, but not in controls. The conformation of the animals' liver was normal.

Figure 2 Cell cycle of tumor cells treated with as-hTERT/saline *in vivo*. A: Cell cycle of tumor cells treated with saline. The apoptosis peak was 7.92%(#). B: Cell cycle of tumor cells treated with as-hTERT. The apoptosis peak was 21.12%(*).

As-hTERT could retard tumor cell growth. In the group in which the drugs were injected in combination with HepG2.2.15 cells, tumors were undetectable subcutaneously during the whole study period (10 weeks, 0%, 0/7), while the saline and random sequence controls failed to inhibit tumor growth. In

two weeks, tumors were developed in all of the animals in control teams (100%, 8/8). There was a significant difference between as-hTERT treated and control animals (P<0.01).

If the drugs were injected 24 h after the animals were injected with the cells, in three weeks, tumors were detectable in all of the animals in control teams (100%, 8/8), while in team of animals treated with as-hTERT tumors began to appear in two (16.7%, 2/12), and grew very slowly. Furthermore, if the animals without tumor were injected supplementary drugs, subcutaneous tumor was undetectable during the later 6w (0%, 0/6), while in the team of animals without extra addition of the drugs, tumors developed (Figure 3).

Figure 3 Inhibition effects of tumor cells *in vitro*. a: as-hTERT and HepG2.2.15 cells were injected into animals together. There was no tumor growth in ten weeks. So the diameter of tumor was 0 during the whole study period. b: as-hTERT was injected 24 hours postinjection of the cells. Tumor was not grown in animals which were treated with as-hTERT supplementary (c), otherwise (d), tumors grew again, but very slowly. In random (e) and saline control (f), there was no retarding effect on tumorcell growth. Tumors grew very fast, and after eight weeks, the animals died naturally.

Alteration of HBV antigen expression

as-hTERT could inhibit HBV expression *in vitro* and *in vivo*. *In vitro*, the inhibition peaks on HBsAg and HBeAg were 76% and 56% respectively, while *in vivo*, the inhibition peaks were 38% and 73%.

DISCUSSION

Hepatocarcinogenesis is a very complicated event, and many factors were involved in this process, such as activation of oncogenes, inactivation of tumor suppressor genes and hepatitis virus infection[27]. But the most important is the activation of telomerase. Therefore, to inhibit telomerase activity so as to arrest tumor cell growth by antisense technique is of great significance. In most researches, the target gene was hTR, which is the replication template for telomere, but not the regulatory region of hTERT, the most important region which regulates the activity of tolemerase.

Recent studies suggested that hTERT gene expression was controlled mainly at the transcriptional level[28]. Many cis-elements and trans-acting factors that regulate the hTERT gene transcription have been identified[29-31].Among the potential transcription factor binding sites within hTERT promoter region, a typical E-box (CACGTG, -178- -182) which belongs to the bHLHZ family of transcription factors (such as oncogene c-myc), was likely to play an important role in hTERT gene transcription[32-38]. Our results showed that as-hTERT targeting at the binding site of E-box in hTERT promoter region could inhibit the growth of HepG2.2.15 cells *in vitro*. The probable reason was that the regulating effect of E-box on hTERT transcription was eliminated due to as-hTERT complementary

to E-box binding site. Therefore, telomerase activity was decreased, telomere was shortened to the crisis point, and cell growth was arrested, and apoptosis was increased. However, asON could not completely inhibit telomerase activity. This result indicated that E-box is one of the cis-elements which regulate telomerase transcription. Furthermore, it is very important to study on cis-element and transcriptional factors regulating telomerase activity.

AsON targeting at the promoter region of telomerase could inhibit hepatoma cell growth of mice model *in vivo*. Different ways of drugs administration demonstrated different growth inhibitory effects. Apoptosis was detected in tumors injected as-hTERT, but not in cells treated with saline controls. The best growth inhibitory effect on tumor cells was observed in animals injected as-hTERT in combination with the cells. In another team, tumor growth was observed in the mice which were given as-hTERT 24 hours postinjection of HepG2.2.15 cells at the same site, but the tumors grew very slowly. It could not inhibit tumor cell growth completely through this way. However, if the mice were given a smaller dosage of the drug continually, tumor cell growth would be inhibited completely. These results demonstrated that as-hTERT could inhibit tumor cell growth, the earlier the drug were given, the better the effect was. It suggests that as-hTERT can be an effective drug for eliminating the remaining tumor cells after operation.

HBV genome could integrate into the telomerase gene[32,39]. HBV was a potential cis-activation factor which regulated telomerase activity[40]. The expression of HBV gene could increase telomerase activity[41]. This study demonstrated that as-hTERT could affect the expression of HBV antigen both *in vitro* and *in vivo*. The reason may be that as-hTERT inhibited telomerase activity, and cell growth was retarded. Therefore, HBsAg and HBeAg expressions were inhibited. Maybe, there is some relationship between telomerase activity and HBV, which needs to be further clarified.

Furthermore, there was no toxicity on the mice. In summary, we have demonstrated that a short asON which targets at the initiator of hTERT is capable of inhibiting telomerase activity and retarding tumor cell growth both *in vitro* and *in vivo* in a sequence-dependent manner. These results provide further evidence that drugs targeting at telomerase have a therapeutic potential.

Abstract

AIM: To study the nuclear microsatellite instability (nMSI) at BAT26 and mitochondral microsalellite instability (mtMSI) in the occurrence and development of hepatocellular carcinoma and the relationship between nMSI and mtMSI.

METHODS: nMSI was observed with PCR and mtMSI with PCR-SSCP in 52 cases of hepatocellular carcinoma.

RESULTS: mtMSI was detected in 11 out of the 52 cases of hepatocellular carcinoma (21.2%). Among the 11 cases of hepatocellular carcinoma with mtMSI, 7 occured in one locus and 4 in 2 loci. The frequency of mtMSI in the 52 cases of hepatocellular carcinoma showed no correlation to sex, age, infection of hepatitis B, liver cirrhosis as well as positive AFP of the patients ($P>0.05$). In addition, nMSI was detected in 3 out of 52 cases of hepatocellular carcinoma (5.8%) and there was no correlation of the incidence of mtMSI to that of nMSI ($P>0.05$).

CONCLUSION: mtMSI may be involved in the coccurrence and development of hepatocellular carcinoma and it is independent of nMSI.

INTRODUCTION

Mitochondria are the energy-transducting organelles of eukaryotic cells in which fuels to drive cellular metabolism are converted into cellular adenosine triphosphate (ATP) through the process of oxidative phosphorylation. Mitochondria are responsible for generating approximately 90% of ATP. The mitochondrion is the only organelle in the cell, aside from the nucleus, which contains its own genome and genetic machinery[1]. Mitochondrial DNA (mtDNA) is a 16 569 base-pair, double-stranded and closed circular molecule, and encodes 13 polypeptides. All of the polypeptides are components of the respiratory chain/OXPHOS system, plus 24 genes, specifying two ribosomal RNAs (rRNAs) and 22 transfer RNAs (tRNAs), which are required to synthesize the 13 polypeptides. Mitochondrial genome is far more vulnerable to oxidative damage and undergoes a higher rate of mutation than nuclear genome due to its lack of histone protection, limited repair capacity, and close proximity to the electron transport chain, which constantly generates superoxide radicals[2-5]. Accumulation of mutations in mtDNA is approximately tenfold greater than that in nuclear DNA[6].

A high frequency of mtDNA mutations has been identified in cancer of the colon[7], stomach[8], liver[9], pancreas[10], lung[11], breast[12], kidney[13], prostate[14], ovary[15], Barrett' s esophagus[16] and leukemia[17]. The majority of these somatic mutations were homoplasmic, suggesting that mutant mtDNA becomes dominant in tumor cells. In addition, microsatellite instability has also been shown in mtDNA of colorectal and gastric carcinomas[18,19]. Further studies demonstrated that mononucleotide could repeat alteration, missense mutation, and small deletion in NADH dehydrogenase genes and alteration in a polycytidine (C)n tract in the D-loop region of mtDNA could occur in colorectal carcinomas[20]. These results imply that microsatellite instability in mtDNA (mtMSI) of colorectal carcinoma may be resulted from certain deficiencies in DNA repair. Therefore, it has been proposed that somatic mutations and mtMSI play a role in tumorigenesis and development of cancer[21].

Hepatocellular carcinoma (HCC) is one of the most common causes of cancer related mortality worldwide. The incidence of HCC shows a considerable geographical variation with a very high incidence in China. Epidemiological studies in high-risk populations have identified chronic hepatitis B virus (HBV) and chronic hepatitis C virus (HCV) infection as well as dietary exposure to aflatoxin B1 (AFB1) as major factors in the etiology of this disease[22]. It has been reported that the amount of AFB1 combined to hepatocellular mtDNA is 3-4 fold larger than that combined to nuclear DNA(nDNA). This combined product of aflatoxin cannot easily be expelled and stays in mtDNA for a long period[22]. Since there is a prolonged period between initial HBV and HCV infection and emergence of HCC, multiple genetic events may occur to promote the malignant transformation of hepatocytes. Many chromosomal aberrations have been frequently reported in HCCs including loss of heterozygosity (LOH) at numerous loci[23,24]. The repeated destruction and regeneration of liver tissue associated with chronic viral hepatitis would lead to accumulation of mtDNA mutations[25]. Although MSI in nuclear DNA (nDNA) of HCCs has been detected[26-32], little attention has been paid to MSI in mtDNA(mtMSI) in this tumor. In order to elucidate the role of mtMSI in the hepatocarcinogenesis, we examined mtMSI and nMSI in a set of 52 Chinese HCCs.

MATERIALS AND METHODS

Fresh tissues were collected from 52 HCC patients undergoing hepatic resection in the Southwest Hospital, Third Military Medical University, Chongqing, China from 1996 to 2002. Neoplastic and nonneoplastic liver tissues were frozen in liquid nitrogen immediately and kept at -70 ℃ until processing. The 52 patients consisted of 42 males and 10 females, their age ranged from 22 to 71 years with an average of 48.8 years at

diagnosis. Thirty-two patients were positive and 20 were negative for hepatitis B surface antigen (HBsAg). Hepatitis C virus antibody (Anti-HCV) was negative for all cases. Hematoxylin and eosin-stained sections were prepared from the same samples used for mtMSI and nMSI studies and the diagnosis of HCC was confirmed by histology. None of the patients included in the present series had a family history suggestive of HNPCC and none had received previous chemotherapy or radiation therapy. Necrotic tumors were excluded from the study. The tumor samples contained more than 70% malignant cells. Genomic DNA was isolated from tumor and non-tumor liver tissues and blood, using standard proteinase-K digestion and phenol-chloroform extraction protocols.

PCR-single strand conformation polymophism (PCR-SSCP) was performed to amplify the microsatellite sequence of mtDNA using published primers[18]. The primer consisted of 2 D-loop regions and 5 coding regions (Table 1). The reaction conditions and procedures were similar to those reported by Hebano et al[18].

Each PCR was digested by appropriate restriction enzymes and electrophoresed at 300V at 22℃ for 2 hr on a 7.5% polyacrylamide gel containing 50 mmol/L boric acid, 1 mmol/L EDTA and 2.5% glycerol. After silver staining, PCR products showing mobility shifts were directly sequenced using appropriate internal primer and analyzed using 373A automated DNA sequencer (Perkin Elmer Cetus). All analyses were performed twice to rule out PCR artifact.

MSI at BAT26 microsatellite locus was analyzed using PCR method. The sequence of upper stream primer was 5' -TGACTACTTTTGACTTCAGCC-3' and that of down stream primer was 5' -AACCATTCA ACA TTT TTA ACC C-3' . PCR was performed in 20 μl of reaction mixture containing 10 mmol/L Tris-HCl (pH8.3), 50 mmol/L KCl, 1.5 mmol/L MgCl$_2$, 200 μmol/L each deoxyncleotide triphoshate, 0.5 μmol/L of each primer, 0.5 unit Ampli Taq polymerase (Perkin-Elmer Cetus, NowalK), 100 ng genomic DNA and 0.5 μCi [^{33}p] dATP. The reaction was carried out in a thermal cycler at 94 ℃ for 1 min, at 55 ℃-62 ℃ for 1 min, and at 72 ℃ for 1min, for 35 cycles with an initial denaturation step at 94 ℃ for 5 min and final extension step at 72 ℃ for 10 min. The PCR products were then separated on 5% polyacrylamide 7M urea denaturing gel, and visulized by autoradiography. MSI was defined as the presence of a band shift in the tumor DNA not present in the corresponding normal DNA.

χ^2 test was used for statistical analysis and $P<0.05$ was considered as statistically significant.

RESULTS

Fifty-two HCC samples were screened for mtMSI at seven repeat sites using the PCR-RFLP method. Figure 1 exhibits a representative mobility-shift band compared with normal counterpart. mtMSI affecting at least one locus was observed in 11 out of 52 cases (21.2%), in which 7 cases affected 1 locus and 4 cases affected 2 loci. mtMSI occurred in D-loop in 10 cases (19.2%), in which 8 cases occurred in (C)$_n$ region and 2 cases in (CA)$_n$ region. mtMSI occurred in the coding region in 5 cases (9.6%), and concomitant mtMSI locus was found in the D-loop in 4 out of the 5 cases. The frequency of mtMSI in 52 cases of HCC showed no correlation to sex, age, HBV infection, liver cirrhosis and positive AFP of the patients ($P>0.05$, Table 2).

Figure 1 mtMSI in hepatocellular cancer. Arrows indicate conformational variants associated with mtMSI, N: normal DNA, T: tumor DNA.

Table 2 Relationship between MSI and clinical parameters

		n	mtMSI positive	mtMSI negative
Sex	Male	42	10	32
	Female	10	1	9
Age	<30	1	1	0
	30-60	41	8	33
	≥60	10	2	8
HBsAg	Positive	38	8	30
	Negative	14	3	11
Cirrhosis	Positive	37	9	28
	Negative	15	2	13
AFP	Positive	26	6	20
	Negative	26	5	21

The mobility shift in tumor DNA compared to corresponding normal DNA samples representing nMSI is shown in Figure 2. nMSI was found in 3 of 52 cases of HCC (5.8%). In the 3 cases of nMSI, only 1 case showed mtMSI simultaneously. No correlation was found between nMSI and mtMSI in the 52 cases of HCC.

DISCUSSION

It has been discovered so far that mitochondria are the only organelle to have their own genome and to undergo replication, transcription and translation without dependence on nuclear DNA. They are called as the "25th chromosome of human body". Many diseases have been found to be related to the structural and functional defects of mitochondria and consequently they are known as mitochondrial diseases[33]. mtMSI has been found to be a very common phenomenon accompanying gastric carcinoma, colorectal carcinoma and breast carcinoma and may play an important role in the carcinogenesis of these malignant diseases[12,18-21]. To study the role of mtMSI in liver carcinogenesis, we analyzed 52 cases of HCC using seven microsatellite markers known to be altered in gastrointestinal carcinomas. mtMSI in at least one locus was found in 11 of the 52 cases (21.2%) of HCC, implying that mtMSI might occur not only in gastrointestinal cancers but also in hepatic cancers, and it may play an important role in the occurrence of a certain number of HCC.

Unlike other types of cancer, HCC has been found usually preceded by chronic inflammation due to viral infection[34-37]. Matsuyama *et al*[11] reported that the frequency of mtDNA mutations was markedly increased in both noncancerous and cancerous liver specimens compared with control liver tissue. Accumulation of mtDNA mutations in HCC tissue could reflect its malignant potency. The frequency of mtDNA mutations was significant higher in HBV infection-related HCC than in other tumors, which implies that repeated destruction and regeneration of the liver tissue associated with chronic viral hepatitis would lead to accumulation of mtDNA mutations. In the current study, we did not find any obvious relationship between mtMSI and HBsAg, suggesting that HBV infection might play a limited role in the mtMSI pathway of HCC. In addition, we did not find an obvious relationship between mtMSI and sex, age, cirrhosis as well as positive AFP.

MtDNA contains several mono- and dinucleotide repeats. The most frequently used mtDNA in the test of mtMSI is a (CA)n microsatellite starting at 514 bp position of the D-loop[38] and a homopolymeric C tract extending from 16 184 to 16 193 bp of the D-loop, which could be interrupted by a T at 16 189 bp position[39]. Alonso *et al*[40] studied mutations in the mtDNA D-loop region and found three mutations in eight gastric tumors. Richard *et al*[41] studied 40 pairs of normal/cancer breast specimens for the presence of mtMSI and found a 216-fold increase in the D-loop point mutations of cancer cells with regard to the spontaneous rate detected in female

gametes. Maximo *et al*[19] utilized PCR-SSCP to examine mtDNA large deletions and mutations in 32 gastric carcinomas and found that most of the mutations corresponded to insertions/deletions in the D-loop region or transitions in ND1, ND5, and COXI. Earlier studies revealed the presence of mutations in the D-loop of both non-malignant and malignant gastric tumors[42,43]. Analysis of HCCs indicated that mutations in the D-loop were a frequent event and could be used as a molecular tool for the determination of clonality[9,44]. Two recent studies reported the frequency of D-loop mutations in esophageal cancer. One group focused on adenocarcinomas of Barrett' s esophagus. In that study, D-loop alterations were identified in 40% of the patients examined[16]. The other study showed that D-loop mutations were much less frequent in esophageal cancer, occurring in only 5% of the specimens analyzed[45]. Clearly, analysis of mtDNA from more esophageal tumor samples is needed in order to determine the frequency of D-loop mutations and their relevance in this type of cancer. In our series of 52 cases of HCC, mtMSI was found in 11 (21.2%). MtMSI occurred in the D-loop region of 10 cases and in the coding region of 5 cases. Among the 10 cases, mtMSI occurred in (C)n region of 8 cases and in (CA)n region of 2 cases, So (C)n region of D-loop is the site at which mtMSI occurs more frequently than in other regions. Our findings are consistent to those reported by Habano *et al*. and Maximo *et al*[18-20].

Microsatellite markers might provide evidences of faulty DNA mismatch repair (MMR) via the detection of MSI[46-49]. The choice of microsatellite markers may impact on the MSI detection rate. BAT-26, a repeat of 26 deoxyadenosine localized in intron 5 of hMSH2 gene, has been reported as a reliable indicator of replication error phenotype in colorectal cancers, enabling analysis of tumour DNA in the absence of paired normal DNA[50]. The frequency of nMSI in hepatic cancer varied in different reports[51,52]. Karachristos *et al*[52] studied 27 cases of HCC and found none of the tumors examined showed alterations in BAT-26. In our series of 52 cases, 3 cases were found to have nMSI at BAT26 (5.8%).Our finding indicates that nMSI at BAT26 is not common in cases of HCC and support the hypothesis that HCC is a "low" MSI tumor in China. Carcinogenesis of HCC may undergo a different molecular route other than that of nMSI.

Mutation of mtDNA may result in the occurrence of tumor but its mechanism remains unknown. Further studies are required to determine if mtDNA mutations are correlated with malignant transformation. Recently, scholars have shifted their attention to the interactions between mtDNA and nDNA. Fragments of mtDNA are sometimes found in nuclear genes, and the insertion of mtDNA has been suggested as a mechanism by which oncogenes are activated[53]. For example, sequences representing subunits ND4 (Complex I) and subunits cytochrome C oxidases I, II and III (complex IV) have been found in the nuclear DNA of various tissues[53]. In yeast cells, migration of DNA from the mitochondria to the nucleus occurred 100 000 times more frequently than in the opposite direction[54]. In our series of 52 cases of HCC, nMSI was detected in 5.8% and coexistance of nMSI and mtMSI in only 1 out of 3 cases. We failed to confirm there was a correlation of mtMSI to nMSI in our cases of HCC. This finding is in agreement with the recently published data on gastrointestinal cancer[55].

In conclusion, mtMSI could play an important role at multiple stages in the process of carcinogenesis. The mitochondrial production of ROS might be involved in the initiation and promotion of carcinogenesis, in part due to ROS-triggered mutagenesis of both mtDNA and nDNA[56]. Also, other evidences exists for a mechanism of nDNA mutagenesis involving the integration of mtDNA fragments. Many primary tumors revealed a high frequency of mtDNA mutations and

the majority of these somatic mutations were homoplasmic in nature, indicating that the mutant mtDNA has become dominant in tumor cells. The mutated mtDNA was readily detectable in paired bodily fluids from each type of cancer and was 19 to 220 times as abundant as mutated nuclear p53 DNA. By virtue of their clonal nature and high copy number, mitochondrial mutations might provide a powerful molecular marker for noninvasive detection of cancer[57]. Important areas for future research should include intergenomic signaling pathways in carcinogenesis and the potential role of mitochondria and mtDNA mutations in immunological surveillance of tumor cells. Finally, the role of mitochondria in stimulating apoptosis could be exploited in cancer therapeutics[58].

Abstract

AIM: To analyze the genetic and epigenetic alterations of RUNX3 gene, a potential putative tumor suppressor gene, in hepatocellular carcinoma (HCC).

METHODS: PCR-based loss of heterozygosity (LOH) detection, analysis of mutation with PCR-single strand conformational polymorphism (SSCP) and sequencing, and methylation study with methylation specific PCR (MSP) were performed on RUNX3 gene in a series of 62 HCCs along with their matched normal tissues.

RESULTS: Mutation of RUNX3 gene was not found, but one single nucleotide polymorphism with T to A transversion at the second nucleotide of the 18th condon was found. Nine of 26 informative cases (34.6%) showed allelic loss on the polymorphic site and 30 cases (48.4%) revealed hypermethylation of RUNX3 gene in promoter CpG islands. Furthermore, of the 9 cases with LOH, 8 (88.9%) also had hypermethylation.

CONCLUSION: Our findings indicate that inactivation of RUNX3 gene through allelic loss and promoter hypermethylation might be one of the major mechanisms in hepatocellualr carcinogenesis.

INTRODUCTION

Transforming growth factor-β (TGF-β) is a multifunctional cytokine known to be a potent growth inhibitor for most epithelial cells[1,2]. TGF-β signaling pathway is composed of TGF-β type I, type II receptors and Smad proteins, and is transducted by forming heteromeric complex with its type I and type II transmembrane Ser/Thr kinase receptors. Activated type I receptors then activate the cytoplasmic Smad 2 and Smad 3 by phosphorylation, allowing them to form a hetermeric complex with Smad 4. This Smad complex can activate TGF-beta responsive gene transcription only after it is translocated to nucleus and bound to the specific target nuclear matrix site[2]. However, the key process of nuclear translocation and subnuclear distribution for regulating transcription of TGF-β-responsive gene needs a broad range of nuclear proteins[3]. Recently, RUNX proteins, including RUNX3 gene were proved to interact through their C-terminal segment with Smads and recruit Smads to subnuclear sites of active transcription, thus exerting their biological control[4]. The function of RUNX proteins has been considered as the subnuclear acceptor proteins for signal transduction. On the contrary, Smads cannot be directed to the nuclear matrix in the absence of RUNX proteins[4]. Therefore, TGF-β-Smad signal pathway would be disrupted. RUNX3, one member of the RUNT domain family, was recently found with a loss of 40-60% of expression due to a highly frequency of hemizygous deletion and hypermethylation in gastric cancer[5]. Also, the gastric mucosa of RUNX3 knocked out mouse exhibited hyperplasia and suppressed apoptosis and growth-inhibition induced by TGF-β in epithelial cells[5]. Taken together, it is strongly suggested that RUNX3 gene be a novel tumor-suppressor gene.

Hepatocelluar carcinoma (HCC) is one of the most common causes of cancer death in the world, especially in Asia and Africa[6,7]. HCC, like many other kinds of human malignancy, has been reported to overexpress TGF-β[8]. The serum concentration of TGF-β is also elevated with tumor progression[9]. Therefore, HCC cells resistant to the anti-proliferative function of TGF-β may be a critical step in the development of HCC[10]. However, until the present no molecular event has been found to contribute to the impairment of TGF-β signal pathway in HCC[11]. It is well documented that aberrance of molecules of the pathway including TGF-β receptor, Smads 2, 3, 4, 6 and 7 was very rare in HCC[12-14]. The exact mechanism of HCC with loss of TGF-β responsiveness still remains unknown. A growing body of evidence showed that chromosome 1p36 was a common deletion region where just loci of RUNX3 gene exist[15,16]. Several putative tumor suppressor genes are believed to be in this region. But, different types of tumor have different regions of consensus deletion. For example, the consensus deletion of neuroblastoma has been mapped to 1p36.2-36.3, a region distal to the deleted region in HCC. While in HCC, a minimally deleted region of about 4 Mb on chromosome 1p36 was well defined[17]. Within the common deletion region, another candidate tumor suppressor gene, retinoblastoma protein (Rb)-interacting zinc finger gene (RIZ) was also identified[18]. Unfortunately, mutation of RIZ gene was not found in HCC[15]. Its role in hepatocarcinogenesis has not been clarified yet. Most notably, LOH encompassing RUNX3 gene occurs in early stage of HCC, even in precancerous condition[19,20]. In the current paper, we studied the genetic and epigenetic alterations of RUNX3 gene in HCC in order to find out new clues to the development of HCC.

MATERIALS AND METHODS

Tissue samples

Sixty-two frozen HCC specimens and their adjacent normal liver tissue specimens were obtained from Southwest Hospital, Third Military Medical University, Chongqing, China. Informed consents were obtained from every patient. The patients' age ranged 29-72 years with an average of 48.6 years. The male to female ratio was 52:10. The background liver showed cirrhosis in 53 (85.4%) cases, chronic persistent hepatitis in 6 cases

(9.7%), and non-specific change in 3 (3.2%) cases. HBV was detected in 49 cases (79.0%), HCV was detected in 5 (8.1%) and non-virus hepatitis in 8 (12.8%). The number of cases with histological grades I, II and III was 8, 26, 28, respectively. Three pathologists reviewed independently one 5 μm thick section stained with hematoxylin and eosin.

DNA extraction

Frozen tissue samples were ground into very fine powder in liquid nitrogen, suspended in lysis buffer and treated with proteinase K. DNA was extracted by phenol-chloroform-isoamyl alcohol and ethanol precipitation[21]. Adjacent normal liver tissues were used as corresponding normal controls.

Single strand conformational polymorphism (SSCP) and DNA sequencing

A total of 6 exons of RUNX3 gene were screened for inactivation mutations with PCR-SSCP, cyclic sequencing on genomic DNA templates. The primers were designed with OLIGO software program (version 5.0; National Bioscience Inc., Plymouth. MN) using the genomic sequences obtained from GenBank (accession No. NT_004391). PCR primer pairs for amplification of RUNX3 gene are described in Table 1. Each PCR reaction except for exon 2 was performed under standard conditions in a 10 μl reaction mixture containing 1 μl of template DNA, 0.5 μM of each primer, 0.2 mM of each dNTP, 1.5 mM MgCI$_2$, 0.5 unit of Taq polymerase (Ampli Taq Gold™ containing antibody to Taq, Roche), 0.5 μCi of ^{32}P-dCTP (Amersham, Buckinghamshire, UK), and 1 μl of 10X buffer. Advantage^R-GC genomic PCR kit (Clontech Laboratories, Inc., CA, USA) was used to amplify exon 2 containing CpG-rich sequence according to the user manual. The reaction mixture was denatured for 5 min at 95 ℃ and incubated for 35 cycles (denaturing for 30 s at 95 ℃, annealing for 30 s at 51-67 ℃, and extending for 30 s at 72 ℃). A final extension was continued for 5 min at 72 ℃ in a thermal cycler (PE 480, USA). After amplification, the PCR products were denatured for 5 min at 95 ℃ at 1:1 dilution of sample buffer containing 98% formamide/5 mmol/L NaOH and loaded onto a SSCP gel (FMC mutation detection enhancement system, Intermountain Scientific, Kaysville, UT) with 10% glycerol. After electrophoresis, the gels were transferred to 3-mm Whatman paper and dried, and autoradiography was performed with Kodak X-OMAT film (Eastman Kodak, Rochester, NY). For the detection of mutations, DNAs showing mobility shifts were cut out from the dried gel, and reamplified for 30 cycles using the same primer set. Sequencing kit (Perkin-Elmer, Foster City, CA) was used according to the manufacturer' s recommendations. Cycling sequencing products were resolved on a 6% denatured sequencing gel (USB™, Cleveland, USA).

Loss of heterozygosity (LOH) analysis

We found 1 polymorphic site during SSCP and sequencing analysis using the primer sets covering 6 exons. The polymorphic site had highly frequent information of heterozygote in HCC patients. This made it feasible as an intragenic polymorphic marker for LOH analysis of RUNX3 gene. PCR and SSCP conditions for LOH analysis were exactly the same as described above. PCR products from the corresponding normal and tumor DNAs were run on SSCP gel. Allelic loss was scored when the band intensity of one allelic marker was significantly decreased (more than 70% reduction) in tumor DNA as compared with that in normal DNA.

DNA methylation analysis of RUNX3 gene by methylation specific PCR (MSP)

The methylation status of RUNX3 gene was determined by sodium bisulfate treatment of DNA followed by methylation-specific polymerase chain reaction (MSP), as described with modification[22,23]. In brief, about 100 ng DNA was incubated in 0.2 M NaOH at 42 ℃ for 30 minutes in a total volume of 50 μl. After the addition of 350 μl of 3.6 M sodium bisulfate (Sigma) containing 1 mM hydroquinone at pH 5, the samples were incubated for 4-5 hours at 55 ℃ in the dark. The modified DNA was recovered with 5 μl of glassmilk (BIO 101, Inc., CA, USA) and 800 μl of 6 M NaI. The glassmilk catching the modified DNA was washed three times with 70% ethanol at room temperature, and then treated with 0.3 M NaOH/90% ethanol once, washed twice again with 90% ethanol. The DNA was finally eluted from the dried pellet with 30 μl of 1 mM Tris-HCI (pH 8.0) for 15 minutes at 55 ℃. Five μL of bisulfate-modified DNA was subjected to MSP using two sets of primer specific for methylation detection and unmethylation detection as reported previously[5]. PCR was performed in a total volume of 30 μl containing 5 μl template DNA, 0.5 μM of each primer, 0.2 mM of each dNTP, 1.5 mM MgCI$_2$, 0.5 unit of Taq polymerase (Ampli Taq Gold™ containing antibody to Taq, Roche) and 3 μl of 10X buffer. The reaction solution was initially denatured at 95 ℃ for 1 minute. Amplification was carried out for 40 cycles at 95 ℃ for 30 s, at 63 ℃ for 30 s and at 72 ℃ for 30 s, followed by a final extension at 72 ℃ for 5 min. Controls without DNA were performed for each set for PCRs. Ten μl of PCR products was directly loaded onto 2% agarose gel containing ethidium bromide, and directly visualized under UV illumination, and photographed. The size of PCR products was 234 bp.

RESULTS

Frequency of LOH in RUNX3 gene and its clinical significance

We failed to detect a mutation in all six exons and partial intron adjacent to exon in 62 HCCs by PCR-SSCP and sequencing. But the polymorphic site with T to A transition at the second nucleotide of codon 18 was found at exon 1, a relatively high frequency of heterozygotes (26/62) was used as an intragenic marker to examine LOH of RUNX3 gene, and 34.6% (9/26) of informative cases showed allelic loss (Figure 1).

Frequent hypermethylation of RUNX3 gene in HCC

On the basis of the presence of a CpG island in the 5' region of RUNX3 gene, we examined the promoter 2 hypermethylation using two sets of primers specific for MSP reported by Li[5], and 48.4% (30/62) HCCs were found to have hypermethylation (Figure 2). Notably, we found the degree of hypermethylation was quite different among individual tumors by comparing with the intensity between unmethylation and methylation bands under the same PCR conditions. Although our methods could not be used to quantitate methylation, hypermethylation was not found in the matching normal liver tissues.

Biallelic aberrant of RUNX3 gene in HCC

LOH and hypermethylation are two distinct ways to inactivate tumor suppressor gene. It is widely known that both of them were often involved in complete loss of gene function through cooperation. We, here, found 8 cases had hypermethylation in the 9 cases with LOH of RUNX3 gene.

DISCUSSION

RUNX3 gene has been found belonging to the runt domain family of transcription factors acting as master regulators of gene expression in major developmental pathway[3]. At present, three RUNX genes, RUNX1, RUNX2 and RUNX3, have been identified. All the three genes have been found to share a highly conserved region, called runt domain[24]. They have been shown to interact with Smads 1, 2, 3 and 5, and are indispensable in mediating Smads compound nuclear distribution and Smads specific binding to target DNA[25,4]. Therefore, RUNX proteins are important targets of TGF-beta-Smads signaling pathway. It is well documented that mutation of RUNX1 gene was associated with the development of acute myelogenous leukemia, while mutation of RUNX2 contributed to celeidocranial dysplasia (CCD)[25]. Recently, RUNX3 gene was found to play

an important role during the development of gastric cancer. Its absence would lead to abnormal proliferation of gastric epithelial cells, lack of responsiveness to apoptosis and growth-inhibitory effect induced by TGF-beta in knock out mouse. Moreover, wild type RUNX3 gene significantly reduced the tumorigenesis ability of tumor cells, whereas mutant type RUNX3 gene would abolish the tumor suppressor action of RUNX3 in nude mice and drive tumor cells to grow much faster. In human primary gastric tumor, 60% cases do not significantly express RUNX3 gene because of hemizygous deletion and hypermethylation. Correlation between hypermethylation and under-expression or no expression was further confirmed in *in vitro* experiment[5]. These evidences strongly suggest that RUNX3 gene be a tumor suppressor gene.

It is commonly known that TGF-beta-Smad signal pathway is disrupted in HCC, but the exact mechanism of disruption of the signal pathway has still remained to be worked out[8]. Furthermore, LOH of 1p36 encompassing RUNX3 gene was a common event in pathogenesis of HCC[19]. So, it is reasonable to consider RUNX3 gene as a most possible target gene in the development of HCC. In this study, we found 34.6% of HCC showed LOH of RUNX3. This result is in concordance with the previously reported 30% more or less frequency of LOH at 1p36, an early event in the development of HCC[17,20]. Unfortunately, no mutation was discovered in 62 HCCs.

Hypermethylation is a regional event that occurs frequently in GC-rich sequences, called CpG islands, often located within the 5' regulatory regions of non-transcribed genes. In contrast, actively transcribed genes are always in unmethylation status. Inactivation of genes by hypermethylation of their CpG islands has been well clarified[21,26,27]. Now, it has been recognized that hypermethylation of CpG islands in the promoter region is an alternative way to silence some cancer-associated gene as effectively as inactivation by mutation or deletion[28,29]. To date, genes involved in regulation of cell cycle[21,30], DNA repair[31],

angiogenesis[32], and apoptosis[33,34] have been shown to be inactivated by hypermethylation which is also a frequent event in many human cancers including hepatocellular carcinoma[35-37]. For RUNX3 gene, transcription is regulated by two distinct promoters, P1 and P2. The major RUNX3 mRNA is transcribed from P2. The genomic region surrounding the P2 promoter constituted a large (4.2 kb) CpG island with a GC content of 64%[24]. These features showed P2 possessed the hallmark characteristics of GC-rich promoters. So, it is rational that transcription from P2 should be regulated by DNA methylation in theory. In practice, Li *et al*[5] confirmed the presumption in *in vitro* experiment. Our analysis of RUNX3 gene in HCCs provided evidence of promoter hypermethylation, a common alteration as well as an early event. Thus, methylation of the promoter region appears to be the dominant mode of inactivation of RUNX3 gene in human HCC, just the same as in human gastric cancer. Unfortunately, we did not detect the expression of RUNX3 gene due to unavailability of the sample and antibody. However, methylation changes are considered as a surrogate for altered expression of the gene product, thus, the detection of any abnormally methylated site is a strong indication that this mechanism could alter the expression levels of target genes. It was reported that hypermethylation correlated with LOH and often occurred before the allelic loss[38]. We found in our study 48.3%(30/62) of HCCs showed hypermethylation, which was higher than LOH (34.6%), and 88.9%(8/9) of HCCs with LOH had hypermethylation in the promoter of RUNX3 gene, hence being in line with Knudson's two hit hypothesis and consistent with previous reports.

In summary, we have demonstrated a high frequency of RUNX3 gene aberration-allelic loss together with hypermethylation of the remaining alleles in HCC. These observations can provide the evidence that promoter hypermethylation and allelic loss are the major mechanisms for inactivation of RUNX3 gene in HCC. RUNX3 gene may be one of the key tumor suppressor genes at 1p36 which is the common deletion site of RUNX3 gene in HCC. Inactivation of RUNX3 gene functions, resulting in impairment of TGF-beta - Smads signal pathway and other tumor suppressor function, may be closely associated with the development of HCC.

Abstract

AIM: To investigate pulmonary involvement via pulmonary function tests (PFT) and high-resolution computed tomography (HRCT) in patients with chronic hepatitis C virus (HCV) infection.

METHODS: Thirty-four patients with chronic HCV infection without diagnosis of any pulmonary diseases and 10 healthy cases were enrolled in the study. PFT and HRCT were performed in all cases.

RESULTS: A decrease lower than 80% of the predicted value was detected in vital capacity in 9/34 patients, in forced expiratory volume in one second in 8/34 patients, and in forced expiratory flow 25-75 in 15/34 patients, respectively. Carbon monoxide diffusing capacity (DLCO) was decreased in 26/34 patients. Findings of interstitial pulmonary involvement were detected in the HRCT of 16/34 patients. Significant difference was found between controls and patients with HCV infection in findings of HRCT ($\chi^2 = 4.7$, $P = 0.003$). Knodell histological activity index (KHAI) of 28/34 patients in whom liver biopsy was applied was 9.0±4.7. HRCT findings, PFT values and DLCO were not affected by KHAI in patients with HCV infection. In these patients, all the parameters were related with age.

CONCLUSION: We suggest that chronic hepatitis C virus infection may cause pulmonary interstitial involvement without evident respiratory symptoms.

INTRODUCTION

Hepatitis C virus (HCV) is a common infectious agent, and it is estimated that 3% of the world population are infected with HCV. It was reported that HCV caused 20% of acute hepatitis and 70% of chronic hepatitis[1,2]. HCV could be stimulated chronically by immune system[3,4]. There are few studies about pulmonary involvement of chronic HCV infection. These have been done with small patient groups and results on the association between chronic HCV infection and pulmonary involvement could not be found from these studies[5,6].

Although idiopathic pulmonary fibrosis is considered to be idiopathic, inhaled substances are suggested to be responsible for the manifestation of this clinical presentation[7,8]. Onset of symptoms following a viral infection or common cold in some patients suggests that development of the disease may be due to the injury related to the infection. There is evidence that hepatitis C virus, Epstein-Barr virus (EBV), and adenoviruses may be responsible for the fibrosis[9-11].

This study was to investigate the relationship between HCV infection and interstitial pulmonary involvement, and to reveal the relationship among involvement and age, sex, cigarette smoking, severity of hepatitis, and respiratory functions.

MATERIALS AND METHODS

Patients and study design

Thirty-four patients with chronic HCV infection at outpatient clinics of our hospital, were included in the study. Written informed consent was obtained from each patient prior to participation. Ten healthy subjects (6 males, 4 females) were enrolled in the study as control group. Their age, sex characteristics, and smoking habit were similar to the patient group.

Diagnosis of chronic HCV infection was established by the 3rd generation ELISA test (AxSYM HCV version 3.0, Abbott, Wiesbaden-Delkenheim, Germany) and liver biopsy. When liver biopsy was impossible (6 cases), HCV RNA positivity was accepted for the diagnosis.

Patients with previous diagnosis of another pulmonary disease, decompensated cirrhosis, congestive heart failure, suspected malignancy, collagen tissue disease, leukopoenia ($<3\,000/mm^3$), thrombocytopenia ($<80\,000/mm^3$), hepatitis B carriers and drug addicts (current and past users) were excluded. Cases having a history of chronic alcoholism were also not included in the study. All the patients did not receive any treatment for HCV infection.

Medical history was recorded and physical examination was performed in cases who fulfilled the above criteria for study entry. Their age, sex and quantity of cigarette smoking (pack-year) were recorded. Chest X-ray was obtained.

Pulmonary function test (PFT), diffusion test and high-resolution computerized tomography (HRCT) were performed in all cases.

Pulmonary function test

Measurements of vital capacity (VC), forced vital capacity (FVC), forced expiratory volume in first second (FEV1), forced mid-expiratory flow rate (FEF25-75), carbon monoxide diffusion capacity (DLCO) and ratio of DLCO to alveolar ventilation (DLCO/VA) were done in accordance with American Thoracic Society criteria[13] by using the Vmax 22 device (Sensor Medics, Yorba Linda, CA, USA) with single breath diffusion method. None of the patients had received bronchodilator drugs prior to the tests. Measurements were

recorded as the percentage of the predicted value, 80% and above were considered as normal.

High resolution computerized tomography

HRCT images were obtained by the Somatom DRH device (Siemens, Erlangen, Germany), without contrast administration, and with 10 mm interval, 2 mm thick section, 310 mAs, 125 kVp, 4 seconds of imaging time, in bone algorithm, 512x512 reconstruction matrix, and 1 600/-400 parenchymal and 350/50 mediastinal window range.

For evaluation of interstitial involvement with HRCT, the method described by Remy-Jardin et al[13] was used. HRCT scans were evaluated for the presence, distribution, and extent of the following signs: [a] ground-glass attenuation, [b] nodular areas of high attenuation, [c] consolidation, [d] linear areas of high attenuation, classified as nonseptal lines, [e] septal lines, [f] honeycombing, and [g] architectural distortion.

Extension of the involvement was assessed independently for each of the three zones of the thorax defined as follows. The upper zones were above the level of the main carina, the middle zones were between the level of the main carina and the inferior pulmonary veins, and the lower zones were under the level of the inferior pulmonary veins. HRCT scores in the upper, middle, and lower pulmonary zones were determined by visually estimating the extent of the disease in each zone. The HRCT score was based on the percentage of pulmonary parenchyma that showed evidence of each recorded abnormality, and was estimated to be 5% of parenchymal involvement: 25% and below as 1 point, 26%-50% as 2 points, 51%-75% as 3 points, 76% and above as 4 points. The scores for each zone were then added to obtain a global extent score, ranging from 0 to 12, and referred to as the HRCT extent score of each HRCT abnormality. A total score of pulmonary involvement was obtained by summation of the global extent score of all HRCT abnormalities, ranging from 0 to 84, which was the feature referred to as the overall HRCT of disease severity.

Pulmonary interstitial involvement was confirmed with prone position scanning in patients who had HRCT findings. HRCT scans were interpreted in random order by two radiologists without any clinical data, the two observers assessed the scans together to reach a decision by consensus.

Evaluation of liver biopsy

Liver biopsy was performed in 28/34 patients. Histological evaluation of liver biopsy reflecting the activity level of the disease was done according to the Knodell histological activity index (KHAI) described by Knodell et al[14]. Inflammation in portal areas, piecemeal appearance and bridging necrosis at periportal areas and necro-inflammatory activity observed in parenchyma were considered in the evaluation of the severity of hepatitis.

Statistical analysis

Quantitative data were presented as mean±SD. Statistical analysis was performed by Mann-Whitney U test for comparison of PFTs of patients with HCV infection and control group, and Fisher' s exact (chi-square) test for comparison of HRCT findings. Relation among KHAI and age, sex was evaluated by multiple linear regression analysis. HRCT and PFT were considered as dependent variables, KHAI and factors possibly affecting pulmonary pathologies including age, sex and amount of cigarette smoking were considered as independent variables, then separate multiple linear regression analyses for HRCT score, VC, FVC, FEV1, FEF25-75, DLCO, DLCO/VA were performed. $P<0.05$ was considered statistically significant.

RESULTS

Thirty-four patients (15 women and 19 men) with a mean age of 47.6±17.5 years (20-72) were enrolled in the study. Eighteen patients had a history of cigarette smoking and the mean amount of cigarette smoking was 16.5±9.7 pack-year. Ten healthy control cases (6 men and 4 women) with a mean age of 46.2±2.6 years (21-65) were enrolled into the study. Four of them had a history of cigarette smoking.

PFT measurements revealed that VC, FVC, FEV1, and FEF25-75 were below 80% of the predicted value in 9/34, 8/34, 5/34 and 15/34 patients with HCV infection, respectively. DLCO was decreased in 26/34 patients and DLCO/VA ratio was decreased in 18/34 patients. But, there was no significant difference between controls and patients with HCV infection in mean PFT parameters (Table 1). KHAI values were between 2-16 in 28 patients in whom liver biopsy was performed and the mean KHAI was 9.0±4.7 points.

Table 1 Knodell histological activity index (KHAI) and pulmonary function tests (mean±SD) in patients with chronic hepatitis C virus infection and controls

Features	Patients with HCV (n=34)	Controls (n=10)	P
KHAI	9.0±4.7	-	-
VC[a]	86.3±10.9	83.6±7.9	NS

DLCO[a]	66.3±21.3	80.7±15.3	NS
DLCO/VA[a]	77.7±18.0	85.2±14.5	NS

[a]: % predicted; NS: Not significant.

Interstitial pulmonary involvement was found in 16/34 patients with HRCT. Only one case (1/10) had distortion in the controls in HRCT. HRCT findings excluded other causes such as pneumonia, cancer or tuberculosis in patients and control cases. There was a significant difference between controls and patients with HCV infection in HRCT for interstitial involvement (χ^2=4.7, P=0.03) (Table 2). All of our

a: Not significant, R^2: squared multiple correlation coefficient, *F: F* value, β: Partial correlation coefficients, *t: t* value of regression coefficients.

16 patients in whom interstitial pulmonary involvement was found in HRCT had HRCT scores consistent with mild parenchymal abnormalities, there was a negative correlation between HRCT score and DLCO, FVC (*r*=-0.364, *P*=0.035; *r*=-0.400, *P*=0.019, respectively).

Multiple linear regression analysis in which age and sex were considered as independent variables and KHAI was considered as dependent variable, revealed that KHAI was not affected by sex and was related with age, while KHAI was increased with age (Table 3). In order to investigate the possible association between liver pathology (KHAI) and pulmonary data (HRCT, PFT), pulmonary data were considered as dependent variables, KHAI and possible factors affecting pulmonary pathologies including age, sex and amount of cigarette smoking were considered as independent variables, then separate multiple linear regression analyses for HRCT score, VC, FVC, FEV1, FEF25-75, DLCO, DLCO/VA were performed. HRCT score, VC, FVC, FEV1, FEF25-75, DLCO, and DLCO/VA were related with age. HRCT score was positively correlated with age, whereas others decreased with increasing age (negative correlation). When multiple linear regression analysis was used, no significant relation was found between liver pathology and any of the PFT (except DLCO/VA) or HRCT score (Table 4). Although 16 patients had signs consistent with interstitial involvement in HRCT, our findings showed that this was not directly related with liver pathology.

DISCUSSION

In our study, some patients with HCV infection had a mild decrease in PFTs. However, there was no significant difference between patients and controls in PFTs. We determined that there was a significant difference between patients and controls according to the findings in thorax HRCT. The age was related with both pulmonary involvement and liver pathology.

Although the relationship between pulmonary fibrosis and HCV infection was first suggested by Ueda *et al*[9], Irving *et al*[15] held on opposite point. In a study, which investigated 300 patients with clinically evident HCV infection for the presence of pulmonary fibrosis, HRCT assessments revealed a moderate degree of pulmonary fibrosis in 4 cases and severe pulmonary fibrosis in another 4 cases. In all of these 8 cases, there were various degrees of decreases in diffusion capacity that correlated with HRCT findings and less frequently restriction in PFT parameters[5].

In our study, FEF25-75 was below 80% of the predicted value in a small group of patients (5 patients) with normal FEV1 and VC. Decrease in FEF25-75 and normal VC and FEV1 might be an indicator of an early stage small airway disease. Similar to our findings, Mimori *et al*[16] stated that in sarcoidosis patients with normal FEV1 and VC, the increase in the ratio of maximum expiratory flow rate at 50% of vital capacity (V50) to maximum expiratory flow rate at 25% of vital capacity (V25) was a finding of the early stage manifestation of small airway disease.

There are contradictory results in the literature about correlations between PFT and HRCT score in patients with pulmonary fibrosis. Also, studies generally revealed a negative correlation between PFT and HRCT score[5,13,17]. We detected a negative correlation among HRCT, FVC and DLCO in patients with HCV infection.

As HCV infections generally follow a silent course and as they are rarely diagnosed at the acute phase, onset of the disease usually could not be determined[2]. So, duration of the disease was not investigated among factors that would possibly affect the development of pulmonary involvement. HRCT score and PFT parameters were related with age. In our opinion, because duration of HCV infection may not be accurately determined, age may indirectly be a sign of the duration of the disease.

KHAI was related with DLCO/VA and age in our study. Chronic HCV infection is known to result in moderate to severe disorders in liver, particularly in elderly and alcoholics[18]. In our patients, neither any of the PFT parameters except DLCO/VA nor HRCT score was affected by KHAI (Table 3). Change in DLCO was probably related with age. Because KHAI is for the evaluation of liver parenchyma, we believe that it does not reflect the intensity of extrahepatic manifestations.

It is clearly revealed that HCV infection does not only affect

the liver, it also has many systemic manifestations. However few studies about its effect on the lung showed that there was an uncertain relationship between HCV infection and pulmonary involvement[4,18]. We found a negative correlation between HRCT score and DLCO in chronic HCV patients. In some patients (six cases), there was a decrease in DLCO despite normal HRCT findings. Many studies have shown that DLCO could decrease without presence of any radiological finding in the early stage of fibrosis and this decrease might become more significant later[19-21].

Chronic hepatitis C virus infections may cause mild pulmonary involvement without any pulmonary symptoms resulting in a minimal decrease in PFT. In our study, we found that pulmonary involvement was not related with the degree of liver pathology. The relationship between liver pathology and pulmonary involvement must be investigated in large patient population, and also, it should be detected whether alveolitis can demonstrate the early stage pulmonary involvement. However, we suggest that chronic HCV infection patients, particularly elder ones, might be carefully evaluated by HRCT and DLCO even though they have normal chest X-ray or other PFT parameters.

Abstract

AIM: To study the relationship between expression of platelet-derived growth factor-BB (PDGF-BB) and fibrogenesis in chronic hepatitis B.

METHODS: Hepatic tissues from 43 patients with chronic hepatitis B were embedded in paraffin. The sections were stained with HE and picric acid-sirius red to determine inflammatory activity and fibrosis stages. PDGF-BB expression was detected by immunohistochemistry and assessed semiquantatively. Levels of serum hyaluronic acid (HA), pro-collagen III (PCIII), collagen IV (IV-C) and laminin (LN) were examined by radioimmunoassay (RIA).

RESULTS: The expression level of PDGF-BB was found to be positively correlated with inflammatory activity, fibrosis stage and grade of histological findings (τ=0.58, 0.55, 0.55, P<0.01). The positive correlation was also observed between tissue level of PDGF-BB expression and contents of HA, PCIII, IV-C and LN in the circulation (r=0.52, 0.32, 0.40, 0.33, P<0.05).

CONCLUSION: PDGF-BB may play some role in the development and progression of liver fibrosis.

INTRODUCTION

In chronic liver diseases, fibrosis is one of the parameters indicating a progressive process leading to cirrhosis. Hepatic stellate cells (HSCs) are considered to play a central role in the pathogenesis of liver fibrosis[1,2]. During the process, HSCs proliferate and differentiate into myofibroblast-like cells, synthesizing various extracellular matrix (ECM) components including collagen[2,3].

Platelet-derived growth factor (PDGF) is the most potent mitogen for HSCs[4-6], which were currently indicated as the principle cells producing connective tissue in fibrotic liver[7-9]. PDGF was currently indicated as a major inflammatory growth factor playing a central role in the repair process after acute and chronic tissue injuries. Several recent studies have demonstrated a pathogenic role of PDGF in several chronic inflammatory disorders including glomerulonephritis[10,11], scleroderma[12], rheumatoid arthritis[13], idiopathic pulmonary fibrosis[14] and atherosclerosis[15,16]. The presence of inflammatory infiltrates and the excessive deposition of collagenous matrix are the prominent features of chronic hepatitis. Along these lines, PDGF may also be involved in hepatic fibrogenesis.

PDGF consists of two polypeptide chains (A and B). Three isoforms have been described, namely PDGF-AA, -AB, -BB[17-19]. Recent studies have shown that PDGF-AB and -BB isoforms are more mitogenic for HSCs than PDGF-AA[6]. Thus, the expression of the B chain is thought to be more important in hepatic fibrogenesis than that of the A chain.

In this study we used immunohistological methods to detect PDGF-BB in human liver biopsy specimens from 43 patients with chronic hepatitis B. In addition, the levels of serum hyluranic acid (HA), pro-collagen type III (PCIII), collagen type IV (IV-C) and laminin (LN) were examined by radioimmunoassay. The relationship between expression of PDGF-BB, histologic and serum parameters were evaluated.

MATERIALS AND METHODS

Liver and serum samples

Liver tissue samples with various necroinflammatory activities and at different fibrosis stages were obtained by percutaneous liver biopsies from 43 patients with HBV-related chronic hepatitis during routine diagnostic procedures. All of the patients did not receive any anti-inflammatory or anti-fibrotic treatments, such as steroids or interferon. Informed consent was obtained from the patients for the use of their specimens in the investigation. The biopsy specimens were fixed in 10% neutral formalin and embedded in paraffin. Sections of 6 μm in thickness were used for morphological and immunohistochemical examinations. Serum samples were collected and stored at -20 ℃.

Histology

Paraffin sections were stained with hematoxylin and eosin (H&E). Alternatively, the Sirius red stain method was used to demonstrate fibrous tissue components. A polarization microscope (DMLB, Leica, Wetzlar, Germany) was used to distinguish type I from type III collagen fibers[20]. Grades of necroinflammation (0-4) and stages of fibrosis (0-4) were assessed according to the well-established criteria[21,22]. The grades and stages were scored as follows: $0=2^0$, $1=2^1$, $2=2^2$, $3=2^3$, and $4=2^4$.

Immunohistochemistry

The deparaffinized sections were washed with phosphate-buffered saline (PBS; pH 7.4) and incubated in 3% H_2O_2/methanol for 20 minutes to block endogenous peroxidase. After washed three times in PBS, 5 min each, the sections were heated for 10 min in 0.01 M citrate buffer (pH 6.0) using a microwave oven, and then washed three times in PBS, 5 min each, and incubated with a rabbit antibody against human PDGF-BB (Santa Cruz Biotechnology, Inc., Santa Cruz, California, USA)

at a dilution of 1:50 in PBS at room temperature for 5 hours. After washed, the immunologic reaction was demonstrated using a kit (Beijing Zhongshan Biotechnology Co., Ltd. Beijing, China) and visualized in a solution containing 3, 3' - diaminobenzidine tetrahydrochloride (DAB). The slides were rinsed in distilled water, counterstained with hematoxylin, dehydrated, air dried, and mounted. PBS was used to substitute for the primary antibody as a negative control.

Sera-assays for hepatic fibrosis

Serum hepatic fibrosis parameters including HA, C-IV, PCIII and LN, were assessed by radioimmunoassays using the kits from Shanghai Navy Medical Institute according to the manufacturer's instructions.

Statistical analysis

Results were expressed as mean±SD. Statistical analyses were performed with the one-way ANOVA, Kendall and Spearman rank correlation. Two-tailed tests were done. $P<0.05$ was considered statistically significant.

RESULTS

Histological evaluation

The liver tissues of all patients showed various degrees of chronic inflammation and fibrosis. The fibrosis stage was 0 in 7 patients, 1 in 17, 2 in 8, 3 in 6, and 4 in 4. The stage of inflammatory activity was 1 in 13 patients, 2 in 14, 3 in 12, and 4 in 3.

Figure 1 Immunohistochemical detection of PDGF-BB in liver biopsy of a patient with chronic hepatitis B. This case was diagnosed as stage 0. DAB, ×200.

Figure 2 Immunohistochemical detection of PDGF-BB in liver biopsy of a patient with chronic hepatitis B. This case was diagnosed as stage 1. DAB, ×200.

Expression of PDGF-BB in liver biopsy samples

PDGF-BB immunoreactivity was found in a few mesenchymal cells of portal areas and fibrous septa with its products localized diffusely in the cytoplasm compartment. In intralobular areas, some perisinunoidal cells were also immunoreactive in the areas with necroinflammation. The number of positive cells increased with progression of fibrosis (Figures 1-5) and inflammation. Tables 1- 3 describe PDGF-BB expression levels of different groups respectively. Expression level of PDGF-BB was found to be positively correlated with inflammatory activity, fibrosis stages and grades of histological findings (τ=0.58, 0.55, 0.55, $P<0.01$) in Table 4.

Figure 3 Immunohistochemical detection of PDGF-BB in liver biopsy of a patient with chronic hepatitis B. This case was diagnosed as stage 2. DAB, ×200.

Figure 4 Immunohistochemical detection of PDGF-BB in liver biopsy of a patient with chronic hepatitis B. This case was diagnosed as stage 3. DAB, ×200.

**Figure 5** Immunohistochemical detection of PDGF-BB in liver biopsy of a patient with chronic hepatitis B. This case was diagnosed as stage 4. DAB, ×200.

Levels of serum hepatic fibrosis
Positive correlations were found between PDGF-BB expression levels and four serum parameters for hepatic fibrosis, including HA, LN, PC III and C-IV, and their coefficient was 0.38, 0.33, 0.32, and 0.40 ($P<0.05$), respectively (Table 5).

Table 1 PDGF-BB expression levels in liver samples with different stages of fibrosis

Stages of fibrosis	Case numbers	Expression levels (mean±SD)
S_0	7	4.71±1.50
S_1	17	6.47±2.50
S_2	8	11.63±5.66[a]
S_3	6	9.33±2.73[a]
S_4	5	16.50±5.74[a]

Table 2 PDGF-BB expression levels in liver tissues with different grades of necroinflammatory activity

Grades of inflammatory activity	Case numbers	Expression levels (mean±SD)
G_1	13	4.85±1.57
G_2	14	8.21±4.17[a]
G_3	12	10.67±4.12[b]
G_4	4	17.33±6.11[b]

[a]$P<0.05$ *vs* G_1; [b]$P<0.01$ *vs* G_1.

Table 3 PDGF-BB expression scores in liver tissues of different histological grading groups

Grades of histological finding	Cases numbers	Expression levels (mean±SD)
Mild	27	6.59±3.58
Moderate	10	10.20±4.16[a]
Sever	6	15.60±5.37[b]

[a]$P<0.05$ *vs* mild group; [b]$P<0.01$ *vs* mild group.

Table 4 Relationship between PDGF-BB expression levels in liver tissues of different fibrosis stages, necroinflammatory activity and histological grades

	Coefficients as compared with PDGF-BB expression levels (τ)
Stages of fibrosis	0.55[b]
Grades of inflammatory activity	0.58[b]
And histological findings	0.55[b]

[a]$P<0.05$; [b]$P<0.01$.

DISCUSSION

Liver fibrosis has been to be resulted from architectural remodeling and progressive deposition of ECM components such as proteoglycans, fibronectin, and collagen molecules[23]. It is one of the major factors affecting the clinical course of chronic liver diseases. Active fibrogenesis is frequently preceded by, and associated with inflammation. Fibrogenic growth factors and cytokines released by inflammatory cells can promote the proliferation of fat-storing cells, and designate HSCs, which were considered to be the main cellular source of matrix proteins in the liver[24,25]. In HSCs isolated from rat, mouse or human liver and activated in culture, the dimeric forms of PDGF, either PDGF-AB or -BB, appeared significantly more potent than that of -AA[26-28]. The results of these *in vitro* studies implicated that an increased expression of PDGF might occur also *in vivo* after liver tissue injury. The current study showed that most of the cells immunoreactive for PDGF-BB were located in portal areas. In intralobular areas, the positive cells were seen mainly in the areas with necroinflammation. In addition, the number of cells expressing PDGF-BB was correlated both to the inflammatory activity and to the fibrosis progression. We consider that PDGF may enhance the tissue repair after acute liver injury. In chronic liver diseases, however, the presence of reiterative tissue damage associated with a persistent inflammatory state may cause a sustained release of PDGF involved in the deposition of extracellular matrix. In this context, the prolonged effects of this growth factor on fat-storing cells may contribute to the development of tissue fibrosis rather than to effective tissue repair. Therefore, PDGF-BB may play an essential role in the development and progression of liver fibrosis. The management of PDGF activity by antagonists may prevent aggressive liver fibrosis and improve prognosis of hepatitis B.

It has been well known that collagen type I was the predominant ECM component in fibrosis and cirrhosis, but it required specific procedures to discriminate different collagen fibers on tissue sections[29,30]. We used sirius red stain to subtype the fibers as described by Zhang *et al*[20]. Under the polarization microscope, collagen types I and III were stained red and green, respectively.

Our data showed that the expression levels of PDGF-BB in the liver were correlative with the proposed serum parameters for hepatic fibrosis, including HA, LN, PC III and C-IV. ECM is a complex of macromolecules that includes collagens, proteoglycans and glycoproteins. In fibrotic liver tissue there is an increase in all of these matrix components, and they increase in serum in patients with chronic hepatitis B or liver cirrhosis. These ECM components have been used as a serum marker of hepatic fibrosis. Therefore, serum levels of connective tissue metabolites are related, to some extent, with the amount of ECM in the liver. Wang *et al*[31] reported that serum fibrosis markers were fairly well correlated with the staging of fibrosis. Regarding the correlation observed in this study between the serum parameters and the expression of PDGF-BB in liver specimens, tissue PDGF-BB levels may be correlative with the stages of hepatic fibrosis. These findings suggest that measurement of serum PDGF-BB may be useful in estimating the active hepatic fibrogenesis of chronic hepatitis B.

Table 5 Relationship between serum fibrosis parameters and PDGF-BB expression levels in liver tissues of different fibrosis stages

Staging of fibrosis(S)	Cases	PDGF-BB	HA (µg/L)	LN(µg/L)	PCIII(µg/L)	IV-C(µg/L)

Abstract

AIM: A strategy for viral vaccine design is the use of conserved peptides to overcome the problem of sequence diversity. At present it is still unclear whether conserved peptide is safe as a candidate vaccine. We reported it here for the first time not only to highlight the biohazard issue and safety importance for viral peptide vaccine, but also to explore the effect of a fully conserved peptide on HBV replication within the carboxyl terminus of HBx.

METHODS: We synthesized the fully conserved peptide (CP) with nine residues, FVLGGCRHK. HBV-producing 2.2.15 cells were treated with or without 3.5 μM CP for 36 hours. Quantitative detection of viral DNA was performed by real-time PCR. HBV antigens were determined by enzyme-linked immunoadsorbent assay (ELISA). Quantitative analyses of p53 and Bax proteins were based on immunofluorescence. Flow cytometry was performed to detect cell cycle and apoptosis.

RESULTS: Both extracellular and intracellular copies of HBV DNA per ml were significantly increased after incubation with 3.5 μM of CP. HBsAg and HBeAg in the cultured medium of CP-treatment cells were as abundant as untreated control cells. CP influenced negatively the extracellular viral gene products, and 3.5 μM CP could significantly inhibit intracellular HBsAg expression. In response to CP, intracellular HBeAg displayed an opposite pattern to that of HBsAg, and 3.5 μM CP could efficiently increase the level of intracellular HBeAg. Flow cytometric analyses exhibited no significant changes on cell cycle, apoptosis, p53 and Bax proteins in 2.2.15 cells with or without CP.

CONCLUSION: Together with the results generated from the synthetic peptide, we address that the conserved region, a domain of HBx, may be responsible for modulating HBV replication. As conserved peptides from infectious microbes are used as immunogens to elicit immune responses, their latent biological hazard for human beings should be evaluated.

INTRODUCTION

Human hepatitis B virus (HBV) is known as an important cause of acute and chronic hepatitis, cirrhosis, and hepatocellular carcinoma[1]. Although the incidence of new infections has decreased after the introduction of vaccination programmes, HBV infection remains an important global health problem, with the number of chronic HBV carriers exceeding 350 million worldwide[2]. HBV is a small DNA virus belonging to the hepadnavirus family that includes hepatitis viruses of woodchuck, ground squirrel, Peking duck, *etc.* These viral species all contain a highly conserved small open reading frame (ORF) encoding HBV x protein (HBx). HBx is a multifunctional viral regulator that modulates transcription, signaling pathways, protein degradation, and cell responses to genotoxic stress. These modulations affect viral replication and viral proliferation, directly or indirectly. HBx also affects cell cycle checkpoints, cell death, and carcinogenesis[3].

HBx is well conserved among the mammalian hepadnaviruses[4,5]. Regarding the viral life cycle, in related woodchuck hepatitis viruses, ablation of their X protein start codon or creation of C-terminal truncations has been found to decrease viral replication *in vitro* and to inhibit the establishment of productive infection *in vivo*[6,7]. It is not known which pathways influenced by HBx are needed or sufficient to establish an environment required for viral replication. HBx could not only form intracellular aggregates by itself [8-11], but also involve clumping and organelle aggregation leading to an abnormal mitochondrial distribution[12,13]. The precise role of HBx in the HBV life cycle remains uncertain.

Several novel HBV therapeutic peptides containing immunodominant T helper (Th) and cytotoxic T lymphocyte responses (CTL) epitopes of HBV have been screened out. Epitope-based HBV vaccines were designed and synthesized[14]. Epitope peptides derived from HBx have been used in peptide vaccines to induce specific cellular immunity[15]. In order to overcome the problem of sequence diversity, a strategy for vaccine design was the use of conserved peptides[16]. The biological importance of HBx in HBV replication remains largely undefined. In transient transfection assays the full-length X-gene encoding a product in cells appeared to form intracellular aggregates and to accumulate in large granules, with a tendency of apoptosis[9]. There was a fully conserved nine amino acid sequence within the carboxyl terminus of all HBx. Deletion of this segment resulted in a drastic loss of transactivation activity of HBx[17]. To obtain a different approach to investigate the possible functions of the X gene in HBV replication, we recently performed experiments with synthetic peptide derived from HBx. The peptide could avoid forming aggregates and be employed to investigate the effect of HBx on HBV replication. We reportet it here for the first

time to highlight the biohazard issue and safety importance regarding the synthetic peptide used as a candidate vaccine.

MATERIALS AND METHODS

In vitro synthesis of conserved peptide

HBx sequences of hepadnaviruses used for analysis were taken from GenBank. Accession numbers were as follows: arctic ground squirrel hepatitis B virus, U29144; woodchuck hepatitis virus, M19183; woolly monkey hepatitis B Virus, NC_001896; orangutan hepadnavirus, NC_002168; hepatitis B virus subtype adr, D12980; and hepatitis B virus subtype adw, M54923. Sequence alignment was performed with the software provided by Vector NTI (USA). The fully conserved peptide of nine residues from HBx, FVLGGCRHK (Figure 1), was synthesized by the solid-phase method (GL Biochem Ltd.). Purity (>97%) was assessed by high-pressure liquid chromatography, amino acid analysis, and molecular weight determination by mass spectrometry.

The numbers refer to the first amino acid of each peptide. Underlined region is a fully conserved sequence.

Cell culture treated with peptide

2.2.15 cell line containing HBV ayw strain genome derived from a human hepatoblastoma HepG2 cells[18], was grown and cultured in Dulbecco's modified Eagle's medium (Gibco Life Technologies) supplemented with 10% heat-inactivated fetal calf serum. 2.2.15 cells were seeded into 24-well tissue culture plates. Once cell culture dishes were subconfluent (-5×10^6 cells), the culture medium was replaced by the same amount of fresh media harboring CP. Cells were incubated with 3.5 μM CP for 36 hours, the culture medium was collected for the analysis of extracellular HBV DNA and HBV antigens. The cells were washed and detached from the dishes. The collected cells were lysed. After centrifugation, the supernatant was stored for the analysis of intracellular HBV genomic forms and HBV antigens. The protein concentration was estimated by Bradford method.

Real-time PCR assay

Fluorescence quantitation of HBV DNA was performed with real-time PCR reagent kit (Shenzhen PG Biotech, China). The primers and probe were selected in the S gene of HBV genome and generated a product of 70 bp. HBV DNA was extracted from 100 μl of the sample. Real time PCR was done using 2 μl of HBV DNA, 0.06 μl of UNG (1 u/μl), 0.4 μl Taq (5 u/μl) and 37.6 μl PCR mix. After incubation for 5 min at 37 ℃, the DNA polymerase was activated at 94 ℃ for 1 min. The PCR cycling program consisted of 42 two-step cycles of 5 s at 95 ℃ and 30 s at 60 ℃. Viral DNA was extracted and purified from 100 μl of the sample. Amplification and detection were performed with a Line-gene real-time PCR analysis system (Japan). Three independent experiments were performed.

HBsAg and HBeAg assay

Hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) were determined using licensed ELISA kits (Wantai Biotech Inc., Beijing) following the manufacturer's package insert procedure.

Flow cytometric analysis

2.2.15 cells treated with or without 3.5 μM CP for 36 hours were released by trypsinization and resuspended in phosphate-buffered saline at a density of 2×10^6 cells/ml. Quantitative analyses of p53 and Bax proteins were based on immunofluorescence of cells stained with fluorescein isothiocyanate-conjugated monoclonal antibodies (PharMingen, USA) respectively. Cell cycle and apoptosis were monitored using propidium iodide staining of nuclei. Flow cytometry was performed and analyzed on a Becton Dickinson flow cytometer using CellQuest software.

Statistical analysis

Statistical analysis was performed by Student's t test. The data were analyzed with SigmaPlot 2000 software (SPSS Inc., USA). Differences were considered statistically significant when P value was less than 0.05.

RESULTS

Enhancement of HBV DNA replication after CP treatment of 2.2.15 cells

Parallel cultures, with or without CP, were maintained at 37 ℃ for 36 hours, and then investigated for the presence of viral DNA in cell lysates. HBV DNA was analyzed in a quantitative manner for the overall levels of HBV DNA (both extracellular and intracellular DNA) and the relative rate of HBV replication (intracellular DNA). HBV DNA was analyzed by real-time PCR. As shown in Figure 2, both extracellular and intracellular copies of HBV DNA per ml were significantly increased after incubation with 3.5 μM of CP. We observed that HBV DNA replication of treated 2.2.15 cells was substantially enhanced by the conserved peptide.

Figure 2 Quantitative detection of HBV DNA by real-time PCR. HBV DNA levels were significantly increased by 3.5 μM of CP ([a]P=0.005, [b]P=0.038).

Effects of CP on expression of HBV antigens

Cell lysates and culture medium were analyzed for intracellular and extracellular viral gene products. ELISA results revealed that CP affected the expression of HBV antigens differently. As shown in Figure 3, there were no significant differences in extracellular HBsAg from 2.2.15 cells treated with or without CP, and 3.5 μM CP could significantly inhibit intracellular HBsAg expression. Changes in HBeAg were evaluated as well. It was found that there was no statistically significant difference of extracellular HBeAg when the cells were treated with CP or without CP (Figure 4). In response to CP, the intracellular HBeAg displayed an opposite pattern to that of HBsAg. We observed that CP could efficiently increase the level of intracellular HBeAg (Figure 4).

Figure 3 ELISA detection of HBsAg. Three and a half μM CP could significantly inhibit intracellular HBsAg expression ([b]$P<0.001$).

Figure 4 ELISA detection of HBeAg. The level of intracellular HBeAg was significantly increased by 3.5 μM CP ([b]$P<0.001$).

Flow cytometric analysis of virus-host cells treated with CP
When fluorescein isothiocyanate-conjugated monoclonal antibodies were used to assess p53 and Bax proteins, 2.2.15 cells treated with CP or without CP displayed no significant changes (Figure 5). As shown in Table 1, the results exhibited no significant changes of cell cycle and apoptosis in 3.5 μM CP treated cells compared with the cells not treated by CP.

Figure 5 Flow cytometric analysis of Bax and p53 proteins.

Table 1 Percentage of apoptosis and cell cycle phase

HepG2 cells	Apoptosis	G0/G1	G2-M	S
0 μM CP	0.39±0.01	81.21±0.51	11.09±2.11	7.71±2.62
3.5 μM CP	0.62±0.27	79.87±1.22	10.24±0.99	9.89±0.30

DISCUSSION

HBV is a 3.2 Kb DNA virus with only four genes having been identified namely C, S, P, and X[19]. The C gene codes for the core protein and the e antigen, the S gene codes for three related viral envelope proteins known as surface antigens, the P gene codes for the viral DNA polymerase, and the X gene codes for a 16.5-kDa protein. HBV molecule is well organized. The X gene could overlap the viral polymerase gene and the precore gene[20,21], thus increasing the utilization of the small genome. Uchida and colleagues analyzed nucleotide (nt) sequences of HBx from more than 130 clinical HBV isolates. They attempted to establish the correlation of nt substitutions with clinical pathological characteristics. They found the X gene (465nt) was crucial for the replication and expression of HBV because HBx could transactivate HBV DNA, and contained the core promoter, enhancer II, and two direct repeats. There were several mutational hotspots, some of which seemed to relate to the immunological epitopes of the X protein. One was an 8-nt deletion between nt 1 770 and 1 777, which could truncate 20 amino acids from the carboxyl terminus of HBx. This deletion could lead to the suppression of replication of HBV DNA[22]. There was a fully conserved nine amino acid sequence within the carboxyl terminus of all HBx. We synthesized the fully conserved peptide with nine residues, FVLGGCRHK, and quested for its physiological role in regulation of HBV replication.

HBx is regarded as an important multifunctional protein for the viral life cycle and viral-host interactions. HBx has been shown to be essential for viral proliferation in the woodchuck[6,7], but was not central to HBV replication and virion export[23]. In the absence of a convenient animal model system for studying HBV replication, the transgenic mouse could provide an alternative choice. The transgenic mice HBx was not absolutely essential for HBV replication and virion secretion, but replication was significantly decreased in the absence of X protein[24]. Utilizing real time quantitative PCR, we found that CP could increase both the level of intracellular HBV DNA and the production of HBV DNA secretion.

HBsAg and HBeAg were translated from preS/S mRNA and precore mRNA individually. In this report, we demonstrated that CP could induce intracellular HBeAg expression and downregulate intracellular HBsAg expression. The results agreed closely with a recent observation of Xu *et al.*, who found that the presence of HBx increased the level of C gene transcripts approximately three folds in mtTg04 mice. HBx had no apparent effect on the RNA level of the S gene in this mouse line[25]. Our result was also supported by the findings of Reifenberg's research group[26]. They found that the X gene provided in trans could stimulate the expression of C gene when they studied transgenic mice carrying subgenomic HBV DNA. Our data suggest that HBsAg and HBeAg in cultured medium of CP-treated cells were as abundant as untreated control cells. This might be due to the basal level released from 2.2.15 cells before incubated with CP. CP had a negative influence on extracellular viral gene products. Considering the possible influence of CP on the status of host cells might alter the biologic properties of HBV, we performed analysis of cell cycle and apoptosis. Our results showed no significant cellular changes by CP. Despite the association of multiple activities with HBx, none of them appeared to provide a uniform hypothesis regarding the true biological functions of HBx[27]. Taking advantage of the synthetic peptide, we are in an attempt to identify different roles of a domain in HBx in HBV replication.

Synthetic peptide derived HBx may be responsible for modulating HBV replication. HBx has been found to be a short-lived protein and proteolysed by a ubiquitin proteasome pathway[28,29]. We think that some short peptides converted from HBx through intracellular degradation process may still remain their basic functions for HBV replication.

Abstract

AIM: To investigate the anti-angiogenic effect of somatostatin receptor subtype 2 (SSTR2) gene transfer into pancreatic cancer cell line PC-3, and the mechanisms involved in this effect.

METHODS: The full length human SSTR2 cDNA was introduced into pancreatic cancer cell line PC-3 by lipofectamine-mediated transfection. Positive clones were screened by G418 and stable expression of SSTR2 was detected by immunohistochemistry SABC methods and RT-PCR. Enzyme-linked immunosorbent assay (ELISA) was used to detect vascular endothelial growth factor (VEGF) levels in the cell culture supernatants of SSTR2-expressing cells, vector control and mock control cells. Furthermore, the expressions of VEGF and matrix metalloproteinase-2 (MMP-2) were detected by immunohistochemistry SABC methods and RT-PCR in these cells.

RESULTS: VEGF levels in the cell culture supernatants were significantly reduced in the SSTR2-expressing cells (first week, 172.63±21.2 ng/L and after two months, 198.85±26.44 ng/L) compared with the vector control (first week, 790.39±86.52 ng/L and after two months, 795.69±72.35 ng/L) and mock control (first week, 786.42±90.62 ng/L and after two months, 805.32±84.36 ng/L) ($P < 0.05$). The immunohistochemical assay showed a significant reduction of the integral optical density of VEGF and MMP-2 in the SSTR2-expressing cells (42.25±8.6 and 70.5±6.25, respectively) compared with the vector control (85.75±12.9 and 110.52±13.5, respectively) and mock control (82.6±9.28 and 113.56±9.62, respectively) ($P < 0.05$). Conversely, the average gray value of VEGF and MMP-2 was significantly increased in the SSTR2-expressing cells (121.56±8.43 and 134.46±19.95, respectively) compared with the vector control (55.72±5.6 and 62.26±12.68, respectively) and mock control cells (58.48±6.2 and 65.49±9.16, respectively) ($P < 0.05$). Moreover, the expressions of VEGF mRNA and MMP-2 mRNA were significantly reduced in the SSTR2-expressing cells (0.1384±0.017 and 0.2343±0.070, respectively) compared

with the vector control (1.024±0.117 and 0.806±0.119, respectively) and mock control (1.085±0.105 and 0.714±0.079, respectively) ($P < 0.05$).

CONCLUSION: The expression of reintroduced human SSTR2 gene exerts its antiangiogenic effects by down-regulating the expressions of the factors involved in tumor angiogenesis and metastasis, suggesting SSTR2 gene transfer as a new strategy of gene therapy for pancreatic cancer.

INTRODUCTION

The antiproliferative action of somatostatin (SS)/analogues is signaled by specific G-protein coupled receptors, and up to date, six different subtypes (SSTR-1, -2A, -2B, -3, -4, and -5) have been cloned and functionally characterized in various cell systems, including pancreas, adrenal cortex, and brain tissue[1]. However, several studies demonstrated that somatostatin receptor subtypes (SSTRs) were strongly expressed in the normal pancreas, whereas not only a desensitization or mutation of these receptors occurred in pancreatic tumors[2], but also expression of these receptors, especially SSTR2, was frequently lost in human pancreatic adenocarcinomas[3-5]. Despite remarkable biochemical properties of SS analogues *in vitro*, *p*oor therapeutic results with them in Phase I/II clinical trials against the majority of cases of pancreatic cancers[5-7], were due to the loss of gene expression for SSTR2 in pancreatic cancers and relatively low expressions of SSTR3 and SSTR5[8].

VEGF, also known as a vascular permeability factor, is highly expressed in various types of tumors, and is an endothelial cell (EC) specific mitogen. VEGF via binding to its high affinity receptors (Flt-1/VEGFR-1, Flk-1/KDR/VEGFR-2), exerts its mitogenic effect by promoting EC proliferation and migration, thereby playing a crucial role in tumor neovascularization[9,10]. Gupta *et al* reported VEGF as a survival factor for EC, rendering these cells more radioresistant[11]. Several studies showed positive correlations between tumor cell VEGF expression, blood vessel density, tumor growth and metastasis, disease progression and poor prognosis in pancreatic carcinomas[12-14], and suppression of VEGF expression attenuated pancreatic cancer cell tumorigenicity[10], suggesting that over-expression of VEGF might be associated with the aggressive phenotype of this disease and that VEGF should be an important target for anticancer therapy.

On the other hand, matrix metalloproteinases (MMPs) were reported to enhance the degradation of extracellular matrix

(ECM), and thereby hydrolyze the important components of ECM and basement membrane such as types IV, V, VII, X collagens and fibronectin, elastin, *etc* and were closely associated with the invasiveness and metastasis of tumors[15-20]. MMP-2 was the most commonly expressed MMPs in pancreatic tumor specimens but not in normal pancreas and was correlated with the aggressive phenotype (invasive and metastatic potential) of pancreatic carcinomas[21-24]. Ellenrieder *et al* demonstrated that increased expression and activation levels of MMP-2 were strongly associated with elevated expression levels of its activators MT1-MMP (Membrane type 1-MMP) and MT2-MMP (Membrane type 2-MMP) and that it played a significant role in pancreatic tumor cell invasion[25]. The selective MMP-2 and MMP-9 inhibitor MMI-166 exerted its antitumor effects on pancreatic cancer by inhibiting its invasion and angiogenesis[26].

In the present study, we evaluated the potency of introduction of exogenous SSTR2 gene as negative regulators of VEGF and MMP-2 production in pancreatic cancer cell line PC-3 for the following reasons: (1) SSTR2 was strongly expressed in normal pancreas whereas it was frequently lost in human pancreatic adenocarcinoma[2-4]. (2) Antitumor effects of SSTR2 occurred as a consequence of an SSTR2-dependent negative feedback autocrine loop, whereby SSTR2 induced the expression of its own ligand, SS, which also constitutively activated SSTR2[4,27]. (3) SS/analogues exhibited antisecretory effects by the inhibition of release of growth factors and trophic hormones, *e.g.,* growth hormone, insulin-like growth factor-1, insulin, gastrin[2]. In addition, since pancreatic cancer is characterized by the over-expression of several angiogenic factors such as VEGF, bFGF, MMP-2, *etc*, it is necessary to elucidate the effects of the genes or molecules with antiangiogenic properties on pancreatic cancer. Previous studies have reported the antiangiogenic properties of SS/analogues and SSTRs in various tumors[28,29], however the mechanisms involved in the antiangiogenic effects of SSTR2 have been poorly elucidated in this pancreatic cancer cell line PC-3 as yet. Hence, our present study demonstrated that the reexpression of SSTR2 gene in the pancreatic cancer cell line PC-3 devoid of SSTR2, exhibited its antiangiogenic effects by down-regulating the expression of angiogenic factors *in vitro* both at protein and mRNA levels.

MATERIALS AND METHODS

Materials

PC-3, a human pancreatic cancer cell line, was obtained from Shanghai Institute of Cell Biology, Chinese Academy of Sciences. Dulbecco' s modified eagles medium (DMEM), fetal bovine serum (FBS), lipofectamine and geneticin (G418) were purchaesd from Gibco BRL. The full-lenth cDNA of human SSTR2 was kindly provided by G. I. Bell (Howard Hughes Medical Institute, Chicago, IL). Monoclonal antibody of SSTR2, mouse anti-VEGF polyclonal antibody, mouse anti-MMP-2 monoclonal antibody, SABC kit were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). TRIZOL®reagent, RNasin, oligo(dt) 15, dNTPs, M-MLV reverse transcriptase, Taq DNA polymerase and VEGF ELISA kit were from Promega. Eukaryotic expression vector pcDNA3.1 was purchased from Invitrogen (Invitrogen, San Diego, CA).

Plasmid construction and gene transfer

Human SSTR2 cDNA was digested with *EcoRI/XbaI* and cloned in the *EcoRI/XbaI* site of pcDNA3.1. The sequence encoding the signal peptide from alkaline phosphatase was inserted into the *HindIII/EcoRI* site upstream of SSTR2 and an epitope tag derived from influenza virus hemagglutinin A (HA) was fused in the *EcoRI* site between the signal peptide and SSTR2. Recombinant plasmid was purified by QIA prep spin miniprep kit (QIAGEN Co).

PC-3 cells were routinely cultured in DMEM media supplemented with 10% heat-inactivated FBS, 100 u/ml penicillin and 100 u/ml streptomycin, and incubated at 37 ℃ in a humidified atmosphere containing 5% CO_2 in air. Gene transfer was performed according to the manufacture' s protocol of lipofectamine (Gibco BRL). Briefly, about 3×10^5 cells per well containing 2 ml appropriate complete growth medium were seeded in a six-well culture plate, and incubated at 37 ℃ in a CO_2 incubator until the cells were 70% to 80% confluent. A cover slip was plated in each well before seeding. After the cells were ringed with serum free and antibiotics-free medium, the cells were transfected separately with pcDNA3.1-SSTR2 1 μg/lipofectamine 3 μL (experimental group), pcDNA3.1 1 μg/lipofectamine 3 μL (vector control), and only lipofectamine 3 μL (mock control), followed by incubation at 37 ℃ in a CO_2 incubator for 6 hours. Then the medium was replaced by DMEM culture medium containing 20% FBS. After 48 hours, two wells in each group were taken out to detect the transient expression of SSTR2 by immunohistochemical SABC methods, whereas others were continuously cultured for stable expression of SSTR2. G418 (500 mg/L) was added to select the resistant clones after 48 hours. Six days later, when most of the cells died, the concentration of G418 was decreased to 300 mg/L and cells were cultured with G418 for another 6 days. Then the medium was changed every 3 or 4 days and colonies were collected approximately 2 weeks later for the examination of stable expression of SSTR2 by immunohistochemical SABC methods and RT-PCR assay.

Confirmation of SSTR2 protein expression by immunohistochemical staining

The stable expression of SSTR2 in the experimental group cells was detected by using immunohistochemical SABC methods. All the cover slips were dried at room temperature and washed twice with PBS solution (pH 7.2), followed by the treatment with 3% H_2O_2 for 10 min at room temperature. Then the cover slips were incubated in 5% bovine serum albumin in PBS solution for 20 min to block the nonspecific antibody-binding. The cover slips were then incubated with mouse anti-human SSTR2 antibody, diluted in 1:50 in 0.5% bovine serum albumin in PBS for 12 hours at 4 ℃. The bridging antibody (biotinylated goat anti-mouse IgG) and SABC complex were diluted to 1:100 and incubated with the specimens for 20 min at 30 ℃. Finally diaminobenzidine tetrachloride (DAB) was used for color development and the cover slips were counterstained with hematoxylin. Positive rate (brown color cells) was automatically measured with the biological image analysis system 2000 (Opton Germany).

Confirmation of SSTR2 mRNA expression by RT-PCR

Total RNA was extracted separately from PC-3 cells of each group with TRIZOL®reagent following the manufacturer' s instructions. A 2 μg (treated in 5 μL DEPC water in an Ep tube) sample of total RNA was denaturalized by incubating at 70 ℃ for 5 min, and the tube was placed to ice for 3 min, and then reverse-transcribed into complementary DNA (cDNA) by using Moloney murine leukemia virus reverse transcriptase (M-MLV). Briefly, the denaturalized RNA (5 μL) was incubated for 60 min at 37 ℃ and for 5 min at 95 ℃ with 4 μL 5×reverse transcriptase buffer, 1 μL oligo (dt) 15, 1 μL RNasin (50 u/μL), 1 μL dNTPs (10 mmol/L), 1 μL reverse transcriptase (200 u/μL), and 7 μL DEPC water in a total volume of 20 μL. For polymerase chain reaction (PCR), 5 μL of the resulting cDNA, 31 μL of tripled-distilled H_2O, 5 μL of 10×PCR buffers, 3 μL of $MgCl_2$ (25 mmol/L), 1 μL of dNTPs, 1 μL of each of sense and antisense primers (10 pmol/L), 1 μL of each of sense

and antisense β-actin, and 1 μL Taq DNA polymerase (3 u/μL) in a total volume of 50 μL were added. The samples were amplified through 35 cycles, each amplification consisting of denaturation at 94 ℃ for 40 s, primer annealing at 55 ℃ for 40 s and extension at 72 ℃ for 1 min. Cycles were preceded by incubation at 94 ℃ for 5 min to ensure full denaturation of the target gene, followed by an extra incubation at 72 ℃ for 10 min to ensure full extentsion of the products. PCR products were analyzed on 1.5% agarose gel containing ethidium bromide. The sequences of the primers for SSTR2 were sense 5'-CCCCAGCCCTTAAAGGCATGT-3' and antisense 5'-GGTCTCCATTGAGGAGGGTCC-3' (234 bp) and for β-actin, sense 5'-GTGCGTGACATTAAGGAG-3' and antisense 5'-CTAAGTCATAGTCCGCCT-3' (520 bp).

Detection of VEGF mRNA and MMP-2 mRNA expression by RT-PCR

Total RNA was extracted separately from PC-3 cells of each group with TRIZOL®reagent following the manufacturer's instructions. RT-PCR was carried out as described above except some changes in conditions of amplification cycles. For mRNA expression of VEGF, samples of each group were subjected to PCR at an annealing temperature from 60 ℃ to 50 ℃ decreased by 0.5 ℃ per cycle for 20 cycles, followed by an additional 15 cycles at an annealing temperature of 50 ℃ for 35 s. PCR products were analyzed on 1.5% agarose gel containing ethidium bromide and quantified by a complete gel documentation and analysis system. VEGF mRNA expression level was determined by the ratio of VEGF/β-actin protein. The sequences of primers for VEGF were sense 5'-TTGCTGCTCTACCTCCAC-3' and antisense 5'-CTCCAGGCCCTCGTCATT-3' (240 bp) and for β-actin, sense 5'-GTGCGTGACATTAAGGAG-3' and antisense 5'-CTAAGTCATAGTCCGCCT-3' (520 bp).

For mRNA expression of MMP-2, samples of each group were subjected to PCR for 33 cycles, each cycle consisting of denaturation at 94 ℃ for 1 min, primer annealing at 55 ℃ for 35 s and extentsion at 72 ℃ for 1 min. PCR products were analyzed on 1.5% agarose gel containing ethidium bromide and quantified by a complete gel documentation and analysis system. MMP-2 mRNA expression level was determined by the ratio of MMP-2/β-actin protein. The sequences of primers for MMP-2 were sense 5'-GCGGATCCAGCGCCCAGAGAGACAC-3' and antisense 5'-TTAAGCTTCCACTCCGGGCAGGATT-3' (473 bp) and for β-actin were sense 5'-CCTTCCTGGGCAT-GGAGTCCTG-3' and antisense 5'-GGAGCAATGATCTTG-ATCTTC-3' (205 bp).

Determination of VEGF concentration in cultured supernatants by ELISA

After successful stable transfection, VEGF protein levels in the supernatants secreted by the cultured human pancreatic cancer cells of experimental group, vector control and mock control were quantitated by ELISA. To generate the conditioned medium, the cells of each group (4×10^5/well) were incubated in 1.5 ml DMEM for 48 hours. The conditioned medium was then collected and centrifuged at 12 000 rpm at 4 ℃ for 15 min, and then ELISA analysis was performed according to the manufacturer's instructions. Furthermore, to observe the long-term antisecretory effect of SSTR2, ELISA analysis was performed two months after stable transfection. The value of OD (A_{450} values) of each well was measured at 450 nm. The supernatants were harvested in triplicate and the experiment was performed twice.

Detection of VEGF and MMP-2 expressions in vitro by immunohistochemistry

Two cover slips were plated in each well of six-well culture plates, and then the cells of each group (10^5 cells) containing 2 ml appropriate complete growth medium were seeded in each well, and incubated at 37 ℃ in a CO_2 incubator for 48 hours. All the cover slips were dried and washed three times with PBS (pH 7.2) at room temperature, followed by the treatment with the 1:1 mixture of 100% acetone and formaldehyde for 10 min at room temperatue. The expressions of VEGF and MMP-2 were detected by using immunohistochemical SABC methods as described above by using mouse anti-human VEGF polyclonal antibody and MMP-2 monoclonal antibody. Under the light microscope, positive staining (brown yellow) was located in cytoplasm and membrane for VEGF and MMP-2. For the image analysis, 150 cells of clear outline from 10 microscopic fields (15 cells in each field) were selected randomly from each group under 10×40 magnification, and the average gray value and integral optical density of each group were automatically measured by using HPIAS-1000, high resolution pathological image analysis.

Statistical analysis

Results were expressed as mean±SD and the mean values were compared by using the ANOVA (SNK, Student-Newman-Keuls test) in the SAS 8.1 software and $P<0.05$ was considered statistically significant.

RESULTS

Reexpression of SSTR2 after transfection

After 48 h *in vitro* transfection, most of the cells in experimental group demonstrated positive staining for SSTR2 as detected by immunohistochemical SABC methods, whereas almost no positive SSTR2 stainings were detected in vector control and mock control. The cells in experimental group were continuously cultured by adding G418 (500 mg/L) with 20% FBS, and then we were able to select a population of PC-3 cells resistant to the toxic effects of G418. After 2 weeks, all of these cells demonstrated positive staining for SSTR2 detected by immunohistochemical SABC methods (Figure 1). Furthermore, RT-PCR analysis of total RNA extracted from the cells of each group showed SSTR2 mRNA expression in experimental group, but not in vector control and mock control (Figure 2). The results suggested that the exogenous SSTR2 gene was successfully reexpressed in PC-3 cell line devoid of SSTR2.

Effect of SSTR2 on VEGF production in cultured supernatants

In the first week after stable transfection, VEGF levels in the cultured supernatants were significantly decreased in the cells of experimental group (172.63±21.2 ng/L) compared with those of vector control (790.39±86.52 ng/L) and mock control (786.42±90.62 ng/L) ($P<0.05$, Figure 3). Similarly, two months after stable transfection, there was still a significant inhibition of VEGF production in the cells of experimental group (198.85±26.44 ng/L) compared with those of vector control (795.69±72.35 ng/L) and mock control (805.32±84.36 ng/L) ($P<0.05$, Figure 3), however the inhibition of VEGF production in the cells of experimental group was slightly less than that in the first week (Figure 3). There were no statistical difference in VEGF levels between the vector control and mock control (Figure 3). Thus, SSTR2 could suppress the production of VEGF secreted by the cells of experimental group.

Effect of SSTR2 on VEGF mRNA and MMP-2 mRNA expression in vitro

RT-PCR analysis showed that the expression of VEGF mRNA was significantly decreased in the experimental group (0.1384±0.017) compared with the vector control (1.024±0.11)

and mock control (1.085±0.105) ($P<0.05$, Figures 4 and 6). Similarly, the expression of MMP-2 mRNA was also significantly reduced in the experimental group (0.2343±0.07) compared with the vector control (0.806±0.119) and mock control (0.714±0.079) ($P<0.05$, Figures 5 and 6). But there was no statistical difference either in VEGF mRNA or in MMP-2 mRNA expression between the vector control and mock control. These results suggested that the reexpression of SSTR2 gene could suppress the expression of VEGF and MMP-2 at mRNA level *in* vitro.

Figure 1 Immunohistochemical staining of SSTR2 expression after stable transfection The cytoplasmic brown yellow staining represents SSTR2 expression. (A) experimental group, (B) vector control, and (C) mock control (SABC×150).

Figure 2 Expression of SSTR2 mRNA by RT-PCR analysis in experimental group, but not in vector control and mock control. Lane M: DNA marker DL 2000, Lane 1: experimental group, Lane 2: vector control, Lane 3: mock control.

Figure 3 Inhibition of VEGF production in cultured supernatants by SSTR2. VEGF was determined in cultured supernatants by ELISA in the first week and two months after stable transfection. VEGF secretion was significantly reduced in the experimental group compared with the vector and mock controls ($P<0.05$). Values were expressed as mean±SD.

Figure 4 Weak expression of VEGF mRNA in experimental group but strong expression in vector and mock control shown by RT-PCR analysis. The expected length of PCR products was 240 bp (VEGF) and 520 bp (β-actin). Lane M: DNA marker DL 2000, Lane 1: experimental group, Lane 2: vector control, Lane 3: mock control.

Figure 5 Weak expression of MMP-2 mRNA in experimental group but strong expression in vector and mock control shown by RT-PCR. The expected length of PCR products was 473 bp (MMP-2) and 205 bp (β-actin). Lane M: DNA marker DL 2000, Lane 1: experimental group, Lane 2: vector control, Lane 3: mock control.

Figure 6 Significant inhibition of VEGF mRNA and MMP-2 mRNA in experimental group compared with vector control and mock control shown by quantification analysis of PCR products of VEGF and MMP-2 mRNA on 1.5% agarose gel containing ethidium bromide ($P<0.05$). Values were expressed as mean±SD.

Down-regulation of VEGF and MMP-2 protein expression by SSTR2

Positive staining of VEGF (Figure 7) and MMP-2 (Figure 9) was located in the cytoplasm and membrane of the cells. The immunohistochemical staining showed a significant decrease in the expression of both VEGF and MMP-2 protein in the experimental group compared with the vector control and mock control ($P<0.05$). According to HPIAS-1000 and statistical analysis, the integral optical density of VEGF staining was significantly reduced in the experimental group (42.25 ± 8.6) compared with the vector control (85.75 ± 12.9) and mock control (82.6 ± 9.28) and the average gray value of VEGF staining was significantly increased in the experimental group (121.56 ± 8.43) compared with the vector control (55.72 ± 5.6) and mock control (58.48 ± 6.2) ($P<0.05$, Figure 8). However, no significant difference was observed between the vector control and mock control.

Similarly, according to HPIAS-1000 and statistical analysis, the integral optical density of MMP-2 staining was significantly reduced in the experimental group (70.5 ± 6.25) compared with the vector control (110.52 ± 13.5) and mock control (113.56 ± 9.62) and the average gray value of MMP-2 staining was significantly increased in the experimental group (134.46 ± 19.95) compared with the vector control (62.26 ± 12.68) and mock control (65.49 ± 9.16) ($P<0.05$, Figure 10). However, no significant difference was observed between the vector control and mock control.

in experimental group compared with vector control and mock control ($P<0.05$). Values were expressed as mean±SD.

DISCUSSION

The properties of tumor cells to release and induce several angiogenic and antiangiogenic factors which play a crucial role in regulating EC proliferation, migration, apoptosis or survival, cell-cell and cell-matrix adhesion through different intracellular signalings, have been thought to be the essential mechanisms during tumor-induced angiogenesis[9]. The important steps during tumor angiogenesis, such as degradation of basement membrane by proteases and proliferation and migration of EC, were associated with the over-expression of angiogenic factors[9]. Since fundamental requirements of tumor growth are dependent on the blood supply, the antiangiogenic therapy of cancer represents a highly effective strategy for destroying tumors. In addition, antiangiogenic agents, if administered before a tumor develops or becomes vascular supply-dependent, would therefore theoretically act similarly to a vaccine in preventing tumor development, not just tumor growth. Similarly, transfer of antioncogene or molecules with antioncogenic properties constitutes one of the new therapeutic approaches to cancer. SSTR2 could act as an antioncogene in human pancreatic cancer cells and its antiproliferative and antimetastatic effects could occur as a consequence of an SSTR2-dependent negative feedback autocrine loop[4,27]. Furthermore, the loss of SSTR2 during pancreatic tumorigenesis[3-5] was found to be responsible for the poor therapeutic efficacy[5-7] and the aggressive behaviours of pancreatic carcinoma. However, to our knowledge, whether the abberent expression of SSTR2 is associated with pancreatic tumor angiogenesis, has not been reported as yet. But several previous investigations have shown that SS/analogues as well as SSTRs exhibited their antitumor effects through different pathways such as inhibition of release of growth factors and trophic hormones, e.g., growth hormone, insulin-like growth factor-1, insulin, gastrin, etc[2]. In CAM model, the study showed that unlabeled SS analogues inhibited angiogenesis which was proportional to the ability of the analogues to inhibit growth hormone production[8]. Moreover, Mentlein et al reported that VEGF produced by cultured glioma cell lines constantly over-expressing SSTRs, especially SSTR2, was reduced to 25% to 80% by co-incubation with SS or SSTR2-selective agonists (octreotide and L-054 522) in a dose-dependent manner[30]. Interestingly, transfer of SSTR2 gene was found to restore the responsiveness of SSTR2-negative cells to SS analogues, and inhibited the tumorigenicity of pancreatic tumor cells in vitro without administration of exogenous SSTR2 ligands[4]. Similar to these, in our study, we suceesfully reexpressed exogenous human SSTR2 gene in pancreatic cancer cell line PC-3 by lipofectamine-mediated stable transfection and investigated its antiangiogenic mechanisms in the absence of SSTR2 ligand, SS.

The most commonly found angiogenic growth factors such as VEGF could contribute to the progression of many solid tumors by promoting the "angiogenic switch"[31]. In patients with pancreatic cancer, hypervascularity which was correlated with the over-expression of several angiogenic factors such as VEGF, PD-ECGF, MMP-2, etc, was significantly associated with tumor extension, lymph node status and shorter median survival time[9,14,32]. And also since VEGF via binding to its high affinity receptors (VEGFR) on EC, exerted its mitogenic effect by promoting EC proliferation and migration, resulting in tumor neovascularization[9,10], the VEGF-VEGFR system has been considered as a promising target for the development of antiangiogenic tumor therapy[33-37]. In our study, we observed a significant decrease in VEGF production levels in the cultured supernatants of the experimental group (cells reexpressed
SSTR2) when compared with the vector control and mock control ($P<0.05$). We further observed that the antisecretory effect of SSTR2 was similar to or even more durable than that of SS/analogues which was time- and dose-dependent[29], because in our experiment, we observed a significant inhibition of VEGF production in the cultured supernatants of the experimental group, which persisted for at least two months after stable transfection and the inhibitory rate of SSTR2 was slightly less after two months than in the first week after stable transfection, suggesting that there was a long-term induction of SS (ligand of SSTR2) by the SSTR2-dependent negative feedback autocrine loop. By contrast, Hipkin et al reported that the inhibitory effects of SSTR2 gene were not permanent and stable because of its down-regulation or desensitization by long-term exposure to SS[38]. In addition, we observed a significant inhibitory effect of SSTR2 on VEGF expression both at protein and mRNA levels in vitro detected by immunohistochemical and RT-PCR assay, respectively. All of these antisecretory events evoked by SSTR2 expression in PC-3 cell may explain the antiangiogenic effect observed in vitro.

On the other hand, up-regulation of MMPs activity favoured proteolytic degradation of the basement membrane and ECM, thereby releasing angiogenic mitogens stored within the matrix, and has been linked to tumor growth and metastasis, as well as tumor-associated angiogenesis[9]. Furthermore, the aggressive phenotype of pancreatic carcinoma has been reported to be associated with over-expression of MMP-2[21-24]. Due to the high level expression of MMP-2 in clinical and experimental models of pancreatic cancer, inhibition of MMP-2 has shown a great promise with synthetic inhibitors as antitumor agents (antiangiogenesis, antiproliferative and antimetastasis) in preclinical models[39]. Here, we observed that MMP-2 was significantly down-regulated both at protein and mRNA levels in vitro in the experimental group when compared with the vector control and mock control, suggesting that the reexpression of SSTR2 in pancreatic cancer cell line PC-3 could decrease the aggressive phenotype of pancreatic carcinoma. Similarly, Wang et al reported that administration of SS analogue, octreotide, was found to inhibit the migration and invasion of gastric cancer cells in vitro and the metastasis of cancer in vivo via down-regulation of MMP-2 and VEGF expressions, thereby decreasing tumor angiogenesis[29].

In conlusion, our present study shows that the reexpression of SSTR2 gene can inhibit angiogenesis in pancreatic carcinoma by decreasing endogenous levels of VEGF and MMP-2, suggesting that restoration of SSTR2 in pancreatic cancer cells may offer an avenue for antiangiogenic therapy.

Abstract

AIM: To investigate the *in vitro* effects of suicide gene therapy system of herpes simplex virus thymidine kinase gene (HSV-TK) in combination with the treatment of nucleotide analog-ganciclovir (GCV) on human pancreatic cancer, and to provide a novel clinical therapeutic method for human pancreatic cancer.

METHODS: We used a replication defective recombinant retrovirus vector GINaTK (bearing HSV-TK gene) to make packaging cell PA317 produce progeny virions. We then transferred the HSV-TK gene to target cells SW1990 using these progeny virions, and treated these gene-modified tumor cells with GCV to study the sensitivity of the cells to GCV and their bystander effects by routine MTT-method.

RESULTS: Packaging cell PA317/TK was successfully constructed, and we acquired SW1990/TK through virus progeny infection. These gene-modified pancreatic cancer cells were sensitive to the treatment of GCV compared with unmodified tumor cells (t=4.15, n=10, P<0.0025). We also observed a remarkable bystander effect by mixing two kinds of cells at different ratio.

CONCLUSION: Our data demonstrate that HSV-TK/GCV suicide gene therapy system is effective for treating experimental human pancreatic cancer, which is largely resistant to the common therapies, so the suicide gene therapy system may be a potential treatment approach for pancreatic cancer.

INTRODUCTION

Pancreatic cancer is an aggressive malignancy with less than 5% of the patients alive at 5 years and 92% of the patients dead at 2 years[1,2]. Despite of the development in the three routine therapeutic methods of surgery[3], chemotherapy, and radiotherapy, the cure rate for pancreatic cancer has improved only minimally, and the overall survival of patients remains dismal. Its prognosis is extremely poor with current modes of treatment[4,5]. Therefore, it is urgent to develop effective approaches to this lethal disease. With great progresses of gene therapy in recent years[6], much of interest and effort have been focused on the treatment of pancreatic cancer. The use of pro-drug-activating genes is a promising approach for cancer gene therapy, especially herpes simplex virus thymidine kinase gene (HSV-TK) in combination with ganciclovir (GCV), which is currently used in gene therapy-based experimental trials for cancer treatment, and in clinical treatment of brain tumors[7,8].

Virus-originated HSV-TK gene is different from that of mammals, its product thymidine kinase is able to metabolize the nontoxic prodrug, GCV, into a monophosphate derivative, then phosphorylate it further into GCV triphosphate. This metabolite is incorporated into replicating DNA strands and acts as both a DNA synthesis inhibitor and a cell cycle blocker, finally leading to cell apoptosis and death[9,10], which is also called "suicide gene". The therapeutic effect of this system is also based on a "bystander effect" whereby HSV-TK gene modified tumor cells are toxic to nearby unmodified tumor cells when exposed to the antiviral drug GCV. In this study, we wanted to see whether suicide gene therapy system was effective for the treatment of human pancreatic cancer.

MATERIALS AND METHODS

Cell culture

Murine fibroblasts NIH3T3 cells and packaging cell PA317 were propagated in DMEM (Gibico) with low and high concentrations of glucose separately supplemented with 10% heat-inactivated fetal bovine serum (FBS). Human pancreatic cancer cell line SW1990 was maintained in RPMI1640 (Gibico) supplemented with 20% FBS. Transgenic cell PA317/TK and SW1990/TK were maintained in DMEM (10%FBS) and RPMI1640 (20% FBS) respectively, both with 300 µg/ml of G418 (Promega).

Construction of package cell PA317/TK

HSV-TK gene was inserted downstream of the cytomegalovirus (CMV) promoter in a GINa plasmid containing neo open reading frame (NeoORF), the neomycin resistance gene, which is resistant to neomycin analogue G418. Packaging cells PA317 were transfected with a GINaTK plasmid vector (a gift from the Genetic Research Center of Fudan University, Shanghai, China) using Lipofectin as recommended by the manufacturer (Gibico). Transfected cells were selected with 300 µg/ml of G418 in DMEM supplemented with 10% FBS for weeks. Single-clones were selected, expanded, and maintained in G418-containing medium until further experiments. Total cell DNA were extracted for PCR using specific primer sets for HSV-TK gene (Prime 1: 609 bp-630 bp: 5'-CTACACCACACAAC ACCGCCTC-3'; Prime 2: 1 012 bp-991 bp: 5'-TCGCAGCCAGCATAGC CAGGTC-3'). We also used scanning-electronmicroscope (SEM) to confirm the success of gene transfer and the production of viral progeny. Virus titers were determined on NIH3T3 cells by plague assay.

Transfer of HSV-TK gene to pancreatic cancer cells

One day before transfection, we seeded cells to be infected with a density that would allow them to grow logarithmically for at least 2-3 days. The transfection protocol was that the culture supernatant of PA317/TK containing progeny virion was collected and then replaced by fresh DMEM (10% FBS, without G418) within 24 hours before transfection, and passed through a 0.22 μm filter. Then the cell growth medium of SW1990 was replaced with 5 ml of viral supernatant containing 8 μg/ml polybrene to help the adhesion of viruses. Cells were returned to the incubator and incubated for 2 hours, and then 5 ml of growth medium was added and incubated overnight. The next day the supernatant was removed and the cells were fed with. Two days post-infection the selection was started with 300 μg/ml of G418 in RPMI1640. In order to confirm the successful infection we performed PCR as described before. We also extracted total RNA and did RT-PCR to assess the expression of TK gene.

Test of cell sensitivity to GCV

We planted gene-modified pancreatic cell SW1990/TK in 96-well (Nunc) plates with 5 000 cells/well. The next day, GCV was added at a concentration ranging from 0 to 500 μg/ml. five days later, cell survival rate (SR) was determined using routine MTT-method, absorbance (A) values were read on a Bio-Rad micro-plate auto-reader at 490 nm wavelength. Survival percentage was determined by ratios of absorbance values from test conditions over absorbance values from non-infected cells. SR=(A value of the test well ÷ A value of the control)×100%.

Study of bystander effect

SW1990 and SW1990/TK cells were seeded at a total density of 10 000 cells/well in 96-well plates with various proportions. GCV was added at a concentration of 50 μg/ml. Then MTT assay was performed as routine protocols, each ratio was tested at least three times.

Statistical analysis

Uni-variate two-sided analysis of matched *t*-test for dependent samples was used, the dose-response curve was obtained using Microsoft Excel.

RESULTS

Through PCR, we obtained a 404 bp long fragment, which was the expected product of HSV-TK gene (Figure 1). From SEM, we can see easily that the cell surface of transfected PA317 had a lot of progeny viruses compared with their parent cells (Figure 2). These confirmed that TK gene was successfully integrated into the genome of packaging cell PA317, which was secreting virion progeny steadily, so we named it as PA317/TK. The virus titer was 40 000 CFU/ml.

Both PCR and RT-PCR confirmed the successful infection and expression of TK gene in gene-modified SW1990 (RT-PCR product electrophoretogram see Figure 3), and we named this cell as SW1990/TK.

Our experiment demonstrated that transgenic SW1990/TK cells were sensitive to prodrug GCV compared to SW1990 (*t*=4.15, *n*=10, *P*<0.0025). With increase of GCV concentration, SW1990/TK presented typical morphological changes of apoptosis and cell death such as nuclear condensation and oligonucleosomal DNA fragmentation, and finally lyses (Figure 4). The survival rate decreased sharply, especially at 0.5 to 50 μg/ml GCV, while the growth of SW1990 cells was not affected. At the same time, we found that the growth of unmodified cancer cells was inhibited when the concentration

was more than 100 μg/ml, as seen in Figure 5.

SW1990/TK exhibited a "bystander effect" when mixed with TK-negative cells at different ratios. From Figure 6 we can see that the cell survival rate was 40%, 20% and 0% when there was 15%, 30% and 80% of SW1990/TK cells in all, the inhibitory rate (IR=1-SR) was 60%, 80%, 100% respectively. Apparently the IR was much higher than the percentage of SW1990/TK, which reflected the bystander effect.

DISCUSSION

Pancreatic cancer has an extremely poor prognosis due to lack of early diagnostic and therapeutic approaches, few are suitable for surgery and respond to chemo-radiation therapy, mainly because of its silent course and explosive fatal outcome. Most patients had locally advanced or metastatic diseases at the time of diagnosis and were therefore not amenable to resection, whilst chemotherapy and radiotherapy were by and large ineffective[11]. HSV-TK/GCV suicide gene therapy system has been widely studied these years, and is a promising approach to tumor therapy, but its use in human pancreatic cancer has been limited.

In our study, the retrovirus was used as a target gene vector. Among various vectors, retrovirus-mediated gene transfer is restricted to cells that are proliferating and synthesizing DNA at the time of infection but not nondividing cells. It is suitable to gene transfer of malignant cells with rapid proliferation and can improve the targeting of gene transfer. With 40 000 CFU/ml virus titer, it transfers target gene effectively.

Besides the advantage of retrovirus, HSV-TK/GCV suicide gene therapy system shows another superiority: bystander effect. Both the transduction efficiency and bystander effect are essential factors for the success of the anti-tumor effect of HSV-TK and prodrug GCV suicide gene therapy system. Bystander effect is described when nontransduced or genetically unmodified cells are killed as the result of enzyme-prodrug activation during the death of genetically modified tumor cells transduced with a suicide gene. The "bystander effect" greatly amplifies the efficacy of HSV-TK/GCV gene therapy for cancer in which only a fraction of the cells are targeted. The *in vitro* bystander effect in C6/C6-TK5 co-culture was highly significant, the presence of only 5% of C6-TK5 cells led to an overall 78% decrease in cell survival after 5 days of GCV treatment[12]. In our experiment, 15% of SW1990/TK cells could lead 60% cells to death. However, the mechanism of bystander effect is still controversial. Some investigators suggested that intercellular communication was essential for the bystander effect. The correlation between gap junction communication (GJIC) and the extent of bystander effect suggested a role of GJIC in mediating the bystander effect, which could provide a useful system for selective killing of gene-modified tumor cells[13]. Some provided evidences for a role of cell membrane in signal pathways leading to bystander effect.

As we all know, everything has two sides. Inevitably, this system had its own side effect. The most common side effects of GCV in immunocompromised patients were leukemia (7-42%), thrombocytopenia (8-57%), and abnormal liver-function tests (2%). However, side effects in patients with intact immune system have not been reported[14]. As we can see in Figure 5, once the dose of GCV exceeded 500 µg/ml, it did harm to unmodified cells, so control of the dosage of drug administration is important in clinical practice.

The current trend of gene therapy for tumor is to combine

two or even more approaches in order to improve its anti-tumor effect and reduce its side effects. The combination of both suicide systems of cytochrome p450 2b1 (CYP2B1)/CPA and HSV-TK/GCV *in vitro* resulted in a potentiation of the killing effect. This suggested that in order to achieve a potentiation in cell killing when two suicide systems were combined, co-expression of both genes in the same tumor cell would be necessary[15]. Gene therapy with p53 and K-ras modulated herpes viruses might become a palliative treatment option and could be used easily by regional chemotherapy techniques[1]. Pancreatic ductal adenocarcinomas (PDACs) could overexpress various cell-surface tyrosine kinase receptors, including type I high-affinity fibroblast growth factor receptor (FGFR-1). In view of the overexpression of high-affinity FGFRs in cancer cells in PDAC, Kleeff's findings suggested that combined use of AdTK, ganciclovir, and FGF2-Fab' might ultimately be a promising therapeutic approach in a subgroup of patients with PDAC[16].

Besides suicide gene therapy system, there are many other approaches for pancreatic cancer therapy. Based on the relative uniformity in its molecular abnormalities, about 80-90% of tumors have dominant oncogene K-ras mutations and disruption of p16/RB tumor suppressor pathway, about 60-75% have p53 mutations, and more than 50% have SMAD4/DPC4 disruptions, transfer of wild-type p53 and p16 could produce significant growth suppression of pancreatic cancer *in vitro* and *in vivo* [17-19]. The results of Kawakami *et al*. showed that IL-4 receptor-targeted cytotoxin represented a potent agent that might provide an effective therapy for pancreatic cancer[20]. Yan and his group found that adenovirus-mediated E2F-1 gene transfer could sensitize melanoma cells to some chemotherapeutic agents, particularly topoisomerase II poisons *in vitro* and *in vivo*. These results suggested a new chemosensitization strategy for melanoma gene therapy[21]. With the discovery of RNA-interference, some researchers suggested it might be used in tumor therapy[22-24].

Our results indicated that gene modified tumor cells SW1990/TK were sensitive to antivirus prodrug GCV, and showed a remarkable bystander effect on killing tumor cells. In conclusion, HSV-TK/GCV suicide gene therapy system is a promising approach for the treatment of pancreatic cancer. As increasingly more researchers focus on the diagnosis and therapy of this lethal malignancy, we believe that some effective ways would be discovered for clinical treatment of pancreatic cancer.

Abstract

AIM: An investigation into inflammatory bowel disease and colorectal cancer in Veszprem Province was conducted from 1977 to 2001.

METHODS: Both hospital and outpatient records were collected and reviewed comprehensively. The majority of patients were followed up regularly.

RESULTS: The population of the province was decreased from 386 000 to 376 000 during the period. Five hundred sixty new cases of ulcerative colitis (UC), 212 of Crohn's disease (CD), and 40 of indeterminate colitis (IC) were diagnosed. The incidence rates increased from 1.66 to 11.01 cases per 100 000 persons for UC, from 0.41 to 4.68 for CD and from 0.26 to 0.74 for IC. The prevalence rate at the end of 2001 was 142.6 for UC and 52.9 cases per 100 000 persons for CD. The peak onset age in UC patients was between 30 and 40 years, in CD between 20 and 30 years. A family history of IBD was present in 3.4 % in UC and 9.9 % in CD patients. Smoking increased the risk for CD (OR=1.94) while it decreased the risk for UC (OR=0.25). Twelve colorectal carcinomas were observed in this cohort, the cumulative colorectal cancer risk after 10 years in UC was 2%, after 20 years 8.8%, after 30 years 13.3%.

CONCLUSION: The incidence and prevalence rates of IBD have increased steadily in Veszprem Province, now equivalent to that in Western European countries. Rapid increase in incidence rates supports a probable role for environmental factors. The rate of colorectal cancers in IBD is similar to that observed in Western countries.

INTRODUCTION

The pathogenesis of ulcerative colitis (UC) and Crohn's disease (CD) has only been partly understood. Inflammatory bowel disease (IBD) is a multifactorial polygenic disease with probable genetic heterogeneity. Based on this hypothesis, the disease may develop in a genetically predisposed host as a consequence of disregulated immune response to environmental factors, in particular enteric antigens, resulting in continuous immune-mediated inflammation[1,2]. However, the disease phenotype may be affected by various other factors.

IBD represents an important public health problem, as it tends to afflict young people and has a protracted and relapsing clinical course, affecting education, working abilities, social life and quality of life.

Several studies have been done on the epidemiology of IBD[3,4]. The geographical incidence of IBD varies considerably, the highest incidence rates were reported in Northern and Western Europe as well as North America, whereas they were lower in Africa, South America and Asia, including China[5]. It is more common in developed, more industrialized countries, urban residency seems to be a risk factor. The incidence rate of UC varies greatly between 0.5-24.5/100 000 inhabitants, that of Crohn's disease between 0.1-11/100 000 inhabitants worldwide.

Previous studies in Europe suggested that the incidence was decreased from North to South[6,7], but in the early nineties the European IBD Study Group found comparable rates in Southern and Northern Europe[8]. This tendency may be explained by the relative stable incidence in previous high incidence areas, whereas in previous low incidence areas the incidence rose continuously. A further difference is that the previously reported predominance of UC is diminishing, as CD is becoming more prevalent. The reported average incidence of UC in Europe was 10.4, that of CD was 5.6.

Few data have been available about the frequency of IBD in the Eastern European countries. In the early eighties, Vucelic *et al.*[9,10] conducted a prospective survey on the incidence of IBD in Zagreb, Croatia. They reported an incidence rate of 1.5/100 000 inhabitants in UC and 0.7 in CD. Similarly low incidence of UC (1.7) and CD (1.4) was reported in another prospective study in Estonia[11]. Nagy *et al.*[12] reported epidemiological data in IBD from the early 60's to the late 80's among Hungarians. The reported incidence rate was 3.6 in UC and 1.0 in CD. These data were based mainly on hospital reports. No population based survey has been reported.

The elevated colorectal cancer (CRC) risk in patients with long standing IBD has been widely accepted since Crohn's original report. Recent observations suggested that the prevalence of CRC was also higher in CD[13]. The magnitude of the risk complicating IBD varied greatly in different geographic areas and in different studies. From Eastern Europe we found only one publication about CRC in IBD[14].

Recently we reported on the prevalence of extraintestinal manifestations in a large IBD cohort in a long-term follow-up study[15]. The aim of the present study was to determine the incidence and prevalence of IBD and the main epidemiological features of the disease in a province of Hungary in a population based survey.

MATERIALS AND METHODS

Demographical data

Veszprem Province is located in the Western part of Hungary. The province consists of both industrial and agricultural regions.

The number of permanent population was relatively stable, with a slight decrease from 386 462 to 376 211 from 1980 to 1998 (Table 1). The rate of Gypsies is below the Hungarian average (2.5%), few Jewish people live in the province. The ratio of urban/rural residence was also relative stable (the data in 1991 were used for comparison, Table 2).

There are 7 general hospitals in the province, each is staffed by at least one gastroenterologist or internist with special interest in gastroenterology. The majority of the patients (74% of UC patients and 94% of CD patients) were followed-up in the Csolnoky F. Province Hospital in Veszprem. The main data sources were the hospital records, outpatient clinical reports, endoscopical, radiological and pathological reports collected from the Internal Medicine Department, Surgery Department, Outpatient Units and family doctors. Both inpatients and outpatients permanently residing in the investigated area were included in the study. Most of the patients were followed up regularly. Diagnoses (based on hospitalization records, outpatient visits, endoscopic, radiological and histological evidence) generated in each hospital and outpatient unit were reviewed thoroughly, using the Lennard-Jones criteria[16].

Cases having another readily identifiable cause of colitis, such as infectious colitis (including pseudomembranous) were excluded. Anticoncipient or NSAID associated colitis and ischemic colitis cases were also excluded. UC cases with involvement outside the colon, with the exception of "backwash ileitis", were excluded. In some cases the final diagnosis was made years after the beginning of symptoms.

The term indeterminate colitis (IC) was first described by Price in 1978[17] for cases operated on because of non-differentiable fulminating colitis. Today it has been used for IBD colitis cases, when the data were insufficient to differentiate between UC and CD[8].

Before the early eighties the diagnosis was based mainly on rectoscopy, histology, barium enema and upper GI series. Later colonoscopy, double-contrast barium enema and selective enterography were the basic diagnostic methods, CT and in some cases leukocyte scintigraphy were also more frequently performed to help make a more accurate diagnosis (*e.g.* location, activity and complications).

The location in UC was determined by colonoscopy and/or double-contrast colonography based on the macroscopic picture. Patients were classified according to the greatest known extent. In mild to moderately severe active UC cases the location was determined during the active phase, in more severe disease shortly after the active period.

The study was retrospective. Data of IBD patients were summarized yearly, in some cases the diagnosis was changed after re-evaluation. IBD patient data were collected every year from the 7 general hospitals and gastroenterology outpatient units. The provincial IBD register data were centralized in Veszprem, which is the secondary referral center for IBD patients in the province. Patients diagnosed in the same calendar year were included in the incidence calculations. All the residents and IBD patients permanently residing in the province on the 31st of December 1991 and 2001 were included in the prevalence calculations (including patients who had moved to Veszprem Province after diagnosis).

Regular colonoscopic dysplasia-cancer surveillance program with multiple biopsies was carried out in patients with extensive colitis after 8 years, with left-sided colitis after 12 years.

The source of demographic data was the Hungarian Central Statistical Office (KSH).

Table 1 Population of Veszprem Province between 1980-1998

Years	Total	Women	Men
1980	386.462	194.855	191.607
1990	379.246	192.867	186.462
1998	376.211	192.296	183.915

Male/female ratio in 1990: 0.966.

Table 2 Proportion of patients according to places of residence (in 1991) (OR: Odds ratio)

	Urban (*n*)	Rural (*n*)	Total (*n*)
Veszprem Province	208.284	173.089	381.373
Ulcerative colitis	339	221	560
	OR: 1.27		
	(95% CI: 1.07-1.52)		
Crohn's disease	122	90	212
	OR: 1.13		
	(95% CI: 0.85-1.49)		

Statistical methods

For statistical comparison of the data, Statistica 6.0 (Statsoft Inc., USA) was used. Odds ratio (OR) was calculated for potential factors that influenced the prevalence of IBD, including residence (urban versus rural) and smoking habits. For comparisons within group ANOVA analysis with Scheffe post hoc test was used. Yates-corrected Chi-square analysis was performed to compare differences in incidence according to the location of UC or CD during the observed period. Results were expressed as mean±SD if otherwise not stated (NS=not statistically significant).

RESULTS

Incidence

During the observation period 560 new patients with UC (M/F: 288/272, ratio: 1.058) and 212 new patients with CD (M/F: 108/104, ratio: 1.038) were diagnosed in Veszprem Province.

The mean incidence rate for UC was 5.89 (95%CI: 2.15-9.63) cases per 100 000 persons per year. The sex-standardized incidence appeared slightly higher in men (6.19, 95%CI: 2.30-10.08) than in women (5.64, 95%CI: 2.39-8.89), however, the difference was not statistically significant. For the calculation of the sex standardized incidence rates, gender specific population data of Veszprem Province were used (Hungarian Central Statistical Office, KSH). In CD the average 25-year incidence was 2.23 (95%CI: 0.5-3.96), in men: 2.31 (95%CI: 0.64-3.98 and in women: 2.17 (95%CI: 0.34-4). Indeterminate colitis was diagnosed in forty cases (M/F: 22/18), the mean incidence rate was 0.42 cases per 100 000 persons per year.

The incidence of IBD in 5-year intervals is shown in Figure 1. A sharp increase in incidence of UC was observed from 1.66 during 1977-1981 to 11.01 during 1997-2001 (in men from 1.77 to 11.96 and in women from 1.54 to 10.09). For CD, a similar tendency was observed. The incidence rose from 0.41 to 4.68, in men from 0.21 to 5.76, in women from 0.41 to 3.64. An almost continuous rise in incidence was observed for both UC and CD. The incidence of IC also rose during the observed period (from 0 to 0.74).

In contrast to UC, for which the highest incidence rate recorded was in 2001 in both sexes (in men 16.85, in women 11.96), for CD the peak incidence recorded in men was 9.24 in 1998, whereas in women it was 5.72 in 2001.

The ratio of UC/CD incidence rates decreased from 4.05 to 2.35 during the observed periods.

Figure 1 Average and sex-specific incidence of UC, CD and IC in Veszprem Province between 1977-2001.

Age standardized incidence rates

The mean age at diagnosis was 31.7±12.8 years for CD, 38.9±15.5 years for UC and 36.8±13.9 years for IC. For the calculation of age standardized incidence rates, age specific population data of Veszprem Province were used (Hungarian Central Statistical Office, KSH). We observed only one peak incidence. For UC the highest incidence rate was in 31-40-year olds, but the 21-30-year olds incidence rate was in the same range (10.96 *vs* 9.26). For CD the peak incidence was in the 21-30-year olds (Figures 2A and B). The youngest UC patient was diagnosed at the age of 9 years, while the oldest patient just passed 80 years at the time of diagnosis. The youngest CD-diagnosed-patient was 12, the oldest 80 years old.

Prevalences

All the patients permanently living in Veszprem Province were included in the prevalence calculation (even patients diagnosed before 1977, 33 UC cases and 3 CD cases were not included as incidence cases).

On the 31st of December 1991, the prevalence of UC was 59.2 cases per 100 000 persons, that of CD was 17.1 cases per 100 000 persons. On this day the prevalence of IC was 2.9/100 000. The prevalences were significantly increased by the 31st of December 2001. For UC the prevalence was 142.6, while for CD 52.9 cases per 100 000 persons.

The urban/rural ratio was 1.205 in general population in 1991, which was relatively stable during the observed period. Urban residency seemed to increase the risk of UC (OR: 1.27), but it did not affect significantly the risk for CD (Table 2).

Figure 2 Age and sex-specific incidence of UC and CD in Veszprem Province between 1977-2001.

Figure 3 Location of UC or CD (*n*=number of patients).

Location and disease behavior

According to our information 112 of the UC patients had proctitis, 162 proctosigmoiditis, 117 left sided colitis, 84 subtotal and 85 pancolitis (Figure 3A). The age at diagnosis did not affect the location of the disease.

Location of UC did change in the past 25 years, proctitis became more prevalent in the last decade compared to the first 10 years (8.6% *vs* 24.0%, *P*=0.002), while pancolitis cases

were relatively less frequent (39.8% *vs* 27.8%, *P*=0.034). The percentage of left sided colitis did not change (51.6% *vs* 48.2%).

The Vienna classification[18] defines CD patients according to the age at onset, location and disease behavior. In CD ileal disease (L1) was found in 32.1%, colonic (L2) in 26.9% and ileocolonic (L3) in 41.0% of the patients (Figure 3B). Location of CD did also change in the observed period. There was a tendency of colonic location becoming more frequent in the last decade compared to the first one, while the percentage of ileocolonic cases was decreased (L1: 19.2% *vs* 24.1%, *P*=NS, L2: 19.2% *vs* 36.5%, *P*=NS, L3: 61.5% *vs* 39.4%, *P*=0.05). The most commonly associated location was perianal (48 cases). All the patients with upper gastrointestinal location (L4) had lower gastrointestinal involvement, and were classified according to this location (L1-3). In 5 cases the jejunum, in 2 the duodenum, in 5 the stomach and in 2 the esophagus were also affected. Only histologically proven cases were included in the calculation of associated locations. There was no correlation between the location and age at diagnosis.

According to the disease behavior 63 of our CD patients were defined as non-stricturing, non-penetrating (B1), 54 as stricturing (B2) and 95 as penetrating (B3). Fifty-three patients of the 95 penetrating cases had parallel strictures.

In UC group 6.4% of the patients had at least one bowel operation, a much higher frequency was observed in CD (60%, Table 5). There was an association between disease location and the frequency of operations (L1=0.98, L2=0.21, L3=1.93 operations on average, *P*<0.01 among all the groups, ANOVA-Scheffe post hoc test).

Familial incidence

Of the UC patients 19 had one or more close relatives with confirmed UC or CD (Table 3). In CD patients IBD was apparent in 9.9% of the families. The occurrence of IBD was more pronounced in families of CD patients with stricturing disease than in those of CD cases with non-stricturing, non-penetrating disease (B1: 6.6% (4/60), B2: 24.5% (13/53) and B3: 11.7% (11/94), *P*=0.04).

Table 3 Familial occurrence of IBD

Relationship	UC (*n*=560)	CD (*n*=212)
First-degree relative with IBD	17	15
Second-degree relative with IBD	2	6
Familial IBD	3.4 %	9.9%

Smoking

Sixty-seven UC patients (14.3%) were smokers at the time of diagnosis, while the rate of ex-smokers and nonsmokers was 18.4% and 67.3%, respectively (Table 4). In CD patients 102 were smokers at the time of diagnosis (50.5%, which was higher than the Hungarian average of 40.5%, 1991 data, KSH). Among the patients with CD, 13 ex-smokers and 87 nonsmokers were identified. Smoking decreased the risk for UC by 75%, while it almost doubled the risk for CD (OR: 1.94, 95% CI: 1.46-2.59).

Colorectal carcinoma

Colon tumor was observed in 10 patients with UC (Table 6). The average duration of IBD at the diagnosis of colorectal cancer was 18.4 years. The average age at the diagnosis of CRC was 53.4 (27-65) years, 15 years younger than the age of patients with non-IBD CRC at diagnosis (68.2 years, 2000 data, KSH). The male/female ratio was one (5/5). Seven out of the ten patients had pancolitis. Two colorectal cancers occurred in CD patients with a short follow-up (3 and 6 years) period. The location of CD was colonic without ileal involvement. No

family history of IBD was apparent in IBD cases with CRC. Only one out of the twelve patients with IBD and CRC had a family history of CRC.

The cumulative risk for colorectal cancer in patients with UC for 10 years was 2%, for 20 years 8.8%, and for 30 years 13.3%, respectively.

Table 4 Smoking habits in IBD patients at presentation

	UC *n* (%)	CD *n* (%)
Non-smoker	315 (67.3%)	87 (43.1%)
Ex-smoker	86 (18.4%)	13 (6.4%)
Smoker	67 (14.3%)	102 (50.5%)
No data	92	10
Odds ratio for smoking	0.25 (95% CI: 0.19-0.32)	1.94 (95% CI: 1.46-2.59)

(Prevalence of smoking in Hungary in 1991: 40.5%).

Table 5 Surgery in IBD

Surgery in UC	Surgery in CD
• Resection: 8	Not operated: 86 (40.6 %)
• Proctocolectomy: 28	Operated: 126 (59.4 %)
- J Pouch: 25	• 1 operation: 63 (29.7 %)
	• 2-3 operations: 50 (23.6 %)
	• 4-8 operations: 13 (6.1 %)

Table 6 Colorectal carcinoma in IBD

Carcinomas	Age at diagnosis	Duration of IBD	Location of IBD	Location of tumor
UC (*n*=10)	35 yrs (20-56 yrs)	18.4 yrs (9-33 yrs)	Pancolitis: 7 Left sided colitis: 3	Ascending: 2 Transverse: 4 Descending: 2 Rectum: 2
CD (*n*=2)	24 and 45 yrs	3 and 6 yrs	Right colon: 2	Transverse: 2

DISCUSSION

The incidence of IBD varied greatly worldwide. Genetic and environmental factors were assumed to play a significant role in the etiology of the disease[1,2]. The role of genetic factors was supported by ethnical and familial differences and also by twin studies[19-22], while the differences in incidence rates among various geographical areas suggest a role for certain environmental factors. There has been an important change in incidence of IBD in the last few decades. In high incidence countries in Western Europe the incidence rate remained relatively stable, while in previous low incidence areas[9,12] as supported by our data as well, the disease has become more common.

The continuous increase in incidence rates of both UC and CD observed in this study raises further questions. What could be the cause of this change? In the first years the lower incidence rates could be explained partly by the use of less up-to-date diagnostic procedures (*e.g.* the relative low availability of selective enterography or colonoscopy). It is possible that better awareness, either by physicians or by patients, may result in the diagnosis of mild cases that previously might have gone unnoticed. There has also been an important change in patients' behavior in Hungary, as patients tend to seek medical advice more often and with milder symptoms than they did two decades ago. We believe that the increase in the incidence of IBD in the second part of the observed period is real and not

solely due to an improved diagnosis or more extensive search. This idea is also supported by the increase in severe cases that could only be interpreted as real. Our incidence rates in UC (11.01) and CD (4.68) in the last five-year period (1997-2001) were in the range as previously observed in high incidence Nordic countries[7,8,23,24] and they were much higher than the rates reported in Hungary two decades ago[12].

Most studies reported the peak onset of both UC and CD at late puberty - early adulthood period. In some studies a second peak of onset was observed in 50-70 year-olds[25]. The EC-IBD study[8] reported one peak onset in CD in both sexes around the age of 20 (incidence rate in men was around 6.0 and in women 7.7) followed by a continuous decrease. In UC the peak incidence was observed in both sexes in 25-30-year olds (incidence rate was 11.2 in men and 10.7 in women), followed by a continuous decrease in women, while the incidence remained relatively stable in men. In the present study we observed one peak incidence in UC in 30-40 year olds (in men 10.0 and in women 12.1) and also in CD in 20-30 year olds (in men 5.2 and in women 5.9).

IBD could affect both sexes almost equally, with a slight predominance of women in CD, and a male/female ratio ranging from 1.1 to 2.0 in UC[5,8,23]. In our present study the male to female ratio was almost similar with a slight male predominance.

In UC the proportion of extensive colitis was higher, while the percentage of proctitis cases was lower than those in the recent EC-IBD study[8]. Location of UC cases only mildly changed in the observed period. The percentage of pancolitis cases was decreased, in contrast, procitis became more prevalent. However it was still less frequent than observed in the Western-European epidemiological studies[8].

In CD ileal disease was found in one third of the patients, and ileocolonic in 41.0% of the patients. A recent study reported a higher frequency of ileocolonic disease while the percentage of ileal disease was lower[8]. In the current study colonic involvement was observed in almost two-thirds of the patients, and there seemed to be a shift from ileal to colonic location during the observed period.

The rapid increase in incidence rates might support a role for possible environmental factors[26]. Diet, as a luminar antigen was thought to be an important factor in the pathogenesis of IBD[1,27]. In the last two decades there has been a change in the lifestyle in Hungary, as the standard way of living including the diet became more "Western". Other possible environmental factors, such as perinatal events, infections in childhood or measles have not been investigated in this study[26,28,29]. Measles vaccination is universal in Hungary, and the disease is very rare. The birth rate is one of the lowest ones in Europe. Early childhood hygiene is developed, supporting the "oversheltered child" theory[30].

One of the most important environmental factors considered in the etiology of IBD was smoking[1,31]. In concordance with previous data we could identify smoking as a protective factor in patients with UC (OR: 0.25). In contrast, smoking increased the risk for CD almost 2-fold.

The percentage of operations in UC in our study was below the 10-20% rate reported in most series. The reason for this could be the more conservative practice in Hungary and also the greater resistance of patients to surgery. The majority of the operations were proctocolectomies with ileal pouch anal anastomosis (IPAA). The proportion of surgically treated patients in CD was similar to that previously published (60-80%). Almost one third of the CD patients had multiple operations.

There is an increased risk of CRC in IBD, but the reported incidence rates varied greatly. Earlier studies from tertiary referral centers reported rather high cumulative incidence rates of CRC (>10% at 20 years, >30% at 30 years). However, it might reflect referral biases, because of overrepresentation of more serious diseases in these centers that did not represent the usual spectrum of IBD[32]. In population-based studies, that followed a larger number of patients for a long time, in a certain area, lower CRC rates were reported (5.5% at 20 years, 13.5% at 30 years). The rate of colorectal cancers in our study was similar to that reported in previous population-based studies.

The two most important risk factors were the disease duration and extent (in CD the colonic involvement)[32,33]. Other factors involved are early age at onset, pharmacotherapy, disease activity (relapsing-chronically active, number and severity of relapses), smoking habits, family history of CRC, the presence of primary sclerosing cholangitis, backwash ileitis. In our study the UC patients with CRC were non-smokers while the two CD patients were smokers during the follow-up, however our numbers were relatively small to make a reasonable conclusion.

Prophylactic colectomy, regular mesalamine and folic acid treatment, and colonoscopic surveillance might reduce the elevated CRC risk[34,35]. In our study all the patients with IBD and CRC received 5-ASA. In concordance with previous results CRC was diagnosed in only one out of 32 patients with UC and in none of 66 patients with CD taking azathioprine, such azathioprine did not seem to increase cancer risk. Colonoscopic surveillance was the most widely used method to reduce CRC risk, but evidences of its benefits were controversial[36,37]. We also performed colonoscopic surveillance, which might have reduced cancer risk.

There is an additional increased risk of both colorectal and hepatobiliary malignancies in the subset of patients with primary sclerosing cholangitis (PSC) and IBD[38]. In our cohort three colorectal carcinomas developed in the 13 PSC patients, showing an increased risk in this subgroup. The reason for the short interval (3 and 6 years) between the diagnosis of CD and colorectal cancer is not clear. One may hypothesize that the asymptomatic course of IBD may be responsible for the early occurrence of colorectal cancers.

In conclusion, the incidence and prevalence have been steadily rising in the last 25 years and Now it reaches the levels reported in Western European countries. We observed no gender differences. There was a relative high incidence of colorectal cancers in IBD, similar to Western countries. The cause of the continuous rapid increase in the incidence of IBD is unknown, but the incidence supports a possible role for environmental (e.g. diet, lifestyle) factors.

Abstract

AIM: To determine the most effective intervention procedure by evaluation of mid and long-term therapeutic efficacy in patients of stricture of the gastrointestinal tract (GIT).

METHODS: Different intervention procedures were used to treat benign stricture of GIT in 180 patients including pneumatic dilation (group A, $n=80$), permanent (group B, $n=25$) and temporary (group C, $n=75$) placement of expandable metallic stents.

RESULTS: The diameters of the strictured GIT were significantly greater after the treatment of all procedures employed ($P<0.01$). For the 80 patients in group A, 160 dilations were performed (mean, 2.0 times per patient). Complications in group A included chest pain ($n=20$), reflux ($n=16$), and bleeding ($n=6$). Dysphagia relapse occurred in 24 (30%) and 48 (60%) patients respectively during 6-and-12 momth follow-up periods in group A. In group B, 25 uncovered or partially covered or antireflux covered expandable metallic stents were placed permantly, complications included chest pain ($n=10$), reflux ($n=15$), bleeding ($n=3$), and stent migration ($n=4$), and dysphagia relapse occurred in 5 (20%) and 3 patients (25%) during the 6-and-12 month follow-up periods, respectively. In group C, the partially covered expandable metallic stents were temporarily placed in 75 patients and removed after 3 to 7 days via gastroscope, complications including chest pain ($n=30$), reflux ($n=9$), and bleeding ($n=12$), and dysphagia relapse occurred in 9 (12%) and 8 patients (16%) during the 6-and-12 month follow-up periods, respectively. The placement and withdrawal of stents were all successfully performed. The follow-up of all patients lasted for 6 to 96 months (mean 45.3±18.6 months).

CONCLUSION: The effective procedures for benign GIT stricture are pneumatic dilation and temporary placement of partially-covered expandable metallic stents. Temporary placement of partially-covered expandable metallic stents is one of the best methods for benign GIT strictures in mid and long-term therapeutic efficacy.

INTRODUCTION

Benign stricture of gastrointestinal tract (GIT) is caused by postsurgical anastomoses, ingestion of corrosive agents, simple sclerosis after radiation therapy for tumors, digestive ulcer and functional disturbances, which involve different sites including esophagus, stomach, duodenum, colon and rectum. From July 1994, 180 patients with benign GIT stricture were treated with intervention procedures. Our experiences and follow-up data are reported herein.

MATERIALS AND METHODS

Materials

Our cohort comprised 180 patients with benign GIT stricture (101 males, 79 females; age, 12 to 78 years, mean 48.7 years). The subjects were divided into three groups according to the intervention procedures used: 80 patients with pneumatic dilation (group A), 25 with permanent uncovered or partially covered or antireflux covered metallic stent dilation (group B), and 75 with temporary partially covered metallic stent dilation (group C). Among the 180 patients, 8 had simple sclerosis stricture after radiation therapy for esophageal carcinoma, 132 had achalasia, 32 had esophageal and esophagogastric anastomosis stricture (complicated with anastomosis fistula in two patients), 4 had gastroduodenal anastomosis stricture, and 4 had esophageal chemical corrosive stricture. All patients were examined by barium radiography of GIT and gastroscopy before the intervention procedures.

Methods

The GIT was emptied for at least 4 h before intervention procedures. Bleeding and clotting times were examined. The devices used were as follows. The catheter was an SY dumbbell-like catheter (Sanyuan Medical Instrument Research Institute, Jinan, Shandong, China) with a length of 75 cm. The diameters upon saccule dilation were 28 mm, 30 mm, and 32 mm, and length of the saccule was 8 cm. There were two types of metallic stents, one was an imported covered Z-stent made from stainless steel wire (Wilson-Cook Medical Inc, NC, USA), the other made domestically from nitinol and uncovered or partially covered or antireflux covered (Zhiye Medical Instrument Research Institute, Changzhou, Jiangsu, China; Youyi Yijin Advanced Materials Co. Ltd, Beijin, China). The body of the partially covered metallic stents was coated with intracavity silica gel. The areas within 2 cm of both ends of the stent were not membrane covered. The stents were 4 to 14 cm in length and 16 to 30 mm in diameter, with one or two horns (diameter, 20 to 35 mm).

Patients for pneumatic dilation were placed in a supine or

sitting position. Surface anesthesia was first applied to the pharynx. The guidewire was inserted through the mouth and passed through the stricture section as demonstrated by X-ray examination. The catheter with a diameter of 28 mm was introduced through the region of benign esophageal stricture via the guidewire, with the center of saccule at the most-strictured section. The saccule was injected using an injector with the dilated contrast medium or gas. Under fluoroscopy and according to the pain reaction of the patient, pressurization was applied to gradually dilate the saccule. The central portion of the saccule was dumbbell-shaped. When further pressurization flattened the surface of the saccule or when the pressure did not further change, the piston was turned off. The pressure of the saccule was maintained for 5 to 30 min. After the saccule pressure had reduced for 5 min, pressurization was again applied. Typically each treatment involved 3 to 5 dilations, and then the catheter was withdrawn. The second and third treatments with graded pneumatic dilation were carried out using dilators with diameters of 30 mm and 32 mm, respectively. In some patients, the treatment was conducted every 2 weeks until clinical symptoms disappeared.

The placement of metallic stents was performed as follows. In upper GIT, lidocaine (1%) was first sprayed (as a mist) for anaesthesia on the pharynx. Patients were placed in a sitting position or lying on the side. Applicable false tooth were removed and a tooth bracket was mounted. A 260 cm long exchange guidewire was inserted into the stomach. The stent was mounted on the propeller whose front end was coated with sterilized liquid paraffin. Guided by the wire, the propeller on which the stent was mounted was moved through the section of pathological change. Under fluoroscopic control, the outer sheath was slowly withdrawn and the stent was expanded under its own tension. After placing a stent, GIT radiography was performed to observe the patency of the GIT. In group C, 500 to 1 000 ml ice-cold water was injected via a bioptic hole under gastroscope for 3 to 7 days after stent placement, which resulted in retraction of the stent and reduced its diameter. Bioptic pliers were then used to withdraw the stent using a gastroscope. Gastroscopy was performed again to detect complications, such as bleeding, mucosa tearing, or perforation. Patients returned to the ward and consumed cold drinks and liquid food for 2 days before resuming a normal diet. It was preferable for patients to eat solid food since the natural expansion of the food reduced the retraction of the GIT. The criterion for therapeutic efficacy was the diameter of the most-strictured gastrointestinal segment before and after dilation.

For postoperative treatment of pneumatic dilation, barium radiography of the GIT was performed immediately after intervention procedure to observe the patency of the GIT and check the presence of perforations and submucous hematoma. Patients drank fluids 2 h after intervention procedure and were treated with antibiotics, antacids, antireflux drugs, and analgesics. For postoperative treatment of stent placement, barium radiography was used to observe the patency of the GIT. Patients ate semisolid food on the day following intervention procedure. Within one week after stent removal, barium radiography of the GIT was again used to observe the patency of the GIT. Patients were followed-up by telephone and out-patients after 1 month, 6 months, 1 year.

RESULTS

The diameters of the strictured GIT were significantly greater after the treatment of all procedures employed ($P<0.01$). The 80 patients in group A involved 160 dilations (mean 2.0 times per patient). Among them, five graded dilations of increasing diameters were performed in 1 patient, three in 29 patients, two in 18 patients and a single dilation in 32 patients. In the 25 patients of group B, uncovered or partially covered or antireflux covered stents were placed. Stent placement was successful in 100% of the patients. In the 75 patients of group C, 75 partially covered stents were placed and removed under gastroscope guidance 3 to 7 days after intervention procedure. The success rate of stent placement and extraction was 100%. The complications of the treatment are listed in Table 1, and the relapse rates of dysphagia are listed in Table 2.

DISCUSSION

Benign stricture of the GIT is a common complication of gastrointestinal diseases. Its causes are diverse, its treatment is usually difficult. The procedures used included surgery, bougienage, pneumatic dilation, permanent metallic and temporary metallic stent dilation, each having their own advantages and drawbacks[1–7]. Bougienage is now uncommon since it has a poor therapeutic efficacy and many complications. The use of surgery is declining due to the associated large lesion, high risk, and high relapse rate, but it is still one of the most common method of treatment. Pneumatic dilation was primarily used in the plasty of angiostenosis, and then applied gradually to other organs for its reliable therapeutic efficacy. It exhibits a remarkable therapeutic efficacy when used in benign esophageal stricture. Currently, it has been widely used in the nonsurgical treatment of benign GIT stricture. According to most authors[8–31], the graded dilation is more effective than single dilation.

Permanent metallic stent dilation was primarily used in the treatment of malignant obstruction of the GIT, and exhibited a remarkable palliative therapeutic efficacy[32-40]. Cwikiel et al[2] reported an experimental and clinical study of the treatment of benign esophageal stricture with expandable metallic stents. We used uncovered or partially covered or antireflux covered stents in 25 patients of benign GIT stricture in order to reduce the possibility of stent migration. After placement of the uncovered stent, dilation of the stricture was excellent and dysphagia disappeared. Thus we achieved the treatment goal. However, the patients were accompanied by new problems including gastroesophageal reflux or biliary regurgitation, followed by occurrence of restenosis (hyperplasia of granulation tissue). Reflux could be treated with drugs, but this took a long time. Restenosis was reduced after cauterization using hot-point therapy under gastroscope guidance, but it was easy to relapse. Even though an antireflux stent was used, many unexpected results appeared. These difficulties led to dilation using temporary partially covered metallic stents. After their clinical trials, they not only produced fewer complications, but also exhibited excellent therapeutic efficacy. Now their use has been gradually accepted by clinicians.

For the temporary metallic stents, optimal placement time remains to be determined. If the therapeutic efficacy is poor, stents cannot be easily removed after a long-time placement. Usually, the stents are placed within 1 week. Cwikiel et al[2] placed a covered metallic stent in the esophagus of the pigs in an experimental study. One week later, granulation tissue grew and merged with the noncovered area of the stent, resulting in difficulties for removing the stent. The stent could not be removed following the placement for 10 to 14 days or longer. By our experience, stent migration occurred mostly within 1 week. Therefore, after the placement of a partially covered metallic stent, it should be extracted within 1 week. In our series, the stent was easily removed on the third to forth day, but this became quite difficult on the fifth day, and extremely difficult after 6 to 7 days. Song et al[3] reported the removal of a stent 2 months after its placement. In such patients the stent should be completely coated (including its outer layer) so that granulation tissue cannot grow into the lumen. However, the use of this type of stent should be limited to patients with tumor, since in patients of benign GIT stricture, it migrates easily. In terms of the degree of acceptance of patients, therapeutic efficacy, extent of tissue lesion, and incidence of complications, the best method for malignant stricture or obstruction of the GIT is the partially covered metallic stent, and for benign stricture of the GIT, graded pneumatic dilation or temporary partially covered metallic stent dilation should be recommended[41-45].

Sixty percent of patients with the follow-up of 1 year or longer had dysphagia relapse, demonstrating that pneumatic dilation of benign stricture of the GIT had an excellently immediate therapeutic efficacy but a poor mid and long-term therapeutic efficacy. First, this was associated with the diameter of saccule. Kadakia et al[4] suggested that the diameter of the saccule in pneumatic dilation should be 35 to 45 mm, but the incidence of complications was very high (e.g., 15% presented esophageal perforation). We used saccules with a diameter of 28 to 32 mm in order to reduce the incidence of serious complications, but the mid and long-term therapeutic efficacy was not satisfactory. Second, the therapeutic efficacy was associated with the frequency of dilation. One dilation did not produce excellent therapeutic efficacy, since it was affected by various factors such as the correct location of the saccule, pressure applied to the saccule, and variations in the anatomy of GIT. The graded dilation was suggested by most authors. Third, the therapeutic efficacy was associated to the course of the disease. When the course was long, the GIT muscularis would

become fleshy and lose elasticity.

Permanent uncovered or partially covered metallic stents were used in the treatment of malignant stricture or obstruction of the GIT with excellently immediate therapeutic efficacy and poor mid and long-term therapeutic efficacy. This was mainly due to tumor growth. Since uncovered or partially covered metallic stents could only provide palliative treatment for the obstruction, only by adopting a combined therapy for the tumor, can mid and long-term therapeutic efficacy be achieved. In our series, permanent uncovered or partially covered or antireflux covered metallic stent dilations were used in 25 patients of benign GIT stricture, their immediate therapeutic efficacy was excellent and the mid and long-term efficacies were unsatisfactory. The poor mid and long-term outcome for permanent uncovered metallic stent dilation was mainly due to frequent gastroesophageal reflux or biliary regurgitation and restenosis. Three uncovered stents could not be extracted after a 12-month follow-up period, and hence the cardia had to be excised with the stent and surgically reconstructed. Therefore, permanent uncovered metallic stent dilation was not suitable for patients with functional GIT stricture[46-49]. Permanent partially covered metallic stent dilation had poor mid and long-term therapeutic effects. This was mainly due to reflux and stent migration. Temporary partially covered metallic stent dilation used for benign GIT stricture resulted in excellent immediate effect, thus becoming the best method for mid and long-term therapeutic efficiencies. First, design of the stent coincided with the physiological structure of the gastrointestinal tract and the specific pathological manifestations of the benign stricture. The upper outlet of the stent was a large horn without cover, increasing stability of the stent. However, this made removal of the stent more difficult. Second, the diameter of the stents used in this group was 16 to 30 mm. Upon stent dilation, the stricture returned almost to the maximum normal diameter of gastrointestinal dilation. Third, the duration of dilation was very long, with a typical period of stent placement for 3 to 7 days. Why was the therapeutic efficacy of temporary partially covered metallic stent dilation better than that of pneumatic dilation? We thought that this was mainly due to the stent expanding the strictured gastrointestinal region, causing chronic tearing of the strictured wall muscularis. As a stent gradually expanded with the body temperature of the patient, it took 12 to 24 h for a stent to reach 36 ℃. The stent thus expanded completely to reach the expected diameter. In our consideration, the wall muscularis was torn regularly by the metallic stent, and scars were relatively few when repaired. This resulted in a markably lower incidence of restenosis compared to that for pneumatic dilation.

Table 3 Strategies of intervention procedure for different benign strictures in upper gastrointestinal tract

Types of GIT stricture	Strategies
AS	TCSD > PD > PCSD > PUCSD
AS with fistula	PCSD > TCSD
New scar stricture	TCSD >PD > PCSD
Scar stricture	PCSD > TCSD > PD
Functional stricture (achalasia)	TCSD > PD >PCSD with antireflux

AS: anastomosis stricture, TCSD: temporary covered stent dilation, PD: pneumatic dilation, PCSD: permanent covered stent dilation, PUCSD: permanent uncovered stent dilation.

With different intervention procedures compared in consideration of the extents of lesion, incidences of complication, therapeutic efficacies, and degrees of acceptance of patients,

we found that partially covered metallic stents could provide excellent therapeutic effect. However, different strategies should be adopted to different types of lesion (Table 3). Development of biologically removable stents, which can be catabolized in 2 months after their placement, may provide a much longer retention time with no necessity for extraction[50-56].

Abstract

AIM: To study the role of survivin expression induced by chemotherapy agent (doxorubicin) in the development and anti-chemotherapy of cholangiocarcinoma.

METHODS: Expression of survivin was detected by SP immunohistochemical technique in 33 cases of cholangiocarcinoma, 28 cases of adjacent noncancerous bile duct, and 5 cases of benign bile duct lesions. Low concentration of doxorubicin (0.05 mg/l) was added in cultured cholangiocarcinoma cell line (QBC939). The expression of survivin was detected by RT-PCR and Western blot at 24 h and 48 h after adding doxorubicin.

RESULTS: Survivin was expressed in 24 of 33 cholangiocarcinoma cases (72.7%). In contrast, no expression of survivin in adjacent noncancerous and benign bile duct lesions was observed ($P<0.01$). No correlation was found between survivin expression and clinical features. Doxorubicin could markedly ($P<0.001$) up-regulate survivin mRNA and protein expression of QBC939 cells.

CONCLUSION: Overexpression of survivin in cholangiocarcinomas may play an important role in the development of cholangiocarcinoma, its relationship with prognosis of cholangiocarcinoma deserves further investigation. Higher expression of survivin is induced by doxorubicin in QBC939. Survivin expression may resist apoptosis induced by chemotherapy agents.

INTRODUCTION

Survivin, a member of the inhibitors of apoptosis protein (IAP) family, is characterized by a unique structure that discriminates it from other members of the IAP family. It contains only a single BIR repeat and lacks a carboxy terminal RING finger domain. Survivin is expressed in the G_2/M phase of cell cycle in a cycle-regulated manner[1]. It directly binds to and inhibits both Caspase-3 and Caspase-7 activity, leading to arrest of apoptosis[2] .

Survivin expression is not detectable in differentiated normal adult cells of any organ[3], but it is abundantly expressed in embryonic tissues and in a wide range of cancer tissues[4] including neuroblastoma[5], colorectal[6], stomach[7] and breast[8] carcinomas. It has been demonstrated recently that survivin is also frequently expressed in malignant pancreatic ductal tumors[9] and pancreatic adenocarcinoma[10]. Furthermore, the prognostic value of survivin expression has been reported in several human cancers[11].

Inducing apoptosis is the mechanism of chemotherapy agents killing tumor cells. But tumor cells resist chemotherapy agents because not only they overexpress MDR1/P-glycoprotein (P-gp) but also resist apoptosis induced by chemotherapy agents. Studies demonstrating resistance of survivin-transfected cells to anticancer drug-induced apoptosis[2] and sensitization to chemotherapy by survivin antisense treatment[12] have shown that survivin is implicated in sensitization to chemotherapy.

But in cholangiocarcinoma, survivin distribution and its implication for apoptosis inhibition are not clear at present. This study aimed to study the role of survivin expression induced by chemotherapy agent (doxorubicin) in the development and anti-chemotherapy of cholangiocarcinoma.

MATERIALS AND METHODS

Materials

Thirty-three specimens were obtained from patients with cholangiocarcinoma at the Department of General Surgery, Tongji Hospital of Tongji Medical College during the period from 1993 to 2001. There were 21 males and 12 females, and the mean age of the patients was 55.1 years (range from 34 to 79 years). The patients did not receive chemotherapy, radiation therapy or immunotherapy before surgery. Five specimens of benign bile duct lesions were also obtained. Formalin-fixed, paraffin-embedded blocks of tissue samples were taken from pathological archives. Serial sections of 4 μm were prepared from the cut surface of the blocks at the maximum cross-section of the tissue sample. Representative sections were stained with H&E in order to confirm the histopathological diagnosis. Human extrahepatic cholangiocarcinoma cell line QBC939 was established by Professor Wang SG (Third Military Medical University, China) and offered to us as a gift[13]. The cells were maintained as monolayers in RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS, Gibco, USA), 100 units/ml penicillin and 100 mg/ml streptomycin in a humidified atmosphere of 50 mL/L CO_2 at 37 ℃.

Methods

Immunohistochemical staining Immunohistochemical staining was carried out with the SP technique using the SP kit (Zhongshan Biotech Co., Beijing, China) after antigen retrieval by microwave pretreatment. Briefly, deparaffinized sections were immersed in a 0.1 M sodium citrate buffer (pH 6.0) and heated three times for 5 min each at a 15 min interval in a microwave oven at 600 W. After quenched in 3 % hydrogen peroxide and blocked, the sections were incubated with rabbit survivin polyclonal antibody (Neomarkers, USA; dilution 1:200) overnight at 4 ℃. Biotinylated antirabbit immunoglobulin and streptavidin conjugated to horseradish peroxidase were

subsequently applied. Finally, 3', 3'-diaminobenzidine was used for color development, and hematoxylin was used for counterstaining. As a negative control, the sections were processed in the absence of primary antibody. Tissue sections from a hepatocellular carcinoma with a known strong expression of survivin were used as a positive control. A scoring method was used to quantitate the survivin expression in various samples examined. A mean percentage of positive tumor cells was determined in at least five areas at ×400 magnification. Patients with scores of less than 5% were defined as negative, otherwise they were defined as positive.

RT-PCR Low concentration of doxorubicin (0.05 mg/l, Pharmacia & Upjohn Co. Ltd.) was added in cultured cholangiocarcinoma cell line (QBC939). Expression of survivin was detected by RT-PCR before adding doxorubicin and at 24 h and 48 h after adding doxorubicin. Total RNA was prepared from subconfluent cultures with TRIzol reagent (Gibco, USA) according to the manufacture's instructions. The primers were designed to amplify a fragment of survivin cDNA based on the reported sequence for human survivin. To normalize the amount of input RNA, RT-PCR was performed with primers for constitutively expressed β-actin gene. The survivin primers were 5'-CCCCATAGAGAACATAAA-3' (sense) and 5'-GGAATAAACCCTGGAAGTG-3' (antisense), giving rise to a 273 base pair polymerase chain reaction product. The β-actin primers were 5'-GTGCGTGACATTAAGGAG-3' (sense) and 5'-CTAAGTCATAGTCCGCCT-3' (antisense), giving rise to a 520 base pair polymerase chain reaction product. The first strand cDNA synthesis and the subsequent PCR were performed with RNA PCR kit (AMV) using a programmed temperature control system set for 35 cycles, each consisting of denaturation at 94 ℃ for 45 s, annealing at 50 ℃ for 45 s, and extension at 72 ℃ for 45 s. Ten μL reaction mixture was electrophoresed on a 1.5% agarose gel, and the PCR products were visualized by ethidium bromide staining and quantified by an ImageQuant software. Survivin mRNA expression level was determined by survivin/β-actin protein.

Western blot Low concentration of doxorubicin (0.05 mg/l) was added in cultured cholangiocarcinoma cell line (QBC939). Expression of survivin was detected by Western blot before adding doxorubicin and at 24 h and 48 h after adding doxorubicin. Total cells were lysed with cell-lysis buffer [50 mM Tris-Cl, pH 8.0, 150 mM NaCl, 0.02% NaN$_3$, 0.1% SDS, 100 μg/ml PMSF, 1 μg/ml Aprotinin, 1% NP-40]. Twenty μg of protein was separated on 10% of SDS-PAGE gels and transferred to NC membranes. After blocked with 5% non-fat milk, the membranes were incubated with rabbit survivin polyclonal antibody (1:1 000 dilution) at 4 ℃ overnight. After washed three times the membranes were incubated with goat anti-rabbit IgG at room temperature for 1 hour. The signals were developed with the ECL kit (Amersham Pharmacia Biotechnology Inc.).

Statistical analysis
Association between survivin expression and various clinical and pathological variables was examined using χ^2 test or Fisher's exact test. The data of PCR and Western blot were expressed as mean±SD. Student's t-test was used for statistical analysis. $P<0.05$ was considered statistically significant.

RESULTS

Expression of survivin and associated clinicopathological variables
Survivin was prominently found in 24 of 33 cholangiocarcinoma cases (72.7%) by immunohistochemistry. Positive staining for survivin was located in the cytoplasm of tumor cells (Figure

1). In contrast, expression of survivin was observed neither in adjacent noncancerous bile ducts nor in benign bile duct lesions ($P<0.01$). No correlation was found between survivin expression and clinical features (Table 1).

Data were expressed as mean±SD, b vs C (48 h after adding doxorubicin), d vs B (24 h after adding doxorubicin), A: Normal Qbc939.

DISCUSSION

Expression of survivin was detected in 72.7% of cholangiocarcinomas. In contrast, no expression of survivin in adjacent noncancerous and benign bile duct lesions was observed (*P*<0.01). Using a similar polyclonal antibody, survivin expression was detected in 93% of malignant melanomas[14], 81% of basal cell carcinomas, 92% of cutaneous squamous cell carcinomas[15], 70% of hepatocellular carcinomas[16], 88% of gastric carcinomas[17], 100% of oesophageal cancers[18], 88% of pancreatic adenocarcinomas[10] and 74% of ovarian carcinomas[19]. Our study demonstrated a high expression of survivin in cholangiocarcinoma as in other human malignancies.

There was no correlation between survivin expression and any clinical or pathological characteristics of cholangiocarcinoma. A similar absence of correlation was also noted in previous observations including gastric[7,20], colorectal[6,21] and breast cancers[8]. Though many reports have shown that survivin was an independent prognostic factor for various cancers[19,22-27], such a distribution of clinicopathological features and the high prevalence of survivin expression in cholangiocarcinoma might have rendered the power of this study insufficient to demonstrate any correlation between survivin expression and any clinical or pathological characteristics. Thus, the relationship with prognosis deserves further investigation.

Substantial evidences have also shown that during chemotherapy, changes in expression levels of survivin might provide information about chemo-sensitivity or chemo-resistance of tumors[28,29]. In the present study, low concentration of chemotherapy agent doxorubicin (0.05 mg/l) could markedly (*P*<0.001) up-regulate survivin mRNA and protein expression

of QBC939 cells. These results suggested a direct link between survivin expression and bile duct carcinoma cell susceptibility to doxorubicin. That is, higher survivin expression may directly down-regulate chemo-sensitivity. It may be one of the mechanisms of anti-chemotherapy in cholangiocarcinoma.

In summary, a high expression of survivin in cholangiocarcinoma may play an important role in the development of cholangiocarcinoma, the relationship with prognosis deserves further investigation. Higher expression of survivin could be induced by doxorubicin in QBC939 and might resist apoptosis induced by chemotherapy agents. These results provide several exciting therapeutic possibilities. Initial evidence *in vitro* and *in vivo* has shown that targeting survivin may provide a viable approach to kill cancer cells selectively[30,31]. Inhibition of survivin expression by molecular manipulation has been reported to improve the effectiveness of chemotherapy[12,31-33] and produce impact on radiation therapy[34-37].

Abstract

AIM: To investigate the effects of gastric pacing on gastric emptying and plasma motilin level in a canine model of gastric motility disorders and the correlation between gastric emptying and plasma motilin level.

METHODS: Ten healthy Mongrel dogs were divided into: experimental group of six dogs and control group of four dogs. A model of gastric motility disorders was established in the experimental group undergone truncal vagotomy combined with injection of glucagon. Gastric half-emptying time ($GEt_{1/2}$) was monitored with single photon emission computerized tomography (SPECT), and the half-solid test meal was labeled with an isotope-^{99m}Tc sulfur colloid. Plasma motilin concentration was measured with radioimmunoassay (RIA) kit. Surface gastric pacing at 1.1-1.2 times the intrinsic slow-wave frequency and a superimposed series of high frequency pulses (10-30 Hz) was performed for 45 min daily for a month in conscious dogs.

RESULTS: After surgery, $GEt_{1/2}$ in dogs undergone truncal vagotomy was increased significantly from 56.35±2.99 min to 79.42±1.91 min ($P<0.001$), but surface gastric pacing markedly accelerated gastric emptying and significantly decreased $GEt_{1/2}$ to 64.94±1.75 min ($P<0.001$) in animals undergone vagotomy. There was a significant increase of plasma level of motilin at the phase of IMCIII (interdigestive myoelectrical complex, IMCIII) in the dogs undergone bilateral truncal vagotomy (baseline vs vagotomy, 184.29±9.81 pg/ml vs 242.09±17.22 pg/ml; $P<0.01$). But plasma motilin concentration (212.55±11.20 pg/ml; $P<0.02$) was decreased significantly after a long-term treatment with gastric pacing. Before gastric pacing, $GEt_{1/2}$ and plasma motilin concentration of the dogs undergone vagotomy showed a positive correlation ($r=0.867$, $P<0.01$), but after a long-term gastric pacing, $GEt_{1/2}$ and motilin level showed a negative correlation ($r=-0.733$, $P<0.04$).

CONCLUSION: Surface gastric pacing with optimal pacing parameters can improve gastric emptying parameters and significantly accelerate gastric emptying and can resume or alter motor function in a canine model of motility disorders. Gastric emptying is correlated well with plasma motilin level before and after pacing, which suggests that

motilin can modulate the mechanism of gastric pacing by altering gastric motility.

INTRODUCTION

The incidence of gastric motility disorder has been increasing, but the mechanisms of the development of this disease remain obscure, and specific and effective therapy are lacking. The current treatment mainly relies on conventional prokinetic agents. However, some patients with motility disorder can not undergo a chronic treatment with prokinetic drugs because of their side effects[1-3]. In addition, tachyphylaxis may occur sooner or later and refractoriness to prokinetic agents is observed in a large number of patients. The limited efficacy of drugs in gastric motility disorder has led investigators to examine the effect of gastric pacing on gastric emptying. In the wake of cardiac pacing ,some investigators hope that gastric pacing would be a new way to treat refractory gastric motility disorder. The role of gastric pacing with application of implanted gastric serosa electrodes, suction intraluminal electrodes or gastric mucosal electrodes in gastrointestinal (GI) tract has been greatly discussed in western countries[4-23]. Most studies were restricted to animal experiments because of the invasiveness, substantial risk, and complications associated with the surgical procedure. Howerer, the study of surface gastric pacing was rarely reported in medical literature. To determine the therapeutic efficacy of surface gastric pacing, we combined bilateral truncal vagotomy with administration of glucagon to establish a canine model of gastric motility disorder. Then, we observed the effects of surface gastric pacing on gastric emptying and plasma motilin level before and after pacing, and also explored the possible mechanism of gastric pacing.

MATERIALS AND METHODS

Animals and surgical preparation
Ten healthy Mongrel dogs were divided into: experimental group of six dogs (four males and two females) 12.5-17.5 (average 14.5) kg and control group of four dogs (two males and two females) 13.0-17.0 (average 15.5) kg. Bilateral truncal vagotomy was performed in the experimental group under aseptic conditions with intravenous anaesthesia of pentobarbital sodium after an overnight fasting. The initial dosage of the anesthetics was 30 mg/kg,which was supplemented with 3 mg/kg if necessary on the basis of corneal reflex. Artificial ventilation was given during surgery. After surgery, the animal was first transferred to an intensive care cage for a few hours and then to the regular cage after a complete recovery from anesthesia. The protocal was approved by the Institution of Animal Care of the Third Military Medical University.

Experimental procedure
The dogs were allowed to recover completely from surgery for 2 to 3 wk before any study. The study was conducted in

three sessions for each dog and experiments were performed on all the dogs in awake state. The dogs stood quietly on a table in a canvas support sling when gastric pacing was administered and gastric emptying was assessed. In the first session, we established the basic characteristics for gastric emptying in both control dogs and experimental dogs. In the second session, an intravenous injection of glucagon (500 μg/kg)[4,24] was administered. Gastric emptying of semi-solid food was monitored in all 10 dogs in the first 5 min after glucagon injection. Three days later, a second experiment with glucagon was performed, and we utilized gastic pacing to observe if the effects on drug could be altered, and gastric emptying was monitored for 2 h with gastric pacing. In the third session, gastric pacing was performed for 45 min after meal daily for a month in dogs of the experimental group to observe the chronic efficacy of a long-term treatment with gastric pacing, and gastric emptying was assessed for 2 h after cessation of gastric pacing.

Gastric pacing

In order to simulate the basic electrical rhythm (BER) and induce release of acetylcholine from intramural cholinergic fibers, gastric pacing stimulus consisted of two signals: a continuous similar-sine basic wave with a low-frequency (1.1-1.2 times the intrinsic slow-wave frequency) and a superimposed series of high frequency pulses (10-30 Hz), the number of a series of pluse was 15-40/cycle. The pacing signals from a pacemaker were delivered with a pair of bipolar skin electrodes. Stimulating electrodes were placed on commonly used positions of the abdominal region (localization through X ray). A long-term surface gastric pacing was performed for 45 min after meal daily for a month.

Measurement of gastric emptying

Gastric emptying was monitored with single photon emission computerized tomography (SPECT) (GE Inc.,USA). The semi-solid test meal consisted of 90 mg of commercial black sesame powder labeled with 74 MBq of ^{99m}Tc-sulfur colloid and 120 ml water. The study of gastric emptying consisted of two procedures, with or without gastric pacing, in a randomized order. On the day of gastric emptying test, the animal was fasted over 16 h. Immediately after the intake of isotope-labeled semi-solid meal, the maximum count rates were determined. Afer a first image was taken, the other sets were taken at an interval of 15 min for 2 h. The gastric region of interest was outlined by hand on the initial image by a nuclear medicine technologist who had no interest in the outcome of the study. To reduce the error resulted from the physical radioactive decay of isotope ^{99m}Tc, we corrected and normalized the percentage of semi-solid food retained in the stomach over time and chose the linear-fitting decay program to extrapolate $GEt_{1/2}$.

Measurement of plasma concentration of motilin

Plasma level of motilin was determined with commercially available RIA (radioimmunoassay) kits. Blood was collected before and after vagotomy and after a long-term treatment of gastric pacing at the start of phase III of interdigestive myoelectric complex (IMCIII) respectively. Samples of peripheral venous blood were collected in lyophilized tubes containing 40 μl of 0.3 mol/L Na$_2$EDTA and 2 000 u trasylol. Immediately, plasma was separated with centrifugation at 4 000 r/min at 4 ℃. The plasma should be frozen within 2 hours and then stored at -70 ℃ for batch assay with a well-established motilin immunoassay[20] (The motilin kit was supplied by the Radioimmunologic Center of PLA General Hospital, China).

Statistical analysis

Analysis of variance and paired Student's t test and linear correlation analysis (SPSS 10.0 software) were performed to investigate the effects of gastric pacing on gastric emptying and plasma motilin level in dogs of the two groups. Statistical significance was assigned for $P<0.05$. All data were presented as means±SD.

RESULTS

Basic condition

All dogs generally tolerated well the surgical procedure and surface gastric pacing. Large doses of glucagon injected intravenously triggered hyperglycemia in the diabetic setting and plasma glucose levels were increased sharply from 81-114 mg/dl to 200-233 mg/dl. Only two of the ten dogs were sensitively induced by glucagon to show nausea and vomiting, but the adverse symptoms rapidly disappeared and did not lead to any complication. Long-term gastric pacing resulted in a significant weight gain. The average weight (11.3±2.4 kg) after surgery was significantly lower than that before surgery (15.5±3.2 kg, $P<0.01$), but after a long-term treatment with gastric pacing weight gain was found to be 14.7±2.7 kg ($P<0.05$) in dogs of the experimental group.

Effects of vagotomy and glucagon on gastric emptying

Gastric emptying data were collected from each dog in all conditions.Results are summarized in Table 1 and Figure 1. The data before and after vagotomy were compared, and $GEt_{1/2}$ of the dogs undergone truncal vagotomy was significantly increased from 56.35±2.99 min to 79.42±1.91 min ($P<0.001$). To observe the effects of glucagon alone on gastric emptying, we compared the $GEt_{1/2}$ of control dogs and the dogs undergone vagotomy before and after glucagon was administered (no gastric pacing was applied). In comparison with that before injection of glucagon, the $GEt_{1/2}$ of the dogs undergone vagotomy was significantly longer after glucagon was administered (108.24±10.75 min, $P<0.01$). However, the delay of gastric emptying in control dogs after injection of glucagon was not statistically significant (57.73±1.65 min vs 56.15±2.34 min, $P>0.05$).

Table 1 Effects of gastric pacing on gastric emptying parameters

Groups	n	GEt$_{1/2}$ (min)		
		No pacing	Acute pacing	Long-term pacing
Control	4	56.15±2.34	58.52±4.77	
Control + glucagon	4	57.73±1.65	56.90±2.53	
Vagotomy	6	79.42±1.91[a]	74.41±6.10	64.94±1.75[d]
Vagotomy+ glucagon	6	108.24±10.75[b]	76.93±8.55[c]	

All the data were expressed as means ± SD. [a]$P<0.001$ vs control, [b]$P<0.01$ vs before injection of glucagon, [c]$P<0.05$ vs before acute pacing, [d]$P<0.001$ vs before a long-term pacing.

Effects of acute gastric pacing on gastric emptying

To investigate the acute effects of gastric pacing on gastric emptying in dogs undergone truncal vagotomy in combination with injection of glucagon and in control dogs with injection of glucagon, we observed gastric emptying for 2 h during gastric pacing. The $GEt_{1/2}$ of the dogs undergone vagotomy and injection of glucagon was significantly shorter with pacing than that without pacing (108.24±10.75 min vs 76.93±8.55 min, $P<0.01$). However, such an acute pacing had no significant effect on the $GEt_{1/2}$ of control dogs with injection of glucagon (57.73±1.65 min vs 56.90±2.53 min, $P=0.4$) or when only

vagotomy was performed (79.42±1.91 min *vs* 74.41±6.10 min, *P*=0.3).

Effects of chronic gastric pacing on gastric emptying

To investigate the effects of chronic gastric pacing on gastric emptying, we compared the GEt$_{1/2}$ before pacing with that after a long-term gastric pacing of 30 d in the dogs undergone vagotomy. Gastric pacing significantly accelerated gastric emptying in animals undergone vagotomy (79.42±1.91 min *vs* 64.94±1.75 min, *P*<0.001) and significantly decreased retention of gastric isotope (Figure 1).

Figure 1 Effects of vagotomy and gastric pacing on gastric isotope retention during monitoring for 120 min. Data were expressed as means ± SD, *n*=6. a*P*<0.005 *vs* before vagotomy, b*P*<0.005 *vs* before pacing (by analysis of variance at 120 min).

Effects of gastric pacing on plasma gastric motilin

There was a significant increase of plasma motilin concentration in the phase of IMCIII after bilateral truncal vagotomy (baseline *vs* vagotomy, 242.09±17.22 pg/ml *vs* 184.29±9.81 pg/ml; *P*<0.01). But plasma motilin concentration was significantly lower after a long-term surface gastric pacing than that before gastric pacing (212.55±11.20 pg/ml; *P*<0.02).

Correlation of plasma gastric motilin and gastric emptying

Statistic analysis indicated that GEt$_{1/2}$ (79.42±1.91 min) and plasma motilin concentration (242.09±17.22 pg/ml) in the phase of IMCIII of the dogs undergone vagotomy had a positive correlation (*r*= 0.867, *P*<0.01) before surface gastric pacing, that is, vagotomy evoked the increase of plasma motilin level which clearly disrupted gastric emptying. But after a long-term gastric pacing, GEt$_{1/2}$ (64.94±1.75 min) and plasma motilin level (212.55±11.20 pg/ml) had a negative correlation (*r*=-0.733, *P*<0.04), that is, plasma motilin release was inclined to restore its normal level, which might be helpful to improve gastric emptying.

DISCUSSION

We used bilateral truncal vagotomy in combination administration of glucagon to establish a canine model of gastric motility disorders, which can simulate some aspects of diabetic gastroparesis. Our study demonstrated that suface gastric pacing at 1.1-1.2 times the intrinsic slow-wave frequency superimposed series of high frequency pulses (10-30 Hz) was able to entrain propagated slow waves to replace the spontaneous ones and to improve gastric emptying in dogs after vagotomy and injection of glucagon. It is considered that gastric pacing could be proven to be an effective therapeutic approach for the treatment of gastric motility disorders[13,20-22,25-27].

Complete abdominal vagotomy has been shown to induce gastric stasis and delay emptying of solid food in both humans and animals[4,11]. It could change the contractile pattern during interdigestive migrating motor complex III (IMMCIII)[28].

Extrinsic denervation of the antrum could diminish the frequency of antral action potentials and retard gastric emptying of solids. Our study indicated that gastric emptying of semi-solid food was obviously impaired after vagotomy in six dogs and confirmed the finding of previous researchers[4,11] despite difference in their techniques of measuring gastric emptying. Previous studies have demonstrated that glucagon could delay gastric emptying of intact dogs[29], but our study did not find that glucagon was able to delay gastric emptying in the healthy dogs, suggesting that the dogs undergone vagotomy were more susceptible to gastric motility disorder. The mechanisms by which glucagon delayed gastric emptying in both humans and dogs have not been fully understood. This delay might associate with acute hyperglycemia-evoked gastric slow wave dysrhythmias by endogenous prostaglandins[24,30], such as tachygastria, tachyarrhythmia, bradyarrhythmia, asystolia (electrical silence), and gastric fibrillation which is a complete disorganization of gastric electrical activity due to impairment of coupling and propagation of gastric slow waves causing unpropagated antral contractions and exacerbating the hyperglycemia-evoked antral hypomotility[31-33]. In addition, hyperglycemia might have inhibitory effects on the spike potentials that could induce antral contractions or possible indirect effects of glucagon on gastric emptying through the release of hormones or neurotransmitters[4].

At present, controversial findings were reported about the effects of gastric pacing on gastric emptying. McCallum *et al.*[13,20,22] showed that there was an increase in gastric emptying. On the other hand, Eagon *et al.*[6] observed that neither the motility index nor gastric emptying rate was consistently changed by stimulation at any frequency. In our study, we employed a 1.1-1.2 times the intrinsic physiologic slow-wave frequency superimposed series of high frequency pulses (10-30 Hz) in surface gastric pacing which resulted in a significant acceleration of gastric emptying of semi-solid food in dogs undergone vagotomy but not in intact dogs. Our findings were consistent with those of Bellahsene *et al.*[4] who employed a frequency similar to or slightly higher than the intrinsic slow-wave frequency.

Our study also evaluated the effects of total abdominal vagotomy and surface gastric pacing on plasma concentration of motilin in the phase of IMCIII. Motilin is a straight chain peptide containing 22 amino acids and has a molecular weight of approximately 2700. It has been found that plasma motilin levels varied in a cyclic fashion during the fasting state in accordance with the interdigestive migrating motor complex (IMMC), and IMMC III was concurrent with the peak of plasma motilin level[34]. Motilin has been known to induce IMMC III contractions through cholinergic neural pathways, 5-hydroxytryptamine (HT) receptors, and alpha receptors[35,36]. IMMC can clean large indigestible food residues, enhance antroduodenal and gallbladder coordination, stimulate pancreatic and bile secretion, and keep the small intestine free from stasis[37]. Our results showed that there was a significant difference in plasma motilin concentration in the phase of IMCIII before and after the operation and after gastric pacing. The significant increase of plasma motilin level in the dogs after truncal vagotomy might be explained that total abdominal vagotomy or a complete extrinsic vagal gastric denervation could markedly delay gastric empty and induce gastric stasis, and reduce the sensitivity of motilin receptors, which might feedbackly lead to the release of plasma motilin. After a long-term surface gastric pacing, the delay of gastric emptying was improved and plasma motilin level gradually restored normal. At prsent, its mechanism is not clearly determined. In addition, our study showed gastric emptying was correlated well with plasma motilin level in the phase of IMCIII before and after gastric pacing, which implies that there is a possibility for

motilin to mediate the process of gastric pacing by altering gastric motility.

It has been found that gastrointestinal motility is regulated by a spatio-temporally-coordinated electrical pattern called gastrointestinal myoelectrical activity (GMA) that is paced by the GI pacemaker[38]. Recently, it has been recognized that interstitial cells of Cajal known as pacemaker cells could generate rhythmically electrical pacemaker activities (or electrical slow waves) which regulate the frequency of contractions of the tunica muscularis for GI motility[39-44]. The normal patterns of GMA present temporal evolution from endogenous rhythmic oscillation to bursting of spikes associated with contractions, and also order spatial propagation of the oscillating waves. Spatio-temporal modeling of the GMA has been established, thanks to the advances in electronic technology. Therefore, we employed a continuous similar-sine basic wave with a low- frequency (10%-20% high than intrinsic gastric frequency) superimposed a series of high frequency pulses (10-30 Hz) as signals of surface gastric electrical pacing. In contrast to gastric pacing through implanted serosal electrodes and the suction intraluminal electrodes in gastrointestinal tract, surface gastric pacing is more simple and noninvasive. In addition, surface gastric pacing does not require any surgical procedures such as laparotomy or laparoscopy. So this technique is a very attractive, reliable and acceptable candidate method to treat gastric motility disorders.

Although gastric pacing could restore a normal pattern of slow wave and an efficient gastric motor function and improve gastric emptying, its mechanism remains unclear[45]. Recently, Qian et al.[15] reported gastric pacing at a frequency similar to or just above that of the native slow wave to induce gastric slow wave was not via the cholinergic nerves, because although atropine was used to block the vagal activity, gastric pacing could still entrain and normalize the irregular rhythm of gastric slow wave. Moreover, spectral analysis of heart rate indicated that gastric pacing had no effect on the extrinsic autonomic functions. Accordingly, we presume that the mechanism of gastric pacing at a frequency slightly higher than the intrinsic frequency to induce gastric slow wave may be via some other neurohumoral pathways or directly leads to local activation of interstitial cells of Cajal and/or smooth muscle cells. Gastric electrical stimulation with a frequency much higher (about 10-1 200 cycles/min) than that of the intrinsic slow wave probably could act on sensory fibers directed to the central nervous system[46]. Gastric electrical stimulation with a frequency 10-100 Hz might be possibly associated with autonomic and enteric nervous system changes, likely induce the release of acetylcholine from the intramural cholinergic fibers, which in turn stimulated the muscular cell contraction, because its effect was prevented by a previous administration of atropine[47-49]. In addition, gastrointestinal hormones such as motilin or NANC neurotransmitter VIP might also mediate the process of gastric pacing[47,50].

Abstract

AIM: To evaluate the results of salvage resection in the management of persistent or locally recurrent anal canal cancer.

METHODS: Details of all patients with anal canal cancer treated from 1978 to 1994 at Cancer Hospital of Chinese Academy of Medical Sciences (CAMS) were reviewed retrospectively. Sixteen patients who presented with persistent or locally recurrent anal canal cancer received salvage surgery. Before surgery all of the patients had received radiotherapy alone as their primary treatments.

RESULTS: Of the 16 patients, 14 received salvage abdominoperineal resection (APR) and two had transanal local excision. There were no deaths attributable to operation. Delayed healing of the perineal wound occurred in eight patients. Complications unrelated to the perineal wound were found in five patients. The median follow-up time was 120 (range 5-245) months after salvage surgery. Nine patients died of disease progression, with a median survival time of 16 (range 5-27) months. Six patients had a long-term survival.

CONCLUSION: Salvage resection after radiotherapy can yield a long-time survival in selected patients with anal canal cancer. However it offers little hope to patients with T_4 and/or N_{2-3} tumors.

INTRODUCTION

Anal canal cancer is rare and only accounts for 2% to 4% of all anorectal neoplasms[1,2]. Radiotherapy alone or concomitant chemoradiotherapy currently is considered as a standard treatment for most of the patients[3,4]. Although disease control was reported to be excellent, as many as 33% of patients wouldl develop locoregional disease progression[3-5]. Because this disease is uncommon, there has been no randomized study that compares different salvage approaches[6]. The aim of this study was to review our experience in salvage surgery for patients who developed local disease recurrence after radiotherapy.

MATERIALS AND METHODS

Materials

From 1978 to 1994, 83 patients with biopsy-proven anal canal cancer were treated with curative intent at Cancer Hospital of Chinese Academy of Medical Sciences (CAMS). Primary radiotherapy failed to produce any regression of the primary tumor in 16 patients. These 16 patients, including eleven who presented with a persistent disease and five patients who had a recurrent disease, were treated with salvage surgery. Primary tumors were staged in accordance with the criteria of the American Joint Committee on Cancer (AJCC)[7]. Diagnosis of lymph node metastasis was made clinically, with radiological investigations such as computerized tomography scanning, and confirmed histologically. Pretreatment characteristics of these patients are listed in Table 1.

Stage II	7
Stage IIIB	9

Treatment

Of the 16 patients, 15 received external beam radiation therapy (EBRT) alone. The mean dose of EBRT was 40 Gy(range 30-75 Gy). One patient was implanted with ^{192}Ir sources after EBRT. The brachytherapy dose was 14 Gy. No patients received adjuvant or concomitant chemotherapy. After completion of primary treatment, the patients were followed up according to a standard protocol[8].

RESULTS

Surgical results

Among the 16 patients who failed initial therapy, 14 underwent salvage abdominoperineal resection (APR) and two had transanal local excision. Partial prostatic resection was performed on two males. There were no deaths attributable to operation. Fourteen patients had their perineal wounds packed open for hip bath. Healing time of the perineal wound

exceeding 3 months was considered to be delayed, which occurred in eight patients. In four patients the healing time of perineal wound exceeded six months and in one patient the healing was not achieved within two years. Other complications unrelated to perineal wound were recorded in five patients. These included one small bowel obstruction treated conservatively, one perineourethra fistula after prostatic resection, one abdominal wound infection and two neurocystitis.

Oncological results

All the patients were followed up. The median follow-up time was 120 (range 5-245) months after salvage surgery. At the time of the last follow-up nine patients died of disease progression, with a mean survival time of 16(range 5-27) months. In these patients, eight presented with a persistent disease and one had a recurrent disease. The median follow-up time among survivors was 173 (range 98-245) months. Six patients survived for more than 10 years. According to the initial tumor stage, one of seven patients with $T_2N_0M_0$ died 18 months after resection whereas eight of nine patients with $T_{1-4}N_{2-3}M_0$ disease were not controlled. Of the 16 patients, only one patient presented with a second locoregional disease recurrence and was salvaged with radiotherapy.

DISCUSSION

Despite progresses in chemoradiotherapy of anal epidermoid cancer[3,4,9,10], a substantial percentage of patients, particularly those with more advanced disease, still developed a local failure and demand salvage therapy[11,12]. Surgical resection was often recommended as the most appropriate salvage method[13-15]. The overall survival rate for surgical salvage at 5 years was about 30-60%[16,17]. Some investigators reported disappointingly low success rates[18] and alternative approaches have been suggested, such as low dose radiotherapy or combined chemoradiotherapy[19]. In the present study, six of the 16 patients who underwent appropriate surgical treatment survived for more than 10 years. These results are similar to those of Longo *et al*[20], who reported a survival rate of 53% among 17 patients and Ellenhorn *et al*[21], who noted that 44% of 38 patients survived for 5 years after salvage resection.

It is well known that delayed healing of perineal wounds is a common complication for patients after radiotherapy. Earlier investigators reported the perineal wound complication rate was up to 30%[16,17,21]. In the study by Nilsson *et al*[22], the rate of delayed healing was 66 % (22 of 35). No difference was detected in the radiation dose delivered between patients with delayed healing and those in whom healing was achieved within 3 months. Also in rectal cancer, preoperative radiotherapy whether given in 5.0-Gy fractions or using conventional 1.8-2.0-Gy fractions, always made the healing of perineal wounds delay[23]. In 14 patients who received salvage APR, eight presented with a delayed perineal wound healing and one did not have a wound healing within two years. It might help the healing of large defects created in an irradiated field by using an omentoplasty or musculo-cutaneous flap[24,25].

Of the five patients who presented with local recurrence after having achieved complete disease remission, three survived for more than 10 years. In contrast, among the 11 patients who presented with persistent diseases, eight died of the diseases within 3 years. There was a better 10-year survival among patients with recurrences compared with that in patients with a persistent disease. These findings are consistent with those of Nilssio *et al*[22], who reported a significantly better 5-year survival among patients with recurrences (82% *versus* 33%) and Allal *et al*[17](56% *versus* 23%), but contradicted with those of Pocard *et al*[16], who reported that patients with a persistent disease had a longer survival time (74 *versus* 25

months). The difference may be related to the tumors' stage and nodal status at initial presentation, or, alternatively, may reflect more aggressive biologic phenotypes of tumors that are different in response to radiotherapy.

The effect of salvage surgery appeared to correlate with the initial disease stage[26-28]. In the study by Allal *et al*[17], 41% of patients who failed local treatment of $T_{2-3}N_0M_0$ anal canal cancer were successfully salvaged, compared with 17% of patients with $T_{1-4}N_{2-3}M_0$ anal canal cancer. The effects of initial lymph node involvement and tumor extent on patients' outcome after surgical salvage therapy also were stressed by Ellenhorn *et al*[21]. In the present study, eight of 9 patients who died of the disease presented with $T_{1-4}N_{2-3}M_0$ anal canal cancer, whereas most of the survivors had a $T_2N_0M_0$ anal canal cancer.

In summary, salvage APR after radiotherapy has a high complication rate, but can bring a long-time survival in selected patients with anal canal cancer. Since patients with T_4 and/or N_{2-3} tumors could not obtain much benefit from salvage surgery, salvage chemoradiotherapy needs to be further investigated.

Abstract

AIM: The diagnosis of cholangiocarcinoma is often difficult, making management approaches problematic. A reliable serum marker for cholangiocarcinoma would be a useful diagnostic test. The aims of our study were to evaluate the usefulness of a serum CA19-9 determination in the diagnosis of cholangiocarcinoma.

METHODS: We prospectively measured serum CA19-9 and CEA concentrations in patients with cholangiocarcinoma ($n=35$), benign biliary diseases ($n=92$), and healthy individuals ($n=15$). Serum CA19-9 and CEA concentrations were measured by an immunoradiometric assay without knowledge of the clinical diagnosis.

RESULTS: The sensitivity of a CA19-9 value >37 KU·L^{-1} and a CEA value >22 µg·L^{-1} in diagnosing cholangiocarcinoma were 77.14% and 68.57%, respectively. When compared with the benign biliary diseases group, the true negative rates of serum CA19-9 and CEA were 84.78% and 81.52%, respectively. The false positive rates of serum CA19-9 and CEA were 15.22% and 18.48%, whereas the accuracy of serum CA19-9 and CEA were 82.68% and 77.95%, respectively. Serum CA19-9 and CEA concentrations were significantly elevated ($P<0.001$ and $P<0.05$) in patients with cholangiocarcinoma (290.31 ± 5.34 KU·L^{-1} and 36.46 ± 18.03 µg·L^{-1}) compared with patients with benign biliary diseases (13.38 ± 2.59 KU·L^{-1} and 13.84 ± 3.85 µg·L^{-1}) and healthy individuals (12.78 ± 3.69 KU·L^{-1} and 11.48 ± 3.37 µg·L^{-1}). In 15 patients undergoing curative resection of cholangiocarcinoma, the mean serum CA19-9 concentration was decreased from a preoperative level of 286.41 ± 4.36 KU·L^{-1} to a postoperative level of 62.01 ± 17.43 KU·L^{-1} ($P<0.001$), and the mean serum CEA concentration from 39.41 ± 24.35 µg·L^{-1} to 28.69 ± 11.03 µg·L^{-1} ($P<0.05$). In patients with cholangiocarcinoma, however, no correlation was found between serum CEA and CA19-9 concentrations ($r=0.036$).

CONCLUSION: These data suggest that the serum CA19-9 determination is a useful addition to the available tests for the differential diagnosis of cholangiocarcinoma. Serum CA19-9 is an effective tumor marker in diagnosing cholangiocarcinoma, deciding whether the tumor has been radically resected and monitoring effect of treatment.

Qin XL, Wang ZR, Shi JS, Lu M, Wang L, He QR. Utility of serum CA19-9 in diagnosis of cholangiocarcinoma: In comparison with CEA. *World J Gastroenterol* 2004; 10(3): 427-432

INTRODUCTION

Cholangiocarcinoma is a malignant tumor arising from bile duct epithelium. Unlike most human cancers, a pathological diagnosis of cholangiocarcinoma is often extremely difficult because of its location, size, and desmoplastic characteristics[1-3]. Percutaneous fine needle aspiration is frequently not possible because many of these tumors are located in the liver hilum amid large vascular structures[4,5]. Furthermore, tumor masses are often not even identifiable by CT, ultrasound, or magnetic resonance imaging[6-8]. Endoscopic approaches are also of limited usefulness in tissue diagnosis because of the desmoplastic nature of these cancers. Indeed, bile cytology obtained at endoscopic retrograde cholangiography has a sensitivity of only 33-56%[1,9-11], endobiliary brush cytology of 50-68%[12-14], and endoscopic transpapillary biopsy of 53-86% for detecting cholangiocarcinoma[15-18]. Because of the problems in obtaining diagnostic tissues, treatment and management decisions for patients with biliary disease that may be malignant are problematic.

Of the two possible tumor markers available for detecting cholangiocarcinomas, carcinoembryonic antigen (CEA) is a glycoprotein tumor marker with the immunodeterminant present on the protein moiety of the molecule. The other, carbohydrate antigen 19-9 (CA19-9), is a mucin-type glycoprotein in serum with the immunodeterminant present on the carbohydrate moiety of the molecule. Both tumor markers have been investigated for the diagnosis of malignancies in the stomach, colon and pancreas[19-23] but have not been gained widespread use in bile duct. It has been reported that the sensitivity and specificity for CA19-9 value >37 KU·L^{-1} for cholangiocarcinoma with primary sclerosing cholangitis (PSC) were 60% to 93% and 78% to 98%, respectively[9,16,21,24-27]. The corresponding indexes of CEA value >22 µg·L^{-1} were 53% to 84% and 50% to 79%[25-30]. Although widely used as a tumor marker, the clinical value of serum CA19-9 determination in the diagnosis of cholangiocarcinoma in the absence of PSC is unknown. Thus, the objective of this study was to determine the clinical usefulness of CA19-9 value for cholangiocarcinoma.

MATERIALS AND METHODS

Patients

From January 1995 to February 2003, we prospectively obtained serum samples from patients undergoing evaluation for benign and malignant biliary disease at the First Hospital of Xi' an Jiaotong University and Luoyang Central Hospital. Serum samples were also prospectively obtained from healthy individuals who served as the disease control group. Patients with the diagnosis of PSC were excluded from this study. Clinical information was obtained by a thorough review of

the medical histories. This study included 35 patients with cholangiocarcinoma, 92 patients with benign biliary diseases, and 15 healthy individuals. Of the 35 patients with cholangiocarcinoma, the diagnosis was established by surgical biopsy in 25 patients, endoscopic biopsy and brushing in six patients, and fine needle aspiration in four patients. In patients with cholangiocarcinoma, the stage and resectability of the tumors were ascertained using information obtained by imaging studies or at the time of surgery. Unresectability was defined by Bismuth stage 4 cancer arising from the right and left hepatic ducts and extending intrahepatically. Patients with intra-and extrahepatic metastasis were also deemed unresectable.

The benign biliary diseases group consisted of 92 patients and included 26 patients with benign bile duct stricture, 36 patients with cholecystolithiasis, 20 patients with cholecystic polyp, and 10 patients with chronic cholecystitis. The other control group consisted of 15 healthy individuals without any disease.

Methods

Blood samples obtained from patients were stored at -20 ℃ until used. CA19-9 and CEA were assayed by means of an immunoradiometric method with a commercially available CA19-9 RIA diagnostic kit (ELISA-CA19-9, CIS Bio International, France) and CEA RIA diagnostic kit (CIS Bio Industries, Gif-Sur-Yvette, France). Cutoff values recommended for diagnostic purpose were 37 KU· L^{-1} for CA19-9 and 22 μg· L^{-1} for CEA. Values above the cutoff concentrations were considered positive in this study. Sensitivity in detecting each group was compared between CA19-9 and CEA.

Statistics

The results were expressed as mean values ± standard deviation of the mean (mean±SD). Statistical analysis was performed using a statistical program (SPSS, 11.0 Inc, Chicago, IL). Statistical significance in mean values was evaluated by the Student's t test. The one-way analysis of variance (ANOVA) was used to compare the different groups, and the Mann-Whitney rank sum test was used for intergroup comparisons. The relationships between CA19-9 and CEA, total bilirubin, alkaline phosphatase, or AST were determined by linear regression analysis.

RESULTS

Patients' characteristics

The Table 1 shows some of the characteristics of the different groups. Patients with cholangiocarcinoma were significantly older than either patients with benign biliary diseases or healthy individuals. However, the mean total serum bilirubin and serum alkaline phosphatase values were significantly higher in patients with cholangiocarcinoma, compared to the other two groups ($P<0.05$). Thus, the patients with cholangiocarcinoma had a more marked cholestatic profile than the other two groups of patients.

Serum CA19-9 and CEA values in cholangiocarcinoma, benign biliary diseases and healthy individuals

The mean CA19-9 and CEA concentrations were significantly greater in the cholangiocarcinoma group than those in the benign biliary diseases group or healthy individuals group (Figure 1). Table 1 shows the mean serum CA19-9 concentration in patients with cholangiocarcinoma was 290.31±5.34 KU· L^{-1} in comparison with 13.38±2.59 KU· L^{-1} in the benign biliary diseases group and 12.78±3.69 KU· L^{-1} in the healthy individuals group ($P<0.001$). Their corresponding mean serum CEA concentrations were 36.46±18.03 μg· L^{-1}, 13.84±3.85 μg· L^{-1} and 11.48±3.37 μg· L^{-1}, respectively ($P<0.05$).

Comparison of CA19-9 and CEA levels in serum in patients with cholangiocarcinoma and benign diseases

Table 2 shows the distribution of serum CA19-9 and CEA values in patients with cholangiocarcinoma and benign biliary diseases. Of the 35 patients with cholangiocarcinoma, 27(77.14%) had a concentration exceeding 37 KU· L^{-1} in serum CA19-9. Using a CA19-9 concentration of 37 KU· L^{-1}, the true negative rate of a CA19-9 for cholangiocarcinoma was 84.78% when

Table 1 Patients' characteristics in three groups (mean±SD)

Characteristics	Cholangiocarcinoma	Benign biliary diseases	Healthy individuals

False positive rate	11.98%(11/92)	15.22%(14/92)	18.48%(17/92)	23.91%(22/92)	13.04%(12/92)

[*]Number of positive tests/number of patients with cholangiocarcinoma. [**]Number of negative tests/number of patients with benign biliary diseases. [a]$P<0.05$ vs CEA. [△]When the cutoff value of serum CA19-9 was 100 KU· L^{-1}.

assessed as the benign biliary diseases. The sensitivity (true positive) and specificity (true negative) of CEA were 68.57% and 81.52%, respectively (Table 2). Among the 92 patients with benign biliary diseases, the false positive rates of serum CA19-9>37 KU· L^{-1} and CEA>22 μg· L^{-1} were 15.22% (14/92) and 18.48% (17/92), respectively. The combination of CA19-9 and CEA showed the highest sensitivity and specificity, they were 91.43% and 76.09% when CA19-9 or CEA was positive, and they were 62.86% and 86.96% when both CA19-9 and CEA were positive, respectively. If the cutoff value was increased from 37 KU· L^{-1} to 100 KU· L^{-1}, the sensitivity and specificity of CA19-9 were 65.71% (23/35) and 88.04% (81/92), respectively.

Figure 1 Mean serum CA19-9 and CEA concentrations. [a]*P*<0.001, [b]*P*<0.05 *vs* benign biliary diseases or healthy individuals. [c]*P*<0.05 *vs* serum CEA.

Correlation between serum CA19-9 and total bilirubin, ALP, AST or CEA in patients with cholangiocarcinoma

In patients with cholangiocarcinoma, no correlation was found between CEA and CA19-9 concentration (r=0.036). Likewise, no correlation was found among serum CA19-9, or ALP, AST, and total bilirubin (r=0.015, r=0.037 and r=0.145, respectively). Thus, elevated serum CA19-9 value could not be attributed to either cholestasis or hepatocellular injury.

Decrease of serum CA19-9 values in patients with cholangiocarcinoma after undergoing curative resection

Of the 35 patients with cholangiocarcinoma, 15 patients underwent curative resection and 20 had unresectable cancer. The mean preoperative and postoperative serum CA19-9 levels in the respectable group were 286.41±4.36 KU· L^{-1} and 62.01±17.43 KU· L^{-1}, respectively. The corresponding indexes of serum CEA were 39.41±24.35 μg· L^{-1} and 28.69±11.03 μg· L^{-1}, respectively (Figure 2 and Table 3). Thus, patients after curative resection had significantly lower mean serum CA19-9 and CEA concentrations than those before operation (*P*<0.001 and *P*<0.05). The mean serum CA19-9 concentration in the respectable group was 286.41±4.36 KU· L^{-1} as compared to 391.37±5.76 KU· L^{-1} in the unresectable group (Figure 2 and Table 3). Thus, patients with unresectable disease had a significantly higher mean serum CA19-9 concentration than those with respectable disease (*P*<0.05).

Table 3 Preoperative and postoperative change of serum CA19-9 and CEA concentrations in patients with cholangiocarcinoma undergoing curative resection (mean±SD)

Groups	CA19-9 (KU/L)	CEA(μg/L)
After the resectable (*n*=15)	62.01±17.43[a]	28.69±11.03[c]
Before the resectable (*n*=15)	286.41±4.36	39.41±24.35
The unresectable (*n*=20)	391.37±5.76[b]	43.28±20.68

[a]*P*<0.001, [b]*P*<0.01, [c]*P*<0.05 *vs* before the respectable group.

Figure 2 Mean postoperative serum CA19-9 and CEA levels of resectable group and mean serum CA19-9 and CEA levels of the unresectable group.

Relation between serum CA19-9 and CEA values and clinicopathologic features in 35 patients with cholangiocarcinoma

Perineural invasion by malignant cells was found in 23 of the 33 patients and more frequently encountered in cancer of the upper portion of extrahepatic bile ducts. Of the 35 tumors, lymph node metastasis was seen in 18 and venous invasion in 17. Histologically, 35 examples of cholangiocarcinoma were composed of 16 well-differentiated adenocarcinomas, 12 moderately-differentiated adenocarcinomas, 5 poorly-differentiated adenocarcinomas, 1 anaplastic carcinoma, and 1 adenosquamous carcinoma (Table 4). Table 4 shows statistically significant differences in serum CA19-9 and CEA between positive and negative lymph node metastases (*P*<0.01, *P*<0.05), perineural invasion (*P*<0.01, *P*<0.05), and venous invasion (*P*<0.05). However, there appears to be no relationship between the degrees of differentiation of carcinomas and the values of serum CEA and CA19-9.

Table 4 Relation between serum CA19-9 and CEA levels and clinicopathologic features of tumors in 35 patients with cholangiocarcinoma (mean±SD)

	No. of patients	CA19-9 (KU/L)	CEA (μg/L)
Well-differentiated adenocarcinoma	16	261.67±6.31	34.37±11.29
Moderately-differentiated adenocarcinoma	12	270.56±4.57	38.42±19.23
Poorly-differentiated adenocarcinoma	5	302.71±5.81	48.23±23.64

DISCUSSION

Since koprowski *et al.*[19] discovered CA19-9 from the human colon cancer cell line, which has been commonly used in the

diagnosis of pancreatic and biliary malignant diseases. Recently, its usefulness has been demonstrated in the staging, evaluation of resectability, and assessment of prognosis and recurrence, as well as in the initial diagnosis of malignant disorders, especially pancreatic cancer[31-37].

Elevated concentration of serum CA19-9 (>37 KU· L^{-1}) in bile duct cancers has been frequently reported. Torzilli et al.[38] described a positive rate of 97% in patients with cholangiocarcinoma, whereas Hultcrantz et al.[39] described a rate of 76%, and Caturelli et al.[40] described a 68% rate. We have also found an elevation of CA19-9 in 77.14% of cholangiocarcinomas, which was comparable to the rates reported in other studies. Furthermore, as shown in Table 2, the application of CA19-9 for differentiating cancer from benign biliary diseases was inspiring in our study because of its high sensitivity and specificity. The sensitivity and specificity in our study were 77.14% and 84.78%, respectively, which were similar to 78.2% and 81.4% reported by kau et al.[41]. However, the concentration of CA19-9 could raise in patients with benign inflammatory conditions as well as in malignant disease[42-45]. Indeed, Ahrendt et al.[46] reported a moderate increase in CA19-9 concentration in 13.8% of patients with benign biliary tract diseases. The positive serum rate was 28% in patients with acute cholangitis, as reported by Ker et al.[47], and 35.6% in patients with bile duct stones, as reported by Shiozawa et al.[48]. In our present study, an increased concentration of CA19-9 was found in 15.22% of patients with benign biliary diseases. According to Ker et al.[47], CA19-9 was synthesized by normal biliary ductal cells and malignant cells. If bile flow is blocked by biliary obstruction in benign conditions, such as choledocholithiasis, epithelial cells will be markedly impaired by inflammation and will proliferate concurrently. As a result, more CA19-9 may be secreted and leaked out into the bloodstream. An elevated CA19-9 level often returns to normal with appropriate decompression of the common duct or relief of acute cholangitis. However, the increment of CA19-9 in benign diseases is usually not significant, and a concentration of CA19-9 exceeding 480 KU· L^{-1} is rare. In our study, only 2(2.17%) patients with benign biliary diseases exhibited CA19-9 levels >480 KU· L^{-1}.

CEA is mainly secreted by digestive glandular cancers and their metastases. It has also been found in other types of cancer such as breast, lung, ovary, thyroid cancers. The sensitivity and specificity of serum CEA in our study were 68.57% and 81.52%, respectively, which were similar to 63.3% and 78.4% reported by Ramage et al.[49]. The false positive rate of serum CEA was 18.48% (14/92). Serum CA19-9 was obviously superior to serum CEA in the diagnosis of cholangiocarcinoma and often considered the standard marker for pancreatic cancer and cholangiocarcinoma, with which other markers were compared[50-53]. Our data also showed a much higher sensitivity with serum CA19-9 than with serum CEA in detecting cholangiocarcinomas, but the sensitivity and specificity could be raised by combining these two tumor markers. Furthermore, no correlation between the levels of serum CEA and CA19-9 was found (r=0.036).

Serum CA19-9 has been reported to be able to predict resectability of cholangiocarcinoma[54-57]. In our study, marked elevation of serum CA19-9 tended to associate with advanced and unresectable biliary cancers. Both serum CA19-9 and CEA levels had a positive correlation with tumor stage. This positive correlation is theoretically helpful in assessing the therapeutic effect and monitoring tumor recurrence after treatment. CA19-9 and CEA have been claimed to have a prognostic value in cholangiocarcinomas[7,21,24,30,58]. When applied to cholangiocarcinomas, both tumor markers could provide valuable prognostic information. In our study, serum CA19-9 and CEA concentrations were measured in 15 of 35 patients

with cholangiocarcinoma after undergoing curative resection. Within two weeks after operation, the average concentration of serum CA19-9 and CEA was 62.01±17.43KU· L^{-1} and 28.69±11.03 µg· L^{-1}, respectively, with an obvious decrease compared with those before operation (P<0.001 and P<0.05). Hence, serum CA19-9 could provide more important diagnostic and prognostic values than CEA in cholangiocarcinoma.

In summary, serum CA19-9 is an effective tumor marker in diagnosing cholangiocarcinoma, deciding whether the tumor has been radically resected and monitoring the effect of treatment. Serum CA19-9 determination is a useful adjunct in our diagnostic armamentarium for cholangiocarcinoma. However, serum CA19-9 has limitations in diagnosing cholangiocarcinoma. Indeed, our data clearly demonstrated that a negative test could not exclude cholangiocarcinoma. Moreover, for a patient suspected of having biliary cancer, consideration of the presence of acute cholangitis or cholestasis is suggested. If the patient has no evidence of acute cholangitis or cholestasis, a cutoff value of 37 KU· L^{-1} may be appropriate. However, if a patient shows symptoms and signs of acute cholangitis or cholestasis, application of CA19-9 should be delayed until after recovery from acute conditions or a cutoff value of 100 KU· L^{-1} should be used. Additional bile-or serum-based tests are needed in the diagnosis of cholangiocarcinoma. Ultimately, a profile of tests analogous to liver biochemistry measurement of serum or bile tumor markers and genetic analysis for cholangiocarcinoma-associated mutations will need to be developed to assist in the diagnosis of this disease.

Abstract

AIM: To explore an ideal method for extracting protoporphyrin disodium (PPN) from unanticoagulated animal blood, and to study the inhibitory effects of PPN on HBV-DNA duplication and its cytotoxicity to 2.2.15 cell strain.

METHODS: Protoporphyrin methyl ester and other intermediate products were prepared with protoheme separated from protein hydrolysates of coagulated animal blood, which were finally made into PPN and detected quantitatively with an ultraviolet fluorescent analyzer. Ten µg/ml, 20 µg/ml, 40 µg/ml, 80 µg/ml and 160 µg/ml of PPN-aqueous solution were added into culture medium for 2.2.15 cells respectively. Eight days later, the drug concentration in supernatant from the culture medium was detected when inhibition rate of HBeAg, cell survival rate when inhibition rate of HBeAg was 50% (ID50), and when survival cells in experimental group were 50% of those in control group (CD50), and the therapeutic index (TI) was also detected. PPN with different concentration of 10 µg/ml, 20 µg/ml, 40 µg/ml, 80 µg/ml and 160 µg/ml was respectively mixed and cultivated with HepG2 2.2.15 cell suspension, and then the inhibition of PPN against HBV-DNA was judged by PCR.

RESULTS: The extract of henna crystal was identified to be PPN. When the concentrations of PPN were 160 µg/ml and 80 µg/ml, the inhibition rates of HBeAg were 89.8% and 82.4%, and the cell survival rates were 98.7% and 99.2%.

CONCLUSION: It is suggested that PPN can be extracted from unanticoagulated animal blood. PPN can inhibit HBV-DNA expression and duplication *in vitro*, and has no cytotoxicity to liver cells. Further study and application of PPN are warranted.

INTRODUCTION

Protoporphyrin disodium (PPN) is a macrocyclic compound with a conjugated double bond, which is consisted of four pyrrole rings connected by four methylene bonds, and is a derivative of porphine. PPN can be prepared with extracted haemachrome originated from ferrohemoglobin in serum and other chemicals. PPN is a pharmaceutics to improve liver functions and can be used in clinical therapy for recovery of injured liver cells.

PPN could be obtained from fresh anticoagulant animal blood according to reports[1-3]. But the PPN in this study was obtained from fresh unanticoagualted animal blood, and the method has not been reported in the literature.

Hepatitis B is widely occurred in China, and severely affects people's health and the quality of life. In order to find out the relationship between PPN and the expression and duplication of HBV-DNA, hoping to seek for an effective therapy of Hepatitis B, we designed an experimental *in vitro* study.

MATERIALS AND METHODS

Reagents

Unanticoagulated pig blood (from Huainan area), NaOH, zinc powder, chloroform, skellysolve G, 2.2.15 cell strain (from the Institute of Infectious Disease, Peking Medical University), kit for ELISA (from Huamei Biological Engineering Co.,Ltd), kit for PCR (from Huamei Biological Engineering Co.,Ltd).

Instruments

Tissue homogenate instrument (from Shanghai Biaomo), magnetic stirring apparatus, glassy device of reflux, glassy filter, chromatography column with neutral aluminium oxide (from Shanghai-Jinhua Chromatography Equipment Factory), drying oven by electrothermal blow (form Shanghai-Yuejin Equipment Factory), gamma radio immunoassay counters (from State-Operated Factory 262), CO_2 incubator (from Japan), SLT-Spectra-I enzyme analyzer (from America), DNA amplifier (from Zhuhai Hema Bio-Tech Institute), ultraviolet fluorescent analyzer (from Shanghai-Kanghua Biochemical Instrument Manufactory).

Methods

Extraction of protoheme 1L homogenate of unanticogulated pig bloods was added to a container, and 100 g NaOH was added simultaneously during stirring until they were well mixed. When the mixture changed into dilute solution after placement for 24 h, it was heated and stirred by magnetic stirring apparatus at the 80 ℃ to 90 ℃ for 12 hours. When the mixture was naturally cooled to 60 ℃, 1M HCL aqueous solution was added into the mixture till precipitation of protoheme occurred. The precipitation was taken out, washed 3 times with water and dried. Finally about 1.7g of protoheme was obtained.

Preparation of crude protoporphyrin 1.5 g zinc powder divided into six portions was added into the mixture of 250 ml formic acid aqueous solution (85%) and 5 g protoheme under the condition of heating, stirring and regurgitating respectively. Each addition had an interval of 5 minutes. Then they were heated and regurgitated once more for 20 min and then cooled and filtered. Ammonium acetate aqueous solution (20%) was

added into the filtrate, then the solution was filtered when crystals occurred after placement for 12 h. After the crystals were dissolved with 600 ml ammonia water (2%), ammonium acetate aqueous solution (30%) was added into the solute and placed for 12 h till crystallization occurred. The crystals were filtered out and washed 3 times with 600 ml ammonium acetate aqueous solution (2%) and 90 ml distilled water, respectively. Then it was dried into crude protoporphyrin, which was a kind of brown cystalline materials of about 2 g.

Preparation of protoporphyrin methyl ester 5 g crude protoporphyrin was dissolved in 200 ml hydrochloric methanol aqueous solution (1%), and the reactants were heated, regurgitated for 20 min. Then 1 000 ml ammonium carbonate aqueous solution (1%) was added into the above cooled reactants and placed till crystallization occurred. The crystalline materials were taken, and washed 3 times with distilled water, then dissolved in 200 ml chloroform and the solute was taken to pass through chromatography column with 1 000 g neutral aluminium oxide. After the elution with prepared eluting agent of chloroform and petroleum ether with volumetric proportion at the ratio of 1 to 3 was completed, the eluent of protoporphyrin methyl ester was collected and evaporated, and a kind of brown cystalline materials was obtained. Then the brown cystalline materials were crystallized 2 times with chloroform and methanol, and 2 g protoporphyrin methyl ester was acquired.

Preparation of pure protoporphyrin 5 g protoporphyrin methyl ester was dissolved in 150 ml HCL aqueous solution (25%). After placed for 8 h, the reactants were neutralized with NaOH aqueous solution (30%), then crystallization occurred. The crystalline materials were isolated and washed 3 times with distilled water. After being dried, the crystalline materials were re-crystallized 2 times with pyridine, and 2.5 g brown pure protoporphyrin was obtained.

Preparation of PPN The mixture of 10 g pure protoporphyrin, 5 g NaOH and 500 ml anhydrous alcohol was heated and regurgitated for 2 h. Crystalline materials occurred after the mixture was cooled. Then the crystalline materials were isolated, washed 3 times with anhydrous alcohol and dried. Finally, 9 g brown crystalline materials of PPN was obtained.

Inhibitory effects of PPN on HBV-DNA expression *in vitro* 2.2.15 cell strain was prepared based on human cancer cell strain of the liver, HepG$_2$, which had been infected with HBV-DNA, could express all marks of duplications of HBV-DNA effectively[4-17]. Regarding 2.2.15 cell strain as the target cell, the effect of PPN on HBV-DNA was confirmed by detecting the levels of HBeAg in culture supernatants with quantitative methods.

Procedure was as follows: 1×10^5/ml cell suspension was prepared with 2.2.15 cell strain which grew well. One ml cell suspension was added into each of the 24-hole plastic plate respectively and cultivated. After incubation at 37 ℃ for 48 h, fresh culture media with different concentrations of PPN (10 µg/ml, 20 µg/ml, 40 µg/ml, 80 µg/ml, 160 µg/ml) were then replaced every 3 days. Eight days later, supernatants were collected and stored at 20 ℃ for detection of HBeAg levels and cytotoxicity of PPN to liver cells. ELISA was used for detection of HBeAg. The detailed procedure followed the operating instructions. Inhibition rate (%)=(P/N values of the control holes- P/N values of the study holes)/(P/N values of the control holes -2.1)×100%, and ID$_{50}$ represented the concentration of PPN when the inhibition rate of HBeAg was 50%. The cytotoxicity of PPN to liver cells was detected by MTT to determine the survival rate of liver cells. The survival rate of liver cells (%)=values of the study holes (A_{595}-A_{650})/ values of the control holes (A_{595}-A_{650})×100%. CD$_{50}$ represented the concentration of PPN when the number of the survival cells in the detected holes to the survival cells in the study holes was 50%.

Inhibitory effects of PPN on HBV were evaluated with TI (TI=CD$_{50}$/ID$_{50}$). When TI<1, PPN was cytotoxic and poorly effective on liver cells. When 1<TI<2, PPN was cytotoxic and effective. When TI≥2, PPN was mildly cytotoxic and effective. The higher the values of TI, the greater the inhibitory effects of PPN on HBV and the less the cytotoxicity of PPN to liver cells[18,19] (Table 1).

Inhibitory effects of PPN on HBV-DNA duplication *in vitro* PPN was diluted to a series of solutions with different concentrations (including 10 µg/ml, 20 µg/ml, 40 µg/ml, 80 µg/ml and 160 µg/ml) by aseptic techniques for further use. HepG$_2$ 2.2.15 cells in good cultivation were dispensed to the suspension with a concentration of 1×10^5/ml, 6 identical shares of it were subsequently taken out, PPN with the concentration of 10 µg/ml, 20 µg/ml, 40 µg/ml, 80 µg/ml and 160 µg/ml respectively was added to 5 of 6, the remaining one had no PPN. After a period of cultivation, the cells were collected, then whole genome DNA of them was extracted by using CASSupper blood genomic DNA isolation kit and further amplified by PCR. The amplification system included 10×buffer 25 ul, dNTP 3 ul, sense 0.5 ul, anti-sense 0.5 ul, TaqE 1.5 ul and template 2 ul. The parameters included at 95 ℃ for 5 min, at 94 ℃ for 30 s, at 55 ℃ for 30 s, at 72 ℃ for 30 s, 35 cycles and extension at 72 ℃ for 5 min. The final products with DGL-2000 were further performed with routine electrophoresis. During the process of analysing by using agarose gel electrophoresis containing EB, each hole was added 10 ul of products and placed at 80-100V for 20 min. Lastly, the agar plates were observed by ultraviolet fluorescence analysis.

RESULTS

General characterisics of PPN

The prepared PPN was brown crystalline materials, soluble in water, slightly soluble in methyl alcohol, but not soluble in chloroform, diethyl ether or dimethy ketone. PPN displayed absorption peaks at wavelengths of 600 nm, 556 nm and 408 nm, and the maximal absorption wavelength was 408 nm. When exposed to ultraviolet, strong fluorescence could be observed in red[3].

Quantitative detection of PPN

According to the fact that when PPN was dissolved in 1.37M HCL and placed at wavelength of 408 nm, the $E_{1 cm}^{1\%}$ was 4.81×10^3, the purity of PPN extract was detected to be 97.3%.

Inhibitory effects of PPN on HBV-DNA in vitro

Table 1 Inhibition of PPN on HBV-DNA expression *in vitro*

PPN (µg/ml)	OD	Inhibition rate of HBeAg (%)	Survival rate of liver cell (%)
160	1.20	89.8	98.7
80	1.30	82.4	99.2
40	1.50	56.7	100
20	1.85	32.3	100
10	2.30	5.5	100

CD$_{50}$=279.4 µg/ml, ID$_{50}$=37.4 µg/ml, TI=7.47.

Table 1 shows that when the concentrations of PPN were 160 µg/ml and 80 µg/ml, the inhibition rates of HBeAg were 89.8% and 82.4% respectively and cellar survival rates were 98.7% and 99.2%, TI=7.47.

It was obvious that the luminance of amplified bands of samples without addition of PPN was the brightest, while that of samples with addition of PPN decreased gradually accompanying increased concentration of PPN.

DISCUSSION

While fresh anticoagulated animal blood was used as raw materials to prepare PPN, the harvest, transportation, and preservation of the raw materials needed a strict condition, which made the source of raw materials limited, working cost increased and the scale of production limited. In this study, unanticoagulated animal blood was used as raw materials to prepare PPN, that is, the form of the raw materials was improved. Using unanticoagulated animal blood as raw materials to prepare PPN, fine PPN could be obtained. The method is an ideal way of preparing PPN at present. Meanwhile, it can solve the problems mentioned. In addition, during the whole process of preparation, the special, expensive reagents are not necessary and also some reagents can be retrieved for reuse. The method is simple and convenient in its process of preparation and its production cost is lower. If some of amino acids produced during the preparation were studied, analyzed and purified, the additional value of the raw materials would be increased, so that large amount of animal blood resource can be fully utilized.

Protoporphyrin is the necessary component of ferrohemoglobin, myohemoglobin, cytochrome, catalase and tryptophan pyrrolase in human body. Protoporphyrin showed a circular structure in somatic cells, and could easily combine with metallic ion to form metallic porphyrin[21]. In the case of liver disease, liver functions might be in disorder, porphyrin and metallic porphyrin in bile decrease as well as the activity of catalase in liver would decrease. Therefore, PPN could activate the biosynthesis of porphyrin and metallic porphyrin in cells as demonstrated by *in vitro* test, increase the quantity of metallic porphyrin in cells, inhibit the decrease of activity of catalase, improve cellular respiration and regeneration, and decrease the necrosis of liver cells with recovery of its function. Based upon the above metabolic properties, PPN could improve blood flow and utilization rate of oxygen by liver and other related organs, accelerate the respiration of histocytes, improve metabolism of proteins and carbohydrates, enhance effects of complement fixation, and enhance immunity, anti-inflammation and anti-anaphylaxis potentials of the organism. Thus, PPN has been constantly studied and applied as an improving agent of liver functions[22-32]. At present, PPN is being studied for its antineoplastic effects in foreign countries. Inhibitory effects of PPN on expression and duplication of HBV-DNA *in vitro* was studied by us from another point of view. As table 1 shows, PPN could inhibit expression of HBV-DNA *in vitro* and had no cytotoxic action, and it is not difficult to see that the luminance of amplified bands decreased gradually with increased concentration of PPN. The mechanism of action in the above results might be that some intermediary metabolites of PPN in liver cells could affect antisense oligonucleotides (ASONs) located at pre-C and C gene regions of HBV and also adjust genes ENH I of HBV through ASONs. Then it could finally inhibit the duplication of HBV-DNA and the expression of HBeAg in host cells[33-35]. Therefore, further study and application of PPN in clinical therapy of hepatitis B should be carried out.

Abstract

AIM: To explore the possible mechanism of intrauterine infection of hepatitis B virus (HBV).

METHODS: HBV DNA was detected in vaginal secretion and amniotic fluid from 59 HBsAg-positive mothers and in venous blood of their newborns by PCR. HBsAg and HBcAg in placenta were determined by ABC immunohistochemistry.

RESULTS: The rate of HBV intrauterine infection was 40.1% (24/59). HBV DNA was detected in 47.5% of amniotic fluid samples and 52.5% of vaginal secretion samples respectively. HBsAg and HBcAg were detected in placentas from HBsAg-positive mothers. The concentration of the two antigens decreased from the mother's side to the fetus's side, in the following order: maternal decidual cells > trophoblastic cells > villous mesenchymal cells > villous capillary endothelial cells. However, in 4 placentas the distribution was in the reverse order. HBsAg and HBcAg were detected in amniotic epithelial cells from 32 mothers.

CONCLUSION: The main route of HBV transmission from mother to fetus is transplacental, from the mother side of placenta to the fetus side. However, HBV intrauterine infection may take place through other routes.

INTRODUCTION

Hepatitis B virus infection is a worldwide health problem. China is one of the high prevalent areas, with a positive rate of HBsAg in population more than 10%[1]. Recent data indicate that the rate of intrauterine infection of HBV is 10%-44.4%[2,3]. Intrauterine infection is one of important routes of HBV transmission, and the main cause of HBV chronic infection. To explore the possible mechanism of intrauterine infection, we detected HBV DNA in the vaginal secretion and amniotic fluid from HBsAg-positive mothers and venous blood from the neonates by PCR, and also detected the distribution of HBsAg and HBcAg in the placenta by ABC immunohistochemical method.

MATERIALS AND METHODS

Patients

Pregnant women who gave birth in the Hospital of Women' s and Children' s Health Care in Zhaoqing, Guangdong Province, China and their full-term newborns were recruited into this study. All the mothers received a regular prenatal examination in the clinic during pregnancy, and were detected for HBV serum markers (HBVM) by ELISA. Fifty-nine HBsAg-positive mothers and their newborns were studied, 10 HBsAg-negative mothers and their newborns served as control. All the mothers had no threatened abortion or related history, no pregnancy related complications. There was no difference in age, pregnant frequency of mother and gestational age of fetus between the two groups. Sixty-nine mothers gave birth to sixty-nine newborns.

HBV DNA detection

Vaginal secretion of mothers was taken before amnion rupture. After entering labor of the mother, at a proper time or just after amnion rupture, amniotic fluid was taken, and strictly prevented from blood contamination. After birth, 3 ml of neonatal venous blood was taken and separated for serum. All specimens were stored at -20 ℃ and HBV DNAs were detected simultaneously. PCR test kits were purchased from Hua Mei Biological Engineering Company. The tests were performed strictly according to the manufacturer' s instructions.

Determination of HBsAg and HBcAg in placenta

Placental tissues of 1 cm×1 cm×2 cm, were taken from the fetal side and the maternal side respectively, fixed in 10% formalin, embedded with paraffin according to routine procedure and sliced in 5 μm thickness. Rabbit McAb against HBcAg and mouse McAb against HBsAg were used for immunohistochemical test and DAB staining kits were purchased from Wuhan BoShide Biological Engineering Ltd Company. HBsAg and HBcAg positive livers from autopsy were used as positive control, and placentas from HBVM negative mothers served as negative control. At the same time, we used PBS instead of the first antibody as blank control. Dark brown yellow in cytoplasm or nucleus was regarded as strongly positive, brown yellow as positive, and light brown yellow as weakly positive.

Diagnosis of intrauterine infection

The presence of HBV DNA in neonatal venous blood was regarded as intrauterine infection.

RESULTS

HBV DNA status in amniotic fluid, vaginal secretion and neonatal venous blood

The positive rates of HBV DNA in amniotic fluid and vaginal secretions were 47.5% (28/59) and 55.9% (31/59) respectively. No HBV DNA was detected in amniotic fluid and vaginal secretion in control group. Of the 59 newborns born to mothers with HBsAg-positive, 24 were HBV DNA positive in neonatal venous blood, the rate of intrauterine infection was 40.1%

(24/59). No HBV DNA was detected in neonatal venous blood from newborns whose mothers were HBsAg-negative.

HBsAg and HBcAg in placenta

The positive rates of HBsAg and HBcAg in placentas from 59 mothers with HBsAg- positive were 81.4% (48/59) and 61.1% (36/59) respectively. HBsAg in placenta appeared as inhomogeneous dark brown yellow granules in plasma of all kinds of cells. It was 76.27% (45/59) in maternal decidual cells, 72.88% (43/59) in trophoblastic cells, 62.71% (37/59) in villous mesenchymal cells, 52.54% (31/59) in villous capillary endothelial cells, 54.24% (32/59) in amniotic epidermic cells. The positive coloration of HBsAg was seen in part of the villous interstices. The distribution of positive cells was patchy or conglomerate. The stained HBcAg in placentas was homogeneous granule, existing in nuclei of the positive cells which were distributed in focus or dispersion, mainly including 59.32% (35/59) of maternal decidual cells, 55.93% (33/59) of trophoblastic cells, 50.85% (30/59) of villous mesenchymal cells, 44.07% (26/59) of villous capillary endothelial cells, 49.15% (29/59) of amniotic epidermic cells. No HBsAg or HBcAg was detected in placentas of the control. The number of positive cells of HBsAg or HBcAg and the degree of staining were gradually decreased from maternal decidual cells to villous capillary endothelial cells.

On the contrary, the distribution of HBsAg- and HBcAg-stained cells in 4 placentas was gradually decreased from villous capillary endothelial cells to maternal decidual cells. The staining degree of HBsAg and HBcAg was also decreased in the same order.

DISCUSSION

Most researchers hold that the mechanism of HBV intrauterine infection is transplacental infection. In 1987, Lin detected 32 placentas of HBsAg and HBcAg positive mothers using PAP immunohistochemistry, and did not find HBsAg[4]. Tang detected HBV DNA in placentas of induced labor from HBsAg-positive mothers using dot blot hybridization, and found HBV DNA in 2 cases[5]. Lucifora detected 12 placentas of HBsAg carriers with no symptoms by immunohistochemistry and found HBsAg and HBcAg in villous capillary endothelial cells[6,7]. Xu[8] and Yan[9] detected placentas from HBsAg-positive mothers by ABC immunohistochemistry and in situ hybridization and found HBsAg, HBcAg and HBV DNA in all kinds of placental cells. Wang et al detected 24 placentas of HBsAg and HBcAg positive mothers using in situ hybridization and found HBV DNA was mainly distributed in maternal decidual cells, while no HBV DNA- positive cells were in the villi[10]. The results above were different obviously. In the present study, by using PCR for the determination of intrauterine HBV infection and ABC immunohistochemistry for the detection of the presence of HBsAg and HBcAg in placenta, we detected 59 placentas of HBsAg-positive mothers and found the positive rates of HBsAg and HBcAg were 81.4% (48/59) and 61.1% (36/59) respectively. The detection rate of HBsAg and HBcAg, the proportion of positive cells and the degree of staining were gradually decreased from the maternal side to the fetus side of placenta (decidual cells > trophoblastic cells > villous mesenchymal cells > villous capillary endothelial cells). The villous capillary endothelial cells were infected by HBV in 31 mothers, from whom 22 newborns had HBV intrauterine infection. These results indicated that HBV could infect all kinds of cells in placenta, which was the possible mechanism of intrauterine infection that HBV infected cells from maternal decidua to villous capillary endothelia or that HBV infected trophoblastic cells directly, then to villous mesenchymal cells

and villous capillary endothelial cells resulting in fetus infection.

In our study, the number of HBsAg- and HBcAg- positive cells was gradually decreased from villous capillary endothelial cells to maternal decidual cells in 4 placentas. The degree of staining was decreased in the same order from the fetus side to the mother side of placenta. HBV DNA was positive in 2 of the venous blood samples. This indicated that HBV infected the fetus first, and then infected cells in different layers of placenta. In these 4 cases HBsAg and HBcAg were detected in amniotic epidermic cells, HBV DNA in amniotic fluid and vaginal secretion was also detected, suggesting that the ascending infection from vagina might exist, that is to say, HBV in vaginal secretion infected fetal membrane, amniotic fluid, fetus and cells of different layers in placenta or HBV infected fetal membrane first then infected cells in different layers of placenta from the fetus side to the mother's side.

From the 1980's, researchers all over the world have proved that HBV DNA was existent in all generations of spermatogenic cells and sperms in HBV-infected males. Researchers studied male HBV carriers whose wives were not infected with HBV, and their fetuses. The results of HBV DNA sequencing showed that the homology between the father and his son or daughter was 98%-100%. Some researchers found HBsAg in follicular fluid of HBsAg-positive women by immunohistochemistry. Still others found HBV DNA in ovary from a woman who died of severe hepatitis using in situ hybridization. HBV DNA was mainly in plasma of ovum and interstitial cells. Now that human oocytes can be infected by HBV, the possibility of HBV transmission through oocytes may exist. In our study, although the fetus HBV infection through oocyte has not been proved in the 2 cases, we could not exclude the possibility.

In conclusion, intrauterine HBV infection is mainly transmitted through the placenta from the maternal blood to the fetus. HBV infection through vagina or oocytes may exist.

Abstract

AIM: To evaluate the multiple biomarkers of colorectal tumor and their potential usage in early diagnosis of colorectal cancers.

METHODS: Multiple biomarkers (DNA contents, AgNOR, PCNA, p53, c-erbB-2) in 10 normal colorectal mucosae, 37 colorectal adenomas and 55 colorectal cancers were analyzed quantitatively in the computed processing imaging system. Discrimination patterns were employed to evaluate the significance of single and multiple indices in diagnosis of colorectal cancers.

RESULTS: The mean values of the analyzed parameters increased in order of the normal mucosa, adenoma and adenocarcinoma, and this tendency reflected the progression of colorectal malignancy. The parameters including DNA index, positive rates, densities of AgNOR, c-erbB-2, and p53, shape and density of nucleus were relatively valuable for diagnoses. Then a diagnostic discrimination model was established. The samples were confirmed with the model, the sensitivity rates in cancer group and adenoma group were 96.36% and 89.19%, respectively. The value of proliferating cell nuclear antigen (PCNA) in early diagnosis of colorectal cancers was uncertain.

CONCLUSION: The quantitative evaluation of some parameters for colorectal tumor can provide reproducible data for differential diagnosis. The established diagnostic discrimination model may be of clinicopathological value, and can make the early diagnosis of colorectal cancer possible.

INTRODUCTION

Colorectal carcinoma is one of the most common malignant tumors worldwide. Quantitative changes in nucleus, DNA content, PCNA, AgNOR were observed in the progression of tumor[1-6]. Genes such as p53, *cerbB-2* might play a significant role in carcinogenesis[7-13]. Although the biologic parameters of tumors have been assessed extensively, measurement of these parameters has little impact on histological diagnosis. Furthermore, analysis of a single parameter is insufficient to evaluate tumor malignancy. Meanwhile, distinguishing benign from malignant lesions has traditionally been subjective; a quantifiable test is useful for the diagnosis of colorectal cancer. In this study, we used quantitative analysis to examine the potential usage of multiple biomarkers (DNA contents, AgNOR, PCNA, p53, c-erbB-2) in early diagnosis of colorectal cancer.

MATERIALS AND METHODS

Materials

Pathological specimens were obtained from Department of Pathology at Fujian Medical University from 1991 to 1996, including 55 cases of colorectal carcinoma, 37 cases of colorectal adenoma and 10 cases of normal colonic mucosae. The diagnosis was confirmed pathologically. The patients included 35 males, and 20 females with a mean age of 57 ± 12.83 years (range 31 to 84 years). Histologically, there were 15 highly differentiated types, 19 moderately differentiated types, 21 poorly differentiated types, and 13 cases had a local lymph node metastasis and 1 case had the liver metastasis.

Reagents and methods

Schiff reagent, AgNOR staining fluid, antibodies against PCNA, c-erbB-2 and p53 and SP immunohistochemical reagent were purchased from Fujian Maxin Co.Ltd.

Formalin-fixed, paraffin-embedded specimens were cut in to 5 μm in thickness. The slices were stained with Feulgen, AgNOR and the detected antigen, and those in the control group were stained without primary antibody.

Semi-quantitative evaluation

Some silver stained black particles were observed in nuclei and classified. The positive staining rate was calculated[14]. A semi-quantitative evaluation system was used to determine the antigen expression in specimens[15]. Expression of p53 and c-erbB-2 was graded as the following scale: <10% "-",10-25% "+", 26-50% "++", 51-75% "+++", >75 "++++". Expression of PCNA was graded as the following scale: <25% "+", 26-50% "++", 51-75% "+++", >75% "++++".

Quantitative evaluation

The specimens were examined for multiple biomarkers with quantitative analysis using the computer processing image system (American Image Co. 8000 Type). Under the same power field of microscope, 150-200 cells were examined. Multiple biomarkers stained with silver or PCNA included DNA content, DNA index, nucleus area, Abs, granular shape factor, width and length of nuclei, the widest and longest diameter, and density of nucleus.

Statistical analysis

Student's *t* test was used for analysis of variance. Discriminant analysis was done for multiple parameters and indices. The selected significant parameters were used to set up a diagnostic discrimination model. The SAS system for windows (version 6.12) was used for completing all the statistical analyses.

RESULTS

Multiple biomarkers (DNA contents, AgNOR, PCNA, p53, c-erbB-2) were quantitatively processed using the computer processing image system in 10 normal colonic mucosae, 37 colorectal adenomas and 55 colorectal carcinomas. The values of most parameters were increased in the order of normal mucosa, adenoma and adenocarcinoma. The tendency reflected the progression of colorectal malignancy. But the PCNA content was peaked in adenoma and decreased in carcinoma. The values were subjected to discrimination pattern method to evaluate the significance of parameters in multiple indices in order to set up the discrimination model. Then the model was used to recheck the samples. DNA index, shape factor, the widest diameter and density of nuclei were demonstrated to be the valuable parameters in feulgen-stained sections. The concordance rate was 86.02% for cancer group and 80.06% for adenoma group. The relatively valuable parameters in silver stained slides were average number, positive rate, density and aspect factor of particles. The concordance rate of the established model was 79.57% for cancer group and 78.65% for adenoma group. The valuable parameters in PCNA stained specimens were positive rate and density, and the concordance rate was 76.34% for cancer group and 73.55% for adenoma group. The valuable parameters in c-erbB-2 stained samples were Abs, positive rate and density, the concordance rate was 90.32% for cancer group and 90.14% for adenoma group. The valuable parameters in p53 stained positive samples were total positive area and density, and the concordance rate was 86.02% for cancer group and 83.55% for adenoma group. Discriminant analysis was performed for the above parameters. DNA index (X_1), positive rate (X_2), density (X_3) and aspect factor of AgNOR (X_4), density of c-erbB-2 (X_5), density of p53 (X_6), shape factor (X_7) and density of nucleus (X_8) were demonstrated to be the relatively valuable indices. Then a diagnostic discrimination model was established, and the model rechecked the samples, the concordance rates in cancer group and adenoma group were 96.36% and 89.19%, respectively. The models were as follows.

$Y(1)=-412.86-7.30X_1+34.83X_2+1.15X_3+2.54X_4+500.07X_5+17.34X_6+2.54X_7+409.68X_8$

DISCUSSION

Relationship among DNA content, shape parameters of nucleus and colorectal carcinoma

Most tumor cells had a certain amount of abnormal DNA; DNA content of tumor was closely related to biological behaviors[1,2]. Our study showed that the level of DNA content was increased in the order of normal mucosa, adenoma and adenocarcinoma with different significances. It has been confirmed that DNA content is a reliable and objective marker in early diagnosis of colorectal carcinoma and in distinguishing benign from malignant tumors.

In diagnosis of colorectal carcinoma with quantitative analysis as reported[1,2], the results varied with selected parameters. We believed that abnormalities of nuclei were the most important phenomena in hypertrophy of neoplastic cells in addition to abnormal structure of cells or tissues. It is well known that increased mitotic nuclei, multi-hierarchical structure, enlargement and pleomorphism of nuclei are expressed in most rapidly growing neoplasms. We suspected that increased nucleus area and much more irregular shape of nucleus were in accordance with the normal mucosa-adenoma-adenocarcinoma

sequence. Parameters of nuclear shape and density of DNA reflected the malignancy of tumor significantly.

Although we considered that area of nucleus would play an important role in diagnosis of tumor with three-dimensional (3D) image processing, this study failed to show that areas of nuclei could reflect hyperplasic degree of tumor quantitatively. This might be due to the limitation of bi-dimension that could not reveal the whole nucleus.

Previous studies reported that Abs was an objective parameter to reflect the nucleus. But discriminant analysis showed that Abs was not relatively valuable. While Abs and density of nucleus had significant differences among the groups. We reason that sectional shape of nucleus is different from its real shape, so average area of Abs (density of nucleus) reflects of DNA content more objectively.

Relationship between AgNOR and colorectal carcinoma

Variation of the number of nucleolar organizer regions (NORs) could reveal the conditions of cellular activity[16-20]. It was suggested that AgNOR dot count of cells had a potential role in distinguishing benign from malignant tumors and in their early diagnosis[21]. Our results revealed that the count of AgNOR was increased in accordance with the normal mucosa-adenoma-adenocarcinoma sequence. Due to the strong correlation among type of particles, irregular factor and shape factor, irregular factor was rejected from the equations by discriminant analysis first. Type of particles used to be regarded as an important parameter[21], and turned out to have a limited value. The parameters, such as average number, positive rate, density and surface factor of particles were demonstrated to be valuable, and could reflect the characteristics of particles. The concordance rate was 79.57% for cancer group and 78.65% for adenoma group indicating this improved system is sensitive and very precise for quantifying the AgNOR dot count in cells and can provide a valuable objective measurement in differentiating benign from malignant tumors.

Relationship between PCNA and colorectal carcinoma

PCNA is a cell cycle related protein that is maximally elevated in late G1 and S-phase of proliferating cells and a key cycle regulator. It can be used as a marker of proliferation, and directly assessed using a thymidine analogue in suitably labeled pathological materials. Cellular proliferative activity has been accepted as a useful indicator of biologic aggressiveness in colorectal carcinoma[5-17]. PCNA immunohistochemistry could be used as a reliable marker of the proliferative compartment in both normal and neoplastic colonic mucosae[22]. The results revealed that all the parameters were significantly higher in adenoma and adenocarcinoma than in normal tissue, and the parameters in adenoma were higher than those in adenocarcinoma, indicating that multiplicative growth presented in G1 and S-phase when adenoma progressed to adenocarcinoma, and in other phase or in shock period while in adenocarcinoma. So the parameters of PCNA were descent in adenocarcinoma. Therefore we considered that the value of PCNA could distinguish benign from malignant lesions in the earlier stage of tumor.

Relationship among c-erbB-2, p53 and colorectal carcinoma

The c-erbB2 gene could be amplified in human adenocarcinomas, leading to elevated levels of expression of its encoded product, p185[11-23]. It has been shown that the accumulation of several alterations in p53 genes is most important for the conversion of adenoma to carcinoma. Critical genetic changes, including activation of oncogenes, mutation and deletion of tumor suppressor genes and disturbances in transcriptional regulatory sequences, might bring about aberrant expression of growth factors and their receptors in gastrointestinal carcinomas[10].

Mutations in the tumor suppressor gene p53 occur prevalently in a wide range of human tumors. Detection of a mutated p53 could provide useful information for the clinical management of colorectal neoplasms[24-29]. The p53 gene mutation and its subsequent over-expression in colorectal adenomas might therefore be a fundamental genetic event underlying the dysplasia and loss of proliferative control that are the characteristics of adenomas with a malignant potential[30]. Mutant p53 tumor suppressor gene and c-erbB-2 proto-oncogene were involved in human carcinogenesis, and detection of their protein product in human malignancies might influence the evolution of many neoplasms[31,32]. Therefore the aim of this study was to investigate the correlation of c-erbB-2, p53 with occurrence, progression of colorectal carcinoma and to determine the prognostic significance of oncogenes. The results showed that the values of c-erbB-2, p53 were increased in accordance with normal mucosa-adenoma-adenocarcinoma sequence ($P<0.01$), and the levels of c-erbB-2 were obviously increased in normal tissue and adenoma, suggesting that the occurrence of colorectal carcinoma was associated with activation of c-erbB-2, and c-erbB-2 could be considered as a more significant predictor of the occurrence of colorectal carcinoma. Meanwhile the value of total positive area and density of p53 were obviously increased in adenoma and carcinoma, indicating that p53 was a key oncogene in the progression of colorectal carcinoma. These results confirmed that p185 overexpression was associated with the early stages of colorectal cancer, whereas p53 was associated with more advanced stages[31].

Precancerous lesion of colorectal adenoma

The rate of carcinogenesis is associated with proliferation. To evaluate the proliferative degree of colorectal tumor with imaging analysis is helpful for the diagnosis of tumors. Our study of DNA contents, AgNOR, PCNA, p53, c-erbB-2 provided some useful prognostic information, their determination was useful for accurate evaluation of the prognosis.

The entity of carcinomatous change is a complicated process from quantitative to qualitative change. We studied the proliferative lesion with a mathematics model in order to provide the objective markers for accurate diagnosis. The result showed that DNA index, positive rates, density and aspect factor of AgNOR, densities of c-erbB-2, p53, shape factor and density of nucleus were relatively valuable. The result also showed that normal group was correctly diagnosed with the model ($F>0.8$). The 4 fault samples of papillary adenoma with grade 2-3 atypical hyperplasia by pathologic diagnosis were fault diagnosis of adenocarcinoma by the model ($F<0.8$). The 2 highly differentiated colorectal tumors were fault diagnosis of adenoma ($F<0.8$). Comprehensive evaluation showed the strong discriminating power of the model.

This study examined the value of PCNA. No parameter of PCNA was selected for the final model. As strong correlations were observed between PCNA and p53[33,34] we believed that the discriminating power of PCNA was hided by p53 due to the complex interface among the parameters. On the other hand, we doubted the value of PCNA in early cancer. However, some parameters of DNA, AgNOR, p53, cerbB-2 were selected for the model, and the diversity of tumor and occurrence and progression of colorectal tumor were related with multiple factors. Meanwhile, all the 4 indexes played a major role in the diagnosis of colorectal tumor, and inactivation of anti-oncogene and activation of oncogene were existed in the progression of colorectal malignancy.

Quantitative evaluation of some indices of colorectal tumor could provide reproducible data for its differential diagnosis. The discrimination model established can offer subjective parameters for distinguishing benign from malignant tumors.

Abstract

AIM: To explore the effect of antisense oligodeoxynucleotide (As-ODN) of telomerase RNA on telomerase activity and cell apoptosis in human colon cancer.

METHODS: As-ODN was transfected into SW480 cells by liposomal transfection reagent. Telomerase activity of SW480 cells was examined by telomeric repeat amplification protocol (TRAP) and enzyme-linked immunosorbent assay (ELISA). Apoptosis was analyzed by morphology and flow cytometry.

RESULTS: The telomerase activity in SW480 cells transfected with 1.0 µmol/L of As-ODN for 2-5 days, was significantly decreased in a time-dependent manner, and the cells underwent apoptosis. The missense ODN (Ms-ODN) and the control group transfected with SW480 cells did not show these changes.

CONCLUSION: As-ODN can specifically inhibit the telomerase activity of SW480 cells and induce apoptosis.

INTRODUCTION

Colon cancer is one of the most common malignancies both in the world and in China[1]. More and more patients with early colon cancer can now be found due to the improvement in the diagnostic techniques. Although surgery and chemotherapy are effective on patients with localized tumors, the prognosis of patients with advanced or metastatic tumors is not ideal. As a result, it is absolutely necessary to explore a novel treatment modality, namely the gene therapy. Just like other kinds of cancer, colon cancer is now recognized as a genetic disease. Colon cancer cells contain many genetic alterations which accumulate as tumor develops. This makes it possible to treat cancer with gene therapy[2-3].

Telomerase is a ribonucleoprotein consisting of two components, RNA and protein. The RNA gene of telomerase is termed as human telomerase RNA (hTR). Two protein subunits have been found, which were named as human telomerase-associated protein (TEP1) and human telomerase catalytic subunit or human telomerase reverse transcriptase (hTERT)[4,5]. Telomerase activity in humans has been detected in germline and tumor tissues as well as in established cultured cell lines[6]. In normal somatic cells, the absence or low expression of telomerase is thought to result in progressive telomeric shortening with each cell division[7,8]. Therefore, it has been suggested that reactivation of telomerase is a critical step in tumorigenesis and that interference with the regulation of telomerase activity may serve as a basis for cancer therapy[9,10]. However, to our knowledge, whether antisense gene therapy directing against hTR is effective on colon cancer is unknown. We reported here the effect of antisense oligodeoxynucleotide of telomerase RNA on human colon cancer cell line, and investigated the potential value of telomerase as a target for antisense gene therapy of colon cancer.

MATERIALS AND METHODS

Cell culture

SW480 cells, a human colon cancer cell line, were provided by Department of Biology, Wuhan University, China, and maintained in RPMI 1640-10% fetal bovine serum supplemented with 1 mmol/L L-glutamine, 100 U/ml of penicillin plus 100 µg/ml of streptomycin at 37 ℃ under 5% CO_2.

Cell counting

SW480 cells were counted with 5 g/L of trypan blue staining.

Oligodeoxynucleotide synthesis

Two oligodeoxynucleotides were synthesized as described by Feng *et al* and Norton *et al*[11,12]. Antisense oligodeoxynucleotides (As-ODN) with the sequence 5' TAGGGTTAGACAA-3' , which can recognize the RNA template region of telomerase, and missense oligodeoxynucleotide (Ms-ODN) with the sequence 5' TGTAAGGAACTAG 3' were synthesized by Beijing SBS Biotechnology Engineering Company using the 391 DNA synthesizer. The synthesized oligodeoxynucleotides were subjected to electrophoresis (PAGE) and purified (300V, 1.5 h).

Transfection of oligodeoxynucleotides

Transfection of phosphorothiate oligodeoxynucleotides (ODNs) was carried out with liposomal transfection reagent DOSPER (Roche Diagnostic GmbH) according to the manufacturer' s protocol. Briefly, cells were plated onto 6-well plates and incubated until the cells reached 70-80% confluence. The DOSPER was diluted with serum-free medium the day before transfection. Then, the desired amount of ODNs was incubated for 15 minutes with diluted DOSPER. The ODNs/ DOSPER mixture (100 µl) was added dropwise into 900 µl of serum-free RPMI 1640. After incubated for 6 hours at 37 ℃, 1 ml of RPMI 1640 containing 20% FBS was added into each

Groups	Active duration				
	24 h	48 h	72 h	96 h	120 h
As-ODN 10 μmol/L	0.872±0.194	0.406±0.232	0.386±0.146	0.307±0.203	0.289±0.213
Ms-ODN 10 μmol/L	1.063±0.249	1.285±0.179	0.959±0.273	0.109±0.243	1.247±0.178
Positive control	1.725±0.267	1.571±0.418	1.243±0.186	1.236±0.235	1.098±0.347
Negative control	0.349±0.092	0.312±0.076	0.283±0.089	0.063±0.072	0.057±0.023

well. Cells were harvested and analysed after 48, 72, 96 and 120 hours, respectively.

Telomerase activity assay

Telomerase activity was measured by polymerase chain reaction and enzyme linked immunosorbent assay (PCR-ELISA). Briefly, 2×10^6 cells were isolated, mixed with 200 μl of protein extraction buffer by vortes, and left on ice for 30 minutes. One hundred and seventy-five μl of supernatant was collected after centrifugation (16 000×g, 20 minutes, 4 ℃). PCR was performed in a system of 50 μl containing 25 μl of transfer reaction mixture, 2 μl protein extract and 2 μl primers, and 23 μl of nuclease-free water was added. The PCR condition was as the follows: at 25 ℃ for 30 minutes for primer elongation, at 94 ℃ for 5 minutes for telomerase inactivation. Thirty cycles of amplification were performed, each cycle was performed at 94 ℃ for 30 s for denaturation, at 50 ℃ for 30 s for annealing, and at 72 ℃ for 90 s for polymerization. Five μl of the amplified product and 20 μl of the denatured reagent were incubated at room temperature, 225 μl of hybridization buffer was then added and mixed, and 100 μl of them was distributed in the wells of a microtitering plate. After 2 hours of incubation (37 ℃, 300 rpm), 100 μl of anti-DIG-POD working solution was added and incubated for another 30 minutes, followed by the addition of 100 μl of TMB substrate solution, and 100 μl of stop reagent was added at last. The OD value in each well was read at the wave lengths 450 nm and 655 nm on a microtiter plate reader (Bio-RAD Model 550 microplate reader). The result of OD_{450} minus OD_{655} greater than 1.5 unit was judged as a positive control using a protein extract from immortalized telomerase-positive human embryonic kidney cells (293 cells). The negative control was considered as OD_{450} minus OD_{655} less than 0.2 unit by reading the protein extract pretreated with RNase A at 65 ℃ for 10 minutes. Telomerase activity was considered positive when the value of OD_{450} minus OD_{655} of a sample was at least 0.2 unit higher than that of the negative control, otherwise it was considered negative. Each sample was examined more than twice. The final value was presented as mean±SD after a statistical treatment by using t test.

Apoptotic features

To determine whether SW480 transfected with AS-ODN displayed an apoptotic morphology, the tranfected cells were observed under Olympus optical microscope and Hitach transmission electron microscope.

To determine the apoptotic rate and cell cycle distribution, the cells were fixed and stained by propidium iodide (PI, Sigma product), and analyzed by a FACSORT flow cytometer (Becton Dickinson). Briefly, cells were trypsinized, washed once in ice-cold PBS, and incubated with annexin-V-fluoroescein/PI, and then analyzed immediately by FACSORT flow cytometry. All data were analyzed using the Cell Quest software.

Statistical analysis

Results were expressed as mean±SD. Statistical analyses were carried out with the software package SPSS10.0. A P value less than 0.05 was considered statistically significant.

RESULTS

Inhibitory effect of antisense hTR ODNs on telomerase activity

SW480 cells were transfected with As-ODN (1.0 μmol/L) and Ms-ODN (1.0 μmol/L), and collected at 24, 48, 72, 96 and 120 hours after transfection respectively. Telomerase activities were measured by TRAP-ELISA. Following results were found. The telomerase activity of SW480 cells transfected with As-ODN was greatly inhibited compared with that in the Ms-ODN. The telomerase activity of SW480 cells transfected with As-ODN at 72 and 96 hours after transfection was significantly lower than that both at 24 hours and in positive control as shown in Table 1. These findings suggested that this inhibitory action was sequence specific and in a time-dependent manner.

Effect of antisense hTR ODNs on induction of SW480 cell apoptosis

Cytologic morphological changes SW480, transferred with 1 μmol/L As-ODN for 3 days, cytologic morphology was observed under Olympus optical microscope and Hitach transmission electron microscope. It was found that cells rounded up off the plastids, exhibiting cytoplasmic blebbing, fragmentation and chromatin condensation, features of apoptosis. No apoptotic features (normal morphology) were observed in SW480 transfected with 10 μmol/L Ms-ODN (Figure 1).

Figure 1 Morphplogic observation under transmission electron microscope. A: cells had no apoptotic features. B: cell rounded up off the plastic, exhibiting cytoplasmic blebbing, fragmentation and chromatin condensation, features of apoptosis.

Table 2 Effect of ODNs on induction of SW480 cell apoptosis (mean±SD)

Groups	Active duration		
	48 h	72 h	96 h
As-ODN 1 μmol/L	4.99±0.54	8.63±0.59	9.96±0.41
Ms-ODN 1 μmol/L	3.86±0.39	4.88±0.57	4.92±0.67
HRT blank	1.57±0.18	1.79±0.21	1.71±0.32

Detection of apoptotic cells

To determine the apoptotic rate, SW480 cells were transfected with 1 μmol/L As-ODN and Ms-ODN for 2 days. After permeabilization, the cells were stained with propidium iodide and analysed by flow cytometry. The apoptotic rate of SW480 cells transfected with As-ODN increased (4.99±0.54, 8.63±0.59,

and 9.96±0.41 at 48 h, 72 h and 96 h, respectively, *P*<0.001), but no significant changes of apoptosis were observed in SW480 cells transfected with 1 μmol/L Ms-ODN as shown in Table 2, indicating that this apoptotic induction was sequence specific and in a time-dependent manner.

DISCUSSION

Compared with normal somatic cells, cancer cells have an unlimited replicating capacity. This important characteristic of cancer, named immortality, has been gaining more and more attention, seeing that cancer cells might achieve cellular immortality through only a major pathway, the activation of telomerase[13]. Telomerase has been found to play an important role in carcinogenesis, thus becoming the basis of the widely held view of telomerase as a highly selective target for antisense gene therapy of cancer[14].

The RNA component of telomerase (hTR) was crucial to the telomerase activity[15-17]. Human cell lines expressing hTR mutated in the template region could generate the predictive mutant telomerase activity. Recent experiments have shown that antisense gene therapy directing against telomerase RNA component could effectively inhibit telomerase activity and induce apoptotic cell death in ovarian cancer, prostate cancer, bladder cancer, malignant gliomas and human breast epithelial cells[18-22]. However, whether such an anti-cancer effect can be obtained in human colon cancer is still unknown. Therefore, we examined the effect of antisense hTR oligodeoxynucleotide on human colon cancer cell line. As the results showed, our experiment clearly demonstrated that antisense-hTR oligodeoxynucleotide could significantly inhibit telomerase activity and induce apoptosis of human colon cancer cells, which was supported by the results obtained in our previous experiment[23]. All these findings provide the strong evidence that telomerase may be an ideal target for antisense gene therapy of human colon cancer.

Recently, it has been showed that telomerase activity was the dominant mechanism providing telomere maintenance to human immortalized cells. However, the exact mechanisms of how telomerase activity is regulated in tumour cells remain poorly understood. Some researchers have shown that telomerase activity correlated with the growth rate of immortal cells[24-26], whereas others found no significant association between telomerase activity and proliferation index in tissue specimens from breast carcinoma[27], gastric carcinoma[28], and Wilm's tumour[29].

Inhibition of telomerase activity has been proposed as a potential method for the treatment of human malignancies. It is suggested that telomerase inhibition may serve as an effective tool for eliminating tumour cells that have short telomeres. Such tumours may provide reasonable targets for agents that inhibit telomerase. These experiments await the development of specific inhibitors for the components of telomerase complex.

Abstract

AIM: To study the clinical and epidemiological features of patients with clonorchiasis so as to provide scientific evidences for the diagnosis and prevention of clonorchiasis.

METHODS: Stools from 282 subjects suspected of having clonorchiasis were examined for helminth eggs with modified Kato's thick smear and sedimentation methods, and their sera were tested for HAV-DNA, HBV-DNA, HCV-RNA, HDV-RNA and HEV-RNA with polymerase chain reaction (PCR). Clinical symptoms of patients with clonorchiasis only were analyzed, and their blood samples were tested for circulating antigen (CAg) with Dot-ELISA, esoinophilic granulocyte count, and alanine aminotransferase (ALT). Meanwhile, they were asked to provide data of occupation, eating habit, hygienic habit and knowledge of clonorchiasis. In addition, the ecosystem of the environment in epidemic areas was surveyed.

RESULTS: Among the 282 patients, 61 (21.43%) were infected with clonorchis sinensis only, 97 (34.64%) were co-infected with clonorchis sinensis and other pathogens, 92 (32.86%) were infected with hepatitis virus only and 31 (11.07%) neither with clonorchis sinensis nor hepatitis virus. Among the 61 patients with clonorchiasis only, there were 14 (22.95%) subjects with discomfort over hepatic region or epigasfrium, 12 (19.67%) with general malaise or discomfort and inertia in total body, 6 (9.84%) with anorexia, indigestion and nausea, 4 (6.56%) with fever, dizziness and headache (6.56%), and 25 (40.98%) without any symptoms; sixty one (100%) with CAg (+), 98.33% (59/60) with eosinophilic granulocytes increased and 65.00% (39/60) with ALT increased. B-mode ultrasonography revealed 61 cases with dilated and thickened walls of intrahepatic bile duct, and blurred patchy echo acoustic image in liver. Twenty-six cases had stones in the bile duct, 39 cases had slightly enlarged liver with diffuse coarse spots in liver parenchyma. Twenty cases had enlarged gallbladder with thickened coarse wall and image of floating plagues, 9 cases had slightly enlarged spleen. By analysis of epidemiological data, we found that the ecologic environment was favorable for the epidemiology of clonorchiasis. Most patients with clonorchiasis were lack of knowledge about the disease. Their living environment, hygienic habits, eating habits and their occupations were the related factors that caused the prevalence of the disease.

CONCLUSION: The clinical symptoms of clonorchiasis are non-specific, and the main evidences for diagnosis of clonorchiasis should be provided by etiologic examination,

B-mode ultrasonography and clinical history. The infection of clonorchis sinensis is related to occupations, bad eating habits and lack of knowledge about prevention of the disease.

INTRODUCTION

Clonorchiasis, a food-borne infection by eating raw fish contaminated with *Clonorchis sinensis* metacercariae, is more frequently found in individuals along the great rivers and streams in areas of China, northern Vietnam, Korea and other Eastern Asia countries[1-8]. After oral infection, *C. sinensis* often engulfs the biliary epithelial tissues and blood cells in the intestine, and causes cholangitis with marked eosinophilic infiltration, biliary adenomatous hyperplasia, bile duct obstruction, and subsequently cholangiofibrosis[9-21]. In an effort to provide scientific evidences for diagnosis of this disease, clinical and epidemiological data of patients with clonorchiasis were analyzed in this study.

MATERIALS AND METHODS

Subjects
Two hundred and eighty-two individuals suspected of being infected with clonorchiasis were involved in this study, including 187 males and 95 females. Their age distribution was as follows: 29 aged 10-16 years, 182 aged 17-55 years and 71 aged 55-67 years.

Methods
Etiological examination Stools from 282 subjects were examined for helminth eggs with modified Kato' s thick smear and sedimentation methods, and sera of them were tested for HAV-DNA, HBV-DNA, HCV-RNA, HDV-RNA and HEV-RNA with polymerase chain reaction (PCR).
Analysis of clinical symptoms Clinical symptoms of the patients only with clonorchiasis diagnosed by microscopic fecal examinations were expressed as percentages according to the formula (the number of patients with some symptoms/the total number of the patients with clonorchiasis)×100% and subsequently statistical analysis was conducted.
Laboratory examination Blood samples of patients only with clonorchiasis were detected for circulating antigen (CAg) with Dot-ELISA, counted for esoinophilic granulocytes, and tested for alanine aminotransferase (ALT). The number of esoinophilic granulocytes above $0.5×10^9/L$ was regarded as increased, and the value of alanine aminotransferase (ALT) above 30 u/L was judged as abnormal.
Examination by B-mode ultrasonography Abdominal part of the patients only with *C. sinensis* eggs in their stools was examined by B-mode ultrasonography.
Analysis of epidemiological data A questionnaire was given to the patients only with clonorchiasis, including occupation, eating habits, hygienic habits and knowledge about prevention

of clonorchiasis. In addition, we surveyed the ecosystem environments in the epidemic areas.

RESULTS

Etiological examination

Of the 282 individuals investigated, 21.43% (61/282) were confirmed to be infected with *C. sinensis* only by etiological examination, 34.64% (97/282) were infected with *C. sinensis* and other pathogens, 32.86% (92/282) were infected with hepatitis virus only, and 11.07% (31/282) with neither *C. sinensis* nor hepatitis virus (Table 1).

Table 1 Results of etiological examination

Types of pathogens	Case numbers	Percentages (%)
Infection of *C. sinensis* only	61	21.63
Infection of *C. sinensis* and other pathogens	97	34.40
Infection of *C. sinensis* and other helminth	32	11.35
Infection of *C. sinensis* and hepatitis virus	24	8.51
Infection of *C. sinensis*, other helminth and hepatitis virus	41	14.54
Infection of hepatitis virus only	92	32.62
Neither with C. sinensis nor hepatitis virus	32	11.35
Totally	282	100

Analysis of clinical manifestations

Among the 61 patients with clonorchiasis only, 14 (22.95%) subjects had discomfort over hepatic region or epigasfrium, 12 (19.67%) had general malaise or discomfort, 6 (9.84%) had anorexia, indigestion and nausea, 4 (6.56%) had fever, dizziness and headache, and 25 (40.98%) had not any symptoms.

Laboratory examination

The results of laboratory examination of the 61 patients with clonorchiasis only showed that the positive rates of CAg were 100%, eosinophilic granulocytes increased in 98.33% (59/60) patients and the values of ALT increased in 65.00% (39/60).

Examination by B-mode ultrasonography

In B-mode ultrasonography, 61 cases had dilated and thickened walls of intrahepatic bile ducts. Blurred patchy acoustic image was seen in liver. Twenty-six cases had calculi of intrahepatic ducts, 39 cases had slightly enlarged liver with diffuse coarse spots in liver parenchyma. Twenty cases had enlargement of gallbladder with thickened rough wall, floating plagues with postural variation were seen in the gallbladder. Nine cases had slightly enlarged spleen.

Analysis of epidemiological data

Occupational structure The constituent ratios of the occupation of 61 patients with clonorchiasis only were: fishermen 37.7%, fishmongers 9.84%, workers in processing fish products 16.39%, officials 19.67%, students 9.84% and others 6.56%.

Eating habits According to the results of questionnaires sent to 61 patients with clonorchiasis only, there were 26 subjects with habits of eating raw fishes and shrimps, 41 eating undercooked fish and shrimps, 48 with kitchen knives used in both raw and cooked food, 30 grasping food directly after contacting live fish and shrimps with unwashed hands, and 11 drinking unclean or unboiled crude water.

Knowledge about prevention of clonorchiasis All patients, did not have any knowledge about metacercaria of *C. sinensis* that might be in fish and shrimps of Huaihe River System. They had no idea about the possible infection with *C. sinensis* after ingestion of raw and undercook fish and shrimps. Even

if infected with *C. sinensis*, symptoms such as epigastric pain, diarrhea, decreased appetite, dizziness, *etc.*, would occur.

Ecologic survey Among the sixty-one patients confirmed to be infected with *C. sinensis* only, 18 lived in villages along the Huaihe River, 19 lived near fishponds. We found a crowd of domestic animals coming and going on both banks of the river, such as chickens, ducks, dogs, pigs, *etc.*, and murine animals, hares and wild cats running in brushes and weeds near the river. In addition, wild ducks and birds, frolic king were looking for food on the river. Some mollusca, like *viviparidae*, *unionidar*, *bithyniidae*, *lymnaeidae*, and some fish and shrimps, such as *Pseudorasbora parva*, *Ctenopharyngodon idellus*, *Mylopharyngodon aethops*, *Cyprinus carpio*, *Lobstergrow* were found in waterweeds in the river.

About two thousand kinds of mollusca were collected and examined for cercaria of *C. sinensis*, and the positive rate was 0.25% (5/2000). When Ctenopharyngodon idellus was infected with cercaria, we could separate encysted metacercaria from its body. Similarly, the adult worms could be found from cats that were infected by encysted metacercaria. In addition, the positive rate of encysted metacercaria in fish and shrimps was 9.50% (19/200).

DISCUSSION

Clonorchiasis is endemic in East Asian countries and about seven million subjects were estimated to be infected with the fluke[22,23]. After oral infection with *C.sinensis* metacercariae, the organism excysts in the digestive tract and migrates up to the bile duct where it grows into adult worms. Infected humans excrete faeces containing *C.sinensis* eggs, and human infections could be diagnosed by microscopic fecal examination with demonstration of the characteristic eggs[24-26]. In the present study, we examined 282 subjects suspected of being infected with *C. sinensis* with methods of modified Kato' s thick smear and sedimentation, and 61 individuals were found to be infected with *C.sinensis* only, while 97 were co-infected with *C.sinensis* and other pathogens, 92 were infected with hepatitis virus only, 31 had neither *C. sinensis* nor hepatitis virus. Etiological examination is a major method in the differential diagnosis of clonorchiasis and other diseases of the liver and biliary tract.

The prevalence of clinical symptoms was determined by the fluke quantity, frequency of infection and the hosts immunities. Subjects with mild infection of *C.sinensis*, often had symptoms or only some epigastric discomfort, anorexia, dyspepsia, *etc*. Subjects with moderate infection often had inertia, lassitude, dyspepsia, abdominal pain and other mild complaints, all of which could also be obviously observed in the subjects with severe infection and cirrhosis of liver. Portal hypertension and ascites might finally occur[27-32]. The outcome of this study showed there were 40.98% of patients without any symptoms and others with symptoms of epigastric discomfort, general malaise, inertia, anorexia, dyspepsia, nausea, fever, dizziness, headache, *etc*. had no specificity. Differential diagnosis should include schistosomiasis Japonica, fascioliasis and fasciolopsiasis.

During the development of *C. sinensis* in human body, CAg was produced and released into circulation. Generally, CAg might be detected in sera of the subjects three days after infection[33,34]. For this reason, detection of CAg may be used to examine whether live worms exist in human body or not, and for check up of treatment effects. By Dot-ELISA, all of the 61 *C. sinensis* egg-positive individuals were positive, although 40.98% of them had no symptoms. So detection of CAg may provide an evidence for diagnosis of clonorchiasis. In addition, results from this study showed that eosinophilic granulocytes were increased in 98.33% patients, ALT was increased in 65% patients and image changes were found in

liver with B-mode ultrasonography in all patients. These are all helpful in the diagnosis of clonorchiasis.

Both natural and social factors affect transmission of *C. sinensis*. We investigated the ecologic system in the Huaihe River on the spot and saw various kinds of mollusca crawling on water plants and some fish and shrimps swimming in the river, all of which are intermediate hosts of *C. sinensis*. Near the river, a large number of domestic animals, livestock, murine animals, hares and wild cats are reservoir hosts. Moreover, the villagers have got accustomed to feeding fish with their own stools and domestic animals with raw fish and shrimps, which help *C. sinensis* to be transmitted from one host to another. On both banks of the river, simple toilets and pigsties are arranged everywhere, and the villagers brush chamber pots in the river without scruple. Terribly, they live on water untreated from the river. All of these natural environments and human activities contribute to overflowing of *C. sinensis* in this area.

The incidence of clonorchiasis was shown in this study to vary greatly and was related to occupations, and was higher in fishermen, fishmongers, workers in processing fish products, officials than in those with other occupations. Because of bad working and eating habits, they have chances to be infected with encysted metacercaria. Therefore, knowledge about prevention of clonorchiasis should be strengthened in these populations to correct their bad eating and health habits and to reinforce their protection consciousness.

Abstract

AIM: The effects of cobalt, copper, cadmium and barium ions on the cysts of *Entamoeba histolytica* (*E. histolytica*), an amebic dysentery agent, cultured in Robinson medium were investigated.

METHODS: *E. histolytica* cysts and trophozoites isolated from a patient with amebiasis were cultivated in the medium, incubated at 37 ℃ for a period of 4 days and 40×10^4/ml amebic cysts were then transferred to a fresh medium. At the second stage, 0.05, 0.1 and 0.2 mM of selected metal ions were added to the medium, and the effects of these ions on parasitic reproduction compared with the control group were observed.

RESULTS: It was determined that the number of living parasites in all the groups containing metal ions decreased significantly starting from 30 minutes ($P < 0.01$). $CuCl_2$ showed the highest lethal effect on *E. histolytica* cysts, whereas the lowest lethal effect was observed with $CoCl_2$. It was also seen that the number of living cells was decreased as the ion concentration and exposure time were increased, and that there were no living parasites in the medium at the end of 24 h ($P < 0.01$).

CONCLUSION: It may be stated that the effect of ever-increasing contamination of the environment with metal waste materials on parasites should be investigated further.

INTRODUCTION

Amebiasis, which infects nearly 10% of the world population and is responsible for mortality and morbidity in developing countries in particular is caused by a protozoon, *Entamoeba histolytica* (*E.histolytica*)[1]. The form of the agent infecting humans is the 4 nuclei cysts, shed into the environment with feces. The cysts, which can survive in the environment for a long time, can carry on their life cycle with fecal-oral contamination[2,3].

Like many other protozoa, this particular parasite develops complex metabolic structures under different environmental conditions[4]. Reproduction of *E. histolytica* in *in vitro* culture provides a better understanding of its biological characteristics, its pathogenesis and adaptation to environmental conditions[2]. The metabolism of the parasite in a medium environment varies according to the age of the culture, its oxidation-reduction potential, as well as the composition, the temperature of the medium and the accompanying bacteria[5,6]. It was reported that *E. histolytica* cysts reproduced under axenic conditions had cyst walls, which were different from, and weaker than those found under natural conditions[7]. For this reason, it is believed that it would be more appropriate to use xenic media as they reflect the morphological structure and living conditions of the parasite[8]. One of the most commonly and successfully used xenic media is the one defined by Robinson[9].

In these complex biochemical reactions of microorganisms, certain metal cations play an important role as trace elements[10]. However, some of them are not favored by the ecosystems of living cells, and doses which accumulate in the cell in time (metal ions) do not agree with life[11,12]. Heavy metal ions in particular bind to sulphydril (-SH) groups and form complexes, leading to toxic effects on living cells. This situation can be determined by the blurring of the reproduction media of microorganisms especially in the experimental studies carried out with *in vitro* cultures[13]. Setting out from this point, knowing the reaction of *E. histolytica* cysts shed into the environment with feces to the metal ions found in the area for various reasons will especially help understand the impact of the contamination by these ions on the parasite population[14,15].

In this study, we investigated the effects of cadmium (Cd+2), copper (Cu+2), barium (Ba+2) and cobalt (Co+2) ions on *E. histolytica* clinical isolate xenically produced in Robinson medium. In the light of the data we obtained, we also investigated what kinds of effects these metal ions produced with different intracellular concentrations in the parasite depended on time, and whether there were any differences among these ions with respect to their tendency to produce such effects.

MATERIALS AND METHODS

Clinical isolate and culture

E. histolytica fresh clinical isolate was obtained from a patient with amebiasis who came to the laboratory of Dokuz Eylul University Medical Faculty Department of Parasitology. As a result of an examination of the stool samples of the patient by wet mount and Lugol's iodine and trichrome staining methods, *E. histolytica* cysts and trophozoites were determined and the specimen was cultivated in Robinson medium[9]. The tubes were incubated at 37 ℃ for 4 days without subculturing. The cysts were then washed with sterile distilled water at pH 7 and counted with a haemocytometer. The 40×10^4/ml amebae cysts were transferred to a fresh medium under the same conditions and ions prepared at different molarites were immidiately added to the tubes.

Cd+2, Cu+2, Ba+2 and Co+2 ion concentrations

Cd+2 [Cadmium chloride ($CdCl_2.5/2H_2O$) (Merck; NJ, USA)],

Cu^{+2}[Cupric chloride (CuCl$_2$.2H$_2$O) (Merck; NJ, USA)], Ba^{+2} [Bariumchloride (BaCl$_2$.2H$_2$O) (Riedel-de Haën; Seelze, Germany)] and Co^{+2} [Cobalt chloride (CoCl$_2$.6H$_2$O) (Carlo Erba Reagenti; Rodano (Mi), Italy)] ions prepared at 3 different molarities, namely 0.05, 0.1 and 0.2 mM, were added to the study group[15]. The remaining tubes, on the other hand, were kept as control group without addition of metal ions, and also serum was added to the control tubes. Three tubes were prepared for each ion molarity and also for control group. Each determination was performed in triplicate.

Parasite counting

All the medium tubes were incubated at 37 ℃. After 0.5, 1, 2, 3, 5, 7 and 24 h, the tubes were stirred for 5-10 seconds to achieve a homogeneous distribution and a drop of medium specimen was taken with the help of a Pasteur pipet. A drop of 1% eosin saline solution was added to the specimen. Unstained cystic structures were considered to be alive, whereas those which let pink-red stains in were regarded to be dead. Living cysts were counted with a haemocytometer and the measurements were recorded.

Statistical analysis

All the groups in this study were evaluated by means of GLM-repeated measures, post hoc Tukey in the SPSS for windows 8.0 statistical program and Mann-Whitney U test within themselves. $P<0.05$ was considered significant.

RESULTS

The number of living amebae per ml determined in each tube at 0.5, 1, 2, 3, 5, 7 and 24 h after metal ions and serum were added to the medium environment, is shown in Figure 1. The numbers of living cells were significantly decreased in all the groups compared to control group ($P<0.01$). It was determined that the most effective metal ion was Cu^{+2} ($P<0.01$), in contrast the least effective metal ion was Co^{+2}. In all the groups, the number of living cells was decreased as the concentration of the metal ions was increased ($P<0.01$).

Figure 1 Effect of different concentrations of metal ions on *E. histolytica* cysts. X-axis: the molarities of ion concentration. Y-axis: The alteration of living parasite counts dependent on time and ion molarities.

Judging from the facts that they let 1% eosin-saline solution in themselves and that their cell walls degenerated and degranulated, it was found that the amebae cysts were dead after 24 h at each of the 3 concentrations of all the metal ions. It was also observed that heavy metals with larger atomic numbers affected the functions of intracellular physiologic cations, forming metal complexes. Such a complex formed with Cu^{+2} was seen at any concentration for Cd^{+2}, however, the

formation of complexes was started from 0.1 mM. The formation of this complex was indicated by the blurring of the medium.

As for the effect of Co^{+2}, it was found that *E. histolytica* cysts survived until the end of the 7th h at 0.05 and 0.1 mM concentrations, whereas this was not the case for the other metal ions. Similarly, it was observed that at 0.2 mM of Co^{+2} living amebae cysts were found at the end of the first hour only ($P<0.01$).

It was also observed that most of the cysts in the control group tubes, cultivated in a fresh medium, transformed into trophozoites and started to reproduce.

DISCUSSION

To be aware of the effects of toxic metals on living things is of great importance, especially in view of the ever-increasing environmental pollution. A number of researches about the effects of metal ions on the physiologic functions of various microorganisms are available[16-18].

It is believed that the toxic effect of Cd^{+2}, an important heavy metal, might be associated with the denaturation of proteins as a result of its binding to the thiol groups in living cells or with membrane damage stemming from its interaction with Ca^{+2}[17]. It was reported that the toxic effect of Cd^{+2} on the culture medium of *Trypanosoma brucei brucei* was at 0.045 mM level[19]. We determined in this study that when we used 0.05 mM Cd^{+2} as the lowest concentration, the lethal effect leading to the death of living *E.histolytica* cysts started at 0.5 h and was increased time-dependently. We also observed that, Cd^{+2} made the most complexes in the medium starting from 0.1 mM. In this context, the result we obtained was comparable with relevant literature data[19].

Cu^{+2}, however, can interact with radicals, oxygen in particular. These radicals also cause Cu^{+2} to become toxic. A study carried out on pseudomonas by means of spectroscopy, reported that Cu^{+2} caused greater damage than Co^{+2} did[20]. In the present study, we discovered that the lethal effect of metal ions at different concentrations was dependent on time rather than the extent of damage and found that Cu^{+2} ions were more effective than Co^{+2}. Another study in which the toxic effect of cadmium acetate and copper sulphate salts on the mouse trachea culture was investigated, reported that the effect of cadmium acetate was shown after 35 minutes, while that of copper sulphate came about after 85 minutes although equal amounts were added to the medium, accordingly the effect of cadmium acetate on the cell was greater[21]. As a different view, in a study where the cytotoxic effect of cadmium and copper was investigated in the culture of *Merceneria mercenaria*, the cytotoxicity concentration of Cd^{+2} was started at 0.1-1.5 mM and that of Cu^{+2} at 0.01-0.1 mM[22]. In our study, however, we investigated the effect of 0.05, 0.1 and 0.2 mM metal ions on *E. histolytica* cysts in a culture environment. When the effect of both metal ions was investigated starting as early as 0.5 h, we found the toxic effect of Cu^{+2} on amebae cysts to be greater. Cu^{+2} ions also bound to various compounds and formed complexes. These complexes were determined by the blurring of the medium environment and led to toxic effects on *E.histolytica* cysts at each molarity.

On the other hand, Co^{+2} enters the composition of B$_{12}$, the main cofactor. This element accumulates in the core structure of microorganism cells. Ermolli *et al*. reported that 0.475 mM Co^{+2} produced a toxic effect on HaCaT human keratinocytes and that this effect could only be observed after 4 h[23]. It was found in our study however, the lethal effect of Co^{+2} on *E. histolytica* was presented at lower concentrations such as 0.05 mM and was increased dose-dependently. It was also observed that amebae cysts maintained their vitality, though at a minimal level, at all the three concentrations at the end of

the 7th h and that no living parasite remained in the culture medium at the end of the 24th h. In the light of these data, we believe that Co[+2] at low concentrations has a slowly developing lethal effect on *E. histolytica* cysts.

Certain studies aiming at determining the effects of Ba[+2] have been carried out in cell cultures[24,25]. Borella *et al*. reported that addition of 10[(-4)]-10[(-6)] mol/L Ba[+2] to the culture medium did not have any effect on reproduction[24]. When we investigated the effect of 0.05, 0.1 and 0.2 mM Ba[+2] on *E. histolytica* cysts in Robinson medium, we found that the lethal effect was dependent on both the dose and time.

CdCl$_2$, CuCl$_2$, BaCl$_2$ and CoCl$_2$ were used for evaluating the effects of these metal ions on the growth of *E. histolytica* cysts. As it was shown the only anion was chlor, all differed in the metal cations.

It would not be surprising to predict that investigating the effects of various factors causing environmental pollution on the life cycle of parasites, which have an important place among microorganisms, would be one of the objectives of future scientific studies. Accordingly, when the effect of Cd[+2], Cu[+2], Ba[+2] and Co[+2] ions on *E. histolytica* was investigated, we determined that these metal ions, led by Cu[+2], prepared at concentrations of 0.05, 0.1 and 0.2 mM had a lethal effect on the parasite. Considering the fact that the life cycle of *E. histolytica* depends on mature cysts with 4 nuclei shed into the environment with feces, this particular result may have a considerable significance in terms of the ecological balance of the environment, which is being contaminated by various metal waste materials.

Abstract

AIM: It is known that toxoplasmosis rarely leads to various liver pathologies, most common of which is granulomatose hepatitis in patients having normal immune systems. Patients who have cirrhosis of the liver are subject to a variety of cellular as well as humoral immunity disorders. Therefore, it may be considered that toxoplasmosis can cause more frequent and more severe diseases in patients with cirrhosis and is capable of changing the course of the disease. The aim of this study was to investigate the frequency of toxoplasmosis in patients with cirrhosis.

METHODS: Serum samples were taken from 108 patients with cirrhosis under observation in the Hepatology Polyclinic of the Gastroenterology Clinic, and a control group made up of 50 healthy blood donors. IFAT and ELISA methods were used to investigate the IgG and IgM antibodies, which had developed from these sera.

RESULTS: Toxoplasma IgG and IgM antibody positivity was found in 74 (68.5%) of the 108 cirrhotic patients and 24 (48%) of the 50 people in the control group. The difference between them was significant ($P < 0.05$).

CONCLUSION: In conclusion, it was found that the toxoplasma sero-prevalence in the cirrhotic patients in this study was higher. Cirrhotic patients are likely to form a toxoplasma risk group. More detailed studies are needed on this subject.

INTRODUCTION

Toxoplasmosis is a protozoan disease that infects 35-40% of the adult population of the world and demonstrates varying clinical manifestations. Its active agent is *Toxoplasmosis gondii* (*T. gondii*). In man tissue parasitism during the proliferative phase may occur without signs of symptoms. It may lead to a transient illness characterized by lymadenopathy, fever and fatigue, or a severe disease. Severe manifestations of the disease most commonly occur in patients with impaired immunity[1].

In most countries, seroprevalence of toxoplasma ranges between 20% and 60%. The prevalence is quite low in extremely dry and cold regions. It has been reported that the prevalence is rather high in warm and humid areas[2].

Cats, small mammals and birds take place in the usual life cycle of *T. gondii* in nature. Humans join this chain as a result of their close relationship with cats. Toxoplasmosis is never encountered in the small Pacific islands where there are no cats. In the group investigated for toxoplasmosis, the prevalence in Turkey ranged between 44% and 55%[3,4].

Toxoplasmosis may rarely cause various liver pathologies due to granulomatose hepatitis in patients with normal immune systems[1,5-8].

Patients with cirrhosis of the liver demonstrate various cellular and humoral immunity disorders[9-12]. For this reason, it may be thought that toxoplasmosis may lead to more frequent and more severe diseases in patients with cirrhosis and change the course of the disease.

What was investigated in this study was the frequency of *T. gondii* antibodies in the cases of cirrhosis associated with various reasons.

MATERIALS AND METHODS

One hundred and eight patients with cirrhosis from the Hepatology Polyclinic of the Gastroenterology Clinic, and a control group comprising 50 healthy blood donors of similar age and sex were taken in the study. Serum samples were taken from the patients and control group and kept at -20 ℃ until toxoplasma serological tests were performed.

IgM and IgG antibodies from the sera were investigated by IFAT and ELISA methods.

ELISA method

Dissolved antigen was prepared based upon literature data provided by Herlow *et al*, Naot *et al*[13,14]. Serum samples were diluted up to 1/64, 1/256, 1/1 024, 1/4 096 to determine IgM antibodies and up to 1/256, 1/1 024, 1/4 096, 1/8 000, 1/32 000 to determine IgG antibodies. The sera were read at a 405λ wavelength ELISA reader (Titertek II). The mean absorbance values of negative controls were added to the 2 standard deviation values of these absorbance values. Those above the cut-off value obtained were accepted as positive and compared with the values expressed by the control sera to assess the suspected sera. For IgG 1/1 024 and above and for IgM 1/256 and above were accepted as significant titers with regard to active disease[15].

IFAT method

Particle antigen was prepared according to data from Garin *et al*, Remington *et al*[16,17]. Serum samples were diluted and assessed semiquantatively. The dilution of the sera within the scope of the study was 1/16, 1/64, 1/128, 1/256, 1/512, 1/1 024, 1/4 096 for both IgG and IgM. The results obtained were assessed by a fluorescence microscope (Nikon) at 490 nm stimulation, 510 nm barrier filter wavelength and 20×10 magnification. For IgG 1/256 and above and for IgM 1/16 and above were accepted as significant titers with regard to

Table 1 Cirrhosis etiology of 108 patients

[a]$P<0.05$.

active disease[15].

Comparisons between the cirrhotic patients and the control group pertaining to antibody positivity and sex were performed according to Fisher exact age distribution *t* test.

RESULTS

Cirrhosis etiology in patients is shown in Table 1. The cirrhotic patients and the control group demonstrated similar sex and age distributions (Table 2). Toxoplasma IgG and IgM antibody positivity was determined in 74 (68.5%) of the 108 cirrhotic patients and 24 (48%) of the 50 individuals in the control group. The difference was significant ($P<0.05$). Significant titers were found with respect to active disease (IgG 1/1 024 and above, IgM 1/256 and above for ELISA, and IgG1/256 and above, IgM 1/16 and above for IFAT) were found in 31 (28.7%) of the cirrhotic patients and 4 (8%) of the control group. The difference was significant (Table 2).

DISCUSSION

Toxoplasmosis is a protozoan disease that is widespread all over the world and demonstrates varying clinical manifestations. Determination of its incidence in various risk groups in the society and establishment of these risk groups play a significant role in taking the necessary precautions against this disease.

In this study toxoplasma IFAT and ELISA antibody positivity was significantly higher in cirrhotic patients. Besides, the significant titers were found to be higher with regard to active disease.

Toxoplasmosis can be frequently found in the general population all over the world. It has been reported that it was encountered at a higher rate in warm and humid regions compared to cold and dry places[2]. No sero-epidemiologic studies that would properly demonstrate the toxoplasmosis prevalence in the whole population in Turkey have been reported so far. The studies carried out merely reflect the results of those that have been brought to and evaluated in various laboratories with suspicion of toxoplasmosis. In a study carried out in Elazığ, a region of Turkey that is comparatively underdeveloped from the socio-economic point of view, Asci *et al.* found toxoplasma antibodies in 55% of 1 641 serum samples[3]. In a study covering the Aegean region between 1991-1995, Altintas *et al.* determined toxoplasma seropositivity in 4 651 (49.4%) of 9 410 individuals in their study[18]. Sutcu *et al.*

found the toxoplasma IgM positivity was 10% and IgG positivity was 44% in Konya province between 1993 and 1997[4]. The seroposivity rate in Turkey generally varies between 44% and 55%. These values are quite close to the rates we have determined in our control group (48%), but lower than those in cirrhotic patients (68.5%). No other study has investigated the toxoplasma antibody frequency in cirrhotic patients. This study is probably the first one investigating the toxoplasma seroprevalence in cirrhotic patients.

The reasons why both the antibody positivity and titers were significant with regard to active disease are not known. Could toxoplasma, known to cause partial damage to the liver, have a role in the onset and clinical course of cirrhosis?

This study did not contain any research into the activity of toxoplasma. Nevertheless, the fact that antibody titers are higher in cirrhotic patients leads one to think that these people might have an active disease. We are also planning another study to determine whether active disease develops in cirrhotic patients by monitoring the changes in the long-term toxoplasma titers.

To sum up, the toxoplasma sero-prevalence in cirrhotic patients in our study was found to be higher. Cirrhotic patients may well form a risk group for toxoplasma. More detailed studies need to be carried out on this particular subject.

Abstract

AIM: To study the effect of probiotics on interleukin-8 secretion in intestinal epithelia when stimulated by proinflammatory cytokines.

METHODS: Colonic adenocarcinoma HT29 cells were cultured and divided into four groups: control, TNF-α (group T in short), bifidobacterium (group B), lactobacillus (group L). B. Longum and L. bulgaricus were suspended in culture medium with a concentration of 1×10^8 cfu/ml and added into 24 wells respectively. One hour later TNF-α (10 ng/ml) was added into each well of groups T, B, L. The supernatants were collected and measured for IL-8 after 3 hours, nuclear factor-κB (NF-κB) p65 was also examined by Western blotting.

RESULTS: There was less interleukin-8 secretion in HT29 cells when preincubated with B. Longum or L. bulgaricus compared with group T. Less p65 appeared in nuclei in groups B and L compared with group T, as detected by Western blot.

CONCLUSION: Probiotics can suppress interleukin-8 secretion in intestinal epithelia when stimulated by proinflammatory cytokines, which is most likely mediated by NF-κB.

INTRODUCTION

Intestinal epithelium is an important factor of gut mucosal barrier, and participates in innate immunity. Intestinal epithelia are capable of releasing some proinflammatory cytokines such as IL-8 when stimulated by cytokines like TNF-α, and can response to enteric pathogens and release some proinflammatory cytokines which in turn direct the movement of inflammatory cells of the lamina propria[1]. Probiotics, including bifidobacterium, lactobacillus play an essential role in the completeness of intestinal mucosa barrier. For example, some probiotic strains could modulate intestinal mucosal immune response, some could play protective roles by inhibiting the adhesion of pathogenic bacteria to intestinal epithelia. The present study was to investigate the effect of probiotics on IL-8 secretion of intestinal epithelium induced by TNF-α, and its possible mechanism.

MATERIALS AND METHODS

Reagents
rh TNF-α was obtained from Pepro Tech Ec Ltd,UK. Rabbit anti-human NF-κB p65 polyclonal antibody, peroxidase-conjugated goat anti-rabbit IgG were purchased from Santa Cruz Biotechnology Inc.,USA. Human IL-8 ELISA kit was supplied by Jingmei Biotech Co. Ltd., China. BHI-agar was provided by Oxoid Co.,UK. TMB membrane peroxidase substrate system was provided by KPL Inc., USA.

Methods
Bacteria Bifidobacterium longum and lactobacillus bulgaricus LB10 were provided by the Department of Microbiology, Huaxi School of Stomatology, Si chuan University. The strains were grown at 37 ℃ in static, nonaerated BHI-agar to reach the mid-log phase. Bacteria were harvested by centrifugation at 2 500 g for 15 min at 20 ℃. After two washes in sterile PBS pH 7.4, at 25 ℃, the bacteria were resuspended in PBS. Cell counts in the bacteria suspension were estimated by optical density at 600 nm absorbance (BioMerieux, Germany). Then the bacteria were added to the cell culture wells at appropriate dilution to reach a final concentration of 10^8 cfu/ml of medium.
Cells and bacteria coculture HT29 cells were grown in RPMI1640 with 10% fetal calf serum, and divided into four groups: control, TNF-α (group T in short), bifidobacterium (group B), lactobacillus (group L). When grown to confluence in single layer, cells were washed three times with PBS pH 7.4, to remove culture medium and nonadherent cells. The bacteria in culture medium were transferred into individual wells respectively. TNF-α (10 ng/ml) was added into each well of groups T, B, L 1 hour later. The supernatants were collected and centrifuged for measurement of IL-8 after 3 hours.
IL-8 enzyme-linked immunosorbent assays IL-8 enzyme-linked immunosorbent assays (ELISA) were performed according to the manufacturer's instructions. In short, polyclonal goat anti-human IL-8 antibodies were used as capturing antibodies, biotinylated polyclonal rabbit anti-human IL-8 antibodies as detecting antibodies. Streptavidin-HRP and TMBS were added as color indicator. Plates were read at 450 nm of wavelength right after color reaction was stopped with acid. All procedures were performed at room temperature.
Assessment of NF-kB activation by Western blotting Nuclear extracts were prepared according to the protocol described by Schreiber, et al[2]. Nuclear proteins were separated by SDS-polyacrylamide mini-gel electrophoresis at a constant current of 30 mA for 150 min, then transferred to nitrocellulose membranes and stained with ponceau S to verify equal protein loading. Membranes were blocked in 5% milk in Tris-buffered saline for 4 h at 4 ℃, incubated overnight at 4 ℃ with anti-human p65 polyclonal antibody (at a dilution of 1:1 000) followed by 1 h incubation at room temperature with peroxidase-conjugated goat anti-rabbit IgG (1:2 000). Finally,

the membranes were incubated in TMB membrane peroxidase substrate solution.

RESULTS

IL-8 secretion

Concentrations of IL-8 in supernatants of each group are shown in Figure 1. The concentration of IL-8 in control was only 172.2 ± 42.1 ng/L. When stimulated by TNF-α, HT29 cells secreted a large number of IL-8, and the concentration of IL-8 in group T was 639.5 ± 62.3 ng/L. However, when preincubated with B. Longum or L. bulgaricus, HT29 cells produced less IL-8, compared with group T, and the concentrations of IL-8 were 461.8 ± 76.7 ng/L, 515.4 ± 55.4 ng/L in groups B and L, respectively.

Figure 1 Concentrations of IL-8 in each group (mean±SD). Natural interleukin-8 expression was seldom found in HT29 cells of control group. When stimulated by TNF-α (10 ng/ml), HT29 cells secreted a large number of IL-8, and the concentrations IL-8 in groups T, B and L were significantly increased than that in control ($P<0.001$). However, there was some difference in the concentration of IL-8 among groups T, B and L. There was less interleukin-8 secretion in HT29 cells when preincubated with B. Longum or L. bulgaricus in groups B and L compared with group T ($P=0.002$, 0.01, respectively), but there was no difference in concentration of IL-8 between groups B and L ($P=0.068$).

Detection of nuclear p65

There was little NF-κB p65 in nuclei of normal epithelia without any stimuli, and it was very difficult to detect p65 in those cells by Western blotting. The epithelia expressed high levels of nuclear NF-κB p65 when stimulated by TNF-α. Decreased expression of nuclear NF-κB p65 appeared in cells of groups B and L, in contrast to group T, as Western blotting showed (Figure 2).

Figure 2 Expression of nuclear NF-κB p65 in each group. Line 1: group T, Line 2: control, Line 3: group L, Line 4: group B.

DISCUSSION

Intestinal epithelia constitute mucosal barrier of the bowel, and participate in inflammatory or immune responses in gut[3,4]. In some gastrointestinal infectious and inflammatory conditions, such as inflammatory bowel disease (IBD), acute gastroenteritis, inflammatory cells including monocytes, lymphocytes, were activated and accumulated in lamina propria. The cells secrete excessive inflammatory products,

such as TH1 type cytokines, chemokines and a lot of active oxides. Overproduction of cytokines could affect the biological action of epithelial cells. For instance, TNF-α could induce epithelial cells to secrete IL-8, and express membrane Toll-like receptor 4 (TLR4) excessively[5,6]. TLR4 could enable intestinal epithelia hyperreactive in response to lipopolysaccharides (LPS), the component of bacteria walls, and IL-8 had leukocytes chemotactic and stimulatory properties[7]. As more inflammatory cells infiltrate, the inflammatory reaction is therefore amplified.

The normal flora of human gastrointestinal tract contains diverse populations of bacteria which play an essential role in the development of gut mucosal barrier and innate immunity. Some intestinal microflora could exert a protective role against pathogens[8]. Aberrance of gut microflora has been reported in IBD and acute gastroenteritis[9,10]. The aberrant microflora dysregulates mucosal immune reaction. Invasion of some virulent strains into epithelia could break down the integrity of intestinal mucosa, and induce inflammatory cell infiltration[11]. Some researchers found that manipulating the normal intestinal flora using probiotics had a beneficial effect on health by altering the microbial environment, and some components of the flora could down-regulate inflammation when supplemented to patients with gastrointestinal diseases[12,13]. Some studies have been undergoing to explore the possible mechanisms of probiotic action on gut epithelium and mucosal immune system.

In order to imitate the inflammatory condition of gut *in vitro*, we used TNF-α to stimulate human colonic adenocarcinoma HT29 cells, which has basically the same biological properties as normal colonic epithelia. As some probiotic strains could adhere to human intestinal cell surface[14,15], two probiotic strains, B.longum and L.bulgaricus, inhibited the secretion of IL-8 in HT29 cells when stimulated with TNF-α one hour after coculture with the two probiotic strains. It indicated that the strains could trigger anti-inflammatory pathways within the gut epithelium. The epithelia attached to the strains showed immune hyporeaction to TNF-α, and produced less IL-8. Because transcriptional control of IL-8 was mediated by transcription factor NF-κB[15], we investigated the expression of nuclear NF-κB p65 in HT29 cells. There was little NF-κB p65 in nuclei of normal epithelia without any stimuli. TNF-α highly up-regulated the expression levels of nuclear NF-κB p65. However, the epithelia pre-cocultured with two probiotic strains before TNF-α treatment showed a decreased expression of nuclear NF-κB p65. We postulated that such normal florae down-regulated inflammation by inhibiting NF-κB activation in gut epithelium.

Neish reported some nonvirulent Salmonella strains attenuated the synthesis of inflammatory effector molecules in model human epithelia elicited by proinflammatory stimuli by blockade of IκB degradation[16]. In order to investigate such an effect of the bacteria in gut, we selected and cultured two strains of bifidobacterium and lactobacillus under anaerobic conditions. The two strains successfully inhibited IL-8 secretion and NF-κB activation in intestinal epithelia in the experiment. At present, some probiotic compounds have been used in management of some diseases, such as maintenance therapy in IBD[17,18]. Although the mechanism of probiotic action has not been fully understood, the beneficial effects were consistent with an anti-inflammatory state conferred by probiotics[19,20]. More researches need to be done in order to understand the beneficial effect of probiotics on human beings.

Abstract

Balantidium coli is the only parasitic ciliate of man. It is a flattened oval organism covered with cilia, and a gullet at the anterior end. It is infrequently pathogenic for man, although epidemic buds in tropical zones have been described. The infection fundamentally affects the colon and causes variable clinic pictures, from asymptomatic to serious dysenteric forms. We present a case of parasitologically diagnosed as causes of diarrhea in a patient with non-Hodgkin's lymphoma from Turkey. In order to find out the causative etiologic agent of diarrhea, stool samples were examined by native, lugol and flotation methods and we detected moving trophozoites, which were approximately 60 µm long and 35 µm wide. These bodies were diagnosed as *Balantidium coli*. This case underlines that *Balantidium coli* should also be considered as a possible pathogen in immunocompromised patients with diarrhea.

INTRODUCTION

Balantidium coli (*B.coli*), the largest protozoon affecting humans, is a ciliate organism often associated with pigs. The greenish-yellow trophozoites may measure up to 120×150 µm and are capable of attacking the intestinal epithelium, creating ulcers and causing bloody diarrhea similar to that of amebic dysentery. It commonly infects primates, rats and pigs, and has a world-wide distribution. It is the only parasite of the family of *Balantidiidae* that, in rare instances, is pathogenic for humans. Balantidiasis is an infection of the large intestine by the ciliate protozoon, *B. coli*. In many infections (perhaps 80 percent) *B. coli* lives as a commensal in the lumen of the colon and causes no symptoms. A variety of gastrointestinal symptoms, including cramping, abdominal pain, nausea and foul breath, also occur. Encystment usually occurs in the intestinal lumen or stool (human or swine), and the large round cysts transmit the infection through contaminated food or water. Pigs act as carriers and are not often adversely affected by this organism[1,2].

Fortunately, balantidiasis is uncommon in temperate

climates. It is found in association with pigs throughout the tropics, especially the Philippines[1]. Evidence indicates that some infected humans may become asymptomatic cyst carriers, whereas others clear the infection spontaneously. As with amebiasis, this condition probably runs the gamut between mild colitis and severe, potentially fatal dysentery. Treatment of adults and older children is usually accomplished with tetracycline, 500 mg four times daily for 20 days and metronidazole, 750 mg three times daily for five days[3].

Our study in this paper is the first reported case of balantidiasis in a patient with non-Hodgkin's lymphoma from Turkey.

CASE REPORT

A 47 year-old female patient with non-Hodgkin's lymphoma and complaining of diarrhea and abdominal pain was admitted to our hospital. In the patient's history, there were watery, bad smelling, bloody diarrhea (ten times per day) and abdominal pain.

Physical examination revealed mild abdominal tenderness and increased sounds of intestine. In laboratory examination, blood routine tests were found as follows: Hb: 9.6 g/dl, Htc: 31.4%, white blood cells: $0.4×10^9$/L (with 20% granulocytes and 80% lymphocytes), platelets: $56×10^9$/L and sedimentation rate: 40 mm/h. Biochemical tests results were as follows: Fbg: 82 mg/dl, BUN: 40 mg/dl, creatinin: 0.7 mg/dl, total protein: 7.6 gr/dl, AST: 30 U/L, ALT: 32 U/L, ALP: 231 U/L, GGT: 43 U/L, LDH: 342 U/L, albumin: 4.1 gr/dl.

Figure 1 *Balantidium coli* trophozoites in native (A) and lugol (B) preparations (original magnification ×400).

We did not obtain any abnormalities in abdominal ultrasonography and direct X-ray. There was no growth of any pathogens in stool and blood culture.

In order to find the causative etiologic agent of diarrhea, stool samples were obtained from the patient and sent to the laboratory. The stool samples were examined parasitologically by native, lugol and flotation methods. Approximately 60 μm long and 35 μm broad moving trophozoites with cilia were seen. These bodies were diagnosed as *Balantidium coli* (Figure 1).

Consequently, we diagnosed this organism as *Balantidium coli*. The patient was treated with metronidazole 750 mg three times daily for five days. Following the treatment, the symptoms rapidly and completely resolved. Re-examination of a stool sample, however, did not reveal the presence of any organism.

DISCUSSION

Balantidium coli is a protozoon and the only one ciliate that is able to cause disease in man. The trophozoite or vegetative state has oval form covered by a great amount of cilia grouped in row. In its forcebody they are peristoma and citostoma that continue with citofaringe. The later end finishes in the anal pore or citopigio. The cysts are oval or spherical, they measure from 45 to 65 μm in length[2].

Although the distribution of *B.coli* is cosmopolitan, infection in humans takes place by the ingestion of cysts coming from lees of the parasite guests. Of this form, different epidemic buds like the one arising in the Truk Islands after a typhoon, have taken place. That typhoon caused an extensive contamination of superficial and underground water with lees of pigs, which provided the source of water for the population[4] and led to a severe prevalence in psychiatric hospitals[5,6].

Sporadic transmission was also produced by the water, contaminated vegetables crude and fecal-oral mechanism. People in contact with pigs were more likely to be infected, thus, it is said that the Aymara children of the Plateau of Bolivia had a greater prevalence of this infection, although usually they remained asymptomatic[7]. Our patient was personally questioned, she had not contacted with a pig. Probably, she might have got this parasite either via contaminated food or water. This case underlines that *B. coli* should also be considered as a possible pathogen in immunocompromised patients with diarrhea even if they have no contact with pigs.

Abstract

AIM: Inflammatory fibroid polyp (IFP) is a rare benign lesion that may occur throughout the digestive tract. IFP is more commonly found in the antrum of the stomach in particular. It mostly affects adults at the average age of 60 years. These polyps are able to cause abdominal pain, gastrointestinal bleeding, intestinal obstruction or intussusception. In this paper we report a case of gastric IFP with unusual presenting features.

METHODS: A child with gastric IFP was described and the literature was reviewed.

RESULTS: A 4-year-old girl presented with fever for 2 months, arthralgia of knees and ankles, iron deficiency anemia, and hypoalbuminemia. Her stool examination was positive for occult blood. The upper gastrointestinal study demonstrated a large lobulated mass at the upper part of gastric body. Partial gastrectomy *en bloc* with this 5cm×8 cm mass was subsequently performed. Pathological examination was consistent with IFP. Following the mass excision, her fever abruptly declined and disappeared together with anemia and arthralgia. She remained asymptomatic and the abdominal ultrasonography performed at the 24-month follow-up demonstrated no recurrence of the tumor.

CONCLUSION: The etiopathogenesis of IFP still remains unclear. The presence of IFP throughout the gastrointestinal tract and its variable clinical appearances make it difficult to diagnose. The inflammatory symptoms found in this patient support the hypothesis of inflammatory benign lesions of IFP.

INTRODUCTION

Gastric neoplasms are exceedingly rare in children. Murphy *et al.* reviewed 1 403 pediatric gastric pathology reports and found only 3 benign gastric tumors[1]. Attard *et al.* reported hyperplastic-inflammatory polyp was the most common gastric polyps (42%) found in pediatric population[2].

Inflammatory fibroid polyp (IFP) is a solitary polypoid or sessile lesion with an inflammatory basis. It is a rare benign lesion that may occur throughout the digestive tract, but is most often seen in the stomach (approximately 80%)[3]. IFP in the stomach is usually located in the antrum or prepyloric region[4,5]. In large retrospective studies of gastric polyps, 3.1-4.5% were found to be IFP[6,7]. It is slightly more common in women (female:male ratio 1.6:1)[5]. It is found in all age groups, although not often in children, and its maximal incidence is in the sixth decade[7]. The symptomatology is determined by its site. In the stomach, it causes pyloric obstruction, and often in the small bowel, intussusception which is the most common presentation in children.

We report a case of gastric IFP who presented with prolonged fever, arthralgia, hypoalbuminemia, and iron deficiency anemia. Surgical excision led to a complete resolution of those symptoms.

CASE REPORT

A 4-year-old girl presented with high fever for 2 months, arthralgia of knees and ankles, and anemia that required multiple packed red cell transfusions. The lowest hemoglobin was 3.9 g/dL. A provisional diagnosis of juvenile rheumatoid arthritis was made. She was treated with aspirin and prednisolone, but had no improvement. Later she was referred to our hospital in June 2001.

On her admission, the patient's weight was 15 kg (25th percentile for gender and age). Physical examination revealed pale conjunctivae, pitting edema of both legs, the rest was unremarkable. Laboratory tests after multiple blood transfusions showed a white blood cell count of 41 400/mm³, 76% PMNs, 16% lymphocytes, 6% monocytes, and 2% atypical lymphocytes; hemoglobin was 11.4 g/dL (MCV 76 fL, MCH 21.1 pg, MCHC 27.9 g/dL, RDW 21.2%), and platelet count was 684 000/mm³. Stool occult blood was positive. Serum albumin and globulin were 2.1 g/dL and 3.2 g/dL, respectively. Anti DNA, ANA, ANCA, anti Smith, rheumatoid factor, VDRL and LE cell were negative. β_1C was 176.9 mg/dL. ESR was 82 mm/h. Culture of blood, urine, stool, and bone marrow aspirate were negative. Upper GI series demonstrated a large lobulated mass at the upper part of gastric body (Figure 1).

Figure 1 A large lobulated mass at the upper part of gastric body (arrow head) shown by radiography.

Table 1 Literature review of inflammatory fibroid polyp in children (since 1960 in English language)

Year	Reference	Age (y.)	Sex	Location	Clinical manifestations
1966	Samter[8]	4	Male	Colon	Abdominal pain, vomiting, concomitant ruptured colonic diverticulum
1966	Samter[8]	8	Female	Jejunum	Vomiting, intermittent diarrhea, anemia
1972	Persoff[9]	3	Male	Ileum	Abdominal pain, vomiting, diarrhea
1984	Pollice[10]	8	Male	Rectum	Lower GI bleeding, anemia
1987	Schroeder[11]	5	Female	Stomach	Abdominal pain, weakness, vomiting, anemia
Our study	Chongsrisawat	4	Female	Stomach	Prolonged fever, arthralgia, anemia, hypoalbuminemia

At laparotomy, a 5 cm×8 cm mass was found at the body of the stomach. Partial gastrectomy *en bloc* with the mass was performed. Light microscopic examination of the gastric mass showed foci of ulcerated mucosa, focal elongated distorted branching and dilated hyperplastic foveolar and glands, covering a mass consisting of proliferative fibroblasts and blood vessels admixed with mixed inflammatory cell infiltrates in the stroma (Figure 2). The histological finding was consistent with IFP.

The patient developed postoperative convulsion due to steroid-induced hypertension and encephalopathy. She was treated with phenytoin and nifedipine which were later discontinued after 2 and 4 months, respectively. Fever, arthralgia, hypoalbuminemia, and anemia resolved after removal of the polyp. She was discharged 12 days after the surgery. The abdominal ultrasonography performed at the 24-month follow-up demonstrated no recurrence of the tumor and she remained asymptomatic.

Figure 2 Packed spindle-shaped cells, proliferated vessels and inflammatory cells, mostly eosinophils observed in tumor (H&E, 10×40).

DISCUSSION

Current pediatric literature regarding IFP is limited to case reports and small case series as shown in Table 1. Clinical manifestations of IFP are variable, depending on the location and size of the lesion. Most are small and asymptomatic. Nevertheless, it is able to cause anemia due to gastrointestinal bleeding, abdominal pain, vomiting, weight loss, intestinal obstruction or intussusception. Physical examination is usually not conclusive. Imagings such as upper GI series, ultrasonography or computed tomography can help diagnose the mass, but the final diagnosis is generally based on endoscopy and histological examination.

Histologically IFP has been found to be characterized by a submucosal lesion with a mixture of proliferation of fibroblasts and small blood vessels, accompanying a marked eosinophilic infiltration[12]. Since the distinctive structures for diagnosis are located within the submucosa and at the base of the mucosa, the diagnosis may not be possible in most of these polyps by endoscopic biopsy specimen. In the past, IFP was reported under several terms, such as eosinophilic granuloma, submucosal granuloma with eosinophilic infiltration, hemangioendothelioma, hemangiopericytoma, and polypoid fibroma[11,13]. The etiology and the pathogenesis of IFP remain unclear. It has been hypothesized that several factors could damage the gastrointestinal mucosa and expose the stroma to several irritants (chemical, mechanical and biological), and stimulate the formation of polyps among certain people[14]. A polyp of this category is a specific response of gastrointestinal stromal tissue of unknown etiology. Electron microscopic study revealed that IFP represented a reactive lesion of myofibroblastic nature[15]. Thus, it has been now generally accepted that IFP is not a neoplasia, but a reactive process, either to an allergy or a foreign body and has no malignant potential[4-6].

An infective etiology has never been reported in IFP, although several reported cases showed its association with *Helicobacter pylori* infection[3,14]. In one of these reports, the patient also had autoimmune diseases (sarcoidosis, rheumatoid arthritis, and ankylosing spondylitis)[3]. This finding supports the possibility of an immunological reaction as a contributing factor. It is not exactly known that *H pylori* started an immunological reaction which caused the polyp, or it only complicated this finding. Surgery is the main therapy of IFP and the recurrence has not been observed after polyp removal. Small polyps up to 2 cm in diameter can be excised endoscopically.

Our case is unusual in several aspects, such as the patient's young age at the presentation, the location of the mass at the corpus of the stomach, and the autoimmune-like manifestations. We hypothesized that IFP might release cytokines that cause fever and other autoimmune-like symptoms in this patient.

CONCLUSION

Not only is IFP rare in children, but its presence throughout the gastrointestinal tract and its variable clinical appearance make it difficult to diagnose. Patients with IFP may present with inflammatory symptoms and disappearance of the symptoms after polyp removal found in this patient supports the hypothesis of inflammatory benign lesions of IFP.

Abstract

Tumor growth without size restriction depends on vascular supply. The ability of tumor to induce new blood-vessel formation has been a major focus of cancer research over the past decade. It is now known that members of the vascular endothelial growth factor and angiopoietin families, mainly secreted by tumor cells, induce tumor angiogenesis, whereas other endogenous angiogenic inhibitors, including thrombospondin-1 and angiostatin, keep tumor in dormancy. Experimental and clinical evidence has suggested that the process of tumor metastasis depends on angiogenesis or lymphangiogenesis. This article summarizes the recent research progress for some basic pro- or anti-angiogenic factors in tumor angiogenesis.

INTRODUCTION

In the early time of the 20th century, Lewis observed that the vascular architecture depended on the tumor type, and proposed that the tumor environment determined the growth and morphological characteristics of tumor vessels. Hitherto it is the cognition that tumor vascularization is a vital process for the progression of all solid tumors from a small, localized focus to a large tumor with the capability to metastasize[1,2]. This progression begins with the sprouting or intussusception from pre-existing host vessels. Circulating endothelial precursors, shed from the vessel wall or mobilized from the bone marrow, also contribute to tumor angiogenesis[3,4].

Contrarily, adult normal tissue vasculature is quiescent because of the balance between angiogenic promoters and inhibitors. The early development of tumor is dormant because of the same reason. Break of the balance results in physiological angiogenesis such as wound healing and pathological angiogenesis such as tumor angiogenesis.

Tumor-induced angiogenesis is thought to depend on the production of pro-angiogenic growth factors by the tumor cells, which affect the existing vessels[5]. This turns on the tumor "angiogenic switch", and then promotes tumor growth and metastases.

ANGIOGENIC FACTORS

Vascular endothelial growth factors and vascular endothelial growth factor receptors

In 1983, Senger and his colleagues discovered a protein that induced vascular leakage and named it as tumor vascular permeability factor (VPF)[6]. Subsequently Ferrara and Connolly showed that VPF and vascular endothelial growth factor (VEGF) were the same molecule[7,8]. In 1992, Breier and Risau found that the expression of *VEGF* mRNA temporally and spatially correlated with blood-vessel growth in the developing mouse embryo. This supported the idea that VEGF was an angiogenic factor *in vivo*[9]. Later Veikkola and Alitalo also demonstrated that inactivation of one of the two VEGF alleles in the mouse embryos led to severe defects in vascular formation, ultimately resulted in embryonic lethality, whereas increased expression of VEGF seemed to be essential for tumor growth beyond size restriction[10]. *In-situ* hybridization studies have identified that the expression of *VEGF* mRNA is increased in renal[11], ovarian[12], gastric carcinomas[13], and particularly the highly vascular and aggressive glioblastoma[14]. VEGF is considered as a prognostic molecular marker in hepatocellular carcinoma[15]. *VEGF* gene is localized on the short arm of chromosome 6[16], with eight exons and seven introns[17]. Predominant isoforms of *VEGF* are $VEGF_{189}$, $VEGF_{165}$, $VEGF_{121}$, and $VEGF_{205}$. They are generated by alternative mRNA splicing and proteolytic processing. $VEGF_{121}$ differs from all the other higher molecular weight species by the absence of the heparin-binding domain encoded by exon 7 that can bind to neuropilin-1 (NP-1)[18,19]. Therefore, $VEGF_{121}$–diphtheria toxin (DT385) conjugation treatment completely prevents tumor angiogenesis *in vivo* without toxicity to NP-1[20]. VEGF is a major inducer of angiogenesis and structurally resembles (placenta growth factor), VEGF-B, VEGF-C, VEGF-D and the Orf virus derived VEGF (also called VEGF-E)[21-26].

Interestingly, VEGF is highly expressed in most ischemic areas of the tumor, indicating that VEGF expression might be induced by hypoxia. In hypoxic tissue the hypoxia inducible factor-1 (HIF-1) has been proven to play a central role in inducing the transcription of genes that are involved in glycolysis and angiogenesis, including VEGF[27]. Subsequent studies have shown that the mechanisms of hypoxic regulation of VEGF and erythropoietin are similar[28]. *VEGF* gene contains two hypoxia-regulated element (HRE) in the 5' and 3' regions (Figure 1). HIF-1 recognizes and binds HRE[29,30]. Hypoxia also induces an RNA-binding protein, HuR, which can bind to the 3' untranslated region (UTR) of *VEGF* mRNA and increase the mRNA stability[31]. Oncogenes including members of the *ras* and *erbB* families also up-regulate the expression of VEGF[32,33]. The products of *ras* gene activate the HIF-1α and promote the stability of the HIF-1α via Raf/MEK/MAPK and PI3K/PDK-1/AKT pathways[34]. The activated AKT increases the phosphorylation of GSK3β on Ser9, and then enhances HIF-1α stabilization, since unphosphorylated GSK3β inhibits HIF-1α accumulation[35] (Figure 1). Recent studies have indicated that the chronic myelogenous leukemia (CML)-associated oncogene *BCR/ABL* induces VEGF expression in growth factor-dependent Ba/F3 cells by promoting the expression of HIF-1[36]. However, the product of the von

Hippel-Lindau tumor suppressor gene (vHL) inhibits the expression of VEGF[37,38]. The ubiquitin ligase E3 complex containing the vHL tumor suppressor protein increases the HIF-1α degradation[39]. In addition to vHL, other tumor suppressor proteins such as p53 also inhibit the transcriptional activity of HIF-1 by binding to the HIF-1/P300 complex and then promoting Mdm2-mediated ubiquitination and proteasomal degradation of the HIF-1α, which ultimately results in the decrease of VEGF expression[40,41]. These findings indicate that HIF-1 is critical for the regulation of VEGF expression. VEGF expression is also regulated by estradiol in human breast cancer cells[42]. Similarly, 17 beta-estradiol also enhances VEGF expression via the regulation of adenylate cyclase in differentiated THP-1 cells[43].

Figure 1 The regulation of the VEGF expression. HIF1 plays central roles in this regulation.

VEGFs induce angiogenesis through the binding to their relevant receptors that are mainly expressed in endothelial cells. The first VEGF receptor was identified to be Flt1 (FMS-like-tyrosine kinase), also known as VEGFR1[44]. Subsequently, the other highly specific VEGF-binding receptors (KDR, Flk1, or VEGFR2) were discovered[45,46]. Scientists investigated the function of VEGFR1 and VEGFR2 in endothelial cells via Flt1 or Flk1 mutant endothelial cells or an embryonic model. They counted the number of mitotic endothelial cells in embryo to confirm the effect of proliferation of endothelial cells. In VEGFR1 knockout mice, the reason causing early embryonic lethality was not the absence of vascularisation but the disorganized embryonic and extra-embryonic vasculature[47]. This suggests that Flt1 signal pathways mainly regulate normal endothelial cell-cell or cell-matrix interactions during the process of vascular development. The ability of VEGFR1 to bind to VEGF is 10 times stronger than VEGFR2, but the activity of tyrosine kinase of VEGFR1 is weaker than that of VEGFR2. A study demonstrated that Flt1 null mutation resulted in early embryonic death, but Flt1 lacking tyrosine kinase domain homozygous mice developed normal vessels and survive[48]. These observations indicate that Flt1 without

tyrosine kinase domain is sufficient to promote embryonic normal angiogenesis. The effects of VEGFR2 in endothelial cells, such as cell survival and proliferation, are not induced by treatment with VEGFR1 specific ligands or in the VEGFR1 overexpressing cells lacking VEGFR2[49,50]. These data suggest that VEGFR2 plays the central role in VEGF signal transduction in endothelial cells. VEGFR1 is likely to be the antagonist of VEGFR2, acting as a negative regulator of angiogenesis via sequestering VEGF and thus blocking the VEGF signal transduction mediated by VEGFR2. Recent studies have confirmed this conclusion. The *Flt1* gene encodes not only the full-length Flt-1, but also a soluble short form of Ftl-1, designated sFlt1. In placenta, sFlt-1 is abundant in the trophoblast layer during pregnancy, suggesting that it is a negative regulator to excess angiogenesis at the feto-maternal border in mammals[51]. Subsequently Kearney confirmed that Flt-1 normally modulated vascular growth by controlling the rate of endothelial cell division *in vitro* and *in vivo*[52]. The downstream signaling events of VEGF signal transduction pathway via VEGFR2 includes receptor dimerization, transphosphorylation of intracellular VEGFR2 tyrosine residues (Tyr951/996 and Tyr1054/1059)[53], the activation of protein kinase C, and then the activation of the MEK/MAPK pathway to promote endothelial cell proliferation (Figure 2). However, Meyer's data showed that phosphorylation of tyrosine 1212 of VEGFR2 was also necessary for VEGFR2-mediated angiogenesis[54]. In addition to VEGF, scientists have found that there are other molecules that activate VEGFR2 or enhance the expression of VEGFR2. Recent studies have indicated that tumor necrosis factor (TNF) has anti-tumor activity by down-regulating Flk-1 expression in tumor endothelial cells[55]. Moreover, in cardiac capillary endothelial cells, Bradykinin (BK) also stimulates angiogenesis via the activation of the B2- type receptor, which leads to the tyrosine phosphorylation and dimerization of Flk-1 as does VEGF itself [56]. This implies a novel mechanism by which a G protein-coupled receptor activates a receptor tyrosine kinase to generate biological response. In addition to the stimulation of endothelial cell migration and proliferation, VEGF also elevates the survival capacity of endothelial cells *in vitro*. The underlying mechanism is that VEGF activates VEGFR2, which further activates phosphatidylinositol 3-kinase (PI3-K) and Akt[57]. VEGF also prolongs the survival of human dermal microvascular endothelial cells (HDMECs) *in vitro* by inducing expression of the anti-apoptotic protein Bcl-2[58].

Figure 2 The intracellular downstream signaling of VEGF signal transduction via VEGFR2.

Interestingly, new data have revealed that NP-1, originally found to control the neuronal axon guidance, also enhances the mitogenic effects of VEGFR2 signaling in endothelial cells[59]. So far, the potential role of NP-1 in pathologic angiogenesis remains unknown. Some experiments have indicated that VEGF up-regulates NP-1 via VEGFR2-dependent pathway. Endothelial proliferation stimulated by VEGF$_{165}$ is inhibited significantly by antibody neutralization of NP-1. In a murine model of VEGF-dependent angioproliferative retinopathy, intense NP1 mRNA expression was observed in the newly formed vessels[60]. In breast carcinoma cells neuropilin expression also enhances VEGF-inducing cells survival signal[61]. Furthermore, in rat uterus the neuropilins (NP-1 and NP-2) might participate in hormonally regulated changes occurring throughout the female reproductive cycle[62].

The other factor VEGF-C and its receptor (VEGFR3) are essential to the lymphangiogenesis and play a direct role in the metastatic dissemination of tumor cells. It is known that VEGFR3 is mainly expressed in lymphatic endothelium during development[63,64]. Later in embryonic development, VEGFR3 is expressed in lymphatic cells, and further induces lymphangiogenesis[63,64]. However, in early embryonic development without lymphatic vessels, the embryos lacking VEGFR3 gene usually die due to cardiovascular failure[65]. These data indicate that VEGFR3 is necessary in the formation of the primary cardiovascular network. In addition, VEGFR3 is also expressed in the tumor endothelial cells, which helps tumor neovascularization[66].

Angiopoietins and Tie receptors

The second family of growth factors that specifically act on the vascular endothelium has been identified, namely the angiopoietins[67,68]. To date, there are four members of this family, mainly including Ang-1 and Ang-2, which both only bind to the Tie-2 receptor and control the blood vessel stabilization signals[67,68]. The results of early experiments showed that the mouse embryonic development lacking Ang-1 or Tie-2 died in the later stage of angiogenesis because the remodeling and stabilization of the primitive vasculature induced by VEGF was severely perturbed[69-71]. Similarly, the increased Ang-1 expression in human cervical cancer HeLa cells by transgene promotes the growth of human cervical cancers in mice via promoting tumor angiogenesis[72]. In addition to in the active angiogenesis tissue, Ang-1 seems to be widely expressed in the normal adult tissues[73], indicating

that Ang-1 may act on the stabilization of existing vessels. The underlying mechanism is thought to modulate the interaction between endothelial cells and surrounding support cells, such as smooth muscle cells[71,74]. Ang-2 was cloned in 1997. It is thought to be a natural antagonist for the Ang-1/Tie-2 interaction now. The transgenic overexpression of Ang-2 in embryo results in early embryonic lethality, similar to the phenomenon in embryonic development without Ang-1 or Tie-2[68].

The relation of VEGF and angiopoietins in angiogenesis has become a research hotspot (Figure 3). In the onset of cerebral ischemia, the increase of VEGF mRNA goes with the decrease of Ang-1 mRNA. Later increased expression of VEGF/VEGFRs and Ang-1/Tie2 is detected[75]. This data show that Ang-1 works at the later stage of angiogenesis. Other experiments directly demonstrate the above mentioned role of VEGF and Ang-1. The transgenic overexpression of VEGF in the skin of mice induces the formation of numerous leaky blood vessels. In contrast, overexpression of Ang-1 leads to an enlargement of dermal vessels with less leaking, instead of an increase in the number of vessels. If both VEGF and Ang-1 are overexpressed, the size and number of skin vessels are both increased. Furthermore, these vessels are not leaky. Remarkably, it is found that Ang-1 also reduces VEGF-stimulated inflammation by suppressing expression of adhesion molecules, including intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1)[76] and E-selectin[77]. The expression of Ang-2 is not broader than that of Ang-1. Holash *et al* demonstrated that endothelial cells apoptosis occurred prior to the wide spread loss of tumor cells in the necrotic tumor core[78]. This implies that there is a mechanism to induce this process. Ang-2 promotes endothelial cell death and vessel regression if the activity of VEGF is inhibited. By contrast, Ang-2 promotes a rapid increase in capillary diameter and stimulates sprouting of new blood vessels in the presence of endogenous VEGF *in vivo*[79]. These results indicate that the pre-effect of existing blood vessels by Ang-2 is in favor of the step of VEGF-inducing angiogenesis. Thereby, in the regulation of angiogenesis, VEGF can convert the role of Ang-2 from an anti- angiogenic factor to a pro-angiogenic factor. Other data further confirm that Ang-2 expression precedes that of VEGF in the early stage of tumor angiogenesis[80].

Altogether, VEGF/VEGFRs and angiopoietins/Ties co-regulate the tumor vessels regression, growth and maturation.

Figure 3 The interaction relation between VEGF and angiopoietins in the development of tumor angiogenesis.

Expression of Ang-2 without VEGF induces vessels regression in core of a necrotic tumor. Then, hypoxia induces tumor cells to express VEGF. The angiogenic properties of VEGF may be easier to act on the vessels, which are destabilized by Ang-2. Newly formed tumor vessels are abnormal, including highly disorganization, poor differentiation, tortuousness and excessive branch, because continuous expression of Ang-2 in newly tumor vessels inhibits the maturation and stabilization signals via Ang-1. In the later development of tumor angiogenesis, the increasing expression of Ang-1 promotes the maturation of neovascularization. In fact, hyper-vascular hepatomas with aberrant vasculature show high levels of Ang-2 expression in the endothelium.

Other angiogenic factors

The mechanism of tumor angiogenesis is complicated. It involves many factors and some different signal pathways. Therefore, if only one signal molecule (for example VEGF) is blocked, tumor may switch to another molecule (for example bFGF) for the induction of angiogenesis. The basic fibroblast growth factor (bFGF, also known as FGF-2) isolated from a chondrosarcoma was identified to be the first pro-angiogenic factor[81]. bFGF is the main member of FGF family which is a structurally homologous protein family, including at least 20 members. FGF has a high affinity to heparin sulfate protepglycans (HSPGs), which locates on the surface of most cells and within the extracellular matrix[82].

Four receptor tyrosine kinases (known as FGFR-1,-2,-3,-4) can interact with FGF. The FGF/FGFRs signal pathway may play a crucial role in angiogenesis. The FGFR-1 mutant mouse embryos exhibited abnormal embryonic and extra-embryonic vascularization, suggesting that FGF/FGFR-1 plays a role in the development and maintenance of a matured vascular network in the embryo[83]. The mechanisms for VEGF- and FGF-mediated angiogenesis are not the same. In astrocytoma, bFGF and VEGF expression levels positively correlated with tumor growth and angiogenesis. However, bFGF and VEGF expression levels were significantly different in various grades of astrocytoma[84]. In the culture of embryonic stem cell-derived vascular precursors in vitro, bFGF and VEGF both exhibited effects on the survival of angioblasts. However, VEGF induced the formation of primitive endothelial tubes, whereas bFGF did not[85]. This finding suggests that VEGF but not bFGF plays a major role in angiogenesis. The mitogen-activated protein kinase kinase (MEK) inhibitor PD98059 suppresses FGF-induced angiogenesis, indicating that the Ras-MEK-MAPK pathway is important for the biological effect of FGF[86]. Subsequently, Cross et al found that the Shb adaptor protein binding to Tyr766 in the FGFR-1 promoted FRS2 phosphorylation, and further regulated the Ras-MEK-MAPK pathway[87]. FGFR-1-mediated intracellular signal cascades include the Ras pathway, Src family tyrosine kinases, phosphoinositide 3-kinase (PI3K) and the PLC pathway[88]. Some members of the FGF family (such as FGF-3) promote oncogenesis, and are identified as proto-oncogenes[89].

ANTI-ANGIOGENIC FACTORS

In humans or vertebrates, normal vascularization is quiescent, suggesting that in vivo humans or vertebrates should have anti-angiogenic factors against angiogenic factors. Recently, experiments in vitro or in vivo confirm the presence of endogenous anti-angiogenic factors.

The primary anti-angiogenic factors include thrombospondins (TSP), angiostatin and endostatin. Now the TSP family includes five members, known as TSP-1, -2, -3, -4 and TSP-5/COMP. They play multiple functions via binding to matrix proteins, plasma proteins and cytokines[90-93]. Some

reports have shown that TSP-1 and TSP-2 have anti-angiogenic properties. TSP-1 inhibits angiogenesis via a direct way that suppresses migration and induces apoptosis of endothelial cells or via an indirect way that inhibits the mobilization of pro-angiogenic factors and blocks their access to co-receptors on the endothelial cell surface[94]. TSP-2 has the similar functions[95]. The signal pathway of TSP includes TSP/CD36 receptor, cytoplasmic tyrosine kinase p59fyn, caspase-3-like proteases and p38 mitogen-activated protein kinase (MAPK), and results in apoptosis of endothelial cells[94,96,97]. It has been proven that TSP is an anti-angiogenic factor or acts as prognostic predictor in pancreatic ductal carcinoma[98], bladder cancer[99], non-small cell lung cancer[100,101], breast cancer[102], cervical cancer[103] and colon cancer[104]. TSP expression is regulated by several factors. Hypoxia increases TSP-1 expression in endothelial cells by promoting the post-transcriptional stabilization of the TSP-1 mRNA[105]. This property does not match with its anti-angiogenic property. Contrarily, in vitro hypoxia suppresses TSP-1 expression and induces VEGF expression in rodent cells, regardless of the p53 genotype[106]. In cultured fibroblasts, loss of the wild-type allele of the p53 results in reduced expression of TSP-1. Transfection assays have revealed that p53 stimulates the expression of the endogenous TSP-1 gene and positively regulate TSP-1 gene promoter sequences[107,108]. A novel p53-inducible gene, named BAI1, was found in 1997[109]. BAI1 contains five TSP-type 1 repeats, and significantly suppresses angiogenesis. Some oncogenes have been also found to regulate TSP1 expression, including c-jun[110] and H-ras[106]. These data indicate that oncogenes or loss of tumor suppressor genes also regulate TSP expression to turn on the angiogenic switch and promote tumor growth.

A number of experimental studies have demonstrated that a primary tumor inhibits a secondary distant tumor[111,112], indicating that there are some inhibitors from the primary tumor to inhibit the growth of metastases. Endostatin is a circulatory inhibitor, and identified to be an anti-angiogenic factor[113]. It is a 20 kD C-terminal fragment of collagen XVIII. Treatment with endostatin by transgene inhibits angiogenesis and liver tumor growth[114]. In other similar diseases such as rheumatoid arthritis, treatment with endostatin showed beneficial effects[115]. Interestingly, endostatin immunostaining was stronger in area accompanied with blood vessel maturation. Endostatin expression was significantly prominent in vessels of tumor marginal zone where angiogenesis was highly active. These observations suggest that endostatin inhibits angiogenesis by stabilization of newly formed endothelial tubes in angiogenic active region in tumors[116]. Intracellular signaling mechanisms by endostatin remain poorly understood. Jiang et al found that endostatin increases intracellular Ca^{2+} concentration approximately three-fold, indicating that endostatin induces intracellular Ca^{2+} signal[117]. Endostatin also modulates the Wnt signaling by regulating β-catenin stability via a novel glycogen synthase kinase 3(GSK3)-independent mechanism[118].

Angiostatin is another circulatory anti-angiogenic factor. It was isolated from a lung carcinoma cell line and is particularly effective in suppressing metastatic growth when the primary tumor is removed[119]. Angiostatin is a 38 kD fragment of plasminogen. Treatment with angiostatin inhibits angiogenesis in a murine breast cancer model[120]. Now it is found that angiostatin plays a crucial role in inflammation via directly inhibiting neutrophil migration and neutrophil-mediated angiogenesis[121]. Recent studies have shown that angiostatin has structural similarities to hepatocyte growth factor (HGF), which induces proliferation and migration of both endothelial cells and smooth muscle cells via its cell surface receptor, c-met. Therefore, the disruption of HGF/c-met

signaling is a novel mechanism for the anti-angiogenic effect of angiostatin[122]. Experiments by Mauceri *et al* indicated that TNF-α enhances the production of angiostatin in tumor cells by inducing the activity of the plasminogen activator and the release of MMP-9 by tumor cells[123].

CONCLUSIONS

Tumor angiogenesis plays crucial roles in tumor growth and metastases. Tumor angiogenesis is a complex process involving interactions of many molecules and several different or similar signal pathways. Despite the rapid research progress in the field, there are many mysteries regarding the molecular mechanism of tumor angiogenesis. Once we fully understand the precise functions of these pro- and anti-angiogenic factors in tumor angiogenesis, clinical application of those novel research results for tumor therapy would become practical.

Abstract

AIM: To summarize progress in the study of K-ras gene studies in pancreatic cancer and its potential clinical significance in screening test for early detection of pancreatic cancer, and to differentiate pancreatic cancer from chronic pancreatitis in recent decade.

METHODS: Literature search (MEDLINE 1986-2003) was performed using the key words K-ras gene, pancreatic cancer, chronic pancreatitis, and diagnosis. Two kind of opposite points of view on the significance of K-ras gene in detection early pancreatic cancer and differentiation pancreatic cancer from chronic pancreatitis were investigated. The presence of a K-ras gene mutation at codon 12 has been seen in 75-100% of pancreatic cancers, and is not rare in patients with chronic pancreatitis, and represents an increased risk of developing pancreatic cancer. However, the significance of the detection of this mutation in specimens obtained by needle aspiration from pure pancreatic juice and from stools for its utilization for the detection of early pancreatic cancer, and differentiation pancreatic cancer from chronic pancreatitis remains controversial.

CONCLUSION: The value of K-ras gene mutation for the detection of early pancreatic cancer and differentiation pancreatic cancer from chronic pancreatitis remains uncertains in clinical pratice. Nevertheless, K-ras mutation screening may increase the sensitivity of FNA and ERP cytology and may be useful in identifying pancreatitis patients at high risk for developing cancer, and as a adjunct with cytology to differentiate pancreatic cancer from chronic pancreatitis.

INTRODUCTION

Cytology, for detection of pancreatic cancer is limited for the definitive diagnosis by a low sensitivity and accuracy[1-4]. K-ras oncogene as a cytological adjunct can be date back to ten years ago[5]. K-ras oncogene has been found to be activated by specific point mutations restricted to condon 12 in 75 to 100% of pancreatic cancers, but rare in chronic pancreatitis[6-8]. Attempt at detection of such genetic change have been made in plasm[9-12], pancreatic juice samples[13-16], fine needle tumour aspirates[17-19], and stool samples[20-22]. However, at present there exists completely different viewpoints about these preliminary results. In this article we review previous studies of prospective follow-up of patients with chronic pancreatitis positive for K-ras gene at codon 12 and evaluated its significance mutation in detecting early pancrearic cancer and in differentiating pancreatic cancer from chronic pancreatitis.

K-RAS GENE MUTATIONS

K-ras gene is the locus for the c-k-ras protooncogene, lying on chromosome 12p12, and is about 45 000 bp in lenth. It encodes for a 2.0 kb transcript which is highly conserved across species, and is translated into the p21-ras protein. These proteins are located in the plasma membrane and could transduce growth and differentiation signals from activated receptors to protein kinases within the cell[23]. p21-ras protein are in a weak GTP-bound, active state, thereby altering transduction into the cell[23]. The majority of mutations have been found at K-ras codons 12 and 13, and to a lesser extent, at codon 61[24,25]. These mutations are somatic rather than in the germ-line, and consist of single base-pair substitutions which lead to the change of one amino acid in the protein. The wild-type K-ras gene encodes for glycine (GGT) at codon 12, and the most common amino acid substitution is aspartic acid for glycine (46%), followed by valine (32%), arginine (13%), cystein (5%), serine (1-2%), and alanine (<1%). These mutations presumably result in the K-ras protein product (p21-ras) remaining in the GTP-bound, activated state, which may promate cell proliferation. The reason for the specificity of these mutations to condon 12 is not entirely clear. This location appears to confer higher change in the p21 ras protein's 3 dimensional structure and ras-GAP binding characteristics.

K-ras mutations were thought to be an early event in pancreatic tumorigenesis[24]. Is it true? In animal models, weekly exposed to doses of nitrosamines and serially sacrificed at 8,12, 14, 16, or 24 weeks, K-ras mutations were found in 26% of hyperplastic lesions,46% of papillary hyperplastic lesions,76% of carcinomas *in situ*, and 80% of invasive pancreatic carcinomas[25]. In human pancreas, K-ras point mutation at codon 12 is found hyperplasia without dysplasia[26,27], severe dysplasia[26] or carcinoma *in situ*[26] even within multifocal hyperplastic foci of ductal epithelium in histologically normal pancreas[26]. K-ras point mutations rate seems to increase regularly from normal duct cells to flat or papillary hyperplasia observed in chronic pancreatitis tissue[26]. Such epithelial lesions mainly associated with chronic pancreatitis are thought to be potentially premalignant ductal lesions. However, there existed completely different objections about the significance of presence of the presence of K-ras mutations[28,29].

CLINICAL SIGNIFICANCES OF K-RAS MUTATIONS
K-ras mutation and pancreatic cancer screening test
Chronic pancreatitis (CP) was considered to be a risk factor

for the development of pancreatic carcinoma (PC)[30,31]. The detection of K-ras mutations in the duodenal or pancreatic juice has been held to be a tool for pancreatic cancer early diagnosis. One application of K-ras mutation testing for pancreatic cancer is the screening of pancreatic juice samples. In order to evaluate the significance of K-ras mutation, a prospective follow-up of study of patients with CP in the detection of early pancreatic cancer and K-ras mutations at codon 12 has been carried out. In Berthelemy' s series[32], two patients free of pancreatic mass had no evidence of pancreatic cancer, when K-ras was first studied, but developed tumors 18 and 40 months, respectively, after identification of K-ras mutations. Boadas et al[33] collected 50 patients' pancreatic juice samples, including 49 patients with CP and one patient proceeding from a PC family screening. K-ras mutation was detected by PCR-RFLP (restriction fragment length polymorphism). As a result, K-ras mutation was detected in 8/49 patients (16%) with CP, one of whom developed PC during the follow-up, allowing surgical resection of early cancer.

Another interesting clinical application of K-ras mutation testing for pancreatic cancer is the screening of stool samples. Caldas and colleagues[20] tested stool samples from patients with pancreatic adenocarcinoma, cholangiocarcinoma, and chronic pancreatitis for K-ras mutations. Stool samples were frozen, then approximately 1 g was resuspended in buffer, extracted in phenol-chloroform, and precipitated. PCR products resulting from this template were subcloned and plaque hybridizations using specific oligonucleotide probes for different K-ras mutations. Positive stool samples were found in 6 of 11 patients with carcinoma of pancreas (all of which had mutations in paraffin-embedded tumor sections), in none of 3 chronic pancreatitis specimens (all negative on paraffin sections) and in 2 of 3 cholangiocarcinomas (one positive and one negative on paraffin sections, the one negative stool sampal was positive for K-ras mutation on paraffin section). When mutations were detected in stool specimens, 5 of 6 cases had the same amino acid substitution as seen in the paraffin-embedded sections. Negative controls using *E. coli* DNA were performed, and no mutation was detected. The frequency of K-ras mutations approximates only 40-50% in pancreatic cancer, it was presumed that these mutations were derived from exfoliated cells from pancreatic cancer. The sensitivity and specificity of K-ras mutation as a screening tool were not high, and therefore its clinical application is limited at present.

The signification of codon 12 K-ras mutation in CP is still debated. Queneau et al[34] examined the pure pancreatic juice from the diagnosed 36 patients with chronic pancreatitis based on the criteria of Cambridge and Marseilles clissifications. Ten patients were positive for K-ras point mutation at codon 12, pancreatic cancer was discovered at an invasive stage in two patients, respectively in 7 and 17 months after disclosure of a K-ras mutation. Unfortunately the disclosure of pancreatic cancer after follow-up of patients with chronic pancreatitis positive for a K-ras mutation was not associated with an early stage at diagnosis and an improved prognosis. Lohr et al[35] reported that K-ras gene mutation was found in 6 of 66 patients with chronic pancreatitis, pancreatic neoplasm occured in none of the mutation in patients over a mean follow-up period of 26 (4-54) months, no pancreatic cancer developed during follow-up. Analysis of K-ras gene mutation seemed to have little use for detection pancreatic neoplasm in patients with chronic pancreatitis[36,37].

Confliting reports have raised the question whether K-ras gene mutations in chronic pancreatitis are related to the development of pancreatic neoplasm. According to epidemiological date: about 4%[30] patients with chronic pancreatitis will developed pancreatic cancer during the course

of the disease. Interestingly, the risk of cancer seemed predominant in the first few years of chronic pancreatitis[31]. No clinical, morphological, or histocytological information could help differentiate patients with cancer from the others during the follow-up of chronic pancreatitis. Morever, K-ras mutations were found in 63-71% of the microdissected specimens of benign mucous cell hyperplasia of the pancreatic ductal epithelium with chronic inflammation[26]. only about 1% of patients harboring such precursor lesions were believed to develop pancreatic adenocarcinoma. Disclosure of a K-ras point mutation in chronic pancreatitis seemed not sufficiently predictive of malignant transformation,and even in some cases of chronic pancreatitis early occurrence of p53 gene but not K-ras mutations has been reported[38]. Therefore, detection of K-ras mutation cannot be recommended at this time for screening pancreatic cancer.

Utility of K-ras mutation in differentiating pancreatic cancer from chronic pancreatitis

Fine needle aspiration (FNA) of pancreatic cancer and K-ras gene The knowledge that pancreatic cancer frequently harbor K-ras mutations has been applied to the histopathologic diagnosis of pancreatic mass. Because cytologic diagnosis from FNA depends upon accute sampling, a negtive test dose not rule out carcinomas. However, in equivocal cases, detection of K-ras mutation might help to conform the diagnosis of pancreatic cancer. Urgell[19] prospectively examined a total of 84 consecutive having a pancreatic mass who were clinically suspected of pancreatic cancer for the confirmation and follow-up of their chronic pancreatitis. Fine needle aspiration specimens were taken for both cytology and the presence of K-ras mutations. By cytology and/ or the patient' s clinical course (death within a year), the authors concluded that the final diagnoses were 60 pancreatic cancers, 2 mucinous cystic tumours, 4 endocrine tumours and 6 other malignancies, 10 chronic pancreatitis, 1 acute pancreatitis and 1 tuberculosis. Cytology offered a conclusive diagnosis in 63 of 84 (75%) cases, inconclusive report in 21 cases (25%) (9 cases with suspicious cells and 12 cases with insufficient material). The presence of malignant cells in the FNA samples from patients with pancreatic cancer was 65%. No false-positives were detected in the remaining 24 conclusive FNAs. K-ras mutations were detected in 46 of 60 FNA samples (77%) from cancers and no mutations were detected in the remaining 24 FNA samples. The combined molecular and cytological approach offered an 88% sentivity with a 100% specificity. A similar study was performed by Urban and collegaues[17], who examined 20 consecutive patients undergoing FNA for pancreatic lesions. Sixteen samples were successfully amplified by PCR, 10 (of 11) pancreatic cancers and 1(of 1) cystadenocarcinoma had K-ras mutations, while no mutations were found in 3 patients with chronic pancreatitis and 1 patient with an islet cell tumor. Two patients having a benign cytologic diagnosis had K-ras mutations and were ultimately proven to have pancreatic cancers. Pathologic diagnosis alone was established in 13 of 16 cases, but when pathology and K-ras mutations were combined, all the 16 patients were correct ly diagnosed. When adequate samples were obtained, the sensitivity rate was 92% and specificity was 100% in this study. K-ras mutation in combination with cytologic analysis might be a helpful tool for the diagnosis of pancreatic carcinomas.

K-ras point mutation at codon 12 in pancreatic juice Differentiating pancreatic adenocarcinoma from chronic pancreatitis can be quite difficult particularly when both diseases coexist. Cytological distinction between chronic pancreatitis and pancreatic cancer is occasionally difficult because chronic pancreatitis can induce morphological changes

similar to those seen in well differentiated adenocarcinomas. In addition, pancreatic juice can induce the cell injury and degradation duo to disvantages of digestive utility induced by various proteases. The main advantages of the gene technique are its objectivity and the lack of dependence on cell integrity and number. Van Laethem *et al*[39] analysed prospectively the presence of these mutations in brushing samples collected during ERCP in 45 patients (26 males, 19 females) showing a dominant stricture of the main pancreatic duct at pancreatography. Twenty-four were pancreatic adenocarcinomama, sixteen were chronic pancreatitis, and five intraductal mucin hypersecreting neoplasms. Twenty of 45 patients presented equivocal ERCP findings that did not permit a definite diagnosis. K-ras mutations at codon 12 were detected. Result were compared with those provided by routine brush cytology. A definitive diagnose was established for each patient. Mutations were detected in 20 of 24 patients with pancreatic adenocarcinoma, but in none of the the chronic pancreatitis patients and intraductal mucin hypersecreting neoplasms,irrespective of their locations. By contrast, only 13(Carcinoma of the pancreas head) of 24 pancreatic adenocarcinoma were detected by cytological eaxmination, which yielded four false negative and seven (Carcinoma of the body or tail of pancreas) non-contributive results.sensitivity (duo to the neoplastic site lying in the body or tail of pancreas), specificity, and accuracy of molecular biological and cytological methods were 83-76%, 100-83%, and 90-58%, respectively. Notably the mutations could be detected in six patients with small tumours. Watanabe[40] found K-ras mutations from the pancreatic juice in 11 of 20 (55%) pancreatic cancer patients, and in none of 18 patients with chronic pancreatitis. Fifty percent of tumuors of the pancreatic head (4 of 8), 67% of the body (6 of 9), and 33% of the tail (1 of 3) had K-ras mutation. When tumuors were examined by size, 50% of T1 (1 of 2), 43% of T2 (3 of 7), 50% of T3 (3 of 6), and 80% of T4 (4 of 5) had K-ras mutations. Tada[41] found K-ras mutations in the pancreatic juice from 6 of 6 patients with pancreatic cancer, and 1 with intraductal papillary neoplasm. In contrast, 3 patients with chronic pancreaatitis were negtive for mutations, and this method was sensitive enough to detect 3-30 mutant copies of K-ras in the presence of 3000 000 normol copies of the gene (which would be the equivalent to 0.01 ng of mutant DNA in 1 mg of total DNA).

On the contrary, Pugliese *et al*[42] believed that cytology rather than mutation was useful in the diagnosis of pancreatic cancer. In their one report cytological exmination, and detection of K-ras point mutation were performed, sensitivity of cytology was 74%, that of mutations in 87% in cancer and 40% in chronic pancreatitis. The specificity for cytology and mutation was 100% and 60% respectively. Combining cytology with mutation analysis increased the sensitivity to 93% but reduced the positive predictive value. Matsubayashi *et al*[43] reported the occurrence of K-ras point mutations at codon 12 and compared it with cytology in pancreatic juice. K-ras point mutations at codon 12 were detected in seven of 14 (50%) pancreatic cancers, in four of 10 (40%) mucin-producine tumors, in four of 13 (31%) chronic pancreatitis, and in two of (10%) pancreas without definite disorders. K-ras point mutations were detected in nine of 18 (50%) pancreatic juice samples containing cancer cells, in eight of 18 (44%) pancreatic juice samples containing atypical cells, but in none of such samples containing only normal cells. It was concluded that K-ras mutations were not detected in pancreatic cancer exclusively, they could be detected in pancreatic cancer, and also other diseases.

Combining K-ras point mution at condon 12 with cytology could increase its sensitivity and specificity. In Tada' s series[44], cytology and semiquantitatively mutant analysis were performed using EUS-FNA specimens as well as in pancreatic juice in 34 patients with pancreatic masses (26 cancers and 8 chronic pancreatitis). Quantitative analysis of mutant ras gene supplemented with cytology was more effective in differential diagnosis of pancreatic cancer.

Evidence to date suggests that the progression to pancreatic adecarcinoma is multifactorial, and perhaps undefined, genetic mutations play major roles. Molecular profiling indicated a large number of genes were differentially expressed in pancreatic cancer and normal pancreas, but the differences were not significant between pancreatic cancer and chronic pancreatitis[45]. Combining other marker seemed to contribute to increase the sensitivity and specificity of detection of K-ras gene point mutation at condon 12 for differentiation the pancreatic cancer from chronic pancreatitis. Myung *et al*[46] examined the telomerase activity and K-ras gene mutations in pancreatic juice from 31 patients. Of them 12 had pancreatic cancer, 11 had chronic pancreatitis, and 8 were control patients. K-ras gene mutation was positive in 75% (9 of 12) of pancreatic cancers and in 27% (3 of 11) of cases of chronic pancreatitis but in none of the control patients. Telomerase activity was detected in 92% (11 of 12) of pancreatic cancers and in 18% (2 of 11) of cases of chronic pancreatitis. By combining these two methods, the specificity rose to 100%. Alterations of other genes such as p16, have been described in pancreatic cancer, but they have also been found in chronic pancreatitis[47]. Positive for the two mutations could therefore be particularly predictive of malignant conditions and helpful to differentiating pancreatic cancer from chronic pancreatitis. An identical approach has been evaluated with K-ras gene and p53 or p16 alterations,and has given promising results[47, 48].

CONCLUSIONS

Usefulness and status of K-ras gene point mutation at condon 12 are contradictive, the mutation indicates a preneoplastic condition, or cancer at an early stage, and therefore disclosure of K-ras gene point mutation in chronic pancreatitis seems not sufficiently predictive of malignant transformation, and its detection in combination with clinical and morphological follow-up should not be recommended at this time for screening pancreatic cancer,but can be used as an adjunct to cytology for the differentiation of pancreatic cancer from chronic pancreatitis. The finding of K-ras point mutations at codon 12 in cytology or biopsy samples from pancreatic mass can not specifically confirm the diagnosis of pancreatic cancer. Only raises the possibility for early surgical intervention if these patients are at high risk of developing pancreatic cancer in the future. Further studies are needed to define the value of K-ras mutation screening in patients with other evidences suggesting the presence of pancreatic cancer. Chronic pancreatitis may be positive for the mutation in the absence of cancer, and pancreatic cancer does not necessarily have the mutation. The ultimate gole is to detect pancreatic cancer at a early stage and avoid unnecessary pancreaticoduodenectomies for chronic pancreatitis.

Abstract

AIM: To examine the expression of Egr-1, c-fos and cyclin D1 at both transcript and protein levels in esophageal carcinoma and to correlate the level of their expressions with precancerous and paracancerous esophageal lesions and esophageal carcinoma.

METHODS: *In situ* hybridization and immunohistochemistry were used respectively to detect the expression of mRNA and proteins of Egr-1, c-fos and cyclin D1 in 70 cases of esophageal squamous cell carcinoma and their corresponding para-cancerous mucosa and upper cut edge mucosa.

RESULTS: *In situ* hybridization and immunohistochemistry showed positive staining of all three mRNAs in the cytoplasm and those of the proteins in nuclei. Overexpression of Egr-1, c-fos and cyclin D1 mRNAs and their proteins was found in dysplasia and squamous carcinomas. The expression level of Egr-1 and c-fos was high, and cyclin D1 was low in dysplasia mucosa, whereas the expression of Egr-1 was decreased, c-fos was maintained and cyclin D1 was increased in the cancers. The expression of both c-fos and cyclinD1 was consistent between the mRNA and protein in their corresponding high expression lesions.

CONCLUSION: The expression of Egr-1, c-fos and cyclin D1 varies in esophageal precancerous lesions and cancer tissues, suggesting an involvement of these genes in the development of esophageal carcinoma.

INTRODUCTION

Esophageal carcinoma is one of the most common malignant tumors in China[1,2]. Its pathogenesis and development are closely related to the expression of some proto-oncogenes and their products[3,4]. Our previous studies have shown that Egr-1 inhibited the growth of esophageal carcinoma cell line Eca109 after exogenous introduction of Egr-1 gene[5,6], but there has been no report on the expression of Egr-1, c-fos, and cyclin D1 mRNAs and their proteins so far. In this study, we examined the expression of Egr-1, c-fos and cyclin D1 mRNAs by *In situ* hybridization and their proteins by immunohistochemistry in 70 specimens from esophageal carcinoma, upper cut edge mucosa and para-cancerous tissues. The purpose was to understand the expression of Egr-1, c-fos and cyclin D1 in esophageal carcinoma and their association with the development of tumor.

MATERIALS AND METHODS

Sample collecting and processing

Fresh surgical resection specimens of esophagus including tumor mass, the upper cut edge mucosa and adjacent mucosa of the tumor mass were taken from 70 patients with esophageal carcinomas who had not received chemotherapy or radiotherapy before the operation. All specimens were collected from Department of Pathology, Shantou University Medical College, between January and December of 2001. The specimens were fixed in 10% neutrally buffered formalin containing 1/1000 of diethyl pyrocarbonate (DEPC, Sigma Chemical Co., USA), paraffin embedded, sectioned to 4 μm thickness, and HE stained.

Histopathology analysis

The diagnosis of esophageal epithelial para-cancer was made by histopathology according to the criteria of Liu *et al.*, which identified 42 cases of normal epithelium, 54 cases of simple hyperplasia and 44 cases of dysplasia. Seventy cases of esophageal carcinoma were diagnosed using WHO histological tumor classification. These included 2 cases of carcinoma *in situ*, 23 cases of grade I, 33 cases of grade II and 12 cases of grade III squamous cell carcinoma. There were 23 cases with invasion of the tumor into the superficial muscular layer, and others into the serosa. In addition, 26 of 70 cases showed lymphatic metastasis.

In situ hybridization

Eukaryotic expression vector of PCMV-Egr-1 plasmid was donated by Dr. Huang RP (Molecular Medicine, Northwest Hospital, WA, USA). The final construct contains the neogene (5.5 kb fragment) driven by the respiratory syncytial virus (RSV) promoter and the Egr-1 gene (2.1kb fragment) driven by the human cytomegalovirus (CMV) promoter. The plasmid was confirmed by gene amplification, purification and double endonuclease cutting, then the products were determined by agarose gel electrophoresis, the 327 bp DNA fragments was recovered by promega DNA purification kit and was labeled with digoxigenin using random priming method (Boehringer Mannheim Biochemica, Germany). The expression of Egr-1

was detected by enhanced sensitive *in situ* hybridization detection kit I (POD) from a commercial Kit (Boster Company, China) according to the manufacturer's instructions. Sections were dewaxed in xylene, hydrated in graduated ethanol, and then incubated in 3% hydrogen peroxide in methanol for 30 min. The tissue was then digested in 20 μg/ml proteinase K at 37℃ for 20 min, fixed in 40 g/L PFA for 10 min, and cooled in 90% ethanol at -20℃ for 5 min. The digoxigenin-labeled cDNA probe was denatured in hybridization buffer (1:40) at 95-100℃ for 10 min and cooled at -20℃ for 3 min. The tissues were then overlaid with the probe, covered with a coverslip and incubated at 42℃ overnight. The expressions of c-fos mRNA and cyclin D1mRNA were also detected by *in situ* hybridization with digoxigenin-labeled gene probes, which were supplied in commercial kits (Boster Company, China), according to the manufacturer's instructions. Following hybridizations, the sections were washed with SSC and incubated with mouse anti-digoxigenin antibody, biotinylated goat anti-mouse and then streptavidin-biotin complex (SABC) for 30 min respectively. The staining was visualized with 3.3'-diaminobenzidine (DAB). The human breast tissue and the known positive esophageal carcinoma tissue were used as positive controls. The hybridization buffer without the probe and sections pre-digested by RNase (10 μg/ml) before Egr-1, c-fos and cyclin D1 detection were used as negative controls.

Immunohistochemistry
The expression of Egr-1, c-fos and cyclin D1 proteins was analyzed using Egr-1 (SC-110) and c-fos (SC-52) rabbit polyclonal antiserum (1:200) and cyclin D1 (A-12) monoclonal antibody (1:100) (Santa Cruz Biot Co, USA) and the SABC and DAB visualization methods according to the manufacturer's instructions (Boster Company, China). The human breast tissue and the known positive esophageal carcinoma tissue were used as positive controls. Negative controls were designed by using PBS instead of Egr-1, c-fos antiserum or cyclin D1 monoclonal antibody.

Assessment of the staining
In situ hybridization showed brown signals of Egr-1, c-fos and cyclin D1 mRNAs in the cytoplasm. The positive immunostaining of Egr-1, c-fos and cyclin D1 proteins was shown as brown signals in the nuclei. The percentage of positively stained cells was evaluated for each tissue section by counting approximately 1000 cells at a high power field. The cases having positive cancer cells accounting for more than 75% of all cancer cells on the slide were defined as a score of 3+ (strong), about 25-75% of all cancer cells were defined as a score of 2+ (moderate), and less than 25% were defined as a score of 1+ (weak). The score of - (negative) was given to cases having no positive cancer cells seen.

Statistical analysis
Statistical analyses were performed using χ^2 test and χ^2 rectified test. A *P* value less than 0.05 were considered to be statistically significant.

RESULTS

Expression of Egr-1, c-fos and cyclin D1 in esophageal precancerous lesions and cancer tissues
In normal epithelia of esophageal mucosa, the expression of Egr-1 mRNA and protein was found in the basal layer of mucosa (Figure 1). The level of expression increased gradually from simple hyperplasia epithelia to dysplasia, but decreased significantly in cancer tissues in which only a few cases of well-differentiated squamous cell carcinoma had Egr-1 expression (Figure 2). A very few cases of normal epithilia and simple hyperplasia epithelia showed c-fos mRNA and protein expression, and the highest expression level was seen in dysplasia of para-cancerous area and squamous cell carcinomas (Figure 3). The cyclin D1 mRNA and protein were found in a few simple hyperplasia epithelia and dysplasia epithelia, but showed the highest expression level in cancer tissues (Figure 4). The expression levels between mRNA and protein in both c-fos and cyclinD1 genes were consistent in their correspondent highest expression lesions. However, the expression levels of both Egr-1 and cyclin D1 were significantly different between cancer group and dysplasia epithelia group (*P*<0.01, *P*<0.01). The expressions of Egr-1, c-fos and cyclinD1 mRNAs and their proteins in esophageal precancerous lesions and cancer tissues are shown in Table 1.

Association of expression of c-fos and cyclin D1 with differentiation degree of cancer tissues

Of the three genes examined, the expression of Egr-1 mRNA and protein was low and the expression of c-fos and cyclin D1mRNAs and their proteins was high in esophageal cancer tissues. Furthermore, the expression of c-fos and cyclin D1 was different in different grades of esophageal carcinoma. The positive cases of c-fos appeared to be predominantly those with well or moderately differentiated squamous cell carcinoma, whereas the positive cases of cyclin D1 were mostly those with poorly differentiated squamous cell carcinoma. The cyclin D1 expression level in poorly differentiated squamous cell carcinoma group was significantly higher than that in well, or moderately differentiated squamous cell carcinoma group ($P<0.01$). The expression status of c-fos and cyclin D1mRNAs and their proteins in differently differentiated cancer tissues are shown in Table 2.

Association of expression of c-fos and cyclin D1 with lymphatic metastasis in esophageal carcinoma

Esophageal carcinomas were grouped according to different metastasis status and no association was found between the presence of lymphatic metastasis and the expression of c-fos and cyclin D1mRNAs and their proteins in esophageal carcinomas ($P>0.05$, $P>0.05$, Table 3).

DISCUSSION

Regulations of cell growth are dependent on a number of gene families including proto-oncogene, growth factor, growth factor receptor and immediate early transcription factor gene. Egr-1, located on chromosome 5q31.1, is one of the immediate early gene families, and a nuclear protein that contains three zinc-finger domains and could regulate cell growth and differentiation by activating cyclin D1 to promote the progression of cells from G0/G1 phase into G2/M phase[7-9]. It has been reported that Egr-1 was originally in dormancy but might be activated through membrane depolarization by induction of stress, ischemia, hypoxia, bacterial toxin, cell factors, ionizing radiation and some oncogenic factors[10-12]. Using in situ hybridization and immunohistochemistry on a series of esophageal precancerous lesions and cancer tissues, Egr-1 mRNA and protein were detected in tissues of normal epithelia and simple hyperplasic epithelia of esophagus. However, the level of Egr-1 mRNA and protein expression was much higher (61.4% and 47.7%, respectively) in dysplasia but significantly decreased in cancerous tissues. It is possible that the paracancerous mucosa might be subjected to a higher level of stimulation, which was consistent with the findings that Egr-1 expression could be activated by many factors[13,14]. High expression of Egr-1 might preserve the stability of chromosome and suppress proliferation, and also improve differentiation and apoptosis of cells[15,16].

C-fos proto-oncogene has been found belonging to a class of cellular genes known as one of the immediate early genes and its protein product is a transcription factor, which could be strongly induced by a number of mitogens[17-19]. The present work found that the expression level of c-fos mRNA and

protein was very low in normal esophageal epithelia and simple hyperplasia epithelia, but was high in dysplasia mucous epithelia and cancer tissues of the esophagus. This finding was similar to those in some previous reports[20-22]. The development of esophageal carcinoma has been identified as a successive course from simple hyperplasia of basal cells, dysplasia, and carcinoma *in situ* to invasive carcinomas. In the cases of c-fos expression, the abnormal expression might be an early molecular event of the pathogenesis and development of esophageal carcinoma. To a certain degree, the expression level could determine the progress or regression of the pathological changes.

Cyclins are a family of cell-cycle-associated nuclear proteins and cyclin D1 is a member of this family, which could contribute to cell cycle progression through G1 phase and has been found to be closely related to the regulation and control of cell cycle[23]. The role of cyclin D1 in cell cycle control appeared to be mediated through the cyclin-dependent kinase (Cdk)/cyclin D1 complex. Some studies have indicated that cyclin D1 was involved in esophageal carcinoma and that its overexpression might be a useful prognostic factor[24-28]. Others argued that the overexpression of cyclin D1 in esophageal cancer tissues might not predict the prognosis independently[29-32]. In the current study, we found that cyclin D1 mRNA and protein expression was high in esophageal carcinoma compared with that in pre-cancerous tissue and the degree of positive expression was stronger in poorly differentiated squamous cell carcinomas. It seemed that the high level of expression of cyclin D1 indicated the poor prognosis. However, no correlation was found between cyclin D1 expression and lymphatic metastasis of squamous cell cancer. Our study suggested that overexpression of cyclin D1 could be used to help clinicians take more rational measures for post-operation patients who showed no metastasis to lymph nodes.

The pathogensis of esophageal carcinoma is a course in which the oncogenes and tumor suppressor genes act or counter act to each other. This interation could determine the development of esophageal carcinoma[33-35]. The progress from normal esophageal mucous epithelia to simple hyperplasia, atypical hyperplasia and cancer is usually atributed to the decreased expression of tumor suppressor genes and increased expression of oncogenes. Our studies found that the expression of Egr-1 was decreased, c-fos was remained and cyclin D1 was increased during the progress of esophageal mucous epithelia from precancerous lesions to cancer. The activity of Egr-1 was reduced, but the activity of c-fos and cyclin D1 was enhanced. This resulted in abnormal regulation and control of cell cycle in the basal layer cells of esophageal mucous epithelia leading to the development of esophageal carcinoma. Neverthless, the mechanism of the involvment of these genes in the development and progress of esophageal carcinoma remains to be further investigated.

Abstract

AIM: Pituitary tumor transforming gene (PTTG1) is overexpressed in a variety of tumors, including carcinomas of the lung, breast, colon, as well as in leukemia, lymphoma and pituitary adenomas. However, there is little information on its expression in gastric carcinoma. We sought to investigate the expression of PTTG1 in gastric carcinoma and to explore the relationship between its expression and clinicopathological factors.

METHODS: We studied 75 primary human gastric adenocarcinomas, including 17 mucosal carcinomas, 21 submucosal infiltrative carcinomas, 12 carcinomas invading proprial muscle layers, 6 carcinomas reaching the subserosa, and 19 carcinomas penetrating the serosal surface. Immunohistochemical analysis was performed using paraffin-embedded sections of gastric adenocarcinomas.

RESULTS: PTTG1 was expressed heterogeneously in carcinomas. Positive PTTG1 staining was observed in 65.3% of the carcinomas (49 of 75). Its expression did not correlate significantly with either the histological type or the depth of infiltration of the gastric carcinomas. However, a statistical analysis showed significant differences between the primary adenocarcinomas and the associated metastatic lymph nodes.

CONCLUSION: The results of this study demonstrate that PTTG1 expression is enhanced in metastatic lymph nodes in comparison to that in primary carcinomas. We suggest that PTTG1 may contribute to lymph node metastases in gastric carcinoma.

INTRODUCTION

Gastric carcinoma is one of the most common causes of malignancy-related death worldwide. Recent molecular biological studies suggest that genetic instability may play an important role in the pathogenesis of gastric carcinogenesis[1]. There are at least two distinct genetic instabilities in gastric tumorigenesis. One is chromosomal instability and the other is instability of the microsatellites. In the former, diminished expression of tumor suppressor genes, such as p53, Rb, APC, MCC and DCC, plays an important role in carcinogenesis. Whereas in the latter, the defective repair of mismatched bases results in an increase in the rate of point mutations[2-4].

Aneuploidy is a numerical imbalance in chromosomes caused by missegregation during cell division. A critical event that promotes equal partitioning of chromosomes during mitosis is the proper and timely separation of sister chromatids attached to each other and to the mitotic spindle. Interestingly, pituitary tumor transforming gene (PTTG1) is a securin that acts as an inhibitor of chromatid separation[5].

PTTG1 is a novel oncogene that has been identified by Pei *et al*[6]. PTTG1 overexpression in mouse fibroblasts and NIH 3T3 cells induced cellular proliferation and transformation, both *in vitro* and *in vivo*[6,7]. PTTG1 is overexpressed in a variety of tumors, including carcinomas of the lung, breast, colon, as well as in leukemia, lymphoma and pituitary adenomas[8-11]. The expression of PTTG1 in normal tissues is restricted with the highest expression occurring in the testis[6,8,9]. PTTG1 is expressed in a stage-specific manner in germ cells during the spermatogenic cycle, suggesting that it may play a role in male germ cell differentiation[12]. PTTG1 also regulates the secretion of basic fibroblast growth factor[8].

In the present study, we investigated PTTG1 expression and explored the relationship between its expression and clinicopathological factors in 75 gastric carcinoma specimens.

MATERIALS AND METHODS

We studied 75 primary human gastric adenocarcinomas, including 17 mucosal carcinomas, 21 submucosal infiltrative carcinomas, 12 carcinomas invading proprial muscle layers, 6 carcinomas reaching the subserosa, and 19 carcinomas penetrating the serosal surface. All tumor specimens were obtained from patients at the Nagasaki University Hospital between 2001 and 2002. Each tumor was assigned a histological type and a depth grading of infiltration according to the

Japanese Classification of Gastric Carcinoma by the Japanese Gastric Cancer Association[13]. The primary human gastric adenocarcinomas were classified histologically as follows: 4 papillary adenocarcinomas, 18 tubular adenocarcinomas of the well differentiated type, 22 tubular adenocarcinomas of the moderately differentiated type, 7 poorly differentiated adenocarcinomas of the solid type, 10 poorly differentiated adenocarcinomas of the nonsolid type, 12 signet-ring cell carcinomas, and 2 mucinous adenocarcinomas. Diagnosis was established by two independent pathologists (CY Wen and T Nakayama) and cases of questionable diagnosis were omitted from the study.

Immunohistochemistry

Formalin-fixed and paraffin-embedded tissues were cut into 4 μm sections, deparaffinized in xylene, and rehydrated in phosphate-buffered saline. Deparaffinized sections were subsequently preincubated in 3% H_2O_2 for 30 min, followed by incubation in normal bovine serum to prevent nonspecific binding and subsequently incubated overnight at 4 ℃ in a primary polyclonal antibody directed against human PTTG1 (2 μg/ml) (Zymed Laboratories, Inc. South San Francisco, CA, USA). Next, the slides were incubated in biotinylated anti-rabbit immunoglobulin G followed by avidin-horseradish peroxidase and the reaction product was resolved using diaminobenzidine (DAB) (Vectastain ABC kit; Vector Laboratories, Burlingame, CA, USA). For the PTTG1 expression, pituitary adenoma served as a positive control, and the slide with the primary antibody omitted was used as a negative control. Analysis of the immunohistochemical staining was performed by two investigators (CY Wen and T Nakayama). PTTG1 expression was classified into three categories depending on the percentage of cells stained and/or the intensity of staining: -, 0% to 10% positive tumor cells; +, 10% to 50% positive tumor cells; and ++, >50% positive tumor cells.

Statistical analysis

Statistical analyses were performed using Spearman's correlation coefficient by rank test and the Mann-Whitney U test. A P value <0.05 was accepted as statistically significant.

RESULTS

PTTG1 protein was detected in the cytoplasm. Benign gastric epithelia showed focal and patchy immunoreactivity of PTTG1 with faint to mild staining intensity. The results of immunohistochemical analysis are summarized in Table 1. PTTG1 was expressed heterogeneously in carcinomas. Positive PTTG1 staining was observed in 65.3% of carcinomas (in 49 out of 75). The correlation between PTTG1 immunoreactivity and tumor histological type is shown in Table 1. Tubular adenocarcinomas of the well and moderately differentiated types

were stained strongly for PTTG1 (Figure 1). However, poorly differentiated adenocarcinomas of the solid and nonsolid types exhibited weak PTTG1 expression (Figure 2) and mucinous adenocarcinomas were negative for antibody reaction.

Figure 1 Immunohistochemical demonstration of PTTG1 staining in tumor cell cytoplasm. Tubular adenocarcinomas of the well differentiated type were stained strongly for PTTG1. (×200).

Figure 2 Relatively weak PTTG1 expression, poorly differentiated adenocarcinomas of the solid type. (×200).

The relationship between immunoreactivity and the depth of tumor infiltration is shown in Table 2. PTTG1 staining was positive for tumors with mucosal infiltration (74.7%) or submucosal infiltration (76.2%), whereas expression was markedly weaker in tumors infiltrating proprial muscle layers, subserosa, and serosal surface. PTTG1 expression did not correlate with either histological type or depth of infiltration of gastric carcinomas (Tables 1,2).

PTTG1 expression in primary adenocarcinomas and metastatic lymph nodes are compared in Table 3. PTTG1 staining was mostly negative for the primary sites, i.e., 7 out of 19 tumors were positive (36.8%), whereas 79% of the metastatic sites were immunoreactive (15 out of 19). Statistical analysis showed a significant difference in staining intensity

DISCUSSION

It is now widely accepted that cancer results from the accumulation of mutations in genes that regulate cell birth or death. An underlying genetic instability might be a prerequisite for the generation of multiple mutations that lead to cancer[14,15]. For example, losses or gains in the number of whole chromosomes (aneuploidy) have been found in nearly all major human tumor types, including gastric cancers[16, 17].

A large number of potential targets made putative cancer cells susceptible to several mechanisms that may lead to chromosome instability[18]. The finding that PTTG1 codes for a securin involved in regulating chromatid separation during cell division suggested that securin overexpression might disrupt cell division, generate chromosomal instability and, thereby, increase cell susceptibility to mutations during subsequent divisions[5].

In the present study, we investigated the correlation between PTTG1 expression and histological classification, invasive depth and lymph node metastasis in gastric carcinomas. PTTG1 expression was enhanced in metastatic lymph nodes in comparison to that found in primary carcinomas. Shibata *et al*[19] recently showed a significant correlation between high PTTG1 expression, advanced pathological stage of cancer and lymph node metastasis in esophageal cancer. Heaney *et al* reported that high PTTG1 expression correlated with extension to the bowel wall, metastasis, vascularity and Dukes' staging[10]. These findings suggest that enhanced PTTG1 expression may be a marker for invasive carcinoma.

Pei[20] recently reported that PTTG1 could bind to the c-myc promoter near the transcription initiation site and activate c-myc transcription in transfected cells. These findings suggest that PTTG1 may act as a transcription activator and may be involved in cellular transformation and tumorigenesis via activation of the c-myc oncogene. Furthermore, PTTG1 induces angiogenesis, a key determinant and rate-limiting step in tumor progression and metastatic spread, through basic fibroblast growth factor. Poor prognosis in patients exhibiting high PTTG mRNA expression might reflect an angiogenic phenotype in addition to the acquisition of chromosome instability[6, 21].

In conclusion, the results of this study demonstrate that PTTG1 expression is enhanced in metastatic lymph nodes in comparison to that in primary carcinomas. We suggest that PTTG1 is a marker of lymph node metastasis in gastric carcinomas.

Abstract

AIM: To study the anti-neoplastic effect of Haimiding and its mechanisms of action.

METHODS: Experiments using MTT and colony formation were carried out to study the *in vitro* anti-neoplastic action of Haimiding, its *in vivo* anti-neoplastic action was studied by observing its effect on the weight of tumors in FC mice and S_{180}, H_{22} tumor bearing mice, as well as their life spans. The effect of Haimiding on cell apoptosis and different stages of cell cycles in human gastric carcinoma cells were studied by flow cytometry. Its effect on $[Ca^{2+}]_i$ of human gastric carcinoma cells and the source of Ca^{2+} during the change of $[Ca^{2+}]_i$ were observed by confocal laser scanning technique.

RESULTS: Haimiding showed a definite cytotoxicity to 8 human tumor cell lines, which was most prominent against BGC-823, E_{ca-109} and HCT-8 tumor cells. It also exhibited an obvious inhibition on colony formation of the above tumor cell lines, which was most prominent in E_{ca-109} tumor cells. It showed obvious inhibition on the growth of tumor in FC mice and S_{180} bearing mice as well as prolonged the life span of H_{22} bearing mice. It was able to induce apoptosis and elevate intracellular $[Ca^{2+}]_i$ concentration of tumor cells. The source of Ca^{2+} came from both extracellular Ca^{2+} influx and intracellular Ca^{2+} release.

CONCLUSION: Haimiding is composed of a TCM preparation and 5-flurouracil. Its anti-neoplastic potency is highly enhanced by synergism as compared with either one of its components. Its mechanisms of anti-neoplastic action can be attributed to its action to initiate apoptosis of tumor cells by opening the membrane calcium channel and inducing intracellular Ca^{2+} release to elevate $[Ca^{2+}]_i$ of the tumor cells.

INTRODUCTION

Haimiding (HMD) is an anti-neoplastic preparation made of a traditional Chinese medicine (TCM) preparation and 5-fluorouracil (5-Fu). Its TCM preparation consists of active ingredients from the extracts of *Sargassum fusiforme* (Harv.) Setch, *Ecklonia kurome* okam, *Astragalus chrysopterus* Buge, and *Sophora flavescens* Aits. The present study was to observe the *in vivo* and *in vitro* anti-neoplastic activities of HMD, and the effect of HMD on apoptosis of human gastric carcinoma SGC-7901 and intracellular $[Ca^{2+}]_i$, so to better understand the mechanism of its anti-neoplastic action.

MATERIALS AND METHODS

Materials
Drug samples Sterile HMD powder with or without 5-Fu for parenteral use (Lot No.010606) was prepared by the Pharmaceutical Laboratory, Institute of Materia Medica, Harbin Commercial University. 5-Fu (Lot No. 990304) was provided by Haipo Pharmaceutical Factory, Shanghai, China.
Cancer cell lines Human oral epithelial KB, human esophageal carcinoma cell E_{ca-109}, human proventriculas BGC-823, human pulmonary adenocarcinoma A-549, human colon HCT-8, human breast MCF-7, human ovary A_{2780} and human liver Bel-7402 were provided by the Department of Pharmacology, Institute of Materia Medica, Chinese Academy of Medical Sciences. SGC-7901 was from College of Public Health, Harbin Medical University.
Test animals Kunming strain mice were provided by Veterinary Department of Harbin Medical University, pure 615 strain mice were provided by Institute of Materia Medica, Chinese Academy of Medical Sciences.
Tumor bearing mice strain FC mice, S_{180} A and H_{22} mice of same sex weighing 20 ± 2 g were supplied by Institute of Materia Medica, Chinese Academy of Medical Sciences.
Reagents Bovine serum and RPM1-1640 culture medium were products of Gibo. MTT was provided by Sigma. Fluo-3/AM fluorescence probe was from Molecular Probe Co., USA. Verapamil was a product of Heng Rui Pharmaceutical Factory, Jiangsu Province, China.

Methods
Anti-neoplastic study *in vitro*
MTT test[1,2] About 1200 cells were added to each well of a 96 multi-well culture plate. After 24 h each dose of the drug was added to 3 different wells in the test group. Vehicle was added as control in another group. The plate was placed into a humidified incubator (CAN-111, Japan) containing 5% CO_2 and incubated at 37℃ for 4 d. Ten μl MTT stock solution (5 mg/ml) was added to each well and shaken well, the incubation was continued for a further 4 h. One hundred μl

acidified 10% sodium dodecanoate sulfonate (SDS) (pH=4.7) was added to each well, which was then left overnight. The absorbance was determined by an El-311 enzyme labeling apparatus (El-311, Bio-Tek, USA) at a wave length of 570 nm and a reference wave length of 630 nm. The drug concentration inhibiting 50% of cell growth (IC_{50}) was measured.

Experiments on formation of colonies[3,4] About 100 test cells were inoculated onto a 35 mm plastic petridish for 24 h and the assigned dose of test drugs was added to each dish. The culture liquid was discarded on the 9th day and the residue was washed 3 times in PBS. The cells were fixed in 10% formaldehyde solution and stained with 0.25% gentian violet. The number of colonies containing more than 50 cells in each dish was counted under a microscope. Vehicles were used instead of test drugs as blank control.

Anti-neoplastic studies *in vivo*
Effect of HMD on tumor weight of FC mice[5] Tumor cells were transplanted to 615 FC mice. Nine days after transplantation, FC mice bearing the well growing tumor were placed in an ice basin inside an enclosed aseptic working table. Tumor tissues, were separated and then cut into small pieces and homogenized with a glass homogenizer. The homogenate was made into a suspension containing about 5.6×10^6/ml of tumor cells with sterile normal saline in the conventional way[6], and 0.2 ml of the suspension was transplanted to the right axilla of each 615 strain mouse. After 24 h, the mice were weighed and randomized into 3 HMD groups (treated respectively *ip* with high, medium and low doses of HMD, equivalent to 27.05 g/kg, 13.53 g/kg and 6.76 g/kg of crude drugs in 0.4 ml injectable solution, once daily), a 5-Fu group treated *ip* with 25 mg/kg 5-Fu in 0.4 ml solution once daily, and a compound TCM group treated *ip* with HMD (without 5-Fu) equivalent to 13.50 g/kg of crude drug in 0.4 ml solution daily. A blank control group was treated *ip* with 0.4 ml normal saline once daily. All drugs were withdrawn on the 11th day. The animals were sacrificed on the next day and their tumors were resected and weighed. Results of 3 repeated experiments were collected and the data were statistically analyzed. The rate of tumor inhibition was calculated according to the following equation:

$$\text{Rate of inhibition (\%)} = \frac{\text{Mean tumor wt of blank -} \text{mean wt of test group}}{\text{Mean tumor wt of blank}} \times 100$$

Effect of HMD on tumor weight of S_{180} bearing mice[5] S_{180} tumor cells were transplanted into Kunming strain mice. After 7 days, ascites was drawn from the mice bearing well growing tumor under aseptic condition. The tumor cells were diluted with sterile normal saline in ice-bath to 4:1 to produce a suspension containing about 5.8×10^6/ml of tumor cells. This suspension should have a semi-transparent creamy appearance. Any ascitic fluid with blood streaks should not be used. The mice were transplanted by *sc* injection of 0.2 ml of the suspension to the right axilla of each Kunming mouse according to the procedure described in "National Requirements for *in vivo* Screening of Anti-neoplastic Drugs"[7]. After 24 h, the transplanted mice were weighed and randomized into groups to be treated with different doses of test drugs. Their tumors were resected, weighed and the rate of tumor inhibition was calculated as above (results of 3 repeated trials).

Effect of HMD on life span of H_{22} bearing mice[8] Kunming mice were transplanted with H_{22} tumor cells. The mice bearing well growing transplanted tumor were selected after 7 d, and their ascites were drawn under aseptic condition and diluted in ice-cold sterile normal saline to a concentration of 4:1. The tumor cells were mixed well to generate a suspension containing about 6×10^6 tumor cells/ml, and 0.2 ml of the

suspension was transplanted *ip* to each Kunming mouse. After 24 h, the mice were weighed and randomized to different dosage groups as described above. The number of dead mice was recorded every day until no survival left. The rate of life prolongation was calculated according to the following equation:

$$\text{Rate of life prolongation (\%)} = \frac{\text{Survial days in treated group -} \text{survial days in blank}}{\text{Survial days in blank control}} \times 100$$

Effect of HMD on apoptosis of gastric carcinoma cells[9]
Culturing of tumor cells: Human gastric carcinoma SGC-7901 cells were resuscitated conventionally and cultured in RPMI 1640 culture medium (Gibo) containing 0.1 mass fraction of bovine serum and incubated at 37℃ with 95% relative humidity in an incubator containing a volume fraction of 0.05 CO_2. The cells were generated every 2-3 days.
Experimental groups: Culture flasks containing human gastric carcinoma SGC-7901 cells were divided into 5 groups, 10 flasks each. HMD was added to each flask in the 3 dosage groups to a final concentration of 50 μl/ml, 100 μl/ml and 200 μl/ml, respectively. 5-Fu was added to another group of 10 flasks to a final concentration of 100 μl/ml. A similar amount of culture media was added to the remaining 10 flasks as blank control. They were incubated in an incubator containing 5% CO_2 for 24 h.
Determination of cell apoptosis by flow cytometry[7]: Nine volumes of 70% ethanol were added to 1 volume (about 10^6 cells) of cell suspension and fixed at -20℃ for 12 h. The cells were kept in 70% ethanol at -20℃ for 2-3 weeks, centrifuged and washed in PBS solution. The resulting cells were again suspended in 1 ml of PI staining solution, and stained at room temperature for 30 min. The red fluorescence FCM was detected with a laser (488 nm) or blue light (BG 12 light filter).

Effect of HMD on $[Ca^{2+}]_i$ of gastric cancer cells Culturing of cells Human gastric carcinoma SGC-7901 Cells, after resuscitated conventionally, were cultured in RPMI-1640 medium containing 0.1 mass fraction of bovine serum and incubated at 37℃ with 95% relative humidity in an incubator containing 0.05 volume fraction of CO_2. Every 2-3 days were taken for a generation.

Experimental grouping and treatment with test drugs
Trypan blue was used to show the number of cells, which was adjusted to about 2×10^5/ml with culture medium, and stored in different culture bottles.

The experiments consisted of 6 groups (A, B, C_1, C_2, C_3 and D) and 4 different periods of time (12, 24, 36 and 48 h). Groups A and B were negative and positive controls respectively. Groups C_1, C_2 and C_3 were low, medium and high HMD dose groups, and group D was medium dose of HMD plus verapamil.

When the cells attached to the wall after culturing, the culture medium of each group was adjusted to different concentrations. Group B was adjusted to a final concentration of 50 μg/mL of 5-Fu, groups C_1, C_2 and C_3 to a final concentration of 200 μg/ml, 100 μg/ml and 50 μg/ml of HMD, respectively and group D to a final concentration of 100 μg/mL of HMD plus 20 μg/mL of verapamil. Group A, as a negative control was cultured in RPMI-1640 medium containing 10% bovine serum. These media were cultured for 12, 24, 36 and 48 h respectively, and the resulting cells were collected.

Determination of free Ca^{2+} concentration in cells[39] SGC-7901 human gastric carcinoma cells, digested after addition of test drugs at different times, were collected and washed twice with 0.1 mass fraction RPMI-1640 and then stained with 0.25 mass fraction of trypan blue. The viable cell count was over 95%. The cell suspension was preheated at 37℃ for 5 min and then washed 2-3 times in PBS and calcium free Dakins solution, stained with 100 μl Fluo-3/AM solution at 37℃ for 45 min. A cell suspension was prepared with an appropriate amount of

calcium free Dakins solution. The change of intracellular Ca^{2+} concentration was examined under a confocal laser scanning microscope (Insught Plus-type IQ, meridian, USA), using the intensity of fluorescence light as the criteria of Ca^{2+} concentration, and was observed with a 40× objective lens at an exciting wavelength of 488 nm.

Statistical analysis

t test was used for statistical analysis and results were expressed as mean±SD.

RESULTS

Anti-neoplastic activity of HMD in vitro

Cytocidal activities of HMD against 8 human cancer cell lines are shown in Table 1. It demonstrated that the actions were more prominent in BGC-823, E_{ca-109} and HCT-8 cell lines in a dose dependent manner. Results from regression calculation showed that IC_{50} of HMD against BGC-823, E_{ca-109} and HCT-8 was 25.28 mg/ml, 12.78 mg/ml and 28.29 mg/ml (equivalent to the crude drug) respectively.

Effect of HMD on formation of BGC-823, E_{ca-109} and HCT-8 cell colonies in cell culture

HMD had an obvious inhibitory effect on colony formation of BGC-823, E_{ca-109} and HCT-8 tumor cell lines, being most prominent in E_{ca-109} in a positive dose-effect manner. The data are shown in Table 2.

Anti-neoplastic action of HMD in vivo

Effect of HMD on tumor weight of FC mice HMD at doses of 27.05 g/kg· d, 13.53 g/kg· d and 6.76 g/kg· d demonstrated an obvious inhibitory effect on the growth of tumor in FC mice in a positive dose- effect manner. The inhibitory effect of 13.53 g/kg HMD (containing 25 mg 5-Fu) was more potent than 25 mg/kg of 5-Fu alone with statistical significance ($P<0.05$). Results are shown in Table 3.

Effect of HMD on tumor weight of S_{180} bearing mice HMD at doses of 27.05 g/kg· d, 13.53 g/kg· d and 6.76 g/kg· d significantly inhibited the growth of S_{180} sarcoma in tumor-bearing mice in a positive dose-effect manner ($P<0.01$, $P<0.05$). Results are shown in Table 4.

Effect of HMD on life span of H_{22} bearing mice HMD at doses of 27.05 g/kg· d, 13.53 g/kg· d, and 6.76 g/kg· d obviously prolonged the life span of H_{22} bearing mice in a positive dose-effect manner. HMD at 13.53 g/kg (containing 25mg 5-Fu) showed a more potent effect than that of 5-Fu alone ($P<0.05$), and HMD without 5-Fu ($P<0.05$). Results are shown in Table 5.

Effect of HMD on tumor cell apoptosis and their cell cycles

Studies on the effects of HMD on cell apoptosis and cell cycles of tumor cell lines showed that HMD was able to induce cell apoptosis to a certain degree (Tables 6 and 7), which was statistically significant ($P<0.01$) as compared with the blank control. 5-Fu, however, was devoid of such an effect. HMD caused a decrease of cells at stage S, resulting in cells differentiation at G_0-G_1 and G_2-M stages. But most cells remained at stage G_2-M with an increase of HMD doses.

Effect of HMD on intracellular $[Ca^{2+}]i$ of tumor cells Changes of intracellular $[Ca^{2+}]i$ in human gastric carcinoma cells after treated with HMD for 12 h. It showed that HMD significantly increased the intracellular free calcium ion concentration ($P<0.001$) in a dose dependent manner (Tables 8-11). Calcium ion concentration of the verapamil group

Table 12 Changes of $[Ca^{2+}]i$ in human gastric carcinoma cells after treated with HMD for different times

Different durations of treatment (h)	No. of cells	$[Ca^{2+}]_i$ (FI)
12	28	916.78±151.46
24	23	672.65±165.16
36	26	684.31±148.41
48	28	787.00±178.19

The experimental results indicated that when HMD was used for treatment of tumor cells, an increase of intracellular free calcium ion concentration was observed regardless of the duration of treatment. But comparatively, at the early stage of treatment (12 h), the range of increase was most evident (Table 12).

DISCUSSION

Gastric carcinoma, as one of the most common human malignant tumors, ranks the first leading cause of gastrointestinal cancer-related mortality worldwide. In China, it now ranks the second. It has been shown that tumor apoptosis played an important role in its growth, invasion, metastasis and recurrence[10-29].

HMD is a compound TCM preparation for injection in combination with modern synthetic drugs. It has an obvious anti-neoplastic activity shown by extensive pharmacological studies. In the present study in vitro experiments with MTT and cell colony formation were carried out to assess its inhibition on 8 human cancer cell lines. It showed that HMD could inhibit the growth of cancer cell lines. The anti-neoplastic activity of HMD was most prominent against human gastric carcinoma BGC-823, human esophagus carcinoma E_{ca-109}, and human colon carcinoma HCT-8 cell lines in a dose dependent manner. These results were consistent with the clinical effects of HMD on dysphagia and regurgitation, suggesting that HMD was extremely sensitive to carcinomas of the digestive tract. In vivo anti-neoplastic activity of HMD was studied by transplanting various cancer cell lines (proventricular FC, S_{180} sarcoma and H_{22} liver cancer) into experimental animals to observe its inhibition on tumor growth. It showed that HMD could inhibit the growth of FC and S_{180} tumors in a positive dose-effect manner. It also significantly prolonged the life span of H_{22} bearing mice, though its potency was not comparable to those obtained in FC and S_{180}-bearing mice. This indicates that HMD is more potent for solid tumors than ascitic carcinoma, which also conforms with the clinical obserbations.

HMD injection is composed of 2 parts, a compound TCM formula and a synthetic drug 5-fluorouracil (5-Fu). In the above in vivo and in vitro anti-neoplastic studies, controls with TCM formula or 5-Fu alone were included to compare their individual and combined efficacy. Results showed that the anti-neoplastic action of HMD injection exceeded that of TCM formula or 5-Fu alone (at the same dosage level). Thus, it seemed that TCM formula and 5-Fu had an excellent synergism when used in combination.

To obtain a deeper understanding of the mechanism of the anti-neoplastic action of HMD on human gastric carcinoma, we carried out further studies on the induction of cell apoptosis of human gastric carcinoma SGC-7901 by HMD.

Cell apoptosis, as an autonomic process of organisms, is intrinsically different from necrosis in pathological conditions. Cell apoptosis is a "suicidal" process on its own accord under physiological condition, though it may also involve some pathological events. But, undoubtedly it plays an important role in the recovery and maintenance of normal physiological function. Carcinogenesis is not merely due to abnormal cell proliferation and differentiation. but the mechanisms of cell apoptosis, which leads to neoplastic occurrence, development, evolution, metastasis and eventually death of tumor-bearing hosts should also be duly considered. The mechanism of cell apoptosis in the etiology of carcinogenesis might be induced by many factors, such as inactivation and mutagenesis of apoptotic gene or inhibition of the process of apoptotic gene expression, apoptotic mechanism caused by chemical carcinogens or virus, apoptosis insufficiency of precancerous cell, apoptosis insufficiency of cancer cells due to immunological response of the organism, inhibition of tumor cell apoptosis by adhesion factor and growth factor of the host, attempts of tumor cells to avoid apoptosis by lowering their dependence on survival signal while enhancing their survival competence thereby aggravating the disease with metastasis[30].

The relationship between cell apoptosis and carcinogenesis provides us a new pharmacological mechanism and target for the study of anti-neoplastic drugs. As an anti-neoplastic drug, if it is very potent to induce tumor cell apoptosis and to activate the programed cell death process, then it can avoid a great number of untoward side effects due to the release of waste material resulted from cell necrosis, and alleviate the damage of normal cells caused by chemotherapy and prolong the life of patients.

Experimental studies of the effect of HMD on apoptosis of human gastric cancer cell line showed that there was a definite trend to promote cell apoptosis, but with the increase of dosage no further increase of cell apoptosis could be observed. This might be due to the fact that the increased dose caused a sufficient amount of tissue necrosis, which overshadowed cell apoptosis. The positive control 5-Fu was found unable to induce cell apoptosis which coincided with the finding that 5-Fu could enhance the tolerability of cells toward apoptosis as reported in the literature[30]. Therefore it seems to be possible that the effective ingredient responsible for the induction of apoptosis is the polysaccharides present in HMD formula. Sea weed polysaccharides is known to possess cytotoxicity that can inhibit and kill cancer cells directly, and when excited by low doses of a cytotoxic agent it can induce cell apoptosis, while polysaccharides from astragalus chrysopterur can enhance the cytotoxicity of NK cells of mice. Such NK cell induced death of the target cell is known as apoptosis.

It has been found that the majority of active cells were proliferating at the S stage of DNA synthesis, while the differentiated cells were stagnant at the G_1/G_0 stage[31], when DNA synthesis was not in progress. Anti-neoplastic agents can markedly change the kinetic features of cell cycle such as that occurred in tumor cells from S_{180} mice by the action of HMD. Moreover, different doses of HMD had different effects on cell cycle kinetics. At small (50 μg/ml) and medium (100 μg/ml) doses, HMD could block cell growth at G_1/G_0 stage and S stage. Larger doses of HMD could cause the cells to remain at G_2 and M stage resulting in an obvious increase of G_2 and M cells,

indicating that different doses of HMD showed different anti-neoplastic mechanisms. Regarding its induction of cell apoptosis, HMD also showed several different mechanisms.

HMD exerts its anti-neoplastic action by inducing cell apoptosis of the tumor cells. Ca^{2+} has been found to play an important role in the transmission system of this pathway[37]. To clarify the relationship between the mechanisms of the anti-neoplastic activity of HMD and the intracellular Ca^{2+} concentration, we tried to observe the effect of HMD on the Ca^{2+} concentration in cancer cells by confocal laser scanning microscopic technique.

Calcium presents in the body in two different forms: the combined form and the ionic form (Ca^{2+}). Only the ionic form shows physiological activity. Such calcium ions are divided into intracellular and extracellular types. It was shown that Ca^{2+} concentration in extracellular fluid was about 10^{-3} mol/L, while the intracellular concentration was only 10^{-7} mol/L. They were always maintained at this definite level with intracellular concentration being only 1/10 000 of that of the extracellular one. It has become increasingly evident nowadays that this seemingly negligible change of intracellular Ca^{2+} concentration interferes with many physiological and metabolic functions, especially transmission of cellular signals. At present, Ca^{2+} is regarded as a rather important second messenger and at the same time, participates in or coordinates with the metabolism of other second messengers and the regulation of cell functions.

In the transmission of cell signals, either intrinsic or extrinsic signals pass through the cell membrane to get into cytoplasms and enter into cell nuclei to induce changes of gene expression. Three pathways for a signal to cross over cell membrane have been found[38]: through the mediation of tyrosine protein kinase, G-protein or the ionic channel[32]. The signal transmission in cytoplasm was mainly accomplished by the messenger adenylate cyclase, lipositol and calcium calmodulin[33]. Five corresponding transmission pathways which can induce apoptosis may be derived from the above 3 messengers. They are the Ca^{2+} signal system in cells, the cAMP/PKA signal system, the DG/PKC signal system, the tyrosine protein kinase system, and the acylsphingosine pathway. The main signal molecules in these messengers include cAMP, IP_3, PKC and Ca^{2+}, in which Ca^{2+} could play a pivotal role in the transmission[7,38]. Therefore, in our study on the mechanism of transmission of apoptosis signal to tumor cells, Ca^{2+} was first selected.

In the present study, Fluo-3/AM was used as the fluorescence indicator, and confocal laser scanning microscopy technique was used to determine the dynamic change of $[Ca^{2+}]i$ in human gastric carcinoma SGC-7901 cell line after different durations of drug administration. Therefore, the study was performed at 4 different stages of 12, 24, 36 and 48 h. In each stage, the dose-dependent manner of the effect of HMD on intracellular $[Ca^{2+}]i$ was observed. Experimental results showed that the Ca^{2+} concentration of all the HMD treated groups, regardless of the stage, was higher than that of the negative blank control ($P<0.001$), and the extent of elevation by high, medium and low dosage of HMD was dose-dependent. As to groups dosed for different length of time, the group dosed for 12 h showed a most drastic elevation of Ca^{2+} concentration. All the other time groups showed a larger Ca^{2+} concentration change than the negative control though smaller than that of the 12 h group. This result conformed with literature reports that the elevation of Ca^{2+} was closely related to the early apoptosis.

Cohen and Duke[34] found a continual increase of $[Ca^{2+}]i$ when apoptosis of thymocytes was induced by glucocorticoid. Further studies found that the intrinsic endonuclease which caused DNA fragmentation was Ca^{2+} and Mg^{2+} dependent and the activity of this enzyme was obviously enhanced as the concentration in cytoplasms was elevated. Similarly, when VP-16 or TNF was used to induce apoptosis of breast cancer cells, $[Ca^{2+}]i$ was also elevated to activate the Ca^{2+} dependent endonuclease, causing DNA fragmentation and cell apoptosis[35]. As shown in the present study HMD could induce apoptosis of cancer cells, and cause an increase of intracellular $[Ca^{2+}]i$ similar to the changes of $[Ca^{2+}]i$ when apoptosis of other cancer cell lines occurred[38], which could explain why Ca^{2+} could activate Ca^{2+} dependent endonuclease leading to apoptosis.

While Ca^{2+}, with its pivotal role in those signal transmission systems may induce cell apoptosis through several different approaches: (1) to activate the Ca^{2+} dependent endonuclease causing apoptosis; (2) the elevation of Ca^{2+} activates PKC directly and at the same time helps DG to activate PKC, which is a bifunctional kinase that not only regulates cell differentiation but also induces cell apoptosis; (3) after the elevation of Ca^{2+}, it combines with CaM to form a complex Ca· CaM, which activates adenylate cyclase (AC) resulting in the activation of cAMP/PKA signal system, thereby activating PKA to induce tumor cell apoptosis; (4) Ca^{2+} could control the activity of glutamyl transferase resulting in cell apoptosis, though its exact mechanism is still unclear. In brief, Ca^{2+} plays a specific role in transmission of cell signals of apoptosis. HMD is capable of inducing tumor cell apoptosis by elevating intracellular $[Ca^{2+}]i$.

Ca^{2+} comes from two sources when cellular $[Ca^{2+}]i$ increases. One is the inflow of Ca^{2+} from extracellular sources, mainly by opening calcium channels, The other is the release of Ca^{2+} from intracellular calcium storage. Ca^{2+} in cells is mainly stored in endoplasmic reticulum/seroplasmic reticulum and is mainly regulated by IP_3. To trace the source of Ca^{2+} when intracellular $[Ca^{2+}]i$ in gastric carcinoma cells was elevated by HMD, we tried on an additional "verapamil group", with the use of a calcium channel blocker added to the medium dosage group of HMD. We deduced that one of the following results might occur. (1) If Ca^{2+} only came from extracellular calcium inflow, the $[Ca^{2+}]i$ value should be similar to that of the negative control. (2) If Ca^{2+} came only from the release of intracellular storage, the $[Ca^{2+}]i$ value should be similar to that of the medium dose of HMD group. (3) If the Ca^{2+} came from both extracellular Ca^{2+} inflow and intracellular Ca^{2+} release, the $[Ca^{2+}]i$ value should be between those of negative control and medium dose HMD with statistical significance. Results of the experiment showed that the $[Ca^{2+}]i$ value was higher than that of the negative control, but lower than that of the medium dose HMD group with statistical significance ($P<0.001$). It indicated that HMD elevatd intracellular $[Ca^{2+}]i$ to induce tumor cell apoptosis and caused the opening of calcium channels, which facilitated Ca^{2+} inflow and interacted with receptors on the membrane to produce IP_3 for the release of Ca^{2+} from its storage.

From this study we conclude that HMD shows a remarkable cytotoxicity against tumor cells. Its mechanism of action is to increase intracellular $[Ca^{2+}]i$ by opening the calcium channels of cell membrane, and initiate the release of Ca^{2+} from its storage to induce tumor cell apoptosis.

Abstract

AIM: To examine the expression of nuclear factor kappaB (NF-κB) and its target genes in intestinal metaplasia (IM), dysplasia (DYS) and gastric carcinoma (GC) infected with *Helicobacter pylori* (*H pylori*) and to investigate the mechanism underlying *H pylori* cytotoxin associated gene A (cag A) infection leading to gastric adenocarcinoma.

METHODS: Expressions of NF-κB/p65 and its target genes: c-myc, cyclinD1 and bcl-xl were immunohistochemically examined in 289 cases of gastric biopsy and resection specimens from patients with IM, DYS and GC infected with *H pylori*. *H pylori* in the above mentioned tissues was detected by Warthin-Starry stain and rapid urease tests. IgG antibody to cagA in sera of the patients was measured by ELISA.

RESULTS: The positive rates of NF-κB/p65 were significantly higher in groups with cagA of IMI-II(28/33), IM III(48/52), DYSI(27/31), DYS II-III(28/32), GC(35/40) than in groups without cagA of IMI-II(4/17), IMIII(3/20), DYSI(3/20), DYSII-III(6/21), GC(10/23). The expressions of c-*myc*, cyclinD1, and bcl-xl were significantly higher in groups with cagA of IM III(47/52, 49/52, 46/52), DYSII-III(29/32, 26/32, 25/32) than in groups without cagA of IM III(8/20, 7/20, 5/20), DYSII-III(10/21, 8/21, 3/21), which were in conformity with the expression of NF-κB in IM III, and DYSII-III. A significantly higher expression level of NF-κB/p65, c-*myc*, cyclinD1 and bcl-xl was detected in intestinal type GC(27/28, 18/28, 22/28, 24/28) than in diffuse type GC(8/12, 3/12, 3/12, 6/12), respectively.

CONCLUSION: There may be two different molecular mechanisms in the occurrence of intestinal and diffuse type gastric carcinomas. Intestinal type gastric carcinoma is strongly associated with high expression of c-*myc*, cyclinD1 and bcl-xl through NF-κB/p65 activated by *H pylori* cagA. Inhibiting the activity of NF-κB is an effective and promising way to prevent intestinal type gastric carcinoma.

INTRODUCTION

A close link between gastric carcinoma and *H pylori* infection has been found[1-6]. Animal models of gastric carcinoma induced by *H pylori* provide strong evidence[7-10]. There is a close association between *H pylori* cagA infection and non-cardio gastric carcinoma[11-13]. However, the exact mechanism of *H pylori* cagA leading to gastric carcinoma remains indistinct.

NF-κB is a sequence-specific transcription factor known to be involved in inflammatory and immune responses. A wide variety of genes regulated by NF-κB includes those encoding cytokines, antimicrobial peptides, adhesion molecules[14]. Recently, it has been found that NF-κB contributes to the activation of genes encoding regulators of anti-apoptosis and cell proliferation. Hence, the role of NF-κB in tumorigenesis has attracted increasing attention. It is well documented that cagA of *H pylori* can activate NF-κB and *H pylori* cagA infection often causes chronic atrophic gastritis accompanied by intestinal metaplasia and dysplasia. NF-κB is not only involved in inflammatory responses but also related to carcinogenesis[15-18]. We deduce that NF-κB may be an important link between these two processes. This study was to investigate the possible association between *H pylori* cagA infection and the expression of NF-κB/p65 and its target genes in GC. Warthin-Starry staining and rapid urease tests were performed to detect *H pylori*. ELISA was employed to measure IgG antibody to cagA. HID/AB/PAS staining method was used to distinguish sulphates, neutral and acid mucin. Immunohistochemical techniques were employed to determine the expression of NF-κB/p65 and its target genes in specimens of IM, DYS, and GC.

MATERIALS AND METHODS

Patients and specimens

A total of 289 cases were recruited from patients suffering from gastritis who underwent endoscopic examination and biopsy and from gastric cancer patients received surgical resections from 2001 to 2002 at Zhongnan Hospital, Wuhan. Among the 289 cases, 179 were male and 110 were female. The average age was 48.5 years (range, 19-75 years). From each patient four samples were taken from gastric antrum and corpus, respectively. Rapid urease tests were done first. Patients who obtained positive results had their blood samples taken, which were stored at -20℃ until ELISA assay. No patients had received chemotherapy or radiation therapy before surgery. Samples were fixed in 10% neutrally buffered formalin for histological, histochemical and immunohistochemical studies.

Pathological analysis

For histological evaluation, formalin-fixed tissues were embedded in paraffin, cut into 4 μm thick sections and stained with H&E. GC was histologically divided into early stage and advanced stage, with or without lymph node metastasis, intestinal type and diffuse type[19].

Intestinal metaplasia was classified into three sub-types according to both morphological and histochemical criteria. Dysplasia was divided into three grades[20-21].

ELISA

The presence of serum anti-cagA IgG antibody was tested with commercial enzyme-linked immunosorbent assay (ELISA) kits (Jing Ying Biotechnology Company, Shanghai). Briefly, a recombinant protein fragment of cagA, a purified form of *Escherichia coli* cell lysates, was used as an antigen and fixed to a 96-well plate in carbonate-bicarbonate buffer. After incubation of treated wells with serum diluted 1:100, alkaline phosphatase-conjugated goat anti-human IgG was added. After addition of phosphatase substrate, absorbance was read at 405 nm. Based on the results from *H pylori*-negative controls, a value of ≥0.18 was considered to be positive of IgG antibodies.

Histochemistry

Mucin histochemical studies were performed using HID/AB/PAS staining described by Walsh *et al* and Xin *et al*[22,23]. IM I (complete type) showed a positive staining of AB (blue color). IM II (incomplete small intestinal type) had PAS (magenta color) and AB positive staining. IM III (incomplete colonic metaplasia) had both positive A B (blue color) and HID staining (sulphomucins brown in color) (as shown in Figure1).

Warthin-Starry stain was carried out using standard histological laboratory methods. Positive *H pylori* showed dark-brown-stained bacillary structures in epithelium of mucosa or in glandular recess (as shown in Figure 2). Samples of positive ELISA and rapid urease test or Warthin-Starry stain were considered to be *H pylori* cagA positive. Samples of positive rapid urease test and Warthin-Starry stain were considered to be *H pylori* positive.

Immunohistochemistry

Serial 4 μm thick sections were made and mounted on poly L-lysine coated slides. Paraffin sections were immersed in xylene for 5 minutes and hydrated using a gradient series of alcohol. Antigen retrieval was routinely performed by immersing the sections in citric acid buffer (pH 6.0), in a microwave oven for 15 min. Endogenous peroxidase activity was blocked with 3% hydrogen peroxide for 10 min and then incubated with a primary antibody in a humidified chamber at 4℃ overnight. Primary antibody was monoclonal mouse anti-NF-κB/p65 antibody (Santa Cruze) at 1:200 dilution. Monoclonal mouse anti-cyclinD1, c-*myc* antibody (Maixin Biotechnology Company), monoclonal mouse anti-bcl-xl antibody (Beijing Zhongsheng Biotechnology Company) and ultrasensitive SP kit were obtained from the above-mentioned two companies. Sections were counterstained for 5 min with Delafield' s haematoxylin and then mounted. Human colon cancer having infiltration of lymphatic cells with intense staining for NF-κB, c-*myc*, cyclinD1, bcl-xl was used as a positive control. As a negative control, PBS was used instead of primary antibodies. Expressions of NF-κB, c-*myc*, cyclinD1, bcl-xl in carcinoma cells, metaplastic and dysplastic epithelia were evaluated according to the ratio of positive cells and defined as negative (0-9%) and positive (10-100%). Positive cells of NF-κB/p65 mainly showed a plasmatic staining (Figure 3). Positive cells of c-*myc*, cyclin D1 showed nuclear and plasmatic staining and bcl-xl showed a plasmatic staining (Figure 3).

Statistical analysis

Differences among groups were evaluated by using Chi-square test and Fisher' s exact test. Differences were considered to be statistically significant at $P<0.05$.

RESULTS

The highest positive rates of NF-κB/p65 and its target genes were in IM III among IM I-II, IM II, DYS I, DYS II-III and GC, but there were no significant differences among them (Table 1). The expression of NF-κB/p65 was significantly

higher in groups with *H pylori* cagA of IMI-II(28/33), IM III (48/52), DYSI(27/31), DYSII-III(28/32), GC(35/40) than in groups without *H pylori* cagA of IMI-II(4/17), IM III(3/20), DYSI(3/20), DYSII-III(6/21), GC(10/23) as shown in Table 2. The expression of c-*myc,* cyclinD1, bcl-xl was significantly higher in groups with cagA of IM III(47/52, 49/52, 46/52), DYSII-III(29/32, 26/32, 25/32) than in groups without cagA of IM III(8/20, 7/20, 5/20), DYSII-III(10/21, 8/21, 3/21) (Figure 4), which was conformable to the expression of NF-κB in IM III, DYSII-III, as shown in Table 2.

The expression of NF-κB/p65, c-*myc*, cyclinD1, and bcl-xl was significantly higher in intestinal typeGC(27/28, 18/28, 22/28, 24/28) than in diffuse type GC(8/12, 3/12, 3/12 and 6/12), respectively (Figure 5), as shown in Table 3. It was also observed that the expression of NF-κB/p65, c-*myc* was higher in advanced GC (26/27, 18/27) than in early stage GC(9/13, 3/13) (*P*<0.05). The expression of c-myc was higher in groups with lymph node metastasis(19/30) than in groups without lymph node metastasis (2/10) (*P*<0.05) (Table 3).

We also observed the expression of NF-κB/p65, c-*myc*, cyclinD1 in inflammatory cells of gastric lamina propria and stroma, and 5.6% nuclear staining of NF-κB/p65 was in the groups with *H pylori* cagA in the tissues of IM, DYS and GC.

DISCUSSION

NF-κB was first identified as a regulator of expression of the kappa light chain gene in murine B lymphocytes but has subsequently been found in many different cells[14]. NF-κB is made up of protein dimers that bind to a common sequence motif known as the κB site. The activated form of NF-κB is a heterodimer, which usually consists of two proteins: a p65 subunit and a p50 subunit. In unstimulated cells, NF-κB is found in cytoplasm and is bound to IκB, which prevents it from entering nuclei. When cells are stimulated, specific kinase phosphorylate IκB results in IκB's rapid degradation by proteasomes. The release of NF-κB from IκB would result in passage of NF-κB into nuclei, where it binds to specific sequences in promoter regions of target genes and further activates target genes[24-28].

   H pylori cagA is one of the virulent strains of *H pylori*. Studies have demonstrated that activation of NF-κB by *H pylori* requires genes in cag PAI (pathogenicity island). CagA protein of *H pylori* PAI can be translocated into gastric epithelial cells by a type IV secretion system encoded by cagPAI and is tyrosine-phosphorylated. Tyrosine phosphorylated cagA could induce changes in the tyrosine phosphorylation status of distinct cellular proteins and further activate NF-κB[29-32]. In the present study, we found that high expression of NF-κB/p65 was detected in the tissues of *H pylori* cagA group with metaplasia, dysplasia and gastric carcinoma. We also observed that expression of NF-κB/p65 was mainly localized in cytoplasm. Although nuclear localization of NF-κB was considered as equivalent to NF-κB activation, it showed 5.6% positive rate in *H pylori* cagA group in our study, which was similar to that of Nakayama *et al*[33]. Though it seems difficult to determine whether immunohistological detection of a certain protein reflects its dynamic localization, we believe that large amounts of NF-κB/p65 in the cytoplasm of tissues infected with *H pylori* cagA may be easily activated by cagA of *H pylori*, even by a slight stimulation of cagA protein. NF-κB/p65 activated by cagA up-regulated the expression of target genes in IM, DYS and GC, and might play an important role in the occurrence and development of gastric carcinoma caused by *H pylori* cagA infection. As one of the NF-κB target genes[34,35], bcl-xl belongs to the anti-apoptosis gene family and exerts its anti-apoptosis effect by inhibiting the release of apoptosis inducing factors.

Some investigations showed that tumor cells with activated NF-κB were not sensitive to radio and chemotherapeutic agents, while inhibition of NF-κB activity could enhance the radio- and chemosensitivity of cancer treatment[36,37].

Activated NF-κB has also been shown to directly stimulate the transcription of genes that encode c-*myc and* cyclinD1 because a kB binding site is present within the c-*myc*, and cyclinD1 promoter [16,38-40]. c-*myc* is known to be a strong inducer of proliferation and is believed to be critical for the oncogenic properties. Studies showed that aberrant c-*myc* expression was widespread in tumor cells and important for multistep carcinogenesis[41,42]. However, proliferation induced by c-*myc* requires the concomitant mutant of p53. In gastric precancerous lesions infected with *H pylori*, mutants of p53 were often confirmed[43,44]. cyclinD1 is a cell cycle regulatory gene. It is essential for G1 phase progression and has been implicated in the pathogenesis of several human malignancies, including gastric carcinoma[45-47].

As evidenced here, high expressions of c-*myc*, cyclinD1, bcl-xl concomitant with NF-κB/p65 in the tissues of cagA+ of IM III and DYS II-III could drive cells inappropriately through the cell cycle to evade apoptosis, resulting in uncontrolled proliferation characteristic of neoplastic cells. In addition, weak to moderate staining of NF-κB/p65, c-*myc*, cyclinD1 of inflammatory cells in the stroma of gastric lesions was observed. The above results, taken together, could be explained in two ways. First, *H pylori* cagA infection led to gastritis, and activated NF-κB. Activated NF-κB could promote inflammatory cells and epithelium of gastritis to produce large amounts of reaction oxygen species (ROS), cyclooxygenase-2 (COX-2), IL-6, and IL-8[48-53]. ROS played an important role in damaging DNA of epithelium of gastric lesions[54,55]. COX-2 could suppress epithelial cell apoptosis leading to cell proliferation. Some studies showed that overexpression of COX-2 had a strong association with gastric carcinoma[56,57]. IL-6, and IL-8 could directly induce proliferation of epithelium[58,59]. Second, cagA of *H pylori* activated NF-κB in IM III and *DYS* II-III. Activated NF-κB up-regulated the expression of c-*myc*, cyclinD1, bcl-xl, and prevented the death of epithelial cells that had undergone chromosomal rearrangements or other types of DNA damage. c-*myc,* cyclinD1 enhanced the proliferation of epithelial cells with mutant genes, leading to gastric carcinoma. Such cells are normally eliminated by means of checkpoint control, such as the p53 pathway. As previously mentioned, mutated p53 was often found in precancerous lesions of gastritis infected with *H pylori* cagA. The present study showed that the expression of NF-κB/p65, c-*myc*, cyclinD1 and bcl-xl was significantly higher in intestinal type carcinoma than in diffuse type carcinoma, suggesting that the occurrence of the two types of gastric adenocarcinomas may have different molecular mechanisms, which is similar to other author' s viewpoint[60,61]. *H pylori* cagA infection can lead to intestinal type gastric carcinoma which is strongly associated with the up-regulation of c-*myc*, cyclinD1 and bcl-xl through NF-κB. Moreover, the expression of NF-κB and c-*myc was* higher in advanced stage than in early stage GC. There was no relationship between stages of gastric adenocarcinoma and expression of c-*myc*, cyclinD1, while higher expression of c-*myc* was detected in the group with lymph mode metastasis as compared with the group without. It is concluded that high expression of NF-κB/p65 and its target genes in *H pylori* cagA group of IM III, *DYS* II-III and intestinal type GC may play an important role in various stages of *H pylori* cagA induced intestinal type gastric carcinoma. In GC infected with *H pylori* cagA, the expression of NF-κB/p65, c-myc is associated with infiltration of gastric carcinoma. Moreover, expression of c-*myc* is linked with lymph node metastasis of gastric carcinoma.

Our results suggest that there may be two different molecular mechanisms in the development of intestinal and diffuse type gastric carcinomas. Intestinal type gastric carcinoma is associated with the high expression of c-*myc*, cyclinD1 and bcl-xl through NF-κB/p65 activated by *H pylori* cagA. A better understanding of the molecular mechanisms would contribute to the prevention and prognosis of gastric carcinoma.

Abstract

AIM: Through exploring the regulation of gene expression during hepatocarcinogenesis induced by aflatoxin B₁ (AFB₁), to find out the responsible genes for hepatocellular carcinoma (HCC) and to further understand the underlying molecular mechanism.

METHODS: Tree shrews (*Tupaia belangeri chinensis)* were treated with or without AFB₁ for about 90 weeks. Liver biopsies were performed regularly during the animal experiment. Eight shares of total RNA were respectively isolated from 2 HCC tissues, 2 HCC-surrounding non-cancerous liver tissues, 2 biopsied tissues at the early stage (30th week) of the experiment from the same animals as above, 1 mixed sample of three liver tissues biopsied at the beginning (0th week) of the experiment, and another 1 mixed sample of two liver tissues from the untreated control animals biopsied at the 90th week of the experiment. The samples were then tested with the method of Atlas™ cDNA microarray assay. The levels of gene expression in these tissues taken at different time points during hepatocarcinogenesis were compared.

RESULTS: The profiles of differently expressed genes were quite different in different ways of comparison. At the same period of hepatocarcinogenesis, the genes in the same function group usually had the same tendency for up- or down-regulation. Among the checked 588 genes that were known to be related to human cancer, 89 genes (15.1%) were recognized as "important genes" because they showed frequent changes in different ways of comparison. The differentially expressed genes during hepatocarcinogenesis could be classified into four categories: genes up-regulated in HCC tissue, genes with similar expressing levels in both HCC and HCC-surrounding liver tissues which were higher than that in the tissues prior to the development of HCC, genes down-regulated in HCC tissue, and genes up-regulated prior to the development of HCC but down-regulated after the development of HCC.

CONCLUSION: A considerable number of genes could change their expressing levels both in HCC and in HCC-surrounding non-cancerous liver tissues. A few modular genes were up-regulated only in HCC but not in surrounding liver tissues, while some apoptosis-related genes were down-regulated in HCC and up-regulated in surrounding liver tissues. To compare gene-expressing levels among the liver tissues taken at different time points during hepatocarcinogenesis may be helpful to locate the responsible gene (s) and understand the mechanism for AFB₁ induced liver cancer.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major malignant tumors with a high mortality worldwide, especially in some areas of Southeast Asia and sub-Sahara. The standardized incidence of HCC in these high-risk regions usually exceeds 100 cases per 100 000 population[1]. HCC is also one of the few malignant tumors with a relatively defined etiology. It has been postulated that chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infection and exposure to dietary aflatoxins could contribute to an extraordinarily high risk of HCC in some regions[2-7]. However, it is similar to most of other tumors that the molecular mechanism of tumorigenesis is still to be explored.

Tree shrews (*Tupaia belangeri chinensis*) are small, squirrel-like mammals. Formerly they were considered belonging to the primate order. Currently, they have been classified into a separate order Scandentia, and are considered to be independent of both primates and insectivores[8]. Tree shrews have been used in biomedical researches since early in the 1960' s. Originally most of the researches were on tree shrew' s visual and nervous systems, until Reddy *et al.*[9] successfully induced liver cancer in tree shrew by aflatoxin B₁ (AFB₁) in the 1970' s. Latterly, Yan *et al.*[10,11] reported that tree shrews could be infected with human HBV and there was a synergistic effect between HBV infection and AFB₁ intake on inducing tree shrew' s HCC. Walter *et al.*[12] reported their results from *in vivo* and *in vitro* studies on tree shrews infected with HBV. Tree shrews were then applied in studies on HCC chemoprevention, p53 gene mutation and oncogene expression in hepatocarcinogenesis[13-16]. Since tree shrew is the only known animal that can be infected with human HBV, with the exception of chimpanzee, it has become an animal of interest in researches related to human hepatocarcinogenesis. The

experimental model of tree shrew's hepatocarcinogenesis was established by Yan *et al.* early in the 1980's[10]. One of the characteristics of this model is that the animals can stand repeated liver biopsies during the experimental period. This makes it possible to observe dynamically the sequential changes in liver tissues from the same animal during the course of hepatocarcinogenesis.

cDNA array is a new technology developed in recent years, subsequent to the progress in the human genome project. This new technique can be used to analyze gene expression. It has been applied widely in many research areas including changes of gene expressing level in liver cancer[17-23]. In this study, we used the technique of cDNA array to study gene-expressing patterns of tree shrews' liver at different time points during AFB_1-induced hepatocarcinogenesis. HCC and its surrounding non-cancerous liver tissues, liver tissues biopsied prior to the development of HCC from the same animals, and normal control animals at start of the experiment and at the time when HCC developed in AFB1-treated animals, were compared. The dynamic changes of gene expression level by cDNA array during hepatocarcinogenesis are reported here.

MATERIALS AND METHODS

Animal experiment and collection of liver tissue samples
Adult tree shrews were purchased from Kunming Institute of Zoology, Chinese Academy of Sciences (Yunnan, China). Their body weights ranged from 100 to 160 g. After acclimatized to the facilities, all the animals were screened for sera alanine aminotransferase (ALT) and sera hepatitis B virus surface antigen (HBsAg), as well as histopathology of liver biopsies. The healthy animals were then divided into AFB_1 group and control group. Only tree shrews in AFB_1 group were fed with AFB_1 (150 μg/(kg· d), 5 d/w) in milk, from the 1st week to the 90th week of the experiment.

All the animals throughout the experiment were housed in suspended, stainless steel wire cages individually, under a controlled environmental condition with a 12 h light/dark photoperiod. They had free access to tap water and a diet containing rice, corn, wheat bran, soybean, egg, whole milk powder, sugar, salt, vitamins and minerals, *etc*. They were also fed with reconstituted powdered milk and fruit daily.

Liver biopsies were performed regularly during the experiment, under ketamine hydrochloride anesthesia. Tumors and their corresponding non-cancerous liver tissues were taken when animals were sacrificed. All tissue samples were immediately frozen by liquid nitrogen and stored at -80℃.

Eight shares of total RNA were prepared from the tissue samples, 2 from two cases of HCC and 2 from the non-cancerous counterparts respectively, 2 from the 30th-week (before HCC developed) biopsies of the same animals respectively, 1 mixed sample by three biopsies taken before the animals were grouped and treated with AFB_1 (0th week of the experiment), and another 1 mixed sample by two biopsies taken at the 90th-week (around the same time as HCC tissues were taken) from the control group. More detailed information of the samples is presented in Table 1. All liver tissues analyzed in this study were form female tree shrews.

Preparation of total RNA
Total RNAs were extracted from the specimens of liver tissue by a phenol/chloroform-based method. Briefly, 0.5 g of frozen tissue was pulverized in liquid nitrogen, lysed by adding 17.5 ml of denaturation solution (Trizol, GIBCO BRL), followed by phenol/chloroform extraction and isopropyl alcohol precipitation. The samples were then purified by DNase I and RNase inhibitor followed again by extraction and precipitation as above. Two μl and 5 μl RNA from each

sample were taken respectively for checking concentrations by measuring OD at 260 nm and 280 nm, and for checking quality by electrophoresis on a denaturing formaldehyde/agarose/EtBr gel. The purified total RNA samples were stored at -80℃ prior to use.

Table 1 Sources of total RNA samples

Number and type of samples	Animal treatment
HCC tissue	
1 Tree shrew in AFB_1 group died of HCC at the 88th week of treatment with an amount of AFB_1 up to 10.4 mg.	
2 Tree shrew in AFB_1 group died of HCC at the 89th week of treatment with an amount of AFB_1 up to 11.3 mg.	
HCC-surrounding non-cancerous liver tissue	
3 Autopsy tissue from the same animal and at the same time as #1.	
4 Autopsy tissue from the same animal and at the same time as #2.	
Liver tissue taken before HCC developed	
5 Biopsy tissue from the same animal as #1, at the 30th week of AFB_1-treatment with a total amount of 3.1 mg AFB_1.	
6 Biopsy tissue from the same animal as #2, at the 30th week of AFB_1-treatment with a total amount of 3.2 mg AFB_1.	
Liver tissue taken before AFB_1-treatment	
7 Biopsy tissue mixture from 3 animals before they were grouped and treated (0th week of the experiment).	
Homochronous control	
8 Biopsy tissue mixture from 2 animals in control group at the 90th week of the experiment.	

Probe synthesis, labeling, purification and hybridization
Atlas™ human cDNA expression array (catalog No. 7740-1, lot No. 9090199) kits were purchased from Clontech Laboratories, Inc. (Palo Alto, CA, USA). There were 588 of human cDNAs for the known genes related to different kinds of human tumors, along with 9 housekeeping cDNAs as positive control for normalizing mRNA abundance. The 588 cDNAs were functionally divided into 16 classes. Each sequence of cDNA was 200-600 bp in length and spotted in duplicate with 10 ng of cDNA/dot on the array membrane. Some information of the genes and their functional categories are shown in Table 2.

Probe synthesis, labeling, purification and hybridization were performed according to the manufacturer's instructions. Briefly, cDNA probes were synthesized from 5 μg aliquots (2 μl) of the total RNA samples by the gene-specific CDS primer mix supplied with the Kits, labeled with α-^{32}P-dATP (10.0 mCi/ml, NEN Life Science Company, USA) by the method of reverse transcription and purified through column chromatography. Atlas array membrane was prehybridized for 2 hours and hybridized to the cDNA probes overnight (7 rpm, 68℃). After washed, the membranes were exposed to the phosphorimage system (BIO RAD, GS-525, USA) for 4 hours, the hybridized intensity of each dot was scanned and calculate. The membranes were finally exposed to Kodak X-ray film with intensifying screen for 24-72 hours at -80℃ and then developed.

Data analysis
The intensity of each hybridized dot on each membrane was calibrated according to the formula: calibrated intensity of dot = (original intensity of dot - background intensity of membrane)/ (intensity of housekeeping gene ubiquitin C - background intensity). The background intensity was taken from the middle of each membrane. The ratio of intensity between two compared dots ≥2.0 was considered as gene expression level up-regulated, ≤0.5 as down-regulated. If the same comparison of the two tissue specimens (*i.e.*, the two cases of HCC

compared to their corresponding non-cancerous liver tissues respectively) had the same pattern of change (*i.e.*, both up- or down-regulated), the average ratio was considered as "validated value". Otherwise the ratio was considered as "invalidated value" perhaps due to individual variations or some other unknown factors.

The gene expressing levels in the 5 types of liver tissue were compared by 6 different ways, namely, liver tissues taken from AFB$_1$-treated animal before the development of HCC (30th week of the treatment, BC) and before AFB$_1$ treatment (0th week of the experiment, BA), HCC-surrounding non-cancerous liver tissue (NCL) and its corresponding BC, HCC and its corresponding NCL, HCC and its corresponding BC, HCC and BA, HCC and the liver tissue taken from control group around the same time as HCC (90th week of the treatment, C). Among these 6 ways of comparison, the first three were compared according to the possible sequence of hepatocarcinogenesis (normal liver → liver before HCC developed → HCC-surrounding non-cancerous liver → HCC), the last four were for comparing HCC tissues with the other 4 types of liver tissues. The genes showing changes at least twice among the first three ways of comparison or thrice among the last four ways of comparison, or in the 6th way plus any one of the other three among the last four ways of comparison were

considered as "important genes".

All the data of hybridized dot's intensity were analyzed with Excel software (Microsoft).

RESULTS

Up to the 90th week of the animal experiment, 2 cases showed HCC in AFB$_1$ group, and the first case of HCC appeared at the 88th week. The average amount of AFB$_1$ fed to animals in this group was 10.5 mg. All the HCCs were confirmed histopathologically. No HCC developed in control group until the 90th week of experiment.

The A_{260}/A_{280} ratio for the 8 shares of total RNA was between 1.8-2.2. The electrophoresis showed intactness of all isolated RNA samples.

The intensity of ubiquitin C on each hybridized membrane was most distinct and steady among the 9 housekeeping genes. Generally, the profiles of differentially expressed genes were quite different in different ways of comparison, and the genes in the same function group usually had the same tendency for up- or down-regulation in a given type of comparison. Among the checked 588 genes, 89 (15.1%) were considered as "important genes" according to the criteria mentioned above. Table 2 shows the detailed information for these genes.

Table 2 Differential expressions of important genes

Coordinate	Genbank	Gene Name	1 BC/BA	2 NCL/BC	3 HCC/NCL	4 HCC/BC	5 HCC/BA	6 HCC/C

1 BA: liver tissue from animals before AFB1 treatment (0th week of the experiment). BC: liver tissue from the same HCC animals after AFB1 treatment for 30 weeks. HCC: hepatocellular carcinoma tissue from the same animal after AFB1 treatment. NCL: HCC-surrounding non-cancerous liver tissues from the same HCC animal. C: liver tissue from untreated animals taken at the time when HCC developed in AFB1 treated animals. 2 The numbers followed the name of functional classes are the amount of the important genes identified in this class and their percentage. 3 ↑: up-regulation; ↓: down-regulation. The numbers followed are the averages of the two checked samples. 4 *: Genes might be of more importance.

DISCUSSION

Tree shrew is a kind of animals classified more closely to human being than the common laboratory animals. Park *et al*. reported that tree shrew's wild-type p53 showed 91.7% and 93.4% homologies with human p53 nucleotide and amino acid sequences respectively, and 77.2% and 73.7% homologies respectively with mice[14]. With limited information of tree shrew's genome and no commercial gene chip for tree shrew was currently available, in this study we used human cDNA-array kit to explore tree shrew's gene expression patterns during AFB1-induced hepatocarcinogenesis. The results of hybridization implied that the method used in this study was practicable. Besides, the incidence of HCC (10/15 and 0/12 respectively for AFB1 group and control group at the 135th week of the experiment, data unpublished) and the liver histopathological changes in this study were similar to those of our former experiments[11,24], which demonstrated the tree shrew model of AFB1-induced HCC was reliable.

In the former reports on differentially expressed genes of liver cancer, the usual method was to compare the levels of gene expression between HCC tissues and its surrounding tissues[17-23,25,26]. These so-called "normal" HCC-surrounding tissues, however, frequently involve the changes of hepatitis and/or liver cirrhosis. The present study, by using biopsy tissue from a given animal at different time points during AFB$_1$-induced hepatocarcinogenesis, showed a dynamic profile of gene expression not reported previously. It is notable that a set of genes were up- or down-regulated in HCC-surrounding liver tissue but without any differences with the HCC counterpart. This phenomenon further indicated that the HCC-surrounding liver tissue was no longer normal even in terms of molecular biology. In these HCC-surrounding liver tissues, some growth factors, effectors or their receptors such as thrombin receptor, and some transcriptional factors such as SWI/SNF-related matrix-associated actin-dependent regulator of chromatin subfamily A member 2 (SMARCA 2) were up-regulated, but the genes related to apoptosis were down-regulated. These changes inevitably resulted in abnormality of the tissue response to the environment, and kept in anti-apoptosis condition. Apparently, the HCC-surrounding liver tissue was at a precancerous status at molecular level. Actually, there were only a few genes that were continuously up- or down-regulated during hepatocarcinogenesis. This study also showed that some genes were up-regulated during the early stage but down-regulated during the late stage of hepatocarcinogenesis, the reason of this phenomenon awaits further elucidation.

By comparing the 5 types of tissues taken at different time points, the genes differentially expressed during the course of AFB$_1$-induced hepatocarcinogenesis could be categorized into the following 4 types.

Type I, genes that were continuously up-regulated in HCC vs HCC-surrounding non-cancerous liver tissue (NCL) and NCL vs liver tissue taken before HCC developed (BC). This type of genes was rare. Only two were found among the 588 checked genes, namely genes for neurotrophic tyrosine kinase receptor-related protein 3 and cAMP-dependent protein kinase type I beta regulatory subunit (PRKAR1B). Their ratio for HCC vs NCL was 2.6 and 11.4 respectively, and the ratio for NCL vs BC was 5.5 and 4.0 respectively. The gene for nuclease-sensitive element DNA-binding protein (NSEP) probably would also be included into this type.

Type II, genes that had similar expressing levels in HCC and NCL tissues which were higher than that in BC. This type of genes included the genes in the functional group of modulators, effectors and intracellular transducers, and transcription factors and DNA-binding proteins, etc. This pattern of change might imply that these genes were up-regulated after the initiation of hepatocarcinogenesis but kept at a persistent level in the late stage. Moreover, it strongly indicated that a tremendous change in HCC-surrounding liver tissues at molecular level, implying the HCC-surrounding non-cancerous liver tissue was precancerous rather than normal.

Type III, genes that were down-regulated in HCC tissue vs NCL tissue. They included several groups of genes. (1) Genes related to apoptosis. Most of apoptosis-inducing genes were down regulated but a few of anti-apoptosis genes such as IAP were exceptionally down-regulated (0.4) too. The overall trend caused by this pattern of gene expression change, however, favored cell survival. This phenomenon was also seen in some other studies[27-29]. (2) Genes for DNA-repairing were generally down-regulated. The down-regulation of this group of genes might imply the alteration of response of HCC cells to the signals from the surrounding environment. (3) Genes for growth factor, cytokines and chemokines. (4) Genes for interleukins, interferons and hormones.

Type IV, genes that were up-regulated before the appearance of HCC but down-regulated after the development of HCC, including genes related to DNA-repair, genes related to growth factor and cytokines, genes for interleukins, and genes related to hormones. Their up-regulation might putatively imply the acute phase response of related genes to genotoxicity. The down-regulation might imply the defective expression of related genes during carcinogenesis, or some other up-regulated genes might functionally compensate for these genes. Table 3 shows the detailed information about these four types of genes.

Table 3 Four types of differentially expressed genes

Type I, genes that up-regulated both in HCC vs NCL and NCL vs BC.
Modulators, effectors & intracellular transducers
    neurotrophic tyrosine kinase receptor-related 3
    cAMP-dependent protein kinase type I beta regulatory
    subunit (PRKAR1B)
Type II, genes that had similar expressing level in HCC and NCL but higher than that in BC.
II-1. Modulators, effectors & intracellular transducers
    thrombin receptor (TR)
    epidermal growth factor receptor substrate 15 (EPS15)
II-2. Transcription factors & DNA-bingding proteins
    SWI/SNF-related matrix-associated actin-dependent
    regulator of chromatin subfamily A member 2 (SMARCA2)
    octamer-binding transcription factor 2 (OCT2)
    mitochondrial transcription factor 1 (MTTF1)
    transcriptional repressor protein yin & yang 1 (YY1)
    nucleobindin 1 (NUCB1)
II-3. Growth factor & chemokine receptors
    endothelin receptor type B (ETB)
II-4. Cell surface antigens & adhesion proteins
    myeloid cell surface CD33 antigen
II-5. Growth factors, cytokines & chemokines
    hepatocyte growth factor-like protein
Type III, genes down-regulated in HCC vs NCL.
III-1. Apoptosis-associated proteins
    p53 cellular tumor antigen
    TNF-related activation protein (TRAP)
    N-myc proto-oncogene
    receptor (TNFRSF)-interacting serine-threonine kinase 1 (RIPK1)
    tumor necrosis factor C (TNFC)
    NIP1 (NIP1)
    BCL2/adenovirus E1B 19-kDa-interacting protein 3 (BNIP3)
    BCL2 homologous antagonist/killer 1 (BAK1)
    inhibitor of apoptosis protein 3 (IAP3)
    WSL protein + TRAMP + Apo-3 + death domain receptor 3 (DDR3)
    cysteine protease ICE-LAP3
III-2. DNA synthesis, repair & recombination proteins
    nuclear factor IV
    xeroderma pigmentosum group B complementing
    protein (XPB; ERCC3)
    70-kDa thyroid autoantigen (TLAA)
    replication protein A 70-kDa subunit (RPA70)
    excision repair cross-complementing rodent repair deficiency
    complementation group 1 (ERCC1)
    colon cancer nonpolyposis type 2 protein (COCA2)
    UV excision repair protein RAD23 homolog B (hHR23B;
    XPC repair-complementing complex 58-kDa protein)
    growth arrest & DNA damage-inducible protein 153 (GADD153)
    DNA damage repair & recombination protein 50 homolog (RAD50)
III-3. Growth factors, cytokines & chemokines

thrombomodulin (THBD)

hepatoma-derived growth factor (HDGF)

T-cell activation protein 2 (AT2)

neuroleukin (NLK)

neuregulin 1 (NRG1)

bone morphogenetic protein 3 (BMP3)

small inducible cytokine subfamily A member 2 (SCYA2)

hepatocyte growth factor (HGF)

calgranulin A (CALA)

AFGF + HBGF-1 + ECGF-beta

III-4. Interleukins & interferons

interleukin 2 (IL2)

interleukin 1 alpha (IL1-alpha)

interleukin 4 (IL4)

interferon beta 1 (IFN-beta 1)

interleukin 12 beta subunit (IL12-beta)

interleukin 12 alpha subunit (IL12-alpha)

III-5. Hormones

insulin-like growth factor-binding protein 3 (IGFBP3)

Type IV, genes up-regulated before HCC appearance but down-regulated after HCC developed.

IV-1. DNA synthesis, repair & recombination proteins

replication factor C 36-kDa subunit (RFC36)

DNA topoisomerase II alpha (TOP2A)

DNA damage repair & recombination protein 52 homolog (RAD52)

DNA ligase III (LIG3)

muscle-specific DNase I-like (DNL1L)

IV-2. Growth factors, cytokines & chemokines

granulocyte colony-stimulating factor (GCSF)

heregulin-beta3

thrombopoietin (THPO)

connective tissue growth factor (CTGF)

IV-3. Interleukins & interferons

interleukin 7 (IL7)

interleukin 3 (IL3)

interleukin 6 (IL6)

interleukin 11 (IL11)

IV-4. Hormones

cellular retinoic acid-binding protein II (CRABP2)

corticotropin-releasing factor-binding protein

It has to be noticed that cDNA array, the method used in this study has some limitations. First, this method only shows mRNA but not the protein expression level of related genes. Second, even if the expression level of mRNA may equally reflect the expression level of protein, it can not represent the functions of these gene products such as phosphorylation/ dephosphorylation, methylation, acetylation or glycosylation. The status of protein phosphorylation is very critical for cellular signal transduction, and there is accumulating evidence that suggests the relationship between the status of methylation and activation of gene in hepatocarcinogenesis[30-33]. Therefore, the genes showing differential expressions at mRNA level must be further studied on their protein expression level and their modified status. The present study, however, provides a preliminary clue to the differential expressions of mRNA during AFB$_1$- induced hepatocarcinogenesis, particularly at different stages of carcinogenesis from the same animals. Since the development of most human HCCs in China are attributed to the synergistic effects of AFB$_1$ and HBV, the study on tree shrew's hepatocarcinogenesis induced by both AFB$_1$ and HBV is now in progress, and the preliminary result was published recently[34].

Abstract

AIM: To compare the therapeutic effect of transcatheter arterial chemoembolization (TACE), laparoscopic radiofrequency ablation (LRFA), and conservative treatment for the therapy of decompensated liver cirrhosis patients with hepatocellular carcinomas (HCC).

METHODS: Between October 2000 and July 2003, one hundred patients with histologically proven primary HCC and clinical decompensated liver cirrhosis (Child classification B or C) were included in this study. Forty patients received LRFA (LRFA group), twenty received TACE (TACE group), and forty received conservative treatment (control group). We compared the survival, recurrence, and complication rates in these three groups, making adjustment using the tumor metastatic node staging system.

RESULTS: The major complication rate in the TACE group (9/20) was significantly higher than that in the LRFA group (7/40). For patients with TMN stage II HCC, the survival rate of the LRFA group was better than that of the TACE and control groups ($P=0.003$) but the recurrence rates befween the LRFA and TACE groups did not differ.

CONCLUSION: The LRFA group of patients had better clinical outcomes in terms of survival and complication rates in comparison with the TACE group or conservative treatment in patients with decompensated liver cirrhosis, especially in TMN patients with stage II HCC. LRFA is thus an appropriate alternative treatment for poor liver function among patients with HCC.

INTRODUCTION

Surgical resection is the preferred treatment for patients with hepatocellular carcinomas (HCC), as it offers the potential for cure of primary hepatic malignancies[1,2]. Unfortunately, only 10% to 20% of patients with HCC are suitable candidates for resection because of constraints of size, location, extent of the tumors[3] or poor liver function. The impaired liver function of HCC patients is thus a major limitation for surgical resection.

Over the last decade, other treatment modalities have been used in the management of these patients with unresectable HCC, such as cryoablation[4], microwave coagulation therapy[5,6], alcohol ablation, laser photocoagulation, high-intensity ultrasound, regional chemotherapy infusion[7], transcatheter arterial chemoembolization (TACE)[8], and radiofrequency ablation (RFA)[9].

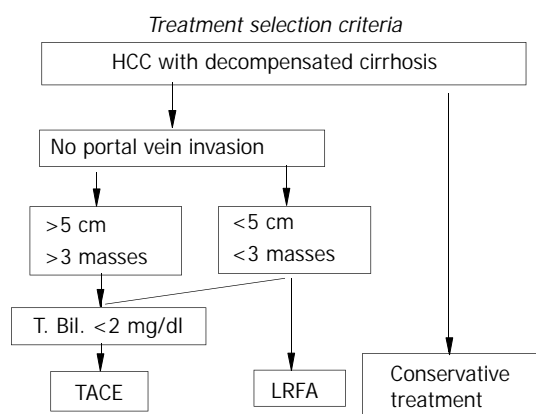
Recently both TACE and RFA have received increasing attention as promising treatments for patients with unresectable HCC[4,8]. TACE is a liver-directed therapy that takes advantage of the relatively selective vascularization of hepatic arterial tumors. HCC derives approximately 80% to 85% of their blood supply from the hepatic artery, whereas the portal vein as well as the hepatic artery supply the normal hepatic parenchyma. Chemotherapeutic agents can thus be delivered angiographically with concomitant embolization to increase local chemotherapeutic dwell time and induce tumor ischemia[10].

Investigation and use of thermal ablation have increased with advances in radiofrequency ablation (RFA) technology. This approach has been used to treat small lesions measuring 5 cm or less in diameter, and complete necrosis was achieved in 76-100% of lesions[4]. It has few complications while achieving safe[11] and excellent local control[12].

The aim of this study was to compare the therapeutic effect of TACE, laparoscopic RFA (LRFA), and conservative treatment for patients with decompensated liver cirrhosis (Child classification B or C) with HCC.

MATERIALS AND METHODS

Between October 2000 and July 2003, one hundred patients with histologically proven primary hepatocellular carcinoma were included in this study. All patients were Child classification B or C[12] and not suitable to receive surgical resection. Patients with tumor size larger than 5 cm or with more than three tumors were considered suitable for repeated TACE or conservative treatment. Patients with serum total bilirubin concentrations of more than 2 mg/dL were considered for LRFA or conservative treatment. Patients with fewer than three tumors smaller than 5 cm were considered for TACE, LRFA or conservative treatment, according to their own preferences or those of their families (Figure 1). Forty patients received LRFA (LRFA group), twenty received TACE (TACE group), and forty received conservative treatment (control group). We compared the

survival, recurrence, and complication rates in these three groups. The comparison was based on the AJCC TMN staging system modified in 1998[13].


Treatment selection criteria

Figure 1 Criteria of treatment selection.

LRFA technique

Patients were considered for LRFA if they had less than three tumors smaller than 5 cm, regardless of the proximity of the lesions to major portal or hepatic vein branches. The LRFA needle was passed transcutaneously under laparoscopic ultrasound guidance in the operation room with the patient under general anesthesia. The Radio Therapeutics RF3000 system (Radio Therapeutics Corp, Mountain View, CA) was used in this study. It uses an insulated monopole LeVeen needle electrode consisting of ten hook-like projections that were deployed after the cannula was inserted into the target tissue. Once in place, power was applied by the RF3000 generator, which can deliver up to 100 W. Power was increased in a stepwise fashion beginning at 50 W until the maximum power was reached. Tumor ablation was continued at maximum power until tissue impedance increased to the point when power output fell rapidly (termed 'roll-off'). If roll-off was not achieved, ablation was continued at maximum power for 15 min. This procedure was repeated until roll-off, or for 10 min if roll-off could not be achieved.

Small tumors (less than 3 cm) were ablated after a single passage of the electrode array into the center of the lesions. For larger tumors (more than 3 cm), the electrode array was repositioned at 2 cm intervals and ablation was carried out as above to allow complete destruction of the tumor with a 1 cm margin. For tumors located in the posterior segment or lobes of the liver where trans-abdominal needle insertion was impossible, trans-thoracic needle insertion was performed using a chest tube.

TACE technique

Vascular access was obtained via the right common femoral artery and a guide wire was advanced under fluoroscopic guidance. A 5-Freches sheath was then inserted over the guide wire. The superior mesenteric artery was selected and an angiogram was completed to identify any aberrant arterial anatomy and verify portal vein patency. The celiac axis was then selected and an angiogram was completed. The catheter and guide wire were used to select the proper hepatic artery and a limited angiogram was completed to identify the branches of the hepatic artery. The right or left hepatic artery was selected for lesions in the right or left lobe, respectively, and an angiogram was completed. Any tumors were identified using a rapid contrast blush method.

Once the vascular supply of the tumor had been identified, chemoembolization of the supplying artery was started.

Doxorubicin (50 mg: NovaPlus, Novation, Irving, TX) with one-third of a vial of 250-355 μm diameter polyvinyl alcohol particles (Boston Scientific, Natick, MA) was used as the chemoembolic agent. Successful embolization of the feeding vessel was confirmed by angiogram. The catheter and wire were then removed and direct pressure was applied for 20 minutes.

Follow-up

Computed tomographic (CT) scans were obtained from all patients one week postoperatively to document ablation. Follow-up CT scans were obtained every three months for one year and every six months thereafter. Serum Alpha-fetoprotein (AFP) concentrations were also monitored postoperatively. Elevated AFP concentrations, increases in size, or changes in the computer tomography (CT) contrast-enhanced appearance of the original tumors were used to diagnose any tumor recurrence.

Any mortality within one month after surgery (30 days) was recorded. Any complications were registered on a computer database for each patient. Major complications were regarded as any prolongation of stay in hospital caused by hepatic failure, pulmonary embolism, stroke, pneumonia, upper GI bleeding, or refractory ascites. Hepatic failure was defined based on symptoms such as hepatoencephalopathy, varices bleeding and the need for readmission and further treatment. Minor complications were regarded as those that did not cause any extension of hospital stay, such as pneumothorax, wound infections, burns and post embolization fever.

Statistical analysis

Analyses were performed using S-Plus®2000 for Windows statistical software (CANdiensten, Amsterdam, The Netherlands). The level of significance was set at $P<0.05$ for all tests. Continuous variables were expressed as mean±SD, and tested using Student's t test and categorical variables were tested using Fisher's exact test. Survival rates were calculated using the Kaplan-Meier method and compared using the log-rank test.

RESULTS

The demographic data of these three groups of patients are summarized in Table 1. The mean ages and follow-up times of the three groups were not different. In this population, males predominated, the main etiology of HCC was hepatitis B virus (HBV) infection and the second was hepatitis C virus infection. This situation is common in Asia. All patients had decompensated liver cirrhosis and most were classified as Child class B, 33/100 were Child class C. Portal vein thromboses only appeared in the control group ($n=12$). The mean tumor diameter of the LRFA group was significantly smaller than that of the TACE and control groups (3.2±1.0 cm vs 6.8±3.7 cm and 6.5±3.1 cm, respectively; $P<0.05$). All three groups had patients with TNM stage II tumors (Table 2). We chose these patients to compare the survival and recurrence rate among the three different groups. The mean tumor diameter did not differ significantly. It was 3.4±0.8 cm ($n=37$) for LRFA patients, 3.7±1.0 cm ($n=9$) for TACE patients and 3.6±0.9 cm ($n=10$) for the controls. There were 11/37, 1/9 and 4/10 TMN stage II patients with Child class C, respectively, among these groups (too few for statistical significance).

Two patients died of hepatic failure within one month, one in each experimental group. We excluded these from the survival analysis. The complication and recurrence rates are summarized in Table 2. The major complication rate of the LRFA group was significantly lower than that of the TACE group ($P<0.05$). Three patients developed hepatic failure and two developed upper gastrointestinal tract (UGI) bleeding in both treatment groups. One patient in the LRFA group and

two in the TACE group developed refractory ascites after treatment. In the TACE group, one patient developed a pulmonary embolism and another had a stroke within three months. In the LRFA group, one patient developed pneumonia within three months. The minor complication and recurrence rates were not different after one and two years.

Patients classified as Child class B or C were also graded with TMN stage II tumors, the survival rate of the LRFA group was better than both the TACE and control groups (Figure 2) (*P*=0.003), whereas the recurrence rates for the LRFA and TACE groups were not significantly different (Figure 3).

Table 1 Demographic data

	LRFA	TACE	Conservative treatment
No. of patients	40	20	40
Age (years)	66.5±9.5	65.0±7.9	69.0±5.7
Sex (male/female)	35/5	17/3	32/8
Etiology (HBV/HCV)	29/11	11/9	26/14
Child-Pugh class B/C	28/12	17/3	22/18
AFP > 400 ng/ml	22	13	25
Portal vein thrombosis	0	0	12
Tumor diameter (cm):	3.2±1.0[a]	6.8±3.7[a]	6.5±3.1
–in TNM stage	3.4±0.8 (37)	3.7±1.0 (9)	3.6±0.9 (10)
II tumors[b]			
TNM stage I tumors	3	0	0
TNM stage II tumors	37	9	10
Child grade C in	11/37	1/9	4/10
TMN stage II tumors			
–in stage III tumors	0	11	14
–in stage IV tumors	0	0	16
Mean follow up (months and ranges)	12.5 (3–30)	11.3 (2.5–29)	10.5 (3.1–30)

[a]Mean tumor diameter in the LRFA group was significantly smaller than that in the TACE group (*P*<0.05). [b]TNM stage was allocated according to the 1998 modified edition[13].

Table 2 Comparison between LRFA and TACE treatment groups in mortality, complication, and recurrence rates

	LRFA (*n*=40)	TACE (*n*=20)	*P* value
One-month mortality[a]	1 (2.5%)	1 (5%)	
Major complications: total	7 (17.5%)	9 (45%)	<0.05
Hepatic failure[b]	3	3	
Pulmonary embolism	0	1	
Stroke	0	1	
UGI[c] bleeding	2	2	
Pneumonia	1	0	
Refractory ascites	1	2	
Minor complications: total	7 (17.5%)	7 (35%)	
Pneumothorax	3	0	
Wound infection	2	0	
Burns	2	0	
Post embolization syndrome[d]	0	7	
Local recurrence rate			
One year	12	7	
Two years	19	11	

[a]One-month mortality, [b]Hepatic failure: readmission due to chronic hepatic failure within three months after procedure, [c]UGI: upper gastrointestinal tract. [d]Post embolization syndromes included fever, pain, nausea, vomiting, leukocytosis and adynamic ileus.

Figure 2 Kaplan-Meier curves of survival rates of TACE-, LRFA- and conservatively-treated groups of patients with TMN stage II hepatocarcinomas.

Figure 3 Kaplan-Meier curve of recurrence rate of TACE and LRFA in TMN stage II.

DISCUSSION

It is very difficult to perform randomized clinical trials among patients with HCC, as each treatment modality has its own specific indications and contraindications. In this study, there were some internal biases, such as tumor size and location, occurrence of portal vein thrombosis, treatment modalities, and liver functions. For example, if the tumor was larger than 5 cm or very near the artery, the patient could only choose TACE or conservative treatment. This made it difficult to compare these three different treatment modalities.

Systems for staging and classifying cancers are attracting interest worldwide. Such systems allow a selection between primary and adjuvant therapy, estimation of prognosis, assistance in evaluating the results of treatment, facilitation of the exchange of information among treatment centers, and contribution to the continuing investigation of human cancers[13]. Among these scoring systems, Child classification[14], Okuda, Cancer of the Liver Italian Program (CLIP), Barcelona Clinic Liver Cancer (BCLC), TMN[15], and Child-Pugh staging are the most widely used for classifying patients with HCC. In this study, we needed a staging system that included both liver function parameters and tumor parameters and allowed the patient groups to be statistically comparable. We combined the Child classification (classes B and C patients) and the TMN staging system (less than three tumors with their diameter less than 5 cm) to select a comparable set of patients. Based on this analysis, the survival rate of the LRFA group was better than that of the TACE and control groups. Thus, LRFA is a good adjuvant therapy for decompensated cirrhotic patients with TMN stage II HCC tumors, especially if the tumors are smaller than 5 cm. The mechanism is unknown.

RFA had an advantage over surgical resection or other palliative treatments in that it could spare more normal liver tissue and pose less risk than surgery[16]. It was more effective

and required less sessions than percutaneous ethanol injection (PEI), and had fewer complications than cryosurgery[17]. As with resection of liver tumors, the goal of the RFA methods was to destroy the tumor and a small margin of the adjacent normal liver[18]. RFA offered some significant advantages over other palliative techniques, such as brief treatment time, precise production of necrotic lesions, and minimal morbidity. RFA is thus a potentially valuable treatment for patients with unresectable liver tumors. It is safe, effective, and repeatable, and local control of hepatic tumors using RFA has been shown to be effective and to prolong the survival of patients with unresectable or advanced liver tumors[11,19]. We found similar results here.

RFA can be performed by percutaneous, laparoscopic or exploratory surgical means. The laparoscopic approach could offer a minimally invasive procedure with the ability to perform intra-operative laparoscopic ultrasound guidance for better tumor detection and more accurate targeting[20]. The decompensated liver was relatively small and lay low in the hepatic fossa, making the percutaneous RFA needle approach difficult. During laparoscopic RFA, achieving a pneumoperitoneum would cause elevation of the diaphragm, which increased the operative space to avoid adjacent organ injury and facilitated needle placement.

The goal of chemoembolization therapy is to prolong tumor exposure to the chemotherapeutic agent and to add an ischemic component (*i.e.*, particles) to enhance tumor necrosis. This treatment is based on the hypothesis that increased exposure time leads to improved response. The localized nature of this treatment could reduce many adverse side effects compared with systemic chemotherapy agents, which have been proven ineffective[19]. By contrast, TACE has the disadvantage in that chemoembolization damages more normal liver tissue than RFA. This causes more postoperative complications, such as liver failure. We think that is why the survival rate of the TACE group of patients was lower than that of the LRFA group in this series.

The major complication rate among the LRFA-treated patients in this study (17.5%) was significantly higher than that reported by Iannitti *et al.* (7.1%)[21] and Curley *et al*[22]. The complication rate was 8% in Child class A patients, 6.5% in Child class B patients and 27.6% in Child class C patients. All the patients in our study had significantly impaired liver function (Child class B or C) and a high major complication rate was expected. These major complications in the LRFA group arose from the decompensated cirrhotic liver except for the development of pneumonia.

The major complication rate seen in the TACE group in this study (45%) was significantly higher than that in other studies (20%)[23]. As in the LRFA group, the major complications were caused by severely impaired liver function. TACE treatment could damage normal liver tissue and induce post-embolization hepatic failure. We believe that this caused the high complication rate in our study.

In conclusion, decompensated cirrhotic liver patients with TMN stage II HCC treated with LRFA had better clinical outcomes, such as survival and lower complication rates than those treated with TACE. We suggest that LRFA may be a better choice for treating Child class B or C patients with TMN stage I or II HCC.

Abstract

AIM: To reveal new tumor markers and target genes from differentially expressed genes of primary tumor samples using cDNA microarray.

METHODS: The ^{33}P labeled cDNAs were synthesized by reverse transcription of message RNA from the liver cancerous tissue and adjacent non-cancerous liver tissue from the same patient and used to hybridize to LifeGrid 1.0 cDNA microarray blot containing 8400 known and unique human cDNA gene targets, and an expression profile of genes was produced in one paired human liver tumor tissue. After a global analysis of gene expression of 8400 genes, we selected some genes to confirm the differential expression using Northern blot and RT-PCR.

RESULTS: Parallel analysis of the hybridized signals enabled us to get an expression profile of genes in which about 500 genes were differentially expressed in the paired liver tumor tissues. We identified 4 genes, the expression of three (Beclin 1, RbAp48 and Pir51) were increased and one (aldolase b) was decreased in liver tumor tissues. In addition, the expression of these genes in 6 hepatoma cell lines was also showed by RT-PCR analysis.

CONCLUSION: cDNA microarray permits a high throughput identification of changes in gene expression. The genes encoding Beclin 1, RbAp48, Pir51 and aldolase b are first reported that may be related with hepatocarcinoma.

INTRODUCTION

Hepatocellular carcinoma (HCC), an aggressive malignancy with poor prognosis and one of the most common tumors in human beings, has become a leading cause of cancer-related death in adults from Asia and sub-Saharan-Africa[1]. The multiple pathogenic factors, including food contamination with aflatoxin B1 and infection with hepatitic B virus and hepatitic C virus and the subsequent multistage pathogenesis of HCC have been extensively studied. In addition, tumor suppressor genes, such as Rb and p53[2], may play a significant role in hepatocarcinogenesis. However it is not clear how these disorders result in HCC. Recent advances in molecular genetics have identified various genetic abnormalities in tumors. However, little is known about the genetic alterations responsible for specific phenotypes of HCC.

With the advent of cDNA microarray technology, genome-wide expression of hundreds of genes can be simultaneously analyzed, facilitating differential expression monitoring of a large number of activated or suppressed genes under various biological conditions, including carcinogenesis[3-5], drug discovery and development[6]. With cDNA microarrays, it is now possible to perform a large-scale expression survey to identify candidate target genes[7]. Efforts to classify human HCC based on gene expression profile using cDNA microarray have been successfully processed in recent year[8-12]. Shirota *et al.* found that 10 genes were up-regulated and 9 genes were down-regulated in >50% HCC and identified the changes of 22 genes associated with the degree of differentiation of HCC[8]. Kawai *et al* showed that AFP-producing hepatoma cell lines shared a distinct expression profile of genes in various categories compared with those of AFP-negative hepatoma cell lines and non-hepatotic cancer cell lines[10]. Xu *et al* identified that 156 genes were down-regulated and up-regulated in >50% of cancer samples of HCC[12]. So much work has focused on HCC expression profile, however the data are still far less.

In this study, we used cDNA microarray representing 8400 cDNA clusters to analyze HCC specific expression profile. The aims were to identify complex alterations of genes expression responsible for the development of HCC and to identify differentially expressed genes and differentially expressed novel genes of potentially biological or medical importance for HCC. In this report, we showed that 523 genes were differentially expressed over 4 folds in the microarray analysis. We confirmed 4 genes which were consistently up or down-regulated in >50% of HCC samples.

MATERIALS AND METHODS

Tumor materials and cell lines

All samples were obtained from Eastern Hepatobiliary Surgery Hospital and Zhongshan Hospital (Shanghai, China). All patients were diagnosed as HCC. Tissue specimens were quickly frozen shortly after surgical resection and stored in liquid nitrogen. Tissue for cDNA microarray hybridization was obtained from a 47-year-old male patient with primary hepatocellular carcinoma stage III, HBV positive.

The HCC cell lines HepG2, SMMC-7721, Bel-7404, Bel-7402, HuH7and the line of normal liver cells L02 were obtained from the Cell Bank of the Chinese Academy of Sciences

(Shanghai, P.R. China). HepG2, HuH7, Bel-7404 and Bel-7402 cells were cultured in Dulbecco' s Modified Eagle Medium (DMED; Life Technologies Inc., Grand Island NY, U.S.A.) supplemented with 10% fetal calf serum (FCS; Life Technologies Inc.) and L02 and SMMC-7721 cells were cultured in RPMI medium 1640 (Life Technologies Inc.) plus 10% FCS.

RNA preparation and poly A+ mRNA preparation

Total RNA was extracted with TRIZOL reagent (Life Technologies, Inc., N.Y., USA). Tissue samples were homogenized in 1ml of TRIZOL reagent per 50-100 mg of tissue and incubated for 5 min at room temperature, then 200 μl chloroform was added and mixed vigorously and incubated at room temperature for 2-3 min. After centrifugation at 1 2000 rpm for 15 min at 4℃, the aqueous phase was transferred to a fresh tube, mixed with an equal volume of isopropanol, and incubated at room temperature for 10 min. Total RNA was collected and washed in 75% ethanol. Total RNA was run on a denaturing formaldehyde agarose gel to check quality. Poly A+ RNA was isolated using the oligotex mRNA mini kit (Qiagen, Hilden, Germany) according to the manufacture' s instructions. Two hundred micrograms of total RNA was routinely used for mRNA isolation.

cDNA microarray hybridization

Gene expression was analyzed using the Human Life Grid 1.0 array (Incyte Genomics Inc. California, USA). Approximately 8 400 human PCR products chosen from Incyte Genomics' s library of proprietary clones were girded onto a 12×22 cm nylon membrane in a double-spotted pattern at a density of approximately 16 800 spots and 27 controls. ^{33}P-labeled cDNA probe was generated by reverse transcription of 1 μg of each analyzed polyA+ RNA sample in the presence of α-^{33}P dCTP and the percent label incorporation was not less than 40%. Each cDNA probe was then hybridized to a microarray. Overnight incubation was followed by stringent washing as recommended by the manual. Membranes were exposed to phosphor screen overnight. The data were analyzed by Incyte Genomics.

Northern blot and semi-quantitative RT-PCR

All probes were obtained by amplification of gene fragments by PCR under conditions listed in Table 1. For conventional Northern blot analysis, 15 μg total RNA was fractionated by electrophoresis through 1% agarose gel containing formaldehyde and blotted in 20×SSC onto Hybond-N+ nylon membrane (Amersham Pharmacia Biotech, Ltd. Buckinghamshire, UK) by capillary force overnight. The blotted RNA was immobilized by incubating at 80℃ for 1 h. Hybridization was performed at 68℃ in ExpressHyb hybridization buffer (CLONTECH Inc.,

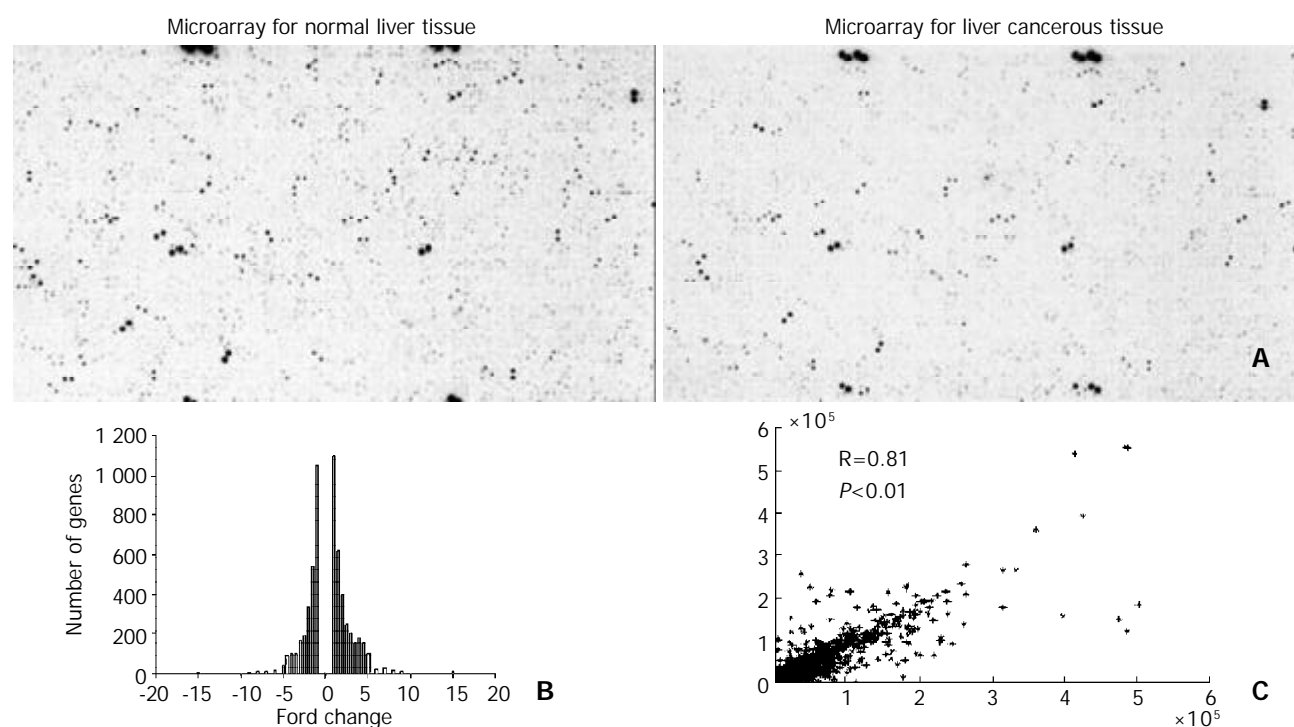
California, USA) for 3 h. Membranes were washed once in 2×SSC, 0.1% SDS at room temperature, twice in 0.1×SSC, 0.1% SDS at 68℃ for 20 min and exposed to X-ray film (Eastman Kodak Co., Rochester MA) at -80℃ for 1-6 d. Three μg total RNA was reverse transcribed in 20 μl reaction mixture with Superscrip^{TM} II (Life Technologies Inc., NY., USA). The PCR cycle number at the linear phase of amplification was chosen to compare differential gene expression among different genes.

RESULTS

Global gene expression analysis of HCC by high density cDNA microarray

The ^{33}P labeled cDNAs were synthesized by RT of message RNA from one liver cancerous tissue and adjacent normal liver tissue from the same patient and used to hybridize to Life Grid 1.0 cDNA microarray blot. General expression profile of 8400 genes was obtained (Figure 1A). We first performed a global analysis of gene expression of 8400 genes and compared the gene expression profiles for normal liver and liver tumor tissues. To eliminate data with low reliability, genes whose expression was regarded as absent in both normal liver and liver tumor by software analysis were excluded, and genes for which two spots were greater than 2.5 fold different and one of the spots was not 2 fold above background were also excluded. There were 6542 remaining genes in normal liver and liver tumor tissues. Fold changes in gene expression between normal liver and liver tumor are shown in Figure 1B. About 92% genes had no significant expression change. The result reflected the reliability of the gene expression profile. The scatter plot of intensity of all genes on arrays of liver tumor and adjacent normal liver was statistically examined to evaluate the accuracy of experiment (Figure 1C). A high correlation was observed. This result suggested a high reliability of the experiment for analysis of differentially displayed genes by cDNA microarray analysis of this sample.

Characterization of expression profile of HCC

Among the 6542 genes expressed in paired liver tumor tissue, 256 genes were up-regulated and 267 genes were down-regulated, which were greater or less than 4 fold in liver tumor tissue. Known functioning genes differentially expressed (>4 fold) in HCC were classified into six functional categories with respect to selected functional properties of their products. The six categories were included in cell division; cell, organism defense; metabolic enzymes, transporters ion channels; nuclear proteins; cell structure, extracellular matrix; cell signaling, communication. The numbers of classified genes are shown in Table 2. The group of ' other genes' summarized individual genes that could not be included in any of the above categories.


Microarray for normal liver tissue   Microarray for liver cancerous tissue

Figure 1 Parallel analysis of gene expression in paired human liver tumor sample (A). Histogram analysis of fold change in differentially expressed genes in cDNA microarray (B). Scatterplot of two cDNA microarray analyses of normal liver and liver tumor samples. Each point stands for a gene with the X coordinate value as the gene expression level in the normal liver microarray and the Y coordinate value as the gene expression level in the liver tumor microarray. A R of 0.81 was produced and suggested high reliability of the experiments (C).

Table 2 Classification of number of known functioning genes differentially expressed (>4 folds) in HCC

Gene functions	Number of down-regulated genes in HCC	Number of up-regulated genes in HCC
Cell division	17	14
Cell, organism defense	39	24
Metabolic enzymes, transporters ion channels	17	9
Nuclear proteins (transcription factors, DNA processing enzymes)	21	20
Cell structure, extracellular matrix	10	6
Cell signalling, communication	37	26
EST	41	53
Other genes	84	102

Figure 2 Northern blots of RbAp48, Beclin 1 and aldolase b genes in paired liver tumor (T) and normal liver tissues (N). RT-PCR analysis of Pir51 in the same paired HCC samples. 18S rRNA shown as a loading control.

Verification of differentially expressed genes in cDNA microarray

To verify the data, we then performed Northern blot analysis and RT-PCR analysis. Only genes with expression levels that were altered by >4 fold between normal and tumor tissues were selected. These analyses were carried out with a total 10 paired HCC samples. We identified 4 genes that were differential expression in >50% paired samples. Three genes were up-regulated and one was down-regulated. Northern blot analysis of Beclin 1 and RbAp48 mRNA showed a significantly increased expression level in 50% paired tumor samples (Figure 2), which could not be detected in normal liver tissues. Northern blot analysis of aldolase b mRNA showed a significantly decreased expression level in 70% paired tumor samples. Northern blotting signal of Pir51 was difficult to obtain, the semi-quantitative RT-PCR carried out in the linear detection range was used to estimate the relative amount of mRNA. Pir51 mRNA was up-regulated by RT-PCR analysis in 60% paired tumor samples (Figure 2).

In contrast we investigated the expression of Beclin 1, RbAp48, Pir51 and aldolase b in one hepato (L02) and 5 hepatoma cells lines by RT-PCR analysis. RbAp48 was detected in L02, Bel-7404, HepG2, Bel-7402 and HuH7, was undetectable in SMMC-7721. Beclin 1 was detected in L02, SMMC-7721, Bel-7404, and HepG2, was weak or undetectable in Bel-7402 and HuH7. Pir51 was expressed in all of hepatoma cell lines detected excluding HuH7. The data also showed that only HepG2 cells, most of cells had not, had a weak expression of aldolase b, (Figure 3). These results from cells coincided with that from tissues (Figure 2). The data of 4 genes obtained from microarray and Northern bolt or RT-PCR are summarized in Table 3. The fold changes of the 4 genes by Northern blot analysis were significantly consistent with cDNA microarray.

Table 3 Genes showing differential expression levels in liver cancerous tissue and adjacent normal liver tissue

Gene Name	GenBank access number	Density in filter for tumor liver	Density in filter for normal liver	Fold change by microarray	Fold change by Northern blot
Beclin 1	AF077301	6 971	0	99	99
RbAp48	X74262	14 029.9	0	99	99
aldolase b	XM_005563	2 765	26 589	-9.65	-4.7
Pir51	NM_006479	8 654.61	323.2	26.8	5.7

GenBank access number, density, fold change verified by cDNA microarray and Northern blot were described.

Figure 3 RT-PCR analysis of RbAp48, Beclin 1, Pir51 and aldolase b expression in one hepato (L02) and 5 hepatoma cell lines (SMMC-7721, Bel-7404, HepG2, Bel-7402, HuH7). β-actin was shown as an internal control.

DISCUSSION

In this study, we used cDNA microarray to identify the genes that may play roles in hepatocarcinogenesis. We demonstrated up- or down-regulated genes in liver cancerous tissues commonly found in patients, and compared them with those in adjacent normal tissues. Then we selected several differentially displayed genes for further verification by Northern blots or RT-PCR. Four genes (Beclin 1, RbAp48, Pir51 and aldolase b) were confirmed to have a differential expression pattern in normal and cancerous liver tissues. The low percentage appeared to be the heterogeneity of tumors[12]. The genes identified through this approach are potential candidates for factors implicated in carcinogenesis, and are useful in both cancer diagnosis and HCC therapy.

Beclin 1 has been found to be a novel Bcl-2-interacting cellular protein which was mono-allelically deleted in 40-75% of sporadic human breast cancers and ovarian cancers[13], and also a mammalian autophagy gene that could inhibit tumorigenesis and could be expressed at decreased levels in human breast carcinoma[14]. It has been considered as a tumor suppressor gene in breast cancer[14,15]. However, our results showed that the expression of Beclin 1 mRNA was increased in liver tumor tissues and HCC cell lines and could not be detected in normal liver tissues. Beclin 1 has an unknown function in HCC. Overexpression of Beclin 1 in neurons *in vivo* could inhibit Sindbis virus replication, reduce central nervous system (CNS) apoptosis, and provide protection against fatal Sindbis virus infection, which might play a role in host defense against Sindbis virus infection[16]. 80% of HCC patients were infected with HBV or HCV, increased expression of Beclin 1 might be induced by the infection of virus. The enhanced expression of Beclin 1 in HCC provided us important information to further determine its new biological role.

RbAp48 was isolated as an Rb binding protein[17]. RbAp48 was found to be one of the three subunits of chromatin assembly factor 1[18,19] and components of histone deacetylase complexes[20,21]. RbAp48 could also interact with a complex of CREB binding protein and phosphorylated CREB[22]. RbAp48 was physically associated in the presence of Rb and HDAC1, suggesting that RbAp48 could be involved in transcription repression of E2F responsive genes[23]. Binding of RbAp48 correlated with the ability of Rb to block cell proliferation[17,24]. Furthermore, the *C. elegans* homologues of both Rb and RbAp48 were recently cloned as two proteins that belong to the same Ras-inhibitory way[25]. However, the mechanisms by which RbAp48 gene product regulated tumor growth are largely unknown. RbAp48 mRNA was also shown to increase in HCC tissues. Although the biological significance of this finding needs further study, our results showed that altered expression of RbAp48 gene might be related to HCC development.

Aldolase B, fructose-biphosphate Aldolase, an important enzyme for glucose and fructose metabolism, is a liver-specific gene. Some hepatic genes, for instance, albumin, ornitin transcarbamylase and transthyretin, were down-regulated in carcinogenesis of hepatocytes[26,27]. This down-regulation was mainly attributed to the diminishing of some of liver-enriched transcription factors (LETF). Kovalenko *et al.*[28] reported AlF-C1 enriched in fetal and regenerating livers, and down-regulated the aldolase B gene promoter in rat hepatoma cells. In our results, aldolase B was down-regulated in HCC samples and HCC cell lines, which may reflect the function change of liver cancer from metabolism to proliferation.

Pir51 protein could strongly interact with human Rad51 recombinase[29]. Eukaryotic Rad51 protein has been reported to play a central role in homologous recombination by carrying out the pairing of homologous DNA molecules and initiating the strand exchange reaction[30,31] and mammalian Rad51 was essential for cell proliferation. Rad51 activity is regulated by its associated proteins. Pir51 protein could bind to both single and double stranded DNA and was capable of aggregating DNA[29]. However, functional significance of biochemical properties of pir51 is unclear.

In conclusion, our data demonstrate that profiling of HCC samples can help reveal genes that are commonly expressed in HCC. Information from these studies may be useful in the development of therapeutic drugs for liver cancer.

Abstract

AIM: To evaluate the effects of 3,3'-diethyl-9-methylthia-carbocyanine iodide (DMTCCI) on DNA primase activity and on apoptosis of human hepatocellular carcinoma BEL-7402 cells.

METHODS: DNA primase assay was used to investigate DNA primase activity. MTT assay was applied to determine cell proliferation. Flow cytometric analysis, transmission electron microscopy, DNA fragmentation assay were performed to detect DMTCCI-induced apoptosis. Expression levels of p53, Bcl-2, Bcl-xL, Bad, Bax, survivin, Caspase-3 and poly (ADP-ribose) polymerase (PARP) were evaluated by immunoblot analysis. Caspase-3 activity was assessed with ApoAlert Caspase-3 colorimetric assay kit.

RESULTS: DMTCCI had inhibitory effects on eukaryotic DNA primase activity with IC_{50} value of 162.2 nmol/L. It also inhibited proliferation of human hepatocellular carcinoma BEL-7402 cells with IC_{50} value of 2.09 µmol/L. Furthermore, DMTCCI-induced BEL-7402 cell apoptosis was confirmed by DNA fragmentation (DNA ladders and sub-G1 formation) and transmission electron microscopy (apoptotic bodies formation). During the induction of apoptosis, expression of Bcl-2, Bcl-xL and survivin was decreased, and that of p53, Bad and Bax was increased. Caspase-3 was activated and poly (ADP-ribose) polymerase (PARP) was cleaved in BEL-7402 cells treated with DMTCCI.

CONCLUSION: The present data suggest that DMTCCI has inhibitory effects on eukaryotic DNA primase and can induce apoptosis of BEL-7402 cells. The modulation of expression of p53 and Bcl-2 family proteins, and activation of Caspase-3 might be involved in the induction of apoptosis.

INTRODUCTION

In eukaryotes, DNA primase is the only enzyme catalyzing RNA primer synthesis and initiating DNA replication as well. DNA primase combines tightly with DNA polymerase α. The complex, consisting of four subunits with a molecular weight of 180 kD, 68 kD, 58 kD and 49 kD respectively, is formed. DNA primase consists of p58 and p49 subunit, and the latter is the catalytic core[1]. PRIM1, the gene encoding DNA primase, is located on 12q13. It was found that 12q13-15 was amplified in many kinds of tumors, such as bladder cancer, glioblastoma, neuroblastoma, chronic lymphocytic leukemia, follicular central lymphoma, malignant fibrous histiocytoma, testicular germ cell tumor, breast cancer, sarcoma, primary alveolar rhabdomyosarcoma, Ewing's sarcoma and osteosarcoma. It was found that DNA primase activity in replicating cells was 5 to 6 times that in static cells. DNA primase could be regarded as a candidate target for cancer chemotherapy. In recent years, a few DNA primase inhibitors have been discovered, including fludarabine and its analogues, sphingosine, suramin, actinomycin, L-ATP, nucleotide analogues, Evans blue and aurintricarboxylic acid[2-4]. However, there have been no anticancer drugs targeting DNA primase mainly in clinical use.

Hepatocellular carcinoma (HCC) is one of the most lethal malignancies in the world and there has been no effective preventive measure for this highly malignant disease up to date. In China, HCC has ranked the second of cancer mortality since 1990's[5,6]. In this study, we found 3,3'-diethyl-9-methylthiacarbocyanine iodide (DMTCCI) could inhibit DNA primase activity. To explore the therapeutic potential of DMTCCI, we treated hepatocellular carcinoma BEL-7402 cells with DMTCCI and observed the proliferation inhibition and apoptosis induction effects. It was suggested that the modulation of expression of p53 and Bcl-2 family proteins, and activation of Caspase-3 might be involved in the induction of apoptosis.

MATERIALS AND METHODS

Drugs and reagents

DMTCCI (Figure 1), poly(dT) and MTT were purchased from Sigma-Aldrich (USA). RPMI-1640 medium was purchased from GIBCO. DE-52 was purchased from Serva. Phosphocellulose–11 was obtained from Whatman. [α-^{32}P]ATP was purchased from Amersham Biosciences. Anti-Caspase-3 antibody was obtained from Cell Signal Technology. Other antibodies were purchased from Santa Cruz Biotechnology. ApoAlert Caspase-3 colorimetric assay kit was purchased from Clontech. Ehrlich's ascites carcinoma (EAC) cells and hepatocellular carcinoma cell line BEL-7402 were obtained from the Cancer Center, Sun Yat-sen University, Guangzhou, China.

DNA primase assay

DNA primase-polymerase α complex was purified from mice EAC cells by chromatography (with DE-52 and

phosphocellulose-11 column) as described previously[7]. The standard reaction mixture (30 µL) contained 50 mmol/L Tris-HCl (pH 7.2), 0.1% PEG6000, 0.1 mg/mL bovine serum albumin (BSA), 3 mmol/L dithiothreitol (DTT), 6 mmol/L $MgCl_2$, 33 µg/mL poly(dT), 2 mmol/L ATP, 400 µmol/L [α-^{32}P] ATP (74 KBq), 10% glycerol and 5 units of mice DNA primase-polymerase α complex. Appropriate amounts of DMTCCI stock suspended in 0.1% DMSO were incubated with the standard reaction mixture for 30 min at 37℃. Then, the reaction products were spotted onto GF/C filters (Whatman), which were then washed three times in 5% trichoroacetic acid and twice in 95% ethanol. Filters were dried and the acid-precipitable radioactivity was determined with a liquid scintillation counter (Beckman). DNA primase reaction was measured by the formation of RNA oligomers. In order to explore the mode of inhibition of DMTCCI on DNA primase activity with respect to templet poly[dT], the concentrations of poly[dT] were established at 67, 100, 133, 167 and 200 mg/L with 0, 25 and 50 nmol/L of DMTCCI, respectively. The CPM counts were determined. In terms of Dixon plots, the mode of inhibition of DMTCCI on DNA primase activity was shown. Ki values of DMTCCI on DNA primase activity were calculated in accordance with Michaelis-Menton equation.

Figure 1 Chemical structure of 3, 3' -diethyl-9-methylthia-carbocyanine iodide (DMTCCI).

Cell culture
Human hepatocellular carcinoma cell line BEL-7402 was cultured in RPMI1640 medium supplemented with 10% fetal bovine serum, penicillin (100 IU/mL) and streptomycin (100 µg/mL) at 37℃ in a 5% CO_2 humidified atmosphere.

MTT assay
The logarithmically growing BEL-7402 cells were plated at a density of 1×10^4 cells/well into a 96-well plate. The stock of DMTCCI was diluted with medium, then added to the wells for the desired final concentrations. After 3 days' exposure to DMTCCI, 10 µL MTT (5 mg/mL) was added to each well and incubated for an additional 4 h, and then the liquid in the wells was evaporated. To dissolve the formazam, 200 µL of DMSO was added. Control wells were treated with 0.1% DMSO alone. The absorbance was detected in the microplate reader 550 model at 570 nm wavelength. Growth inhibition was equal to (1-absorbance of the treated wells)/(absorbance of the control wells)×100%. IC_{50} value was determined using a POMS software.

Flow cytometric analysis
Cells were harvested by trypsinization, washed twice with ice-cold PBS, resuspended in ice-cold PBS, and fixed with 70% ethanol. When ready to stain with propidium iodide (PI), the cells were centrifuged. After the ethanol was removed, the cells were washed once in PBS. The cell pellets were then resuspended in 1 mL of PI/Triton X-100 staining solution (0.1% Triton X-100 in PBS, 0.2 mg/mL RNase A, and 10 µg/mL propidium iodide) and incubated for at least 30 min at room temperature. The stained cells were analyzed using a FACScan flow cytometer in combination with BD Lysis II Software (Becton Dickinson).

Transmission electron microscopy
BEL-7402 cells treated with DMTCCI (8 µmol/L) for 48 h were collected and washed once in PBS. Cells were fixed in half-strength Karnofsky' s fixative, postfixed in 1% collidine-buffered osmium tetroxide, dehydrated in a graded series of ethanol and propylene oxide, and embedded in LR white resin. Sections were cut and stained with both uranyl acetate and Reynold' s lead stain. Electron micrographs were photographed with a JEM-1200 electron microscope.

DNA fragmentation assay
The integrity of DNA was assessed by agarose gel electrophoresis. Cells (1×10^6) were centrifuged for 5 min at 3000 g, washed once in PBS, and cell pellets were solubilized in 100 µL of lysis buffer (50 mmol/L Tris-HCl, pH 8.0, 10 mmol/L tetraacetic acid, 0.4% SDS, 0.5 g/L proteinase K) and incubated for 8 h at 50℃, then 10 µL of 0.5 g/L RNase A was added. The samples were incubated for 1 h at 50℃ and heated to 70℃ for 5 min, then 100 µL of phenol:chloroform:isopropanol (25:24:1) was added. After centrifugation, the supernatants were transferred to new tubes, and twice volume ethanol (ice cold) was added. After centrifugation, the pellets were suspended in TE buffer (10 mmol/L Tris-HCl, 1 mmol/L tetraacetic acid) and loaded on 1.8% agarose gel for electrophoresis. The gel was stained with ethidium bromide, and photographed with UV illumination.

Immunoblot analysis
After treatment, the cells were washed in phosphate-buffered saline (PBS), and lysed in 100 µL of lysis buffer (10 mmol/L Tris-HCl, pH 7.4, 5 mmol/L $MgCl_2$, 1 mmol/L EDTA, 25 mmol/L NaF, 100 µmol/L fresh Na_3VO_4 and l mmol/L dithiothreitol). Cell lysates were centrifuged for 10 min at 14 000 g. Protein concentration in the supernatant was determined by Bradford protein assay. Equal amounts of protein (40 µg) were resolved on 10% SDS-polyacrylamide gel, and transferred electrophoretically to PVDF membrane. The membranes were blocked with fat free dry milk (5%) in TBST (10 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, 0.1% Tween-20), and then incubated with primary antibodies for 1 h at 4℃, washed three times in TBST for 30 min, and then incubated with secondary antibody (horseradish peroxidase-conjugated) for 2 h at room temperature. After the secondary antibody was washed, the bound antibody complex was detected using an ECL chemiluminescence reagent. All Western blots were performed three times in independent experiments.

Caspase-3 activity assay
To analyze Caspase-3 activity, DMTCCI-treated cells (1×10^6 cells) were washed twice in PBS and resuspended in cell lysis buffer (10 mmol/L HEPES, pH 7.4, 2 mmol/L EDTA, 0.1% CHAPS, 5 mmol/L DTT, 1 mmol/L PMSF, 10 µg/mL pepstatin A, 10 µg/mL aprotinin, and 20 µg/mL leupeptin). The rest of the protocol followed the manufacturer' s instructions (Bio-Rad). A specific inhibitor of Caspase-3, DEVD-fmk, was used to confirm the specificity, as suggested by the manufacturer. Absorbance was read with the microplate reader 550 model at 410 nm and the activity units were determined according to the instructions provided with the kit.

RESULTS
Inhibition of DNA primase activity by DMTCCI
DNA primase is responsible for the synthesis of RNA primers on both leading and lagging strand DNA during semi-conservative DNA replication. When DNA primase activity was assayed in the presence of various concentrations of DMTCCI, our data showed that at the concentrations of 18.5, 37.0, 111.0, 333.3 and 1 000 nmol/L of DMTCCI, the

inhibitory rates were (24.9±2.0)%, (31.4±5.0)%, (38.5±3.8)%, (52.5±6.4)% and (80.4±2.9)%, respectively, with IC_{50} value of (162.2±7.8) nmol/L (Figure 2). The Dixon plot analysis demonstrated that DMTCCI inhibited mammalian DNA primase by a non-competitive mechanism (Ki=60.5 nmol/L) (Figure 3). The kinetics of the blockade indicated an allosteric modulation by DMTCCI of DNA primase activity.

Figure 2 Inhibitory effect of DMTCCI on DNA primase activity. Appropriate amounts of DMTCCI were incubated with the standard reaction mixture containing DNA primase-polymerase α complex purified from mice Ehrlich's ascites carcinoma cells for 30 min at 37℃. DNA primase reaction was measured by the formation of RNA oligomers. Results were expressed as mean±SD for three independent experiments.

Figure 3 Kinetic analysis. Primase activity was measured in the absence or presence of DMTCCI using the indicated concentrations of DNA template poly[dT]. A Dixon plot was made on the basis of the data. Basically similar results were obtained in three separate repetitions of the experiment.

Growth inhibition of BEL-7402 cells by DMTCCI

After 3 days' exposure to DMTCCI, cell survival was analyzed by MTT assay. The results of MTT assay showed that DMTCCI inhibited cell proliferation of BEL-7402. At the concentrations of 0.3125, 0.625, 1.25, 2.5, 5, 10 and 20 μmol/L, the inhibitory rates were 16.9%, 27.7%, 38.5%, 49.2%, 67.7%, 81.5% and 87.7% respectively. IC_{50} value was 2.09 μmol/L (Figure 4).

Figure 4 Effect of DNA primase inhibitor DMTCCI on proliferation of BEL-7402 cells. BEL-7402 cells were treated with various concentrations of DMTCCI as indicated for 72 h. Cell viability was determined with MTT assay and shown as survival rate.

Detection of apoptosis by flow cytometry

To examine whether BEL-7402 cells underwent apoptosis when they were treated with DMTCCI, the cells were stained with propidium iodide, followed by examination of the appearance of sub-G_1 population using flow cytometry. After treatment with 2 μmol/L, 4 μmol/L, 8 μmol/L of DMTCCI for 24 h, cell death became apparent. As evidenced by the appearance of sub-G1 population, the apoptotic indexes in BEL-7402 cells were 10.8%, 16.5% and 24.3%, respectively. At 36 h, the apoptotic indexes were 14.0%, 26.2% and 33.1%, respectively. At 48 h, the apoptotic indexes were 21.8%, 28.6% and 41.0%, respectively (Figure 5).

Transmission electron microscopy

Transmission electron microscopy showed that morphological changes typical of apoptosis were observed in BEL-7402 cells treated with DMTCCI. The cytoplasm shrank and the chromatin of cells became condensed and marginated. Chromatin was fragmented into apoptotic bodies in which

Figure 5 Flow cytometric analysis of BEL-7402 cells treated with DMTCCI. Untreated cells (control) or cells treated with DMTCCI were stained with propidium iodide, their DNA content was measured by flow cytometry. The data shown are representative of three experiments performed.

internal organelles were preserved, while most of control cells had centrally located round nuclei with prominent nucleoli and uniform morphology (Figure 6).

Figure 6 Morphological changes typical of apoptosis in BEL-7402 cells treated with 8 μmol/L of DMTCCI for 24 h. BEL-7402 cells showed apoptotic morphological changes of the chromatin being condensed and marginated. A: Control. ×5 000; B: Treated with DMTTCI 8 μmol/L. ×7 000.

Internucleosomal DNA damage in DMTCCI-treated BEL-7402 cells

Genomic DNA fragmentation was assayed as a hallmark of apoptotic cell death. As shown in Figure 7, agarose gel electrophoresis of DNA extracted from cells treated with DMTCCI revealed ladders of DNA fragmentation, indicative of induced apoptosis in BEL-7402 cells.

Figure 7 DNA fragmentation of BEL-7402 cells induced by DMTCCI. BEL-7402 cells were incubated in the absence or presence of DMTCCI 8 μM for 12 h, 24 h, 36 h, 48 h. Cells were harvested. DNA was isolated and DNA fragmentation was visualized as oligonucleosome-sized fragmentation in ethidium bromide after DNA agarose gel electrophoresis. This figure is a representative of three experiments.

Effect of DMTCCI on p53 in BEL-7402 cells

DNA damage could activate tumor suppressor gene p53, thereby inducing cell growth arrest, which could allow time

for DNA repair. To investigate whether p53 protein was associated with DMTCCI-induced apoptosis, we examined the change in p53 levels during the apoptotic process in BEL-7402 cells. Western blot analysis showed that the level of p53 protein increased following DMTCCI treatment in a time-dependent manner (Figure 8).

Figure 8 Down-regulation of p53 in BEL-7402 cells by DMTCCI. BEL-7402 cells were incubated with 8 μM DMTCCI for indicated time. Cells were harvested, lysed and resolved in 10% SDS-polyacrylamide gel. p53 protein levels were determined by immunoblot analysis. β-actin was used as a control.

Effect of DMTCCI on the expression of Bcl-2 family proteins

The Bcl-2 family proteins play a prominent role in the regulation of apoptosis. In this study, DMTCCI induced the expression of pro-apoptotic proteins, Bad and Bax, and downregulated the anti-apoptotic proteins, Bcl-2 and Bcl-xL in BEL-7402 cells. We deduced Bcl-2 family members might play a role in apoptosis induced by DMTCCI in BEL-7402 cells (Figure 9).

Figure 9 Effects of DMTCCI on levels of Bcl-2, Bax, Bcl-xL and Bad in BEL-7402 cells. BEL-7402 cells were treated with DMTCCI (8 μM) for indicated time, total protein was isolated by immunoblotting analysis. After electrophoresis on a 10% SDS-polyacrylamide gel, the protein was transferred to a PVDF membrane. The membrane was analyzed by immunoblotting with anti-Bcl-2, Bax, Bcl-xL and Bad antibodies, respectively. β-actin protein was used as a control.

Figure 10 Down-regulation of survivin in BEL-7402 cells by DMTCCI. BEL-7402 cells were incubated with 8 μM DMTCCI for indicated time. Cells were harvested, lysed and resolved in 10% SDS-polyacrylamide gel. Survivin protein levels were determined by immunoblot analysis. β-actin was used as a control.

Effect of DMTCCI on survivin in BEL-7402 cells

Survivin is a member of the inhibitors of apoptosis protein family that is believed to play a role in oncogenesis. BEL-7402 cells treated with 8 µM of DMTCCI for 6, 12, 24, 36 and 48 h were collected. Western blot analysis showed that the level of survivin protein decreased following DMTCCI treatment in a time-dependent manner (Figure 10).

Caspase-3 activity in DMTCCI-treated BEL-7402 cells

The results shown above indicated that DMTCCI induced apoptosis in BEL-7402 cells. To probe into the mechanism of apoptosis, we detected Caspase-3 activity following treatment of BEL-7402 with DMTCCI. As shown in Figure 11, Caspase-3 activity was apparently increased at 6 h and reached a peak at 24 h in response to DMTCCI treatment in BEL-7402 cells.

Figure 11 Inhibition of DMTCCI on activity of Caspase-3 in BEL-7402 cells. BEL-7402 cells were harvested after exposure to 8 µmol/L of DMTCCI for indicated time. Activity of Caspase-3 was measured by ApoAlert caspase-3 assay kits. Cell lysates were prepared for each sample and used in the Caspase-3 activity assay using the colorimetric substrate DEVD-pNA. Absorbance was read at 410 nm and This figure is a representative of three experiments.

Cleavage of Caspase-3 induced by DMTCCI in BEL-7402 cells

Caspase-3, a member of the Caspase family, was shown to play an essential role in apoptosis induced by a variety of stimuli[8-10]. We examined whether Caspase-3 was activated during DMTCCI-induced apoptosis in BEL-7402 cells. Activation of Caspase-3 was determined by monitoring proteolysis of the 35-kDa procaspase-3 to 17-kDa fragments. Figure 12 shows the appearance of the 17-kDa fragments of the active enzyme following exposure to 8 µmol/L DMTCCI for 24 h, indicating that DMTCCI efficiently activated Caspase-3 in BEL-7402 cells.

Figure 12 Effect of DMTCCI on levels of proteins of Caspase-3 in BEL-7402 cells. BEL-7402 cells were treated with 8 µM DMTCCI for the indicated time. Western blot analysis was performed with anti-Caspase-3 antibody. β-actin was used as a control.

Cleavage of PARP induced by DMTCCI

Caspases are synthesized as inactive proenzymes. When activated, they could specifically cleave both relevant cellular substrates and zymogens to promote apoptosis[11,12]. One of the substrates for Caspase protease during apoptosis was PARP, an enzyme that appears to be involved in response to environment stress. Proteolytic cleavage of PARP could result in a characteristic shift of the protein upon electrophoresis from 116 to 89 kDa. PARP cleavage was used as an indicator of caspase activation in response to DMTCCI treatment. PARP could be cleaved 24 h after DMTCCI treatment (Figure 13).

Figure 13 PARP cleavage in BEL-7402 cells induced by DMTCCI. After BEL-7402 cells were treated with 8 µM DMTCCI for the indicated time, total protein was isolated by immunoblotting analysis. After electrophoresis on a 10% SDS-polyacrylamide gel, the protein was transferred to a PVDF membrane. The membrane was analyzed by immunoblotting with antibody against PARP. β-actin protein was used as a control.

DISCUSSION

In this study, we found DMTCCI could inhibit proliferation of hepatocellular carcinoma BEL-7402 cells. DNA replication is a prime target of cancer chemotherapeutics. For example, DNA polymerase α inhibitors have been widely used in chemotherapy. DNA primase could combine tightly with DNA polymerase α as a complex. It could play a critical role in coupling replication to repair and in checkpoint control during S phase, as well as in telomere maintenance[1]. However, DNA primase has not been well studied as an anticancer target since its structure and function were not clarified until recently. DNA primase is considered as a key enzyme in DNA replication because it is the only enzyme that can initiate the synthesis of new DNA strands *de novo*. We believe new target helps improve existing treatment and overcome drug resistance. Nevertheless, our study showed DMTCCI could suppress cell proliferation at concentrations that were comparable to Ki values for its inhibition on DNA primase. The growth suppression of human hepatocellular carcinoma BEL-7402 cells by DMTCCI was well correlated with DNA primase inhibition.

Apoptosis plays important roles in the control of various biological systems, such as immune responses, hematopoiesis, embryonic development, and carcinogenesis. Apoptosis is an active cell death and could be triggered by a variety of pharmacological and physiological agents[13-15]. In this study, we reported firstly that DMTCCI induced apoptosis in BEL-7402 cells demonstrated by DNA fragmentation, flow cytometry analysis and transmission electron microscopy.

P53 protein has been implicated in DNA damage recognition, DNA repair, cell cycle regulation and particularly in triggering apoptosis after genetic injury[16-18]. To examine whether DMTCCI-induced apoptosis was associated with p53, we measured the level of p53 in BEL-7402 cells. Western blot analysis revealed that p53 protein level increased following DMTCCI treatment in a time-dependent manner, indicating that p53 might be involved in DMTCCI-mediated apoptosis.

It has been found that apoptotic process is controlled by several genes, including inducers and repressors, some of them belong to the Bcl-2 family[19]. Bcl-2 family could be divided into two classes: those such as Bcl-2 and Bcl-xL, are able to

block apoptosis, and others, such as Bad and Bax, have proapoptotic effects[20-22]. The balance between the anti-apoptotic and pro-apoptotic Bcl-2 family members may be critical to determine if a cell undergoes apoptosis. The death promoting protein Bax counteracts the anti-apoptotic effects of Bcl-2 by forming a heterodimer with Bcl-2. The ratio of Bcl-2 to Bax, rather than the levels of individual proteins, was considered to be critical in determining the survival/death of cells[23-25]. Bad could compete for the binding to Bcl-xL and Bcl-2, thereby affecting the level of heterodimerization of these proteins with Bax[26]. Our data showed that the expression level of protein Bad and Bax was increased, and that of Bcl-2 and Bcl-xL was decreased in BEL-7402 cells treated with DMTCCI. Taken together, the significant increase of Bad and Bax, and decrease of Bcl-2 and Bcl-xL would favor Bad to compete for Bcl-xL, resulting in much more free Bax into homodimers, which might induce apoptotic response in BEL-7402 cells.

Survivin has recently been identified as a novel inhibitor of apoptosis (IAP). Acting as one of the substrate inhibitors of Caspases, survivin blocks the activation of different effector Caspases. Overexpression of survivin could lead to the suppression of apoptosis triggered by diverse proapoptotic signals[27-29]. In this study, DMTCCI decreased the level of survivin in BEL-7402 cells, indicating that survivin might be involved in DMTCCI-mediated apoptosis.

It has been found that apoptosis is coordinated by a family of cysteine proteases, the Caspases, which are activated upon receipt of divergent pro-apoptotic stimuli[30-32]. In this study, we found that Caspase-3 was activated during DMTCCI-induced apoptosis in BEL-7402 cells. Caspase-3 is believed to be the main executioner Caspase and its activation has been shown to be essential for DNA fragmentaion as well as chromatin condensation and proteolysis of certain Caspase substrates. During the process of DMTCCI-induced apoptosis, Caspase-3 activity was apparently increased at 6 h and reached a peak at 24 h in response to DMTCCI in BEL-7402 cells. One of the substrates for Caspase-3 during apoptosis was PARP, an enzyme that appears to be involved in response to environment stress. PARP cleavage was used as an indicator of Caspase-3 activation in response to DMTCCI treatment. PARP was cleaved 24 h after DMTCCI treatment. These results suggest that caspase-3 activation is involved in DMTCCI-mediated apoptosis in BEL-7402 cells.

In conclusion, DMTCCI could inhibit proliferation and induce apoptosis of human hepatocellular carcinoma BEL-7402 cells. In this study, the expression of Bcl-2, survivin and Bcl-xL was decreased, and that of Bad and Bax was increased in BEL-7402 cells treated with DMTCCI. Furthermore, we found that Caspase-3 was activated during apoptosis and the processing of Caspase-3 was accompanied by proteolytic cleavage of PARP. These finally led to apoptotic events including apoptotic bodies and DNA fragmentation. These results indicate that the induction of apoptosis by DMTCCI involves the modulation of expression of p53 and Bcl-2 family proteins and activation of Caspase-3. It can be a candidate for the development of new anti-tumor agents targeting DNA primase associated with human cancer, including human hepatocellular carcinoma.

Abstract

AIM: To investigate the frequency of genomic instability in murine hepatocellular carcinoma (HCC) cell lines Hca/A2-P (P) and Hca/163-F(F) with low and high metastatic capacity, and to explore its association with the occurrence and metastasis of hepatocellular carcinomas.

METHODS: Forty microsatellite markers were randomly selected to examine P and F cells for genomic instability using PCR-simple sequence length polymorphism (PCR-SSLP) analysis.

RESULTS: Allelic genes on the chromosomes of P cell line with thirty informative microsatellite loci were paralleled to those of inbred strain C_3H mouse, while those of F cell line with 28 loci were paralleled to those of inbred strain C_3H mice. The frequency of microsatellite alterations was 37.5% and 42.5% in P cell line and F cell line, respectively. There were different alterations of allelic band 9 at loci between P and F cells, among which, the frequency of microsatellite alterations was most commonly seen on chromosomes 3, 7, 11 and 16.

CONCLUSION: Genomic instability in mouse chromosomes 3, 7, 11 and 16 may play a more important role in the development and progression of HCC in mice. It is suggested that these two sub-clones derived from a same hepatic tumor in homozygous mouse present different genetic features.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent human cancers worldwide and has ranked second in China since 1990s[1-3]. The development and progression of HCC are considered as a complex process involving genetic alterations, such as chromosomal deletions, chromosomal translocation, point mutations, and gene amplification. These changes can lead to activation of oncogenes or inactivation of tumor suppressor genes at various stages of HCC[4,5]. Genetic instability or genomic instability in human cancers can be divided into two types: microsatellite instability (MSI) which is usually equated with DNA polymerase errors, and chromosomal instability or loss of heterozygosity (LOH) which can result from errors in chromosome partitioning. Both LOH and MSI are considered as phenotypes of genomic instability[6,7]. LOH is frequently observed on chromosomes 1p, 4q, 5q, 8p, 8q, 9p, 10q, 11p, 13q, 14q, 16q, 17p and 22q in HCC, suggesting that tumor suppressor genes may take part in hepatocarcinogenesis[8-10]. MSI and mutations of defective mismatch repair genes can occur in hepatocytes in some chronic hepatitis, cirrhosis and HCC[11-15]. Inbred strain mice provide the guarantee to study on comparison, reliability and accuracy of molecular genetics in neoplasms, because of their characteristics such as high genetic stability, phenotypic uniformity and homozygous alleles. Moreover, it is very valuable to understand the various molecular changes of development and progression in carcinogenesis[16,17]. We examined genomic instability with microsatellite markers at 40 loci on four chromosomes in HCC with low and high metastatic capacity in mice and analyzed the association of microsatellite altertions and metastatic abilities, in order to provide experimental data for finding new tumor suppressor genes and metastasis associated genes.

MATERIALS AND METHODS

Hepatocellular carcinoma cell lines Hca/A2-P(P) and Hca/16-F(F) with low and high metastatic capacity were used in this study. Two cell lines were routinely cultured in 1640 medium (Gibco) supplemented with 10% fetal bovine serum (Hyclone) at 37℃ with 5% CO_2. Inbred strain C_3H mice were provided by Sino-British SIPPR/BK Laboratory Animal Center (Shanghai, China).

DNA extraction

Genomic DNA was extracted from cancer cells and normal liver tissues of inbred C_3H mice using the standard phenol/chloroform extraction and ethanol precipitation methods[18]. Briefly, normal tissues and cancer cells were incubated with 2 ml lysis/digestion buffer (1% sodium dodecyl sulfate, 1 mM EDTA, 50 mM Tris at pH 8.5, and 100 μg proteinase K/ml) at 52℃ for 16 h. The digested lysate was subjected to two further extractions with an equal volume of chloroform:phenol:isoamyl alcohol (24:25:1). After centrifugation, DNA was precipitated from the aqueous phase by two volumes of cold absolute ethanol and collected with a glass rod[19]. The DNA was further purified with RNase digestion, two steps of phenol/chloroform extractions, and precipitated and collected as described above. The concentration of DNA was determined with both spectrophotometric and fluorometric methods.

Microsatellite markers and polymerase chain reaction

The characteristics of microsatellite loci used in this study are

shown in Table 1. The polymerase chain reaction mixture contained more than 20 ng of genomic DNA, 200 μmol/L of each dNTP, 1.5 mM MgCl$_2$, 0.5 units of AmpliTaq Gold DNA polymerase (PE Applied Biosystems, Foster City, CA), 0.5 μmol/L of each primer, and 10×AmpliTaq Gold PCR buffer in a final volume of 10 μL. After denaturation at 94℃ for 12 minutes, DNA amplification was performed for 15 cycles of 94℃ for 30 seconds, 63℃ for 60 seconds (decreased 0.5℃ of each cycle), and 72℃ for 90 seconds, and then for 25 cycles of 94℃ for 30 seconds, 56℃ for 60 seconds, and 72℃ for 90 seconds, with a final extension at 72℃ for 10 minutes. PCRs were run in a Biometra thermocycler (Biometra, Germany). The PCR products were electrophoresized on 8% denatured polyacrylamide gel under a constant voltage of 30 V/cm for simple sequence length polymorphism (PCR-SSLP) analysis. The gel was stained with silver staining after electrophoresis.

Identification of genomic instability

We scored only the bands in cancer cells by preceding or succeeding compared with those in normal samples. Loss or gain of band(s) and clearly detectable changes in intensity were scored[20]. Scoring was done by two independent observers. A change of band intensities was defined as an increase or decrease of the signal intensity by ≥50% in tumor DNA compared to normal DNA by gray scanning function in an image analysis software.

RESULTS

Microsatellite alterations in HCC cell lines with low and high metastatic capacity in mice

Genomic instability was examined using 40 microsatellite markers spanning 4 chromosomes in HCC with low and high metastatic capacity in mice. The results showed that thirty

[a]Data from GenBank.

Figure 1 Genomic instability in murine hepatocellular carcinomas with low and high metastatic capacity, PCR-SSLP. A: D3Mit18, B: D3Nds2, C: D3Mit17, D: D7Mit17, E: D11Mit5, F: D11Mit11, G: D16Mit5, H: D16Mit4.

microsatellite loci were same as that of C_3H mice, they were D3Mit15, D3Mit16, D3Mit19, D3Mit22, D4Mit1, D4Mit2, D7Mit10, D7Mit12, D7Mit13, D7Mit14, D7Mit16, D7Mit19, D7Nds2, D11Mit1, D11Mit2, D11Mit10, D11Mit12, D11Mit13, D15Mit17, D15Nds1, D16Mit1 and D16Mit7. The results of microsatellite alterations in mouse HCC cell lines are shown in Table 1. Examples of genomic instability in hepatocellular carcinomas with low and high metastatic capacity in mice by PCR-SSLP method are shown in Figure 1. The frequency of microsatellite alterations was 37.5% in P cell line. The frequency of microsatellite alterations on chromosomes 3, 7, 11 and 16 was 40%, 40%, 50% and 20% in P cell line. The frequency of microsatellite alterations was 42.5% in F cell line. The frequency of microsatellite alterations on chromosomes 3, 7, 11 and 16 was 40%, 40%, 40% and 50% in F cell line. Microsatellite alterations at D3Mit18, D3Mit21, D3Nds2, D7Mit15, D7Mit18, D7Mit20, D11Mit4, D11Mit7, D11Mit8 and D16Mit7 in P cell line were same as those in F cell line. Microsatellite alterations at D3Mit17, D7Mit17, D11Mit5, D15Nds2, D16Mit2, D16Mit3, D16Mit4 and D16Mit5 in P cell line were different from those in F cell line. In contrast to inbred strain C_3H mice, the allelotype sizes of 25 microsatellite loci were same as those of C_3H mice, 8 loci with loss of alleles, extra bands showing at 4 loci and band shifting at 3 loci in P cell line, while 23 loci were same as that of C_3H mice, allele loss at 11 loci, extra bands showing at 4 loci and band shifting at 1 locus in F cell line.

DISCUSSION

In the present study, we found that the frequent genomic instability on chromosomes 3, 7, 11 and 16 existed in hepatocellular carcinoma (HCC) cell lines Hca/A2-P(P) and Hca/163-F(F) with low and high metastatic capacity, both of which were derived from an inbred C_3H mouse. Microsatellite alterations at D3Mit18, D3Mit21, D3Nds2, D7Mit15, D7Mit18, D7Mit20, D11Mit4, D11Mit7, D11Mit8 and D16Mit7 in P cell line were same as those in F cell line. These results suggested that there were tumor suppressor genes in these points, inactivation of them might play an important role in the development of HCC in mice. Microsatellite alterations at D3Mit17, D7Mit17, D11Mit5, D15Nds2, D16Mit2,

D16Mit3, D16Mit4 and D16Mit5 in P cell line were different from those in F cell line. These results suggested that there were different genetic alterations in hepatocellular carcinoma (HCC) cell lines with high and low metastatic capacity derived from a homozygous mouse hepatic tumor.

Homologous regions between mouse and human chromosomes have been defined[21]. Mouse chromosome 3 is syntenic to certain regions of human chromosomes 1p13-p22, 1p36-q12, 1q23-31, 3q24-q28, 4q25-q31 and 8. Previous studies suggested that 4q25 and 4q26-27 deletions occurred in human HCC[22,23]. Epidermal growth factor locus is located at the former region. *Cyclin A* and *interleukin-2* loci are located at the latter region, which has a HBV integrated position. Mouse chromosome 7 is syntenic to certain regions of human chromosomes 10q26-ter, 11p15, 15q and 19q13. High frequencies of loss of heterozygosity (LOH) were observed on chromosome 10q26 in human hepatocellular carcinoma[24]. *Ras* and *Bax* genes are located at 1.9cM distance from D7Mit18 locus. More than 50% of colon adenocarcinomas with human microsatellite mutator phenotype examined were found to have frameshift mutations in a tract of eight deoxyguanosines [$(G)_8$] within *BAX*, a gene that promotes apoptosis[25]. Allelic loss and mutation of *Ha-ras* were seen in a variety of humen and mice tumors[26]. Mouse chromosome 11 is syntenic to certain regions of human chromosomes 17p13 and 17q21-qter. Previous studies have shown that high frequencies of LOH were found on chromosomes 17p13.1 and 17p13.3 in human HCC[27,28]. Some studies have demonstrated LOH at the *p53* locus on chromosome 11 and mutational inactivation of the remaining *p53* allele in a significant percentage of carcinomas[29], which also harbored for *BRCA1* tumor suppressor gene and candidate suppressor prohibitin[30,31]. In the present study, we found that the allelic loss at D3Mit18, D7Mit15, D7Mit20, D11Mit4, D11Mit7 and D11Mit8 on 17p13 was present in P and F cells. We found an extra band at D3Mit21 (*IL-2* locus), D3Nds2 (*EGF* locus) and D7Mit18 in P and F cells. These results suggested that chromosomes 3, 7 and 11 might carry candidate tumor suppressor genes, and play important roles in the development of HCC in mice. Additionally, allelic loss occurred at D3Mit17 of P cells, while extra band appeared in F cells. Band shifting was present at D7Mit17 locus in P cells, while extra band appeared in F cells, suggesting that different

sub-clones of the same tumor have heterogeneity.

Mouse chromosome 16 is syntenic to certain regions of human chromosomes 3q21-ter, 12q, 16p, 21q and 22q. It was reported that human chromosome 3q carried a tumor suppressor gene for osteosarcoma, because this chromosomal region was frequently deleted in this type of tumors[32]. LOH was frequently observed on 22q in HCC[33]. Mafune *et al*[34] found that mouse chromosome 16 was deleted in a clone of mouse fibrosarcoma 505 cells, suggesting that chromosome 16 may have a cognate of such candidate tumor suppressor genes and hence deletion of the region might confer malignancy related with metastasis. In the present study, genomic instability at D16Mit2, D16Mit3, D16Mit4 and D16Mit5 was found in mouse HCC with a high metastatic capacity. It was suggested that genes in chromosome 16 were closely related to tumor metastasis, their mutation could result in metastasis of HCC. Band shifting occurred at D16Mit4 locus in P cells, allelic loss was found in F cells due to continuous genomic instability during the development and progression of tumors. Genomic instability at some chromosomes of HCC in mice were studied and some loci related to hepatocarcinogenesis and progression were obtained which might be of great significance in searching new tumor associated genes.

In conclusion, genomic instability in mouse chromosomes 3, 7, 11 and 16 may play an important role in the development and progression of HCC in mice.

Abstract

AIM: To investigate the expression of hypoxia-inducible factor (HIF)-2α/endothelial PAS domain protein1 (EPAS1) in hepatocellular carcinoma (HCC).

METHODS: Expression of HIF-2α/EPAS1 was investigated immunohistochemically on paraffin-embedded sections from 97 patients with HCC. To further confirm that HIF-2α/EPAS1 in HCC tissues also correlated with angiogenesis, a parallel immunohistchemistry study of vascular endothelial growth factor (VEGF) was performed on these 97 cases.

RESULTS: HIF-2α/EPAS1 could be detected in 50 of 97 cases (51.6%), including 19 weakly positive (19.8%), and 31 strongly positive (31.1%), the other 47 cases were negative (48.4%). The expression of HIF-2α/EPAS1was significantly correlated with tumor size, capsule infiltration, portal vein invasion, and necrosis. A parallel immunohistochemical analysis of VEGF demonstrated its positive correlation with capsule infiltration, portal vein invasion, and HIF-2α/EPAS1 overexpression, which supported the correlation of HIF-2α/EPAS1up-regulation with tumor angiogenesis. No apparent correlation was observed between HIF-2α/EPAS1 and capsular formation, presence of cirrhosis, and histological grade.

CONCLUSION: HIF-2α/EPAS1 is expressed in most of HCC with capsular infiltration and portal vein invasion, which indicates a possible role of HIF-2α/EPAS1 in HCC metastasis.

INTRODUCTION

Hypoxia is an essential development and physiological stimulus and plays a key role in the physiology of cancer, heart attack, stroke, and other major causes of mortality[1]. Recently, hypoxia-inducible factors HIF-1α and HIF-2α/endothelial PAS domain protein1 (EPAS1) have been identified. They are basic helix-loop-helix/Per-Arnt-Sim (PAS) transcription factors induced under hypoxia[2,3]. When dimerized with aryl hydrocarbon nuclear translocator (also known as HIF-3α, another basic helix-loop-helix family member), both HIF-1α and HIF-2α can bind to the hypoxia response element in a battery of genes and transactivate their expression, including vascular endothelial growth factor (VEGF)[3,4]. These genes are important for tumor adaptation to hypoxia, implicating the possible role of HIFs in tumor progression. Tumor can not grow larger than 1-2 mm³ in the absence of angiogenesis, because of the lack of oxygen in the center of tumors, which result in apoptosis and necrosis[5]. Many tumors contain hypoxic microenvironments, a condition associated with poor prognosis and resistant to clinical treatment. Along with HIF-1α, EPAS1 is also known as HIF-2α[6,7], HIF-like factor[8], and HIF-related factor[9]. The expression of HIF-2α/EPAS1 has been reported in many human malignancies[10,11]. We chose to study HIF-2α/EPAS1 expression in order to evaluate its clinical significance and identify the relation with some important markers of carcinoma progression, which are also predictors of metastasis.

MATERIALS AND METHODS

Clinical material

We examined 97 surgical resection specimens from patients (76 males, 21 females) with HCC, who underwent surgery at Xiangya hospital between January 1994 and December 2001. The age of patients ranged from 34 to 78 years (61.4±8.9 years). The clinical features of the patients were noted with reference to clinical reports and pathology reports, including Edmondson-Steiner classification. In principle, grades I, II and III-IV and the characteristics of these patients are summarized in Table 1.

Immunohistochemical determination

Tissues were fixed with 10% formaldehyde in phosphate-buffered saline, embedded in paraffin, and cut into 5 μm-thick tissue sections. The sections were deparaffinized in xylene and rehydrated in grade ethanol. Endogenous peroxidase was blocked by immersing the sections in 3% H_2O_2 in 100% methanol for 20 minutes at room temperature. Antigen retrieval was achieved by micro-waving sections at 95℃ for 10 minutes in 0.001 M citrate buffer (pH 6.7). For immunochemical detection of diluted mouse monoclonal antibodies against HIF-2α/EPAS1 (190b) (DAKO, Glostrup, Denmark) and 1:200 diluted mAb against VEGF (Ab3) (Fremont, CA). Substitution of the primary antibodies with normal mouse IgG was used as a negative control. After washing, specimens were incubated with peroxidase-conjugated goat anti-mouse IgG for 30 min at room temperature. The color reaction was developed by incubating the sections with 0.5 mg/ml 3,3' -diaminobenzidine and 3% (vol/vol) H_2O_2 in phosphate-buffer saline for 7 min. The sections were counterstained slightly with Meyer hematoxylin and mounted.

VEGF determination and assessment

Mouse monoclonal antibody Ab3, neomarker (Fremon, CA) for detecting a smaller isoform ($VEGF_{121}$) of VEGF were used for the identification and evaluation of VEGF expression in this study. Staining with VEGF monoclonal antibody required antigen retrieval, which was best done by microwave pretreatment. In brief, paraffin-fixed slides were autoclaved for 7 min in pretreatment before deparaffinization and

rehydration. Evaluation of staining was semiquantitatively graded based on score determination by intensity distribution as strong ++ (dark brown), weak + (brown), or negative + (no staining). The score was determined independently by at least three of four observers.

Statistical analysis

A computer software SPSS 10.0 program was used for statistical analysis. Spearman' s correlation coefficient test was used to assess the relationship between HIF-2α/EPAS1, VEGF expression versus histological grade and tumor size. χ^2 test was used to assess the correlation between HIF-2α/EPAS1, VEGF, versus existence of necrosis, cirrhosis, capsular formation, capsular infiltration and portal vein invasion. $P<0.05$ was considered to be statistically significant.

[a]$P<0.05$ vs the expression of HIF-2α/EPAS1 was significant in HCC tissues with capsule infiltration, portal vein invasion, necrosis, and tumor size. NS, not significant.

RESULTS

In the 97 cases studied, positive staining of HIF-2α/EPAS1 protein was localized mainly in the cytoplasm, and occasionally and faintly in the membrane of HCC cells (Figures 1A and 1B). In general, most positive stains were observed in the perinecrotic regions near the tumor foci (Figure 1C). There was expression of HIF-2α/EPAS1 in cancer cells, whereas no positive staining was seen in the stroma cells of HCC (Figure 1D). Immunoreactivity of HIF-2α/EPAS1 was also observed in macrophages, as previously reported[10]. In addition, we also found positive staining in the intraluminal surfaces of hepatic vessels. All the positive immunoreactivity in macrophages was in the cytoplasm. The immunoreativity was even stronger in macrophages than that in tumor cells (Figure 1E). All the tumor cluster infiltrating to the tissue showed moderate to strong positive staining of HIF-2α/EPAS1 (Figure 1F). Fifty of 97 cases (51.5%) were positive, including 31 strongly positive (31.9%), 19 weakly positive (19.8%). In the 50 HIF-2α/EPAS1-positive cases, 35 cases (64.8%) had necrosis, and 15 cases

(16.27%) had no necrosis. Positive staining was seen in 33.3% of the small-sized HCC (≤2 cm), 62.7% of the medium-sized (2-5 cm), and 57.1% of the HCCs larger than 5 cm. HCC larger than 5 cm in diameter though not significantly different between the two groups, had a relatively lower HIF-2α/EPAS1 expression compared to medium-sized tumors. HIF-2α/EPAS1 staining was seen in 81.2% of HCC patients with capsule infiltration, and 45.6% in those without them. Positive staining was also seen in 68.7% in HCC patients with portal vein invasion, and 34.6% in those without them (Table 1). HIF-2α/EPAS1 positivity was significantly correlated with tumor size, capsule infiltration, portal vein invasion, and existence of necrosis ($P<0.05$ respectively). To further confirm whether HIF-2α/EPAS1 expression in HCC tissues also correlated with angiogenesis, a parallel immunohistochemical study of VEGF was performed on these 97 cases, in which VEGF expression was assessed as a major marker for angiogenesis (Table 2). Positive staining was found mostly in the cytoplasm of tumor cells (Figures 2A and 2B), and only weaker staining in stroma areas was detectable. VEGF expression in tumors had strong correlation with capsule infiltration, portal vein invasion, and necrosis ($P<0.05$ respectively). The overexpression of VEGF in capsule infiltration and portal vein invasion was found to correlate positively with HIF-2α/EPAS1 expression ($P<0.05$, Table 3), supporting the correlation of HIF-2α/EPAS1 upregulation with tumor metastasis and angiogenesis in HCC.

A: HCC with capsular infiltration and portal vein invasion showing strong staining (++) in the cytoplasm of tumor cells. B: HCC without capsular infiltration and portal vein invasion showing weak staining (+) (× 200).

DISCUSSION

Angiogenesis appeared to be one of the crucial steps in tumor' s transition from small, harmless cluster of mutated cells to a large, malignant growth, capable of spreading to other organs throughout the body[12]. HCC is a typical hypervascular tumor of the digestive organs. It seems likely that the formation of tumor vessels precedes tumor growth and is indispensable in maintaining tumor viability, because hepatic arterial embolization frequently causes necrosis and induces a marked reduction in tumor size. In the present study, we investigated the expression of HIF-2α/EPAS1 in HCC tissues. To further confirm whether HIF-2α/EPAS1 in HCC tissues also correlated

with angiogenesis, we performed an immunohistochemistry study of VEGF protein. We also examined the correlation between HIF-2α/EPAS1, VEGF protein expression and clinicopathological features.

Our data showed that tumor size was correlated with HIF-2α/EPAS1. Small HCC had significantly lower HIF-2α/EPAS1 expression compared with medium-sized tumors. What was contrary to previous finding[13,14] was that tumors with large sizes had higher expression than smaller and moderate sizes, even these tumors were relatively less vascular compared with the large-sized ones. However, it has been reported that the intercapillary distance increased as the tumor size or weight increased, possibly because of different rates of endothelial cells and neoplastic cell turnover[15,16]. The turnover time of endothelial cells was 50 to 60 hours while that of the neoplastic cells was 22 hours, and significantly shorter[17]. On the other hand, the characteristics of tumor microcirculation could offer another explanation for the reduction of HIF-2α/EPAS1 expression as the tumor became smaller or larger. Generally, blood flow, oxygen pressure, and pH values were less in tumors than in the counterpart normal tissues[18], and because of the absence of lymphatic vessels, the interstitial pressure was often high in tumors, leading further transport problems[19]. As a result, hypoxia and necrosis were a general phenomenon of tumors, especially large ones[20]. It was assumed that rapid cell proliferation at the center of tumor could lead to increased interstitial pressure, which may lead to compression closure of capillaries and consecutive tumor necrosis[21]. The current results showed that HCCs of 2 to 5 cm in diameter had the highest HIF-2α/EPAS1 expression compared with larger and smaller tumors. This observation could be considered important for regional chemotherapy, because intuitively, tumor, tumor metastasis, and tumor death should be closely correlated with tumor-induced hypoxia and necrosis. Cells in hypoxic regions have been thought to be more resistant to the effects of radiotherapy and many conventional chemotherapeutic agents than their normoxic counterparts[22,23].

We also found strong immunoreactivity in macrophages. The significance of HIF-2α/EPAS1 in these cells warrants further study. As they have been shown to be one of the terminally differentiated cells that can produce a number of potent angiogenic cytokines such as VEGF[24,25], their chemotaxis, infiltration, degranulation may promote tumor angiogenesis and progression. A parallel IHC study of angiogenesis marker demonstrated that in HCC tissues, overexpression of both VEGF and HIF-2α/EPAS1 was coincidentally found, supporting the notion that HIF-2α/EPAS1 expression is correlated with angiogenesis in HCC.

In the current work, significantly more HIF-2α/EPAS1 protein expression was present in perinecrotic regions. This, when taken with the fact that macrophages appeared to be more pro-angiogenic at these sites[26] may help to explain our observation. As HIF-2α/EPAS1 has been shown to be accumulated by hypoxic macrophages in human tumor[11,27], our finding may indicate that HIF-2α/EPAS1 protein may be released by macrophages and is part of the mechanism by which this protein is most expressed in perinecrotic regions. On the other hand, direct support for microenvironmental mechanisms of HIF-alpha activation in diverse types of human tumor could offer an alternative explanation.

Results from our analysis of HIF-2α/EPAS1 expression in perinecrotic areas were consistent with a number of reports from clinical studies on breast[28-30], ovarian[31], and lung[32,33] cancers and in hemangioblastomas[10]. These reports all demonstrated that macrophage hotpots were remotely located from the vascular hotpots of tumors, suggesting that macrophages may preferentially migrate toward areas of relative hypoxia[29]. This in turn might attract macrophages into

tumor, which then contribute to angiogenic process, giving rise to association between high levels of angiogenesis and extensive necrosis[29]. Macrophages might be attracted to necrotic tumors by chemotactic factors, such as VEGF[26,34,35].

As a potent pro-angiogenic cytokine, VEGF has been reported to be overexpressed in both malignant tumors[30,36] and stroma cells[30,34] and macrophages[26,34,37]. Expression of VEGF was up-regulated in poorly vascularized areas of breast carcinomas[28,29,38]. VEGF positive macrophages were restricted to areas of VEGF production[26,28]. Evidence is accumulating that VEGF might be activated in stroma cells, especially in macrophages, with the process mediated by the VEGF receptor ftl-1[35]. Thus, the subcellular mechanisms mediating hypoxia on VEGF gene by macrophages are not known at present. This most likely involved one or more of the pathways activated by hypoxia in transformed cells[37,40], including the activation of such transcription factors as hypoxia-inducible factors (HIFs) 1, 2 (otherwise known as EPAS1). In this study, we observed the overexpression of VEGF protein in tumor and VEGF expression positively correlated with HIF-2α/EPAS1 expression. We found that the highest VEGF expression was detectable mostly in tumor areas and only weaker staining in necrotic and stroma areas was detectable.

It is widely accepted that angiogenesis necessitates the degradation of extracellular matrix, this process requires protease activation and release. Plasmin was thought to be one of the key proteases involved in this process[39]. Angiogenesis also appear to be involved in the invasion of tumors into surrounding tissues, because this invasion requires concomitant neovascularization through the sprouting of endothelial cells in the tumor stroma. It has been reported that VEGF induced both urokinase-type plasminogen activator (PA) and tissue type PA in endothelial cells[40], and hypoxia might promote cellular invasion by stimulating the expression of urokinase type plasminogen activator (uPAR)[41]. Therefore, enhanced expression of these angiogenic factors would likely indicate the ability of tumors to invade the tumor stroma as well as the ability to promote the development of new blood vessels. Based on these considerations, we examined both portal involvement and capsule infiltration. These two clinicopathological features have been thought to be the most important clinical factors in assessing liver tumor, and HCC in particular, as they were strongly correlated with the metastasis of HCC[42-44]. Our results were in agreement with this concept. We found that the portal vein involvement and capsular infiltration were correlated with the expression of both HIF-2α/EPAS1 and VEGF proteins. HCC patients with capsular infiltration and portal vein invasion had more HIF-2α/EPAS1 and VEGF expression than those without them, indicating that HIF-2α/EPAS1 and VEGF expression may be associated with a poor prognosis of patients with HCCs.

The clinical significance of HIF-2α/EPAS1 expression in tumors remains largely unexplored as monoclonal antibodies available for immunohistochemistry have been recently developed. Talks et al recently reported the expression of HIF-alpha in a panel of normal human tissues and benign or malignant tumors and first showed the expression of the molecule in a good percentage of human carcinomas[11]. However, studies on the HIF-2α/EPAS1 expression with angiogenic factors and receptors, with microvessel density or with other molecular markers or with prognosis of human carcinomas are few. Investigations regarding these angiogenic factors which have been partially done for endothelial carcinoma[3,33,45], and regarding the status of signal transduction via HIF-2α/EPAS1 when the receptors do and do not bind to this protein and when dimerization with aryl hydrocarbon receptor nuclear translocator occurs between HIF-2α/EPAS1 and other HIF-α protein family, should help clarify the significance

of HIF-2α/EPAS1 in human cancers, including HCC.

In this study, we found cytoplasmic immunoreactivity of HIF-2α/EPAS1, but equivocal staining was sometimes observed in the nuclear which we did not regard as positive. Although it was assumed that nuclear HIF was the active form, clearly it was synthesized and also degraded in the cytoplasm[45,46]. These findings, at least in part, could explain the cytoplamic location of HIF-2α/EPAS1, which was a tumor specific finding and could better reflect the HIF up-regulation pathways in paraffin embedded material. This suggestion was in accordance with the scoring system proposed by Zhong *et al*[46].

In conclusion, HIF-2α/EPAS1 expression in HCC and its clinical association with necrosis seem to be a good predictive tool and possibly a target therapy for metastasis of liver cancer, especially HCC. The finding that medium-sized HCCs had the highest expression of HIF-2α/EPAS1 compared with smaller and larger HCCs can be used, after further evaluation, as a therapeutic guide during the selection of cases for chemotherapy.

Abstract

AIM: To develop a novel non-viral gene delivery system, which has a small particle size and a high transfection efficiency to hepatocyte and hepatoma cells.

METHODS: Lipid-polycation-DNA lipopolyplex (LPD) was prepared by mixing plasmid DNA and polylysine. The resulted polyplex was incubated for 10 min at room temperature, following the addition of preformed cationic liposomes. The morphology of LPD was observed by transmission electron microscopy. The diameter and surface charge of LPD were measured by photon correlation spectroscopy (PCS). The nuclease protection ability of LPD was evaluated by agarose gel electrophoresis. Estimation of the transfection efficiency was performed by galactosidase assay in Chang cells and SMMC-7721 cells.

RESULTS: LPD had a regular spherical surface. The average diameter and the zeta potential of LPD were 132.1 nm and 26.8 mV respectively. LPD could protect plasmid DNA from nuclease degradation after 2 hours incubation at 37℃ while the naked DNA degraded rapidly. The average transfection efficiencies were 86.2±8.9% and 72.4±6.5% in Chang cells and SMMC-7721 cells respectively.

CONCLUSION: LPD has a rather small particle size and a high transfection activity. LPD may be a good non-viral vector for application in some gene delivery.

INTRODUCTION

Gene therapy focuses on the therapeutic use of genes, and has achieved considerable advances in the treatment of both acquired and inherited diseases[1,2]. The success of gene therapy rests on the development of a vector that can selectively and efficiently deliver a gene to the target cells with minimal toxicity[3,4]. The vectors used to date can be classified into viral and non-viral groups.

Non-viral delivery systems for gene therapy have been increasingly proposed as safer alternatives to viral vectors. They have the potential to be repeatedly used with minimal host immune response and are targetable, stable in storage, and easy to produce in large quantities. These advantages have provided the impetus to continue their development. So far, several non-viral delivery systems have been developed, such as liposomes[5-7], nanoparticles[8-10] hydrogel[11] emulsion[12] and peptide nucleic acid[13]. Complexes formed between cationic liposomes and plasmid DNA are the predominant non-viral vectors employed for the transfection of eukaryotic cells in research laboratories[14-16]. Currently, several cationic liposomal formulations have also undergone clinical evaluation as vectors for gene therapy in cancer and cystic fibrosis. However, the efficiency and specificity of non-viral delivery systems are not so high. To improve the transfection efficiency, some cationic lipids[17] and polymers[18-20] have been synthesized. Ligand or antibody mediated targeting of gene transfer has also been widely explored[21-24]. Furthermore, nuclear localization sequences (NLS) are studied to help the entry of plasmid DNA from cytoplasm into nucleus[25].

The liver possesses a variety of characteristics that make this organ very attractive for gene therapy[26,27]. The proportion of administered macromolecules internalized by hepatocytes depends on their particle size and biochemical characteristics. Only relatively small molecules can pass the fenestrate of sinusoidal endothelial cells of the liver, since their diameter is about 100 nm[28,29]. Polycations as a formulation component have been shown to enhance the efficiency of liposomes-mediated gene transfer both *in vitro* and *in vivo*. Specifically, lipid-polycation-DNA lipopolyplexes (LPD) have appeared promising as efficient gene-delivery vehicles for systemic administration[30-33]. In this study, we developed a novel lipopolyplex formulation, which is small in particle size and high in transfection efficiency to hepatocytes and hepatoma cells.

MATERIALS AND METHODS

Materials

Plasmid pORF lacZ (3.54 kb) was purchased from Invivogen (USA). Poly-L-lysine (PLL, M_r29 000), dimethyldioc tadecyl ammonium bromide (DDAB) and β-galactosidase reporter gene staining kit were purchased from Sigma. Hepatoma cell line SMMC-7721 and hepatocyte cell line Chang were obtained from Shanghai Cell Institute, China Academy of Sciences. Cell culture media DMEM and RPMI 1640 were obtained from Gibco Co. (USA). Qiagen Giga Endo-free plasmid purification kit was purchased from Qiagen (CA.USA). All the other chemicals and reagents used were of the analytical grade obtained commercially.

Plasmid DNA preparation

Plasmid pORF lacZ (3.54 kb), is a eukaryotic expression vector containing the EF-1α/HTLV hybrid promoter within an intron. The lacZ gene codes for the enzyme β-galactosidase, whose activity allows for quick determination of cells expressing the lacZ gene. pORF-lacZ plasmid DNA was isolated and purified from DH5-α E coli using the Qiagen Giga Endo-free plasmid purification kit. DNA concentration and purity were quantified

by UV absorbance at 260 nm and 280 nm on a GBC UV cintra 10e spectrophotometer. The structural integrity and topology of purified DNA were analyzed by agarose gel electrophoresis.

LPD preparation

Cationic liposomes composed of DDAB/cholesterol were prepared with the molar ratio of 1:1. The lipid mixture was dissolved in appropriate chloroform and a thin lipid film was formed in a round-bottomed flask by drying the solvent using a rotary evaporator. The film was hydrated at $60\,^{\circ}\text{C}$ with the addition of 10 mM herpes buffer (pH7.4). The lipids were resuspended and then undergone ten passes through an extruder with 200, 100 nm polycarbonate membranes respectively. LPDs were formed by mixing equal volumes of DNA and PLL. DNA and PLL were both diluted from the stock with 10 Mm herpes buffer. After mixed, the solution was briefly vortexed, and the resulting polyplexes were incubated for 10 min at room temperature. Concentrated cationic liposomes were subsequently added to the DNA/PLL mixture to achieve the desired final component concentrations and ratios.

Size and zeta potential

Diameter and surface charge of lipopolyplexes were measured by photon correlation spectroscopy (PCS) (Malvern zetasizer 3000 HS, Malvern Instruments Ltd., UK) with a 50 mV laser. Twenty μl of LPD was diluted by 3 ml of 10 mM herpes buffer and added into the sample cell. The measurement time was set at 2 min (rapid measurement) and each run consisted of 10 subruns[34]. The measurements were done at $25\,^{\circ}\text{C}$ at an angel of $90\,^{\circ}$. The size distribution followed a lognormal distribution. The potential of the lipid carriers at the surface of spheres, called the zeta potential(§), was derived from the mobile particles in electric field by applying the smoluchowsky relationship, which was measured at least three times and at an average of appropriate concentrations of samples.

Negative stain electron microscopy

Just prior to use, the former-coated 100-mesh copper girds were prepared by glow discharging. The girds were then floated on 25 μl of samples for 90 s, wicked off, and floated on drops of 1% aqueous uranyl acetate for 90 s. Finally, the samples were wicked off, dried in air and stored at room temperature. Negative stain electron micrographs of LPD were taken using a JEM-100SX electron microscope.

Stability in DNase I

Naked DNA or LPDs were incubated with DNase I solution (0.32 U/μg DNA) at $37\,^{\circ}\text{C}$ for 5 min, 1 h and 2 h respectively. The enzyme reaction was stopped by addition of 0.5M EDTA[35]. Triton X-100 (final concentration 1% v/v) was added to destroy the bilayer structure of liposomes and 0.9% w/v heparin was added to release DNA from PLL/DNA complexes[36]. The samples were carefully added to the wells of a 0.8% agarose gel at a volume (representing 1 μg of DNA per well). The gel was run in TBE buffer containing 0.5 μg/ml EtBr at 100V for 1 h. Subsequently, the gel was removed from the tank and visualized under UV light by molecular analyst software.

Cell transfection

Chang cells and SMMC-7721 cells were cultured in DMEM and RPMI-1640 respectively with 10% fetal bovine serum and streptomycin (100 μg/ml). The cells were seeded at 2×10^5 cells per well onto 6-well plates 24 h before transfection. The cells were about 70% confluence at the time of transfection. Then the cells were washed twice by PBS, and 1 ml of serum-free and antibiotics-free medium was added into each well[37]. For each well in a transfection, LPDs containing 5 μg pORF-1acZ were overlaid and mixed gently. The cells were incubated with LPD for 5 hours at $37\,^{\circ}\text{C}$ in a CO_2 incubator. Following incubation, LPD was removed and the cell surfaces were rinsed thoroughly and treated with 2 ml fresh complete medium. Then the cells were returned to the incubator for a further 45 h to allow intracellular gene expression to proceed.

X-gal staining

Estimation of the transfection efficiency was performed using galactosidase assay[38,39]. After the desired time of incubation, the cells were washed with PBS twice and fixed with 2% formaldehyde and 0.2% glutaraldehyde for 10 minutes at room temperature. Then the cells were rinsed twice and stained by X-gal (20 mg/ml) according to the manufacture's instructions. The cells were incubated at $37\,^{\circ}\text{C}$ overnight and observed under a microscope. The transfected cells were blue after X-gal staining. For each well, five visual fields were chosen randomly. Cells stained blue were counted and the transfection efficiency was calculated as the percentage of the blue cells in each field.

RESULTS

Morphology, particle size and zeta potential

Transmission electron microscopy (Fignre 1) demonstrated the regular spherical surface of LPD. Figure 2 shows the average diameter of LPD being 132.1 nm with a very narrow distribution (polyindex 0.148). Figure 3 illustrates the zeta potential of LPD being 26.8 mV in 10 mM herpes buffer (pH 7.4).

Figure 1 Electronic transmission microscopy of LPD ($\times 35\ 000$).

Figure 2 Size distribution of LPD. The particle size was measured by photon correlation spectroscopy (Malvern zetasizer 3000 HS). The average diameter of LPD is 132.1 nm.

Stability in DNase I

Figure 4 shows that LPD could protect plasmid DNA from nuclease degradation after 5 minutes, 1 hour and 2 hours of incubation at $37\,^{\circ}\text{C}$ while the naked DNA degraded rapidly.
**Figure 3** Zeta potential of LPD. The zeta potential of LPD was 26.8 mV in 10 mM herps buffer (pH 7.4).

Figure 4 Agarose gel electrophoresis of naked DNA and LPD subjected to DNase degradation. Lane 1: LPD incubated with DNase for 5 minutes. Lane 2: LPD incubated with DNase for 1 hour. Lane 3: LPD incubated with DNase for 2 hours. Lane 4: Naked DNA incubated with DNase for 5 minutes. Lane 5: Naked DNA incubated with DNase for 1 hour. Lane 6: Naked DNA incubated with DNase for 2 hours.

Transfection efficiency

Figure 5 and 6 demonstrate that LPD had a rather high transfection efficiency both in Chang cells and in SMMC-7721 cells. The average transfection efficiencies were 86.2±8.9% and 72.4±6.5% in Chang cells and SMMC-7721 cells, respectively.

DISCUSSION

The amount of intact DNA present in LPD cannot be directly assayed by gel electrophoresis as the complexation hinders the binding between DNA and ethidium bromide. Therefore Triton X-100, a widely used detergent is employed to destroy the liposomal bilayer. Furthermore, dissociation of cationic polymer and DNA is also required. Traditionally, DNA is dissociated from PLL by digestion with trypsin and phenol extraction. This procedure is time-consuming and the lost DNA during extraction is immeasurable. Some new dissociation methods have been established based on the fact that the interaction between DNA and PLL was mainly due to electrostatic bonds[40-43]. By raising the pH of electrophoretic buffer above the pKa of PLL, PLL could become less protonated, thus reducing the charge and thereby allowing the complexes to disossociation under electrophoretic conditions. However, when pH was higher than 11.6, ethidium bromide would lose its affinity for DNA and fluorescence was lost. In this study, heparin at final concentration of 0.9% (w/v) was added to release DNA from the complexes[36]. Heparin, as an anionic polysaccharide can bind to PLL by electrostatic interaction. When enough amount of heparin was added, DNA could be completely released from PLL-DNA complexes. The presence of heparin did not interfere with the gel electrophoresis, so the sample could be loaded directly.

The size and surface charge of lipopolyplex could influence their physical stability, *in vivo* distribution, cellular interaction and extent of cell uptake. After intravenous administration, particles larger than 7 μm are normally filtered by the smallest capillaries of the lungs, and particles smaller than 7 μm in diameter may pass the smallest lung capillary beds and be entrapped in the capillary network of the liver and spleen. Particles between 100 nm and 2 μm in size are rapidly cleared from the bloodstream by the mononuclear phagocytic system (MPS). Typically in practice, 80-90% of hydrophobic particles were opsonized and taken up by fixed macrophages of the liver and spleen, often within a few minutes of intravenous administration[1]. Zeta potential measurements can be a useful tool for characterizing colloidal drug delivery systems. They can give information about the surface properties of the carrier and therefore helping determine how the constituent molecules are organized. In this study, the LPDs had a positive zeta potential of 26.8mV. Therefore, they could interact with negatively charged cell surface, which resulted in cellular internalization. Furthermore, plasmid DNA in LPDs was shielded from nuclease digestion due to the formation of charge complexes.

It has become clear that cationic liposome plays several roles in the process of transfection, such as condensing and protecting DNA, binding to cell surface, triggering endocytosis and releasing DNA/lipid complexes from endosome. The size of condensed DNA is thought to be critical for *in vivo* delivery because the particle size influences not only the biodistribution but also the efficiency of cellular uptake through endocytosis. At an appropriate condition, cationic polymer PLL can precondense plasmid DNA more effectively than cationic liposomes. Therefore, LPD has a rather small particle size and a high transfection activity in hepatocytes and hepatoma cells. LPD may be a superior vector for some applications in gene delivery compared to regular DNA/liposome complexes. Structurally, this formulation has been found to be a virus-like particle, each containing a condensed genome as the core and a lipidic shell as the envelope. The liver possesses a variety of characteristics which make this organ very attractive for gene therapy. Although some of the virus-mediated gene transfer systems have been found to be quite effective, their usefulness is limited, given that they induce an immune response, leading to the rapid rejection of transduced cells. To overcome this

problem, our further work will focus on the use of LPD in the treatment of liver cancer.

Abstract

AIM: To construct antisense $VEGF_{165}$ eukaryotic expression vector $PCDNA_3$-as-$VEGF_{165}$ and to study its expression and effect on the proliferation of hepatocarcinoma SMMC-7721 cells.

METHODS: $VEGF_{165}$ cDNA was inserted into polylinker sites of eukaryotic expression vector $PCDNA_3$ to construct $PCDNA_3$-as-$VEGF_{165}$. Then the vector was transferred into human hepatocarcinoma cell strain SMMC-7721 with cation lipofectamine 2000 mediated methods to evaluate the expression of VEGF protein and the inhibitory effect on the proliferation of hepatocarcinoma SMMC-7721 cells.

RESULTS: The detection indicated the presence of VEGF cDNA in normally cultured SMMC-7721 cells by PCR. VEGF mRNA expression was notably decreased in SMMC-7721 cells by RT-PCR after $PCDNA_3$-as-$VEGF_{165}$ transfection. The expression of VEGF protein was dramatically inhibited (142.01 ± 7.95 vs $1\,625.52 \pm 64.46$ pg· ml^{-1}, $P<0.01$) 2 days after transfection, which correlated with the dose of $PCDNA_3$-as-$VEGF_{165}$ gene. VEGF protein was most expressed in $PCDNA_3$ transferred SMMC-7721 cells but few in $PCDNA_3$-as-$VEGF_{165}$ transferred cells by immunohistochemical staining. The apoptotic rate of hepatocarcinoma SMMC-7721 cells was significantly promoted ($17.98 \pm 0.86\%$ vs $4.86 \pm 0.27\%$, $P<0.01$) and the survival rate was notably decreased ($80.99 \pm 3.20\%$ vs $93.52 \pm 3.93\%$, $P<0.05$) due to antisense $VEGF_{165}$ by flow cytometry (FCM). The transfection of antisense $VEGF_{165}$ gene resulted in the inhibitory effect on the proliferation of hepatocarcinoma cells by 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) and the death of all hepatocarcinoma cells on day 6 after transfection.

CONCLUSION: It is confirmed that antisense $VEGF_{165}$ can inhibit the expression of VEGF protein, interfere with the proliferation and induce the apoptosis of hepatocarcinoma cells in our study. Antisense $VEGF_{165}$ gene therapy may play an important role in the treatment of human hepatocarcinoma.

INTRODUCTION

In recent years it has become clear that angiogenesis is not only important in physiological processes such as embryonic development, wound healing, and organ and tissue regeneration, but also plays a pivotal role in tumor progression and metastasis[1]. Neovascularization is critical for the rapid growth of solid tumors[2]. However, most if not all solid tumors appear to be dependent on angiogenesis for their further expansion and preventing tumor cell apoptosis when their size exceeds beyond 1-2 cubic millimeters[3]. Tumor cells promote angiogenesis by secreting angiogenic factors, especially vascular endothelial growth factor (VEGF) or vascular permeability factor (PVF)[4].

VEGF is a specific mitogen for endothelial cells that has been shown to be expressed in many tumor cell lines and vascular smooth muscle cells[5,6] and is important not only for angiogenesis, but also for maintenance of existing blood vessels[7]. VEGF characterized by rapidly growing solid tumors can also derive from immune cells that infiltrate tumors[8]. Increased serum VEGF is found in cancer patients[9] and elevated VEGF levels are reported to be a prognostic clinical factor correlated with decreased survival in patients with breast, ovarian, lung, gastric, liver and colon[10,11] cancers.

Inhibition of VEGF action that controls tumor-induced angiogenesis on a molecular basis may therefore be a successful approach to the treatment of human hepatocarcinomas. Since VEGF is also known as the vascular permeability factor (VPF)[12], inhibition of VEGF may induce a dual therapeutic effect (*e.g.*, antiangiogenic and anti-edematous) in patients with hepatocarcinoma[13].

We constructed successfully antisense $VEGF_{165}$ eukaryotic expression vector $PCDNA_3$-as-$VEGF_{165}$ and transferred it into human hepatocarcinoma cells *in vitro* with cation lipofectamine 2000 mediated methods to evaluate the expression of VEGF protein and the inhibitory effect on the proliferation of hepatocarcinoma cells.

MATERIALS AND METHODS

Plasmid $PCDNA_3$-as-$VEGF_{165}$ constructions
The SMMC-7721 cell line had a high expression of endogenous VEGF protein, and used in antisense $VEGF_{165}$ transfection studies. The entire coding region of human $VEGF_{165}$ cDNA (0.6 kb) containing the 165 amino acid coding regions, was obtained from the PSV-$VEGF_{165}$ plasmid (Preserved by professor Bai-Gen Zhang, Renji Hospital, Shanghai, China), and subcloned into the Pbluescript M13- expression vector (preserved by Biochemistry Department of Nanjing University, Nanjing, China) generating the Pbluescript –$VEGF_{165}$ plasmid

with endonucleases EcoR I and Pst I (MBI) digested. Then the Pbluescript –VEGF$_{165}$ was digested by EcoR I and BamH I to obtain VEGF$_{165}$ cDNA that was reverse inserted into the PCDNA$_3$ eukaryon expression vector (preserved by Shanghai Institute for Biologic Science, Shanghai, China) generating the antisense VEGF$_{165}$ plasmid PCDNA$_3$-as-VEGF$_{165}$. It was confirmed by restriction endonuclease analysis, PCR (Roche) and nucleotide sequencing (Shanghai Sangon Biological Engineering Technology and Service Co. Ltd., China). Then the antisense VEGF$_{165}$ plasmid was amplified by transferring into activated Ecol. DH$_{5\alpha}$ was extracted with QIAGEN plasmid purification kit (QIAGEN) following the manufacturer' s instructions.

ELISA for VEGF protein in cell culture supernatant

The day before transfection, the SMMC-7721 cells were trypsinized, counted, and plated in 24-well plates at 1×10^5 cells per well so that they were 90-95% confluent on the day of transfection. Cells were plated in 0.5 ml of DMEM containing 10% fetal bovine serum (FBS) and no antibiotics. For each well of cells to be transfected, 1.0 µg of DNA (PCDNA$_3$ or PCDNA$_3$-as-VEGF$_{165}$) and 3.0 µl of lipofectamine 2000 (LF2000) reagent were diluted respectively into 50 µl of DMEM without serum and antibiotics, and incubated for 5 min at room temperature. Once the LF2000 reagent was diluted, it was combined with DNA within 30 min, and then incubated at room temperature for 20 min to allow DNA-LF2000 reagent complexes to form. The DNA-LF2000 reagent complexes (100 µl) were added directly to each well and mixed gently by rocking the plate back and forth. The cells were incubated at 37℃ in a CO$_2$ incubator for 48 h until they were ready to assay for transgene expression. The amount of human VEGF protein in cell culture supernatant was quantified by using an ELISA kit for human VEGF (Quantikine, R and D Systems)[14].

Semiquantitative reverse transcription (RT)-PCR analysis[15]

Tripure RNA isolation system (Roche) was used to isolate RNA from hepatocarcinoma SMMC-7721 cells after the transfection of DNA-LF2000 reagent complexes. According to the manufacturer' s instructions, total RNA was resuspended in nuclease-free water (Promega), and the absorbance was read at A260 and A280. The quality of RNA was checked on a 1% denaturing agarose gel to ensure the presence of 28 S and 18 S ribosomal bands. VEGF mRNA expressions were measured using semiquantitative RT-PCR. One µg of total RNA was added to a 50 µl RT-PCR reaction (PCR-Access, Promega). The reaction master mix was prepared according to the manufacturer' s instructions with β-actin (as an internal control for both qualitative and semiquantitative RT-PCR) and VEGF gene-specific primers. The primer sequences were 5_-GAGGGCAGAATCATCACGAAGT -3_ (sense) and 5_-TCCTATGTGCTGGCCTTGGTGA -3_ (antisense) for VEGF. The primer sequences for β-actin amplification were 5_- CCAAGGCCAACCGCGAGAAGATGAC -3_ (sense) and 5_- AGGGTACATGGTGGTGCCGCCAGAC _ (antisense). For quantitation of mRNA, primers were used in a reaction involving one cycle of reverse transcription at 48℃ for 45 min and 30 cycles of denaturation at 94° for 1 min, annealing at 55℃ for 1 min, and extension at 72℃ for 45 s. Then the resulting RT-PCR fragments were electrophoresed on 2% agarose gels at 110 V for 35 min.

VEGF165 cDNA PCR detection

Highpure DNA isolation system (Roche) was used to isolate DNA from normally cultured hepatocarcinoma SMMC-7721 cells. The primer sequences were 5_- GAGGGCAGAATC ATCACGAAGT -3_ (sense) and 5_- TCCTATGTGCTGG

CCTTGGTGA -3_ (antisense) for VEGF. VEGF PCR was 30 cycles of denaturation at 94℃ for 1min, annealing at 55℃ for 1 min, and extension at 72℃ for 45 s. Then the fragments were identified by electrophoresis.

Flow cytometric analysis

The survival rate and apoptotic rate of hepatocarcinoma SMMC-7721 cells after antisense VEGF$_{165}$ transfections were determined by propidium iodide (PI) and annexin V staining. Hepatocarcinoma cells were digested by 0.25% trypsin at 37 ℃ for 20 min and fixed with ice-cold 70% ethanol at a cell density of 1×10^6 ml^{-1}. PI and annexin V were then added and incubated with cells in the dark for 30 min until detected by flow cytometry[16].

MTT assay

The day before PCDNA$_3$-as-VEGF$_{165}$ transfection, the hepatocarcinoma SMMC-7721 cells were trypsinized and counted, plated in 96-well plates at 1×10^4 cells per well. Cells were plated in 100 µl of DMEM containing serum and no antibiotics, and incubated at 37℃ in a CO$_2$ incubator for 48 h until they were ready to transfer antisense VEGF$_{165}$. For each well of cells to be transfected, 0.2 µg of DNA (PCDNA$_3$ or PCDNA$_3$-as-VEGF$_{165}$) and 0.6 µl LF2000 were diluted respectively into 50 µl of DMEM without serum. The DNA-LF2000 reagent complexes (100 µl) were added directly to each well and mixed gently by rocking the plate back and forth. The cells were incubated at 37℃ in a CO$_2$ incubator for 48 h until they were ready to assay for proliferation of hepatocarcinoma cells by MTT.

MTT assay was performed according to the methods of Mosmann[17]. After the culture supernatant was sucked out, 100 µl 5 mg· ml^{-1} MTT (Sigma) stock solution in PBS was respectively added to 4 wells each group each day for 5 days. After 4 h of incubation, 100 µl DMSO (Sigma) containing serum was added into each well. The plate was mixed gently by rocking back and forth until the blue sedimentation was completely dissolved. Then the absorbances were read by Tecan' s sunrise absorbance microplate reader (A-5082)[18].

Immunohistochemistry[19]

The gene transferred hepatocarcinoma SMMC-7721 cells were trypsinized and sliced by cytofuge (Cytocentrifuge System M801-22, StatSpin). The slices containing SMMC-7721 cells were dried at 37℃ overnight, rehydrated and exposed to 0.5 per cent hydrogen peroxide for 30 min to block the endogenous peroxidase activity. They were washed with distilled water and TRIS-HCL buffered saline (TBS) at PH 7.6, and then incubated with 1:5 normal rabbit serum for 10 min to reduce background staining. Next, the slices were incubated with diluted primary antibody at room temperature for 1 h. The antibody, a mouse monoclonal anti-human VEGF (DAKO, UK) was applied at a dilution of 1:200. The slices were then washed and a secondary antibody, horseradish peroxidase-conjugated rabbit anti-mouse immunoglobulin (DAKO, UK) at 1:50 dilution was applied for 30 min at room temperature. Thereafter, the slices were reacted in hydrogen peroxide-diaminobenzidine (DAB) solution to produce a brown color and counterstained with haematoxylin.

TBS was used as washing buffer between each stage of the staining and TBS containing 1 per cent bovine serum albumin was used to dilute the antibody.

Statistical calculations

The data were expressed as mean±SD. Besides a two-sided Student t test with a level of significance at 5%, a multiple-factor ANOVA (Tukey' s test) was performed to analyze the

data of different groups. All the data were analyzed with the statistical software SPSS10.0.

RESULTS

Identification of eukaryotic expression vector PCDNA$_3$-as-VEGF$_{165}$

The eukaryotic expression vector PCDNA$_3$-as-VEGF$_{165}$ was identified by restriction endonucleases cut with EcoR I and BamH I and electrophoresis generating a 600 bp fragment according to the result from GeneBank. The fragment obtained from PCR was 258 bp in length. VEGF$_{165}$ cDNA was reverse subcloned into the site after T7 promoter appeared on the plasmid PCDNA$_3$ by nucleotide sequencing, coinciding completely with the sequence from GeneBank. There were no endonuclease cut sites of EcoR I, Pst I and BamH I by zymogram analysis.

Detection of SMMC 7721 cells after PCDNA$_3$-as-VEGF$_{165}$ transfection

VEGF cDNA was highly expressed in normally cultured hepatocarcinoma SMMC-7721 cells by PCR. But the VEGF mRNA expression was dramatically decreased after PCDNA$_3$-as-VEGF$_{165}$ transfection in hepatocarcinoma SMMC-7721 cells (Figure 1). The expression of VEGF protein in the culture supernatant of hepatocarcinoma SMMC-7721 cells was significantly inhibited (142.01±7.95 *vs* 1 625.52±64.46 pg· ml^{-1}, *P*<0.01) 2 days after antisense VEGF$_{165}$ transfection when compared to PCDNA$_3$ transfected controls, which correlated with the dose of antisense VEGF$_{165}$ gene. VEGF protein was highly expressed in most normally cultured hepatocarcinoma cells by immunohistochemical staining, but only in few hepatocarcinoma cells 2 days after antisense VEGF$_{165}$ transfection (Figure 2).

Evaluation of functions of eukaryotic expression vector PCDNA$_3$-as-VEGF$_{165}$

The apoptotic rate of hepatocarcinoma cells was significantly promoted (17.98±0.86% *vs* 4.86±0.27%, *P*<0.01) and the survival

rate was notably decreased (80.99±3.20% *vs* 93.52±3.93%, *P*<0.05) due to antisense VEGF$_{165}$ by flow cytometry (FCM). The transfection of antisense VEGF$_{165}$ gene resulted in the inhibition on the proliferation of hepatocarcinoma cells using MTT and the death of all hepatocarcinoma cells on day 6 after transfection (Figure 3).

Figure 1 Effect of PCDNA3-as-VEGF$_{165}$ on VEGF mRNA expression of hepatocarcinoma SMMC-7721 cells by RT-PCR. VEGF mRNA expression was negative after PCDNA3-as-VEGF$_{165}$/LF2000 transfected. (Lane 1: PCDNA3/LF2000 transfected, Lane 2: PCDNA3-as-VEGF165/LF2000 transfected; β-actin: 587 bp, VEGF 258 bp).

Figure 2 Immunohistochemical staining for expression of VEGF protein after DNA/LF2000 transfection in hepatocarcinoma SMMC-7721 cells. Positive signal for VEGF protein is brown and located in cytoplasm. A: (×100), B: (×400): PCDNA3 transferred SMMC-7721 cells; C: (×100), D: (×400): PCDNA3-as-VEGF165 transferred.

DISCUSSION

The incidence of hepatic cancer has been gradually increasing in recent years in China. Currently surgical operation is considered exclusively as the sole option for the treatment of hepatocarcinoma, although less than 20% of patients were considered as candidates for resection [20]. hepatocarcinoma is clearly a disease for which alternative therapies must be developed.

VEGF-mediated angiogenesis was considered to be a major contributor to tumor growth and metastasis[21,22]. A number of VEGF antagonists have been developed for inhibiting VEGF-induced tumor angiogenesis and tumor growth. These antagonists include antisense VEGF oligonucleotides, VEGF antibodies, dominant-negative receptors, and soluble VEGF receptors [23-26].

VEGF has been found to band to two tyrosine kinase receptors, VEGFR-1 (Flt-1) and VEGFR-2 (KDR/ Flk-1)[27-29]. Both receptors were expressed on the surface of tumor endothelial cells, but not on tumor cells[30]. Antisense VEGF cDNA[31,32] significantly inhibited tumor angiogenesis and tumor growth in $vivo$ with a paracrine signal transduction system. Angiogenesis played a key role in tumor growth and metastasis.

In previous studies, the putative anti-angiogenic effect of antisense $VEGF_{165}$ was investigated on stably transfected tumor cell lines. C6 and U87 glioma cells stably transfected with a vector encoding antisense $VEGF_{165}$ showed a significant growth inhibition when compared to sense VEGF transferred controls[33,34]. These studies suggested that antisense $VEGF_{165}$ expression could be useful in controlling tumor angiogenesis and tumor growth in $vivo$.

In order to increase the effect of putative gene therapy, we implanted $PCDNA_3$-as-$VEGF_{165}$/LF2000 complexes into human hepatocarcinoma SMMC-7721 cells. We used hepatocarcinoma cells, because we previously observed that normally cultured hepatocarcinoma SMMC-7721 cells showed a high expression of VEGF protein[35]. We achieved a significant promotion of SMMC-7721 cell apoptosis and complete hepatocarcinma cell death on day 6 after antisense $VEGF_{165}$ transfection. VEGF mRNA expression was obviously blocked by antisense $VEGF_{165}$. Since the effect of antisense VEGF mRNA expression was temporary, it bound specifically to the sense counterpart and selectively neutralized the function of $VEGF_{165}$ gene[36]. This approach may also require persistent expression of antisense VEGF or periodic administration of $PCDNA_3$-as-$VEGF_{165}$.

In summary, we succeeded in constructing the antisense $VEGF_{165}$ eukaryotic expression vector $PCDNA_3$-as-$VEGF_{165}$ acting as a $VEGF_{165}$ antagonist, and studied its anti-tumor activity. But the molecular mechanisms of $PCDNA_3$-as-$VEGF_{165}$ mediated apoptosis and inhibitory proliferation of hepatocarcinoma cells still need to be established. Finally, there may also exist other angiogenic pathways in hepatocarcinoma such as the angiopoietin/tie2 system that are not blocked by antisense $VEGF_{165}$[37].

Abstract

AIM: The study investigated if EGF signaling inhibitors, EGF antibody and tyrphostin 51 (a tyrosine kinase inhibitor), mediated the action of EGF on apoptosis and the expression of EGF receptors and p21 (a cyclin-dependent kinase inhibitor) of human colorectal cancer cells.

METHODS: Human colorectal adenocarcinoma cells (SW480) were incubated with 0.6 mL/L dimethyl sulfoxide (DMSO, the control group), 225 ng/mL (37.5 nmol/L) EGF in 0.6 mL/L DMSO, 225 ng/mL EGF+2.5 μg/mL (17 nmol/L) EGF antibody in 0.6 mL/L DMSO, or 225 ng/mL EGF+215 ng/mL (0.8 μmol/L) tyrphostin 51 in 0.6 mL/L DMSO.

RESULTS: After 48 h incubation, the levels of EGF in medium significantly increased ($P<0.05$) in the EGF-treated groups. The numbers of apoptotic cells were significantly fewer ($P<0.05$) in the EGF + EGF antibody and EGF + tyrphostin 51 groups than those in the control and EGF groups after 12 h treatments. The expression of phosphorylated EGF receptors in the EGF, EGF + EGF antibody, and EGF + tyrphostin 51 groups was 176.8%, 62.4%, and 138.1% of the control group, respectively. The expression of p21 protein in the EGF, EGF + EGF antibody, and EGF + tyrphostin 51 groups was 115.7%, 4.8%, and 61.5% of the control group, respectively.

CONCLUSION: The data suggest that EGF antibody and tyrphostin 51 can inhibit the action of EGF on apoptosis in human colorectal cancer cells through down-regulation of EGF receptor and p21 expression.

INTRODUCTION

Colorectal cancer is one of the most common human malignancies. The genetic alterations in colorectal cancer may drive the transition of normal colorectal epithelium to adenomas and adenocarcinomas through increased proliferation and decreased cell death or apoptosis. Several peptide growth factors have been suggested as autocrine growth regulators in cancer cell lines[1]. Anomalous expression of growth factors and/or growth factor receptors, as well as abnormal response to growth factors and/or their receptors may be involved in cellular transformation. Among these growth factors, epidermal growth factor (EGF) is known to play a major role in regulation of cell proliferation. Epidermal growth factor has been shown to be a potent mitogen both *in vitro* and *in vivo* studies to stimulate DNA, RNA, and protein synthesis in the digestive tract[2,3].

Epidermal growth factor exerts its mitotic signal via a tyrosine kinase-type cell surface receptor, the EGF receptor (EGF-R). It has been reported that EGF-R is overexpressed in a number of human tumors[4-6]. The EGF-R level in patients with primary colorectal carcinoma ranged between 4 and 79 fmol/mg membrane protein (Kd=0.1-0.4×10^{-9} M)[7]. Messa *et al*.[6] found that the expression of both EGF and EGF-R significantly increased in neoplastic tissues from patients with colorectal adenocarcinoma compared with that in their adjacent normal mucosa. The overexpression of EGF-R in human epidermoid carcinoma (A431) cells could allow selective growth advantage for tumor cells in the presence of normal or decreased ligand availability, and excessive ligand binding caused down-regulation of growth signaling and furthermore inhibition of growth and induction of apoptosis[4].

Epidermal growth factor affects cell proliferation by modulating the activity of cyclin-dependent kinase complex, a cell cycle regulator[8]. The cyclin-dependent kinase inhibitor p21 (also called WAF1, CAP20, Cip1, and Sdi1) may cause cell cycle arrest by both p53-dependent and -independent mechanisms[9]. EGF has shown to induce p21 expression in different human cancer cell lines[10-16].

Blockade of EGF signaling pathway by several methods affects the proliferation and/or apoptosis in a variety of tumor cell lines[4,17-19]. The EGF/EGF-R inhibitors may have potential for the therapy of tumors that are dependent on EGF-R signaling pathway for proliferation or survival. The purposes of this study were to investigate if EGF signaling inhibitors, EGF antibody and tyrphostin 51 (a tyrosine kinase inhibitor), mediated the action of EGF on apoptosis of human epithelial-type colorectal adenocarcinoma cells with EGF-R expression, and if these inhibitors affected the expression of EGF-R and p21, which are involved in EGF signaling pathway and cell cycle regulation, respectively.

MATERIALS AND METHODS

Cell line and treatments

Human colorectal adenocarcinoma cell line (SW480; BCRC No. 60249) was purchased from Bioresources Collection and Research Center (BCRC) at Food Industry Research and Development Institute (Hsinchu, Taiwan). Cells were grown in 900 mL/L Leibovitz's L-15 medium with 100 mL/L fetal bovine serum at 37℃ without CO_2. When cells reached 90% confluency, cells were switched to serum-free medium for 24 h to deplete growth factors in serum. Cells were then incubated with 0.6 mL/L dimethyl sulfoxide (DMSO, the

control group), 225 ng/mL (37.5 nmol/L, a physiological concentration) EGF in 0.6 mL/L DMSO, 225 ng/mL EGF + 2.5 μg/mL (17 nmol/L) EGF antibody (Research and Diagnostics Systems, Inc., Minneapolis, MN) in 0.6 mL/L DMSO, or 225 ng/mL EGF + 215 ng/mL (0.8 μmol/L) tyrphostin 51 (a tyrosine kinase blocker to inhibit the EGF receptor, Sigma-Aldrich Co., St. Louis, MO) in 0.6 mL/L DMSO serum-free medium for 12 or 48 h. Cells and conditioned medium were collected. Protein contents in cells and conditioned medium were measured by the modified method of Lowry *et al.*[20] using a Bio-Rad DC protein kit (Bio-Rad Laboratories, Hercules, CA).

Measurement of EGF in medium

The secretion of EGF into conditioned medium was measured by a commercial EGF immunoassay kit (Quantikine™, Research and Diagnostics Systems, Inc.)[21]. Serum-free conditioned medium (200 μL) was incubated with murine monoclonal EGF antibody coated in a 96-well plate for 2 h at room temperature, washed 3 times with wash buffer, and then incubated with 200 μL polyclonal EGF antibody conjugated to horseradish peroxidase for 1 h. After several washes, samples were incubated with 200 μL substrate (tetramethylbenzidine:H_2O_2=1:1) for 20 min. The reaction was terminated by 50 μL of 1 mol/L sulfuric acid. The levels of EGF were determined at 450 nm and corrected at 540 nm using an ELISA reader (Multiskan RC, Thermo Labsystems, Helsinki, Finland).

Detection of apoptosis

Apoptosis was analyzed by fluorescence microscopy using an annexin V-fluorescein isothiocyanate (FITC) apoptosis detection kit (Oncogene Research Products, Boston, MA). The externalization of phosphatidylserine was as a marker of early-stage apoptosis using annexin V-FITC binding[22]. Cells (5×10^5) were suspended in 0.5 mL binding buffer (10 mmol/L Hepes, pH 7.4/150 mmol/L NaCl/2.5 mmol/L $CaCl_2$/1 mmol/L $MgCl_2$/40 mg/L bovine serum albumin (BSA)), and incubated with 1.25 μL of 200 μg/mL annexin V-FITC in 50 mmol/L Tris (pH 7.4), 0.1 mol/L NaCl, 10 mg/L BSA, and 0.2 mg/L NaN_3 solution for 15 min in the dark. Cell suspension was centrifuged at 1 000 g for 5 min, resuspended in 0.5 mL binding buffer, and mixed with 10 μL of 30 μg/mL propidium iodide in PBS. Samples were placed on ice in the dark and analyzed by fluorescence microscopy immediately.

Measurement of EGF receptor and p21 proteins

Cell suspension (30 μg total protein) pooled from 7 independent experiments (*n*=7) was mixed with an equal volume of 2×SDS-PAGE sample buffer (0.125 mol/L Tris-HCl, pH 6.8/40 mg/L SDS/200 mL/L glycerol/100 mL/L 2-mercaptoethanol)[23], denatured at 100 ℃ for 3 min, and applied to SDS-PAGE (Bio-Rad Mini-PROTEAN 3 Cell, Bio-Rad Laboratories). Proteins were separated by 7.5% or 10% resolving gel for EGF receptor or p21, respectively, with 4% stacking gel in the running buffer (25 mmol/L Tris, pH 8.3/192 mmol/L glycine/1 mg/L SDS) at 100 V for 1 h. After separation on the gel, proteins were then transferred onto the nitrocellulose membrane (0.45 μm) using a semi-dry transfer unit (Hoefer TE 70, Amersham Biosciences Ltd. Taiwan Branch, Taipei, Taiwan) in Towbin buffer (25 mmol/L Tris/192 mmol/L glycine/1.3 mmol/L SDS/100 mL/L methanol)[24] at 200 mA for 1 h. The membrane was washed briefly with PBS, and incubated with blocking buffer (50 mg/L skim milk/1 mL/L Tween-20 in PBS) for 1 h. After blocking, the membrane was incubated with 1 μg/mL mouse anti-human phosphorylated EGF receptor (eps15, BD Transduction Laboratories, San Diego, CA), p21 (p21[Cip1/WAF1], BD Transduction Laboratories), or α-tubulin (TU-02, Santa Cruz

Biotechnology, Inc., Santa Cruz, CA) antibody at room temperature for 1 h. The membrane was washed 3 times with wash buffer (1 mL/L Tween-20 in PBS), and incubated with 10 μg/mL goat anti-mouse IgG-horseradish peroxide conjugate (Leinco Technologies, Inc., St. Louis, MO,) for 1 h. The blot was washed again 3 times with wash buffer, incubated with ECL™ Western blotting detection reagents (Amersham Biosciences Ltd. Taiwan Branch) for 1 min, and exposed to an X-ray film for 15 s. The bands were quantitated by an image analysis system (Gel analysis system, EverGene Biotechnology, Taipei, Taiwan) and Phoretix 1D Lite software (Phoretix International Ltd., Newcastle upon Tyne, UK).

Statistical analysis

Data are expressed as mean±SD. Data were analyzed by one-way ANOVA to determine the treatment effect using SAS (version 6.12, SAS Institute Inc., Cary, NC). Fisher's least significant difference test was used to make *post-hoc* comparisons if the main effect was demonstrated. Differences were considered significant at *P*<0.05.

RESULTS

The secretion of EGF into medium was significantly higher (*P*<0.05) in the EGF (8.35±0.82 ng/mg protein, *n*=7), EGF + EGF antibody (7.44±1.17 ng/mg protein, *n*=7), and EGF + tyrphostin 51 (8.28±0.84 ng/mg protein, *n*=7) groups than that in the control group (0.49±0.05 ng/mg protein, *n*=7) (Figure 1). However, the level of EGF did not significantly differ among the EGF-treated groups. Annexin V-FITC apoptosis detection assay showed that FITC-positive cells were significantly more often found (*P*<0.05) in the control (5.0±1.8/field) (Figure 2A) and EGF (6.0±1.3/field) (Figure 2B) groups, with a range of 2 to 8 positive cells per field (×100), compared with those in the EGF + EGF antibody (2.1±1.3/field) (Figure 2C) and EGF + tyrphostin 51 (1.9±1.3/field) (Figure 2D) groups, with a range of 0 to 4 cells per field (×100) after 12 h treatments. However, the numbers of apoptotic cells did not significantly differ between the control and EGF groups and between the EGF + EGF antibody and EGF + tyrphostin 51 groups. The expression of phosphorylated EGF-R in the EGF, EGF + EGF antibody, and EGF + tyrphostin 51 groups was 176.8%, 62.4%, and 138.1% of the control group, respectively (Figure 3). The expression of p21 protein in the EGF, EGF + EGF antibody, and EGF + tyrphostin 51 groups was 115.7%, 4.8%, and 61.5% of the control group, respectively (Figure 4).

Figure 1 Levels of EGF in medium after incubation of SW480 cells with 0.06% dimethyl sulfoxide (DMSO, the control group), 225 ng/mL (37.5 nmol/L) EGF in 0.6 mL/L DMSO, 225 ng/mL EGF + 2.5 μg/mL (17 nmol/L) EGF antibody in 0.6 mL/L DMSO, or 225 ng/mL EGF + 215 ng/mL (0.8 μmol/L) tyrphostin 51 in 0.6 mL/L DMSO serum-free medium for 48 h. Data are expressed as mean±SD (*n*=7). a*P*<0.05 significantly different between the control and EGF-treated groups.

Figure 2 Apoptotic cells stained by annexin V-FITC binding (green) after incubation of SW480 cells with 0.6 mL/L dimethyl sulfoxide (DMSO, the control group) (A), 225 ng/mL (37.5 nmol/L) EGF in 0.6 mL/L DMSO (B), 225 ng/mL EGF + 2.5 μg/mL (17 nmol/L) EGF antibody in 0.6 mL/L DMSO (C), or 225 ng/mL EGF + 215 ng/mL (0.8 μmol/L) tyrphostin 51 in 0.6 mL/L DMSO serum-free medium (D) for 12 h. Micrograph magnified by ×100 is the representative of seven independent experiments (n=7).

Figure 3 Expression of phosphorylated EGF receptor (EGF-R) with the molecular weight of 145 kDa visualized by Western blotting (A) and quantitated by an image analysis system (B) after incubation of SW480 cells with 0.6 mL/L dimethyl sulfoxide (DMSO, the control group), 225 ng/mL (37.5 nmol/L) EGF in 0.6 mL/L DMSO, 225 ng/mL EGF + 2.5 μg/mL (17 nmol/L) EGF antibody in 0.6 mL/L DMSO, or 225 ng/mL EGF + 215 ng/mL (0.8 μmol/L) tyrphostin 51 in 0.6 mL/L DMSO serum-free medium for 48 h. Samples were pooled from 7 independent experiments (n=7). Density was calibrated by an internal control, α-tubulin (55 kDa).

Figure 4 Expression of p21 protein with the molecular weight of 21 kDa visualized by Western blotting (A) and quantitated by an image analysis system (B) after incubation of SW480 cells with 0.6 mL/L dimethyl sulfoxide (DMSO, the control group), 225 ng/mL (37.5 nmol/L) EGF in 0.6 mL/L DMSO, 225 ng/mL EGF + 2.5 μg/mL (17 nmol/L) EGF antibody in 0.6 mL/L DMSO, or 225 ng/mL EGF + 215 ng/mL (0.8 μmol/L) tyrphostin 51 in 0.6 mL/L DMSO serum-free medium for 48 h. Samples were pooled from 7 independent experiments (n=7). Density was calibrated by an internal control, α-tubulin (55 kDa).

DISCUSSION

Our data showed that EGF treatment at a dose of 225 ng/mL (37.5 nmol/L) did not further stimulate apoptosis compared with the control group, but significantly increased to nearly 2-fold the expression of phosphorylated EGF-R. Gulli *et al*.[4] demonstrated that exogenous EGF (60 ng/mL; 10 nmol/L) inhibited cell proliferation and induced morphological features of apoptosis in A431 cells with overexpressed EGF-R by induction of a 15-fold increase in EGF-R autophosphorylation, which down-regulated EGF signal transduction. At a lower concentration of EGF (0.06 ng/mL, 10 pmol/L), EGF-R autophosphorylation and cell proliferation increased to 2-fold compared with those in untreated cells[4]. Previous studies showed the expression of EGF-R on the cell surface affected the action of EGF[15,25]. A431 cells grown as three-dimensional spheroids showed growth stimulation in response to nanomolar concentrations of EGF, while monolayer cultures showed growth inhibition[25]. The expression of EGF-R on monolayers of A431 cells was 20-fold greater than that on three-dimensional spheroids. Autophosphorylation of the EGF-R also increased in response to EGF in monolayer cultures of A431 cells. However, EGF prevented apoptosis of human bladder carcinoma 647V cells cultured as three-dimensional spheroids with lower expression of EGF-R[15]. The data indicated that EGF could play a dual role in modulation of apoptosis depending on the level of EGF-R. The overexpression of EGF-R down-regulated growth-stimulating action of EGF when cells were grown in monolayer cultures.

Apoptosis occurred prior to and in response to EGF treatment in SW480 cells. Previous studies found that cell lines, such as A431[4] and human mammary adenocarcinoma MDA-MB-468[26] cells, which overexpress the EGF-R underwent apoptosis in response to EGF treatment. Additionally, apoptosis was greatly enhanced when cells were growth-arrested prior to EGF treatment[26]. Our study showed that apoptosis was also induced in the control group, probably because cells were arrested after 24 h incubation in serum-free medium. However, apoptosis was induced to occur but not further enhanced by EGF compared with that without EGF (the control group) within 12 h. EGF-induced apoptosis may involve activation of activator protein-1[26], inhibition of nuclear transcriptional factor-kappaB (NF-κB)[27] and protein kinase B (PKB/Akt) activation[28], and cell detachment (a decline in cell adhesion)[29,30].

Compared with the EGF group, apoptosis was inhibited after EGF signal transduction was blocked by EGF antibody or tyrosine kinase inhibitor. The expression of phosphorylated EGF-R and p21 decreased in the groups treated with EGF signaling inhibitors, especially in the EGF + EGF antibody group. Our data indicated that the inhibition of EGF signal transduction by EGF antibody or by EGF-R inhibitor decreased apoptosis of human colorectal adenocarcinoma cells, at least in part, through regulation of EGF-R and p21. SW480 cells produced the most transforming growth factor (TGF)β-like rather than TGFα-like activity and had no measurable TGFβ membrane receptors, but EGF receptors were detectable[31]. Additionally, the concentration of endogenous EGF detectable in conditioned medium of the control group was much lower than that of exogenous EGF in the EGF-treated groups. Therefore, apoptosis of SW480 cells was primarily mediated by exogenous EGF and EGF signaling inhibitors through EGF-R signaling pathway in a paracrine rather than an autocrine manner. Previous studies showed that inhibition of EGF signal transduction could reverse the action of EGF on cell proliferation[4,17-19]. Anti-sense EGF-R RNA down-regulated the proliferation[17] and invasive properties[18] of human colon tumor cells. When A431 cells were simultaneously treated with EGF (60 ng/mL, 10 nmol/L) and EGF antibody (15 μg/mL), a significant reduction in EGF-R autophosphorylation reversed the action of EGF on cell proliferation[4]. Tyrphostin, the most potent EGF-R kinase inhibitor, inhibited EGF-dependent proliferation of A431/clone 15 cells, but with little or no effect on EGF-independent cell growth[32]. The phosphorylation of EGF-R was decreased by an inhibitor of EGF-R tyrosine kinase, RG-13022 (α-(3'-pyridyl)-3,4-dimethoxy)cinnamonitrile), in A431 cells[4]. Additionally, another tyrosine kinase inhibitor, CP-358,774 ([6,7-bis(2-methoxy-ethoxy)-quinazolin-4-yl]-(3-ethynylphenyl)amine), inhibited proliferation and triggered apoptosis through arrest of cell cycle progression in the G1 phase by accumulation of p27[KIP1], a mitotic inhibitor, in human colorectal carcinoma (DiFi) cells[19].

Similar to our findings, exposure to EGF at a nanomolar concentration reduced DNA synthesis, arrested cells in the G0/G1 phase, and elevated p21 protein in human squamous carcinoma cells, indicating that p21 plays a role in mediating EGF-induced growth inhibition[10-12]. Additionally, EGF-mediated growth inhibition was associated with induction of p21 in human breast[13, 14], bladder[15], and esophageal[16] cancer cells. EGF-increasing p21 expression was by stabilization of p21 at the post-transcriptional and post-translational levels[12], and activation of signal transducer and activator of transcription (STAT)1 and STAT3[13,16,33]. Consistent with our study, EGF-induced p21 expression was inhibited by the EGF-R tyrosine kinase inhibitor, tyrphostin AG1478 in A431 cells[10].

In conclusion, EGF antibody and tyrphostin 51 can inhibit the action of EGF on apoptosis in human colorectal cancer SW480 cells through down-regulation of EGF receptor and p21 expression. Furthermore, EGF at a higher concentration may have potential for the therapy of tumors with overexpressed EGF-R, which is dependent on EGF-R signaling pathway for proliferation.

Abstract

AIM: To detect the thymidine phosphorylase (dThdPase) expression in human colorectal cancer tissues and cells.

METHODS: Forty specimens resected from patients with colorectal cancer were immunohistochemically stained by 654-1, anti-dThdPase monoclonal antibody, PG-M1, anti-macrophage marker CD68 monoclonal antibody. Morphometrical analysis and positive cell counting were performed. In 27 of 40 specimens, dThdPase activity was also assayed by *HPLC*. Otherwise, the dThdPase level was measured by *ELISA* in 6 colorectal cancer cell lines, LS174T, Clone A, Colo320, CX-1, Lovo, and MIP101, as well as in 2 macrophage-like cell lines, THP-1 and U937.

RESULTS: dThdPase activity was significantly increased in cancer tissues compared with adjacent normal tissue (*P*<0.01). In immunohistochemical analysis, it was confirmed that most cells expressed dThdPase were the stromal cells surrounding cancer nests or along the invasive margin of cancer. Based on their morphometrical characteristics, we found that most of them were tumor-associated macrophages (TAMs). The number of dThdPase-positive stromal cells was significantly correlated with the number of CD68-positive macrophages (*r*=0.76, *P*<0.0001). By *ELISA*, 18.2 *unit/mg* and 19.3 *unit/mg* of dThdPase protein were detected in THP-1 and U937, but only little was detected in 6 colorectal cancer cell lines.

CONCLUSION: The present data suggest that dThdPase expression is seldom detected in colorectal carcinoma cells. TAM is the most important source of dThdPase in colorectal cancer tissues.

INTRODUCTION

Thymidine phosphorylase (dThdPase) is an enzyme involved in pyrimidine nucleoside metabolism. It could catalyze the reversible phosphorolysis of thymidine, deoxyuridine and their analogues to their bases and 2-deoxyribose-1-phosphate[1,2]. 5'-deoxy-5-fluorouridine (5'-DFUR), a prodrug of 5-fluorouracil (5-FU), must be activated by dThdPase in cancer tissues and converted into 5-FU, resulting in induction of the anticancer activity with few side effects in normal tissues[3]. Previous studies have demonstrated that dThdPase is identical to platelet-derived endothelial cell growth factor (PD-ECGF), which is an endothelial cell mitogen[4,5]. dThdPase/PD-ECGF could stimulate chemotaxis of endothelial cells *in vitro* and possess angiogenic activity *in vivo*[5-8], however, the mechanisms by which dThdPase/PD-ECGF contributes to angiogenesis are still unclear.

Studies have reported that certain solid tumors including gastric and breast cancers could express elevated levels of dThdPase as compared with normal surrounding tissues[9-12]. Thus it is reasonable that these tumors are susceptible to 5'-DFUR. In colorectal cancer, it is controversial whether cancer cells or stromal cells are responsible for the increased dThdPase levels. Some immunohistochemical studies reported that cancer cells had dThdPase expression[12,13], while others believed that most cells expressing dThdPase were stromal cells, especially tumor-associated macrophages (TAMs), and lymphocytes[14,15]. Therefore, it is uncertain how 5'-DFUR exerts it's anticancer activity in colorectal cancer.

As we know, dThdPase plays an important role in cell proliferation, tumor angiogenesis, and in chemotherapy with 5'-DFUR. Here we focused on the expression of dThdPase in CD68-positive TAMs in colorectal cancer tissue with immunohistochemistry and an analysis of dThdPase level in 6 colorectal cancer cell lines by *ELISA*.

MATERIALS AND METHODS

Tissue preparation
Resected specimens from 40 patients with colorectal cancer in the First Department of Surgery, Tohoku University School of Medicine (Sendai, Japan) were used for immunohistochemical staining. In the 40 cases, 14 were well-differentiated adenocarcinomas, 25 were moderately differentiated carcinomas, and only 1 was poorly differentiated carcinoma.

Primary antibodies
654-1, a mouse monoclonal antibody that recognizes human dThdPase, was kindly provided by Nippon Roche Research Center (Kamakura, Japan). PG-M1, an anti-macrophage marker CD68 monoclonal antibody, was purchased from DAKO (Glostrup, Denmark). Non-specific mouse IgG1 (East Acres Biologicals, Southbridge, USA) was used as a control antibody.

Cell lines
Six human colorectal cancer cell lines, LS174T, Clone A, Colo320, CX-1, Lovo, and MIP101, and two human macrophage-like cell lines, THP-1 and U937, were used in this study. LS174T was obtained from the American Type Culture Collection (Rockville, MD). Clone A, CX-1, and MIP101 were provided by Dr. JM Jessup (University of Texas,

SA, USA). Colo320, Lovo, and THP-1, a human monocytic leukemia cell line, were purchased from Riken Cell Bank. U937, a human histiocytic lymphoma cell line, was obtained from Institute of Development, Aging and Cancer, Tohoku University (Sendai, Japan). THP-1 and U937 are suspension cell lines induced by phorbol-12-myristate-13-acetate (PMA). PMA-induced THP-1 and U937 were used in various experiments as macrophage-like cells because these cells could express many of normal macrophage characteristics including phagocytosis and adherence[16-18]. All cell lines were cultured in RPMI1640 medium supplemented with 10% fetal calf serum (FCS) and 1% L-glutamine.

dThdPase activity assay

In 40 colorectal carcinoma specimens, 27 were frozen immediately at -80℃ after removal by surgery. Then they were assayed with high performance liquid chromatography (*HPLC*) to detect dThdPase activity by Nippon Roche Research Center[19].

Immunohistochemical staining

Streptoavidin-biotin complex (*SABC*) method was adopted in formalin-fixed, paraffin-embedded sections. Sections were de-paraffinized and incubated with 1% hydrogen peroxide in methanol for 15 min to block the endogenous peroxidase activity. After washed with phosphate-buffered saline (PBS), the sections were incubated with 10% normal rabbit serum for 30 min at room temperature and then incubated with primary antibodies at 1.25 µg/ml for 654-1, 3.6 µg/ml for PG-M1 and 10 µg/ml for control mouse IgG overnight at 4℃. Followed by 3 washes with PBS, the sections were incubated with a second antibody (Histofine SAB-PO (M) kit, Nichirei, Tokyo, Japan) for 120 min at room temperature. After washed with PBS, the sections were then incubated with peroxidase-conjugated streptoavidin (Histofine SAB-PO kit) for 30 min at room temperature, and then developed with 3, 3'-diaminobenzidene (Dojindo, Tokyo, Japan) in 0.05M Tris buffer (pH7.64), containing 0.07% sodium azide and 0.02% hydrogen peroxide for 5 min.

Morphometrical analysis

The dThdPase-positive cells were stained brown in cytoplasms and nuclei, occasionally, brown-stained nuclei alone could also be found. CD68-positive cells were also stained brown but a little darker than dThdPase. The number of dThdPase-positive cells and CD68-positive cells was quantified as follows. In each specimen, we selected five fields where the highest density of dThdPase-positive cells was observed after searching the whole field. In each field, immunoreactive cells were counted using an ocular grid (0.25mm×0.25mm) at magnification×400. Then CD68-positive cells were similarly counted in the corresponding five fields in the serial sections. The average number of positive cells in each section was expressed per 0.0625 mm².

Detection of dThdPase protein levels

dThdPase levels in 6 colorectal cancer cells and 2 macrophage-like cells, THP-1 and U937, were measured by *ELISA* in the study. At least 1×10^7 cells of each cell line were prepared for this assay and *ELISA* was performed by Nippon Roche Research Center. It was reported that the dThdPase levels measured by this assay correlated well with a conventional enzyme assay[19].

Statistical analysis

The significance of differences between means of dThdPase activities in tumor group and normal tissue group was tested by *Student' s t test*, and the correlation between the number of dThdPase-positive cells and CD68-positive cells was evaluated by Spearman' s correlation coefficient test, the significance level was at 0.05.

RESULTS

dThdPase activity in tumor and normal mucosal tissues

The dThdPase activity in cancer tissues was 139.7±42.2 (µg 5-FU· hr⁻¹· ml⁻¹), significantly higher as compared with 61.5±21.4 (µg 5-FU· hr⁻¹· ml⁻¹) in the surrounding normal tissues (Figure 1, $P<0.01$).

Figure 1 dThdPase activity analysis in 27 specimens of colorectal carcinoma. The dThdPase Activity was 139.7±42.2 (µg 5-FU/hr/ml) in cancer tissues, significantly higher than 61.5±21.4 (µg 5-FU/hr/ml) in adjacent normal tissue (*P<0.01*).

Immunohistochemical staining

In corresponding normal colorectal tissues, epithelial cells at the surface of mucosa were weakly immunoreactive for dThdPase and few stromal cells were positive (Figure 2A). Stromal cells were positive for dThdPase in all cancer tissues, while cancer cells were positive for dThdPase only in 3 out of the 40 cases (Figure 2B). The dThdPase-positive stromal cells were distributed mainly around the cancer nests (Figure 2C) or along the invasive margin of cancer (Figure 2D). In the corresponding areas, CD68-positive macrophages were also increased. The distribution patterns of CD68-positive cells (Figure 2E) were similar to those of the dThdPase-positive stromal cells (Figure 2F).

In the counting analysis of positive cells, the number of dThdPase-positive stromal cells was well correlated with the number of CD68-positive cells ($r=0.76$, $P<0.0001$), (Figure 3).

dThdPase levels in 6 colorectal cancer cell lines and 2 macrophage-like cell lines, were assessed by *ELISA*. The protein level of dThdPase was 0.5 unit/mg in LS174T, 8.9 unit/mg in Lovo, and not detected in the other 4 colorectal cancer cell lines. In macrophage-like cell lines, 18.2 unit/mg and 19.3 unit/mg of dThdPase were detected in THP-1 and U937, respectively (Table 1).

Table 1 dThdPase levels in 6 colorectal cancers cell lines and macrophage-like cell lines

	dThdPase level* (unit/mg)
Colorectal cancer cells	
LS174T	0.5
Clone A	<0.4[a]
Colo 320	<1.1[a]
CX-1	<0.3[a]
Lovo	8.9
MIP101	<0.2[a]
Macrophage-like cells	
THP-1	18.2
U937	19.3

[a]Figures indicate levels of detection limit.

Figure 2 Immunohistochemical staining in colorectal cancer tissues. A: In normal colon mucosa, epithelial cells at the surface are weakly positive for dThdPase and few stromal cells are stained. B: In 3 of the 39 cases examined, cancer cells are positive for dThdPase. C: In most cases of colorectal cancers examined, stromal cells around the cancer nests are positive for dThdPase, while cancer cells are negative. D: In some cases, dThdPase-positive stromal cells are along the invasive margin of cancer, cancer cells are negative for dThdPase. E: Immunohistochemical staining for dThdPase and F: for CD68 in the corresponding area of colorectal cancer tissue. dThdPase-positive stromal cells are observed densely along the invasive margin of cancer. The distribution pattern of dThdPase-positive cells (E) is similar to that of CD68-positive cells (F).

Figure 3 Correlation between number of CD68-positive macrophages and dThdPase-positive stromal cells in 40 cases of colorectal cancer. The significant correlation is judged by *Spearman's coeffecient rank* test (r=0.76, P<0.0001).

DISCUSSION

It has been well known that dThdPase expression was selectively increased in various malignant tumor tissues compared with adjacent normal tissues in the same organs[9-12]. Our data of dThdPase activity analysis in cancer and normal tissues by *ELISA* are also supported the suggestion. However, the present immunohistochemical staining showed that stromal cells around the cancer nests or along the invasive margin of cancer strongly expressed dThdPase activity but few cancer cells did. A significant positive correlation was found between the number of dThdPase-positive stromal cells and CD68-positive macrophages (r=0.76, P<0.0001). We also detected certain dThdPase levels in macrophage-like cell lines, THP-1 and U937, but seldom detected it in colorectal cancer cell lines by *ELISA*. Takahashi[20] reported that most cells stained with the same monoclonal antibody (654-1) were also positive for CD68 by double immunohistochemical staining in human colon cancer tissues, while Takebayashi[9] reported that many colorectal cancer cells were also stained strongly as stromal cells did using the different antibody. These differences in dThdPase stained cancer cells were possibly caused by the different antibodies used, which may recognize the different epitopes. Taken together, TAMs should be a major source for dThdPase expression in colorectal carcinomas, although it's mechanism of expression in macrophage is still unclear.

Infiltration of mononuclear inflammatory cells including CD68-positive macrophages has been described as one of the important host reactions in colorectal cancer[21]. These infiltrating cells are more abundantly distributed along the invasive margin of cancer tissues than in cancer tissues. These reports suggest that CD68-positive TAMs have various roles in interactions between host cells and cancer cells.

Macrophages belong to the mononuclear phagocyte system. They form a heterogeneous cell population and further differentiate into promonocytes and bone marrow monocytes, then enter into blood stream and migrate into tissues, where they undergo final differentiation to tissue macrophages, which are present ubiquitously in all tissues. Besides other functions, such as endocytosis, cytotoxicity, macrophages can secrete over 100 cell products. Many evidences showed that TAMs also appeared to be involved in tumor growth regulation, angiogenesis, host reaction, and antitumor immunity in various malignant tissues by some investigators[22,23]. TAM has been found to play an important role in tumor angiogenesis by producing a number of angiogenic cytokines, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), transforming growth factor alpha (TGF-α), tumor necrosis factor-α (TNF-α), and PD-ECGF/dThdPase[24]. Because no macrophage cell line can pass and it is difficult to isolate macrophages, we detected the dThdPase level from macrophage-like cell lines, THP-1 and U937 instead of macrophages,

Using monoclonal antibody anti-CD68 (a macrophage marker), many investigators demonstrated that TAMs were associated with the tumor stage, invasive depth, survival, and angiogenesis in several malignancies[12,13,15,22,25]. Therefore, CD68 is well known to be a best marker of tissue macrophages. Though it was reported that macrophages could express dThdPase in normal gastrointestinal tract tissues[26], however, no report so far has dealt with whether colorectal carcinoma cells or macrophages express dThdPase *in vitro*, the mechanism of expression is still unknown.

It is necessary for 5'-DFUR to be converted into 5-FU by dThdPase expressed in cancer tissues during chemotherapy. De Cesare[27] reported that the effect of 5'-DFUR on human colorectal carcinoma xenografts, it might be due to cytokines induced by TAMs, such as TNF-α, interleukin-1α (IL-1α), and interferon-γ (IFN-γ), resulting in an increase of dThdPase activity in cancer tissues. Some investigators have also reported that transfection of dThdPase cDNA could enhance the sensitivity of cancer cells to 5'-DFUR *in vitro*[28-30], while our another analysis demonstrated that dThdPase was expressed in macrophage-like cells, THP-1, U937, and monocytes could modulate the conversion of 5'-DFUR into 5-FU and exert anticancer effect on 6 colorectal carcinoma cell lines[31]. Further study is needed to investigate the mechanism, which may provide a future strategy for chemotherapy of colorectal cancer patients with 5'-DFUR.

Abstract

AIM: To study the function of N-myc downstream-regulated gene 1 (NDRG1) in colorectal carcinogenesis and its correlation with tumor lymph node metastasis.

METHODS: NDRG1 was detected at its protein level by immunohistochemistry (IHC) and image analysis (IA), and NDRG1 mRNA was detected by *in situ* hybridization (ISH) in formalin-fixed and paraffin-embedded sections with a total of 190 specimens including 38 normal colorectal mucosae, 31 colorectal adenomas, 45 non-metastatic colorectal carcinomas (CRCs), 38 metastatic primary CRC and subsequently regional lymph nodes respectively. At the same time, the correlations of NDRG1 with sex, age of patients and histological types of colorectal carcinomas were observed.

RESULTS: NDRG1 proteins were gradually increased in colorectal carcinogenesis ($P<0.05$ or $P<0.01$). There was a significant difference in the expression of NDRG1 between non-metastatic and metastatic CRCs ($P<0.05$), and the correlation was positive ($P<0.01$, $r_s=0.329$). However, there was no obvious difference in the expression of NDRG1 between the primary sites of CRCs and that in the metastatic sites of corresponding regional lymph nodes, nor was there an apparent difference in sex, age, and histological types. The expression of NDRG1 mRNA was generally in concordance with that of NDRG1 protein.

CONCLUSION: NDRG1 gene may play an important role in colorectal carcinogenesis. In addition, NDRG1 may be a putative tumor metastasis promoter gene and is regarded as one of the molecular biological markers that can forecast early metastasis of CRCs. NDRG1 gene in the metastatic sites of regional lymph nodes may preserve its expression characteristics in the primary sites of CRCs to some extent. The expression of NDRG1 is not affected by sex, age and histological types. The role of NDRG1 in tumor metastatic process can be demonstrated by *in vivo* and *in vitro*.

INTRODUCTION

N-myc downstream-regulated gene 1 (NDRG1) has been repeatedly isolated by different laboratories under different physiological conditions, and it was also called, human RTP (reducing agents and tunicamycin-responsive protein)[1], Drg1 (differentiation related gene 1)[2], cap43 (calcium activated protein)[3], rit42 (reduced in tumor, 42KDa)[4], PROXY-1 (protein regulated by OXYen-1)[5], and the mouse homologue, designated Ndr1[6],TDD5[7], the rat homologue, designated Bdm1[8]. In addition, mammalian NDRG1 has homologues in a wide variety of species, including zebra-fish, fruit fly, nematode, sunflower, Arabidopsis thaliana. The gene was later officially designated NDRG1 by the HUGO Gene Nomenclature Committee[9]. Therefore, we used NDRG1 throughout this report. NDRG1 has been mapped to human chromosome 8q24.2[10,11] and has a length of approximately 60 kb. NDRG1 cDNA contains an open-reading frame of 1 182 bp that encodes a cytoplasmic 43-kDa protein containing a tandem repeat of ten amino acids (GTRSRSHTSE)[12]. NDRG1 is one of the four members of a new gene family, which does not contain any protein motif with known functions[13,14].

Guan *et al*[15] investigated NDRG1 with 8 colon cancer cell lines and 10 colon cancer specimens. They reported that over-expression of NDRG1 induced morphological and molecular changes which were consistent with colon cancer cell differentiation and suppressed *in vitro* invasion and *in vivo* liver metastasis in nude mice. They proposed that NDRG1 suppress colon cancer metastasis by inducing colon cancer cell differentiation and partially reversing the metastatic phenotype, and suggested that NDRG1 might be a putative metastatic suppressor gene in human colon cancer. However, there are still no reports about the study of this gene in large samples of CRCs and progressive growth of colorectal cancer.

In the present report, we detected NDRG1 protein by immunohistochemistry (IHC), and NDRG1 mRNA by *in situ* hybridization (ISH) in patients with colorectal adenomas, non-metastatic and metastatic CRCs, as well as their corresponding regional lymph node metastatic sites and normal colorectal mucosa, to study its functions in colorectal carcinogenesis and its correlation with tumor lymph node metastasis.

MATERIALS AND METHODS

Materials

Specimens obtained from surgical resections, mucosa biopsies of colon and autopsies with a postmortem autolysis period of less than 24 h, were fixed in 10% formalin, embedded in paraffin, and stained by routine HE. They were divided into 5 groups: normal colorectal mucosa used as controls ($n=38$), colorectal adenomas ($n=31$), non-metastatic CRCs ($n=45$), metastatic CRCs ($n=38$) and their corresponding regional lymph node metastatic sites ($n=38$). Two pathologists examined all the specimens. The diagnosis of colorectal neoplasm was made according to the WHO's criteria in 2000[16].

Methods

Immunohistochemistry Immunohistochemistry S-P method

was used to detect NDRG1 protein. Professor Bosman FT generously provided rabbit polyclonal antibody and immunostaining S-P kit was purchased from Fuzhou Maxim Biotechnical Company. Immunohistochemistry was performed as follows. (1) Four-micron sections of human tissues were deparaffinized by xylene, dehydrated in graded alcohol. Endogenous peroxidase activity was blocked with 3% H_2O_2 in methanol at room temperature for 15 min. (2) To retrieve the immunoreactivity, tissue sections were boiled twice in 10 mM sodium citrate, pH 6.0 for 5 min in an 800-W microwave oven. (3) Then, non-specific staining was blocked by incubating in normal non-immune serum at room temperature for 10 min. (4) The rabbit anti-NDRG1 was added to adjacent tissue sections and incubated overnight at 4℃. (5) Biotin-conjugated second antibody was added to the sections and incubated at room temperature for 10 min. (6) S-P complex was added at room temperature for 10 min and DAB was used for the color reaction, and then the slides were counterstained with hematoxylin. The tissue sections were washed with PBS (0.01M, pH 7.4) between each step. Positive and negative controls were simultaneously used to ensure the specificity and reliability of staining. The positive result showed yellow or brown coloration in cytoplasm and /or plasma membranes.

The degree of NDRG1 staining was estimated by semi-quantitative evaluation and categorized by the extent and intensity of staining as follows[17]: (1) The extent of positive cells was estimated as 0=positive staining cells ≤5%, 1=positive staining cells in 6-25%, 2=positive staining cells in 26- 50%, 3=positive staining cells in 51- 75%, 4=positive staining cells >75%. (2) The intensity of staining was scored as 0=achromatic, 1=light yellow, 2=yellow, 3=brown. Combined staining score was used to evaluate the results of NDRG1 staining. The extent of positive cells was multiplied by the intensity of staining and scored as follows: (-)=0, (+) =1- 4, (++)=5- 8, (+++)=9- 12. Two independent assessors unaware of the patient outcome carried out this semi-quantitative analysis.

Image analysis The immunostained sections were examined by using an Olympus microscope (×200) coupled to a video camera, connected to a computer-aided color video image analysis (VIA) system. After being captured and digitized onto the video screen, microscopic images were quantitatively analyzed by using an image analysis software program (HPIAS-1000, Microsoft Windows hosted image analysis system). We selected positive unit (PU)[18] as the quantitatively analysis parameters. The higher the PU value was, the stronger the intensity of immunostaining.

Preparation of NDRG1 cDNA probe and *in situ* hybridization NDRG1 cDNA plasmid (1 ng/μl) was also a gift generously provided by Professor Bosman FT. We transformed bacteria JM109 and amplified NDRG1 cDNA plasmid, digested by KpnI and XbaI (Figure 1). The resulting NDRG1 cDNA fragment (nucleotide from 958 to 2 875, 1.9 kb) was labeled with biotin by using a random primer DNA biotinylation kit (TaKaRa Biotechnology Co., Ltd) according to the manufacturer' s protocol. The concentration of NDRG1 cDNA probe was approximately 30 ng/μl.

In situ hybridization was used for the detection of NDRG1 mRNA. ISH-kit was purchased from Medical Faculty, Peking University. The main steps were as follows. (1) Four-micron sections of human tissues were deparaffinized by xylene, dehydrated in graded alcohol' treated with 0.1 N HCl at room temperature for 10 min and digested with proteinase K at 37℃ for 15 min. (2) The biotin-labeled NDRG1 cDNA probe was added to adjacent tissue sections and incubated in a humidity chamber overnight at 4℃. (3) Then, non-specific staining was blocked by incubating in normal non-immune serum at room

temperature for 45 min. (4) SP-AP complex was added at 37℃ for 1 h. (5) The substrate (BCIP/NBT) showed coloration at room temperature for 10-40 min, or till the coloration was developed and then the slides were counterstained with nuclear fast red. Positive and negative controls were simultaneously used to ensure the specificity and reliability of the staining. A known NDRG1 mRNA positive tissue section was taken as positive control while hybridization liquids without probe were used to replace the NDRG1 cDNA probe as negative control. The positive result showed blue coloration in the cytoplasm and was graded as follows[19]. (-) negative, (+) a small quantity of scattering positive granules, (++) a large quantity of thick positive granules, (+++) positive granules distributed widely in a cluster. Expression of NDRG1 mRNA was compared with that of NDRG1 immunoreactivity to investigate the correlation between the two stainings.

Figure 1 Electrophoretogram of NDRG1 cDNA plasmid cut by enzymes KpnI and XbaI. 1. DNA marker DL2000, 2. Products digested by KpnI and XbaI, 3. DNA marker λHindIII.

Statistical analysis
With statistical package for social science (SPSS) version 10.0, rank sum test was used to calculate the enumeration data, the measurement data were analyzed by one-way ANOVA. A Spearman' s correlation coefficient was used for correlations between markers. $P<0.05$ was considered statistically significant, all reported P values were two-sided.

RESULTS

Detection of NDRG1 protein
Immunoreactivity was not observed in negative control. In normal colorectal mucosa the surface epithelial cells were mainly stained and the majorities were yellow micro-granules located in the cytoplasm and/or plasma membranes while crypt cells were negative. In colorectal neoplasm, the positive staining showed yellow or brown coloration in the cytoplasm and /or plasma membranes distributed in scatter or in a cluster (Figures 2- 3). The immunostaining results of all groups are summarized in Tables 1- 3 and Figure 4. The correlation between the expression of NDRG1 and lymph node metastasis in CRCs is summarized in Table 4.

NDRG1 proteins were gradually increased in colorectal carcinogenesis ($P<0.05$ or $P<0.01$). There was a significant difference in expression of NDRG1 between non-metastatic and metastatic CRCs ($P<0.05$) and the correlation was positive ($P<0.01$, $r_s=0.329$). That is, the higher the NDRG1 protein expression, the greater the possibility of lymph node metastasis. However, there was no obvious difference in expression of NDRG1 between the primary sites of CRCs and that in the metastatic sites corresponding regional lymph nodes. There was a good correlation between color VIA and semi quantitative evaluation of NDRG1 immune reactivity, confirming the validity of quantitative analysis.

Table 1 Comparison between positive rate and positive unit (PU) of NDRG1 protein in all groups

Group	Cases	Positive number and percentage					Positive unit mean±SD
		-	+	++	+++	%	
Normal colorectal mucosa	38	17	21	0	0	55.26	45.34±5.66
Colorectal adenomas	31	6	18	6	1	80.65	48.35±4.79
Non-metastatic CRCs	45	2	24	19	0	95.56	51.62±4.63
Metastatic CRCs	38	0	14	18	6	100.00	54.38±4.39
Regional lymph node metastatic sites	38	2	9	24	3	94.74	54.73±4.56

Table 2 Comparison of positive rates of NDRG1 protein in all groups (P value)

Group	Normal colorectal mucosa	Colorectal adenomas	Non-metastatic CRCs	Metastatic CRCs	Regional lymph node metastatic sites
Normal colorectal mucosa	––	[b]$P<0.01$	[b]$P<0.01$	[b]$P<0.01$	[b]$P<0.01$

Figure 3 Overexpression of NDRG1 in cytoplasm of metastatic CRC. SP×200.

Detection of NDRG1 mRNA

NDRG1 mRNA was not observed in negative control. The positive results showed blue coloration in the cytoplasm distributed in scatter or in a cluster (Figures 5- 6). The expression of NDRG1 mRNA was generally in concordance with the expression of NDRG1 protein. However, the intensity of NDRG1 mRNA expression was weaker than that of NDRG1 protein. The positive cell percentage of NDRG1 mRNA expression was less than that of NDRG1 protein.

High differentiation	23	2	10	11	0
Moderate differentiation	47	0	23	20	4
Poor differentiation	13	0	5	6	2

DISCUSSION

CRC is one of the most common malignant tumors in China. In the last decades, the incidence of CRC has been increasing[19-22] and some reports indicate that the mortality of CRC has been increasing due to the early metastases. Because the dispensable nature of the colon allows removal of primary tumors, the prognosis of colon cancer was directly correlated with the extent of tumor invasion and metastases[23]. How to diagnose and prevent early tumor metastasis was one of the most important topics in recent tumor studies. Molecules involved in cancer metastasis might serve as markers for early detection of metastasis, prognostic judgment and/or as targets for therapeutic intervention[24,25].

Most studies showed that NDRG1 was involved in cellular growth[4,26-28], differentiation[29-31], tumorigenesis[32], metastasis[14] and poor clinical outcome of some tumor[33]. Our study showed that in normal colon NDRG1 protein was expressed mainly on the surface of epithelial cells that border the gut lumen, and the result was in accordance with recent reports[12], indicating that NDRG1 protein was expressed late during differentiation, just before apoptosis and shedding of cells into the colon lumen.

There are many debates about the expression of NDRG1 in CRCs and other carcinomas. It was reported that NDRG1 gene was down regulated in several tumor cell lines and breast cancer, prostate cancer[4,34,35] and renal cancer[36]. In addition, Van Belzen *et al*[2] reported that compared to normal colon mucosa, NDRG1 mRNA expression was decreased in colon adenomas and adenocarcinoma. However, some studies[37,38] indicated that in a variety of cancers, including lung, brain, melanoma, liver, prostate, breast, and renal cancers, NDRG1 protein was over-expressed in cancer cells. We observed that NDRG1 proteins were gradually increased during colorectal carcinogenesis (normal colorectal mucosa→colorectal adenomas→non-metastatic CRC→metastatic CRC) ($P<0.05$ or $P<0.01$), suggesting that NDRG1 gene might play an important role in colorectal carcinogenesis.

Okuda *et al*[14] reported that NDRG1 stable transfection of SW620 metastatic colon cancer cell line with Drg1 cDNA induced morphological changes and down-regulated metastatic colon cancer cells to nearly undetectable levels when compared with primary colon cancer. However, we observed different experimental results and found that there was a significant difference in expression of NDRG1 between non-metastatic and metastatic CRCs ($P<0.05$), and the correlation was positive ($P<0.01$, $r_s=0.329$), indicating that NDRG1 could not inhibit the metastatic ability. On the contrary, NDRG1 might play a role in promoting CRC regional lymph nude metastasis. Our results combined with previous data on the NDRG1 gene products[37-39] suggested that NDRG1 might be a putative tumor metastasis promoter gene and one of the molecular biological markers forecasting early metastasis of CRCs.

There was no obvious difference in expression of NDRG1 between the primary sites of CRCs and those in the metastatic sites of corresponding regional lymph nodes, nor was there an apparent difference in sex, age, and histological types, suggesting that NDRG1 gene in the metastatic sites of regional lymph nodes might still preserve its expressive characteristics in the primary sites of CRCs to some extent and the expression of NDRG1 might not be affected by these clinic pathologic variables.

The expression of NDRG1 mRNA was generally in concordance with the expression of NDRG1 protein. However, the intensity of NDRG1 mRNA expression was weaker than that of NDRG1 protein and the positive cell percentage of NDRG1 mRNA expression was less than that of NDRG1 protein. The discrepancies between mRNA expression and protein levels indicate that regulation at transcriptional, and the translational level might support the recent report[35].

Abstract

AIM: To study the morphologic and cellular immunologic changes after homologous transplantation of the abdominal aorta in rats after programmed cryopreservation (-196℃).

METHODS: Abdominal aorta was harvested from anesthetized Spraque Dawley (SD) rats for cryopreservation (group B) or immediate implantation (group A). The survival rates and apoptotic rates of aortic endothelial cells (ECs) were examined. The patency rates, histology and cellular immunologic changes of the abdominal aorta were examined on days 1, 3, 7, 14, 30, 60 after transplantation respectively.

RESULTS: The survival rate of ECs after programmed cryopreservation was 90.1±1.79%, about 3.4% lower than that of uncryopreservation (93.5±1.96%). The apoptotic rates of ECs was increased after cryopreservation (7.15% vs 4.86%, $P<0.05$). The patency rate of group B was significantly higher than that of group A (91.6±12.9% vs 62.5±26.2%, $P<0.01$). CD4/CD8 ratio, TCR α β and CD11b/CD18 ratio of group B were significantly lower than those of group A ($P<0.05$). Revivification of the cryopreserved abdominal aorta showed normal adventitia and intact smooth muscle cells.

CONCLUSION: Cryopreservation can reduce homologous abdominal aortic antigenecity. Even if without administration of immunosuppressive agents, it is still feasible to implement homologous artery grafting in rats.

INTRODUCTION

Since the first implantation, human allograft vessels have been widely used for surgical treatment of vascular diseases[1]. Approximately 1.5 million vascular reconstitutions are done each year in the United States[2]. Great sphenoid veins are commonly used in coronary artery bypass and peripheral vascular surgery[3]. Arteries are candidates in the management of arterial infection[4] and offer superior patency rates compared with veins[5]. The availability of autologous fresh material is often limited and there is a definite need for cryopreserved substitutes. The long-term preservation of small-caliber arterial allografts has benefited from the improvement in organ harvesting and can be further improved by the advance of other cryobiology techniques [6].

Preservation of vascular grafts at low temperatures using dimethyl sulfoxide (DMSO) as a cryoprotectant (CPA) has been repeatedly reported to be satisfactory after long-term storage. It has been reported that the mechanical properties of grafts and the functions of smooth muscle cells could be adequately preserved[7] but the endothelium was often somehow compromised[8]. Both the intact smooth muscle and endothelial cells are required to obtain full patency[9] and impairment of either of these structures will alter the complete vessel functions. Relations between the viability of vascular endothelial cells at time of implantation and immunologic rejection are the subject of debate and remain poorly understood.

We therefore designed an abdominal aorta allograft model in rats, replicating and comparing in the same animal model most clinical and experimental situations, from fresh aortic autografts to cryopreserved allografts and studied the effects of cryopreservation on the survival rates and apoptotic rates of aortic endothelial cells (ECs), histology and the cellular immunologic changes.

MATERIALS AND METHODS

Experimental animals

Male or female Spraque Dawley rats (Laboratory Animal Center No. SCXK2002-0031 Jiangsu Province) weighing 250 g to 300 g were used as donors and recipients. They were housed in pathogen-free conditions with a 12 h light-dark cycle and were allowed to drink water. Animal care and the experimental protocol were in compliance with the guidelines of the European Community Standards on the Care and Use of Laboratory Animals (No.28871-22A9). The SD rats were fixed in the supine position[10], and anesthetized with 100 mg/kg ketamine and the abdomen was opened with a median incision. The abdominal aorta with a diameter of 1.5 mm was dissociated. Then the blood stream was blocked, and the abdominal aorta was transected and washed with heparin saline. The aortic anastomosis was performed with 8/0 proline. The incision was sewed up and the rat was given 200 000 units of penicillin intramusclarly qd for 3 days.

Cryopreservation and thawing processes

The arteries were harvested according to sterile principle and "non-touch" technique[11] and immersed in the culture medium RPMI1640 (Life Technologies, Gibco BRL.) with 20% fetal bovine serum (FBS) and 15% DMSO (Amresco Co.) contained in a beaker and kept at 4℃ for 1 h. Programmed cryopreservation was performed in a biological freezer (Thermo Forma Co.) from 20℃ to -100℃, following the cooling curve established by Gournier et al[12,13]. The curve involved several stages of controlled time and temperature, and was designed to achieve a mean cooling rate of 1℃/min. Once frozen, aortic segments were stored in liquid nitrogen

(-196℃).

Before operation, frozen aortic segments were taken out of the liquid nitrogen and stored at RT for 5 min. Then they were incubated at 37℃ in a water bath for 5 min and stored in RPMI1640 with 20% FBS.

Experimental design

The following groups were established. Control group (group A) included 24 fresh abdominal aortic segments and cryopreservation group (group B) included 24 abdominal aortic segments cyropreserved. Every four rats of two groups were sacrificed on days 1, 3, 7, 14, 30 and 60 after transplantation and the patency rate of the transplanted arteries was observed. The blood samples were collected from inferior vena cava and the donor arteries were harvested for examination.

Morphology

All transplanted aortae were observed for vascular patency[14] and processed for pathologic study by light microscopy (LM). Specimens for LM were fixed by immersion in 10% formaldehyde and embedded in paraffin to obtain 5 μm-thick cuts. Sections were deparaffinated, hydrated, and stained with hematoxylin-eosin, Masson' s trichrome stain and orcein.

Flow cytometric analysis

The survival and apoptotic rates of ECs were determined by propidium iodide (PI) and annexin V staining. Endothelial cells of abdominal aorta in rats were digested by 0.25% trypsin at 37℃ for 20 min and fixed with ice-cold 70% ethanol at a cell density of $1 \times 10^6 ml^{-1}$. PI and annexin V were then added and incubated with cells in the dark for 30 min until detection by flow cytometry[15].

Monoclonal antibody (10 μl) (Simultest anti-CD4 and anti-CD8, anti-TCR α β[16], Immuntech Co., anti-CD11b and anti-CD18[17], Serotec Co., Simultest control (Becton-Dickinson)) was added to tubes with 25 μl whole blood (heparin anticoagulated). The tubes were incubated at 37℃ in the dark for 30 min and 1 ml of lysing solution was added. After 15 min lysing time, the cells were washed twice with PBS and then 200 μl of fixation buffer (2% formaldehyde + 0.1% sodium azide in PBS (pH 7.4)) was added. The samples were thereafter kept at 4℃ until they were analyzed by flow cytometer (FACSCalibor, BD Co.)[18].

Statistical analysis

The data were expressed as mean±SD. Besides a two-sided Student test with a level of significance at 5%, a multiple-factor ANOVA (Tukey' s test) was performed to analyze the difference between the two groups. All the data were analyzed with the statistical software SPSS10.0.

RESULTS

Survival rate and apoptotic rate of ECs in two groups

The survival rate of ECs without cryopreservation was 93.5±1.96% and that of ECs with cryopreservation was 90.1±1.79%. But the apoptotic rate of uncryopreserved ECs was 4.86±0.252% and that of cryopreserved ECs was 7.15±0.422 %. There was a significant difference between the two groups ($n=4$, $P<0.05$).

Patency condition at each time point of two groups

Generally, all the external appearances of the arteries were normal, but the dissepiments were stiff and the intima was thickened, especially in group A. The inner-walls of vessels were smooth and had no mural thrombus. The patency rates of all six time points in group B were higher than those in group A (Table 1).

Table 1 Aortic patency of groups A and B after transplantation

Group	Patency/total number of aortae at each time point (days)						Patency rate (%)
	1	3	7	14	30	60	
A	4/4	3/4	3/4	2/4	2/4	1/4	62.5±26.2
B	4/4	4/4	4/4	4/4	3/4	3/4	91.6±12.9

Group A *vs* group B, *P*<0.01.

Subpopulation of T cells and TCR*ab*

After transplantation, the number of CD4+ T cells was dramatically increased and reached the peak at 4 weeks post-transplantation. In the following days, the number of CD4+ T cells was maintained at a higher level. On the contrary, the number of CD8+ T cells was decreased. The ratio of CD4+/CD8+ was the highest at 4 weeks and there was a significant difference between groups A and B ($n=4$, $P<0.05$, Figure 1). The expression of TCRαβ was up-regulated soon after transplantation and the tendency of which was similar to that of the ratio CD4+/CD8+. There was also a significant difference between groups A and B. ($n=4$, $P<0.05$, Figure 2).

Figure 1 CD4+/CD8+ expression of groups A and B after transplantation ($n=4$).

Figure 2 TCR α β expression in T cells of groups A and B after transplantation ($n=4$).

Figure 3 CD11b and CD18 expression on PMNs of groups A and B after transplantation ($n=4$).

Figure 4 HE staining of abdominal aorta in rats after transplantation. A: Infiltration of T cells at 4 weeks in group A (×100), B: Excessively thickened intima at 8 weeks in group A(×100), C: Completely recovered ECs of cryopreserved aorta at 4 weeks in group B (×100), D: Intact and slightly thickened intima at 8 weeks in group B (×100).

Ratio of CD11b/CD18

The CD11b/CD18 ratio of the two groups after operation was increased. There was a significant difference at each time point between groups A and B (*n*=4, *P*<0.05, Figure 3).

Pathological and histological changes

Severe fragmental necrosis was observed in the intima of group A. The distribution of inflammatory cells in arteries was intensive, most of them intruded into tunica adventitia and media. Hyperplasia occurred in the intima 4 weeks after operation, smooth muscles in the media were thickened and the lumen of blood vessels became narrow. The intima was thickened excessively 8 weeks after operation and the lumen of blood vessels was markedly narrowed. Calcification and necrosis were observed in parts of the media. In group B few necrosis and fragments were observed and there was no obvious hyperplasia of smooth muscle in the media. ECs recovered completely and the intima remained intact and the intima of aorta was thickened slightly 4 and 8 weeks respectively after operation (Figure 4).

DISCUSSION

Methods of cryopreservation and thawing

Many methods could be used for the cryopreservation and thawing of blood vessel tissues[19-21]. In our study, we cryopreserved the aorta using the biologic freezer with controlled rate and medium containing RPMI1640, 20% calf serum, and 15% DMSO was used as the protective agent. So the formation of ice crystals in tissues and cells was decreased, the thermal stress caused by the dilution shock and the temperature were also decreased, hence the damage to the vessels was minimally reduced. Some studies indicated that vascular endothelial cells cryopreserved by the biologic freezer with controlled rate could achieve a survival rate from 70% to 90%[22-24]. Besides, these cryopreserved cells had similar proliferation and antithrombotic functions as normal cells after

revival[25]. It was indicated that the competence of abdominal aorta in rats was almost entirely preserved in our stud, while the increase of apoptosis in group B was thought to be related with cryopreservation.

Cellular immunologic change after transplantation

Among all components of vascular dissepiment including ECs, smooth muscle cells (SMCs), elastic fibers and collagen fibers, ECs have the strongest antigenicity, which can offer all essential signals that result in the activation of T cells. Therefore, ABO blood type and histocompatibility should be determined and better in combination with the use of immuno-suppressive drugs. The correlation between immunosuppression and long-term patency rate has been confirmed in animal experiments. In our study we found that cell-mediated immunity caused by allografts was reduced dramatically in group B. T cell subpopulation changed after transplantation. Many sensitized CD4+ T cells entered into the peripheral blood and CD8+ T cells gathered at the part of grafts to perform the cytolytic function. The pathological study indicated that cellular immunologic reaction in group B was slight as compared with that in group A. The reduction of immunogenicity in group B might be related with the decrease of antigenicity and the adhesive ability of resuscitated ECs and the shedding of ECs caused by the brushing of blood stream.

The expression of CD11b/CD18 on the surface of polymorphonuclear leukocytes (PMNs) was gradually increased after transplantation, suggesting the activation of PMN. Recent studies have shown that white blood cells play an important role in the proliferation of SMCs and activated PMNs can promote activation of platelets, proliferation of SMCs, release of oxygen-derived free radicals and inhibition of nitrogen monoxide (NO) secreted by Ecs. Besides, the decrease of NO synthesis could reduce the inhibition of CD11b/CD18 expression, which reinforces the interaction between PMNs and Ecs through a feedback mechanism[26]. Our study demonstrated that the lumens of aortas in group A were

markedly narrower than those in group B, but the expression of CD11b/CD18 on PMNs in group A was significantly higher than that in group B. It was confirmed that PMNs could take part in the process of vascular remodeling after transplantation, and the activation of PMNs was closely correlated with the restenosis and cellular immune rejection of allografts.

Effect evaluation

There were many reports about experiments of vascular allografting[27,28]. Chaw et al[29] reported that arteries had a patency rate of 84% 1 to 3 months after transplantation. Pratt et al[30] found that arterial allografts had a patency rate of 93% 2 months after operation. Raman et al[31] reported only 30% arterial patency rate in homologous transplantation 8 weeks after operation with the same method. We used DMSO as the cryoprotectant in programmed cryopreservation of abdominal aorta in rats and found the survival rate of ECs was 90.1% after cryopreservation. Some ECs were brushed out because of blood stream impact, but the remaining live ECs inhibited thrombosis formation after operation. Meanwhile cryopreseration decreased antigenicity of vascular allografts and cellular immune rejection and PMN infiltration, which would greatly promote the allograft restenosis after transplantation. The patency rate of group B was 91.6% 8 weeks after operation, which was significantly higher than that of group A.

The most obvious change of allografts after preservation and thawing was the rapid recovery of vascular endothelial cells and slight proliferation of SMCs intermedium. The recovery of ECs after cryopreservation was helpful to reduce thrombosis. The relative intact endothelium partly reduced excessive repair process after injury of blood vessels and excessive proliferation of SMCs intermedium. The recovered ECs were possibly from the hyperplasia of rest live ECs in donor arteries, the constitution of hyperplasia in recipients[33-35] and the sedimentation of circulating Ecs on vascular walls. Our study showed that ECs of cryopreserved aorta recovered completely 4 weeks after transplantation and the endometrium hyperplasia was mild, while in group A the recovery of ECs was not complete 4 weeks after operation and the hyperplasia of vascular endometrium was severe and proliferation of SMCs intermedium was marked 8 weeks after operation.

Our study showed that ECs of the cryopreserved donor arteries still had strong activity at the time of homologous grafting. Due to the brushing of blood stream, a few ECs were shedded. But the rest live ECs still inhibited the formation of thrombus. Because of cryopreservation, the antigenicity of transplanted arteries, the cellular immune reaction and infiltration of PMNs were decreased. So the incidence of restenosis after homologous transplantation was greatly reduced.

In conclusion, the antigenicity of transplanted aorta can be decreased due to programmed cryopreservation and homologous transplantation of abdominal aorta can be performed in rats.

Abstract

AIM: To investigate the effects of *Ginkgo biloba* extract on cytoprotective factors in rats with duodenal ulcer.

METHODS: Sprague-Dawley rats were randomly divided into four groups: sham operation without ginkgo, sham operation with ginkgo, duodenal ulcer without ginkgo, and duodenal ulcer with ginkgo. Rats with duodenal ulcer were induced by 500 mL/L acetic acid. Rats with ginkgo were intravenously injected with *Ginkgo biloba* extract from the tail at a dose of 0.5 mg/(kg· d) for 7 and 14 days.

RESULTS: Pathological result showed that duodenal ulcer rats with ginkgo improved mucosal healing and inflammation compared with those without ginkgo after 7 d treatment. After 14 d treatment, duodenal ulcer rats with ginkgo significantly increased weight gain (34.0 ± 4.5 g versus 24.5 ± 9.5 g, $P<0.05$) compared with those without ginkgo. Duodenal ulcer rats significantly increased cell proliferation (27.4 ± 4.0 and 27.8 ± 2.3 BrdU-labeled cells in duodenal ulcer rats with and without ginkgo versus 22.4 ± 3.5 and 20.8 ± 0.5 BrdU-labeled cells in sham operation rats with and without ginkgo, $P<0.05$) compared with sham operation rats. Mucosal prostaglandin E_2 concentration significantly increased by 129% ($P<0.05$) in duodenal ulcer rats with ginkgo compared with that in those without ginkgo. Duodenal ulcer rats without ginkgo significantly decreased superoxide dismutase activity in the duodenal mucosa and erythrocytes (19.4 ± 6.7 U/mg protein versus 38.1 ± 18.9 U/mg protein in the duodenal mucosa, and 4.87 ± 1.49 U/mg protein versus 7.78 ± 2.16 U/mg protein in erythrocytes, $P<0.05$) compared with sham operation rats without ginkgo. However, duodenal ulcer rats with ginkgo significantly increased erythrocyte superoxide dismutase activity (8.22 ± 1.92 U/mg protein versus 4.87 ± 1.49 U/mg protein, $P<0.05$) compared with those without ginkgo. Duodenal ulcer rats without ginkgo significantly increased plasma lipid peroxides (4.18 ± 1.12 µmol/mL versus 1.60 ± 1.10 µmol/mL and 1.80 ± 0.73 µmol/mL, $P<0.05$) compared with sham operation rats without ginkgo and duodenal ulcer rats with ginkgo during the experimental period.

CONCLUSION: *Ginkgo biloba* extract can improve weight gain and mucosal healing in duodenal ulcer rats by the actions of cytoprotection and antioxidation.

INTRODUCTION

Extract from the leaves of *Ginkgo biloba* (maidenhair tree) has been used therapeutically for centuries in the traditional Chinese pharmacopeia, and is used for the treatment of asthma and bronchitis[1]. In Western countries, *Ginkgo biloba* extract is administrated as film-coated tablets, a liquid, or by intravenous injection. In Germany and France, *Ginkgo biloba* extract is the most commonly prescribed medicine to improve circulation and cardiovascular health[1]. Standard *Ginkgo biloba* extract, EGb 761, contains 240 mg/g flavonoids (ginkgo-flavone glycosides) and 60 mg/g terpenoids (ginkgolides and bilobalides) which are the most important active ingredients in the extract. *Ginkgo biloba* extract is well known for its antioxidant property to scavenge free radicals, especially oxygen-centered free radicals, such as $OH^{.}$, $O_2^{.-}$, $RO^{.}$, and $ROO^{.}$, and to neutralize ferryl ion-induced peroxidation[2]. It has been reported that the antioxidant activity of *Ginkgo biloba* extract can prove helpful in the prevention and treatment of diseases and degenerative processes associated with oxidative stress.

Oxygen-derived radicals are involved in the pathogenesis of duodenal ulceration[3]. A previous study found that the pathogenesis of duodenal ulcer induced by diethyldithiocarbamate in rats could be significantly prevented by subcutaneous injection of antioxidative agents, such as superoxide dismutase (SOD, 50 000 units/kg), allopurinol (50 mg/kg), or glutathione (200 mg/kg), and antisecretory agent cimetidine (100 mg/kg)[4]. Additionally, SOD injection significantly elevated the rate of alkaline secretion in the duodenum, suggesting that the mucosal antioxidative system including SOD may play a role in the regulation of alkaline secretion and contribute to duodenal mucosal defensive ability. In cysteamine-induced duodenal ulcer rats, Cu, Zn-SOD activity significantly decreased, but lipid peroxidation products determined by thiobarbituric acid reactants significantly increased[5]. The results suggest that an increase of oxygen-derived free radicals and a decrease of Cu, Zn-SOD activity in the duodenal mucosa may be involved in the pathogenesis of cysteamine-induced duodenal ulcer. Non-smokers with peptic ulcer, clinically diagnosed as gastric or duodenal ulcer, had a higher level of malondialdehyde (MDA) in platelets, whereas platelet SOD activity significantly decreased compared with healthy subjects[6].

Several mechanisms of gastroduodenal cytoprotection have been proposed, including increased formation of prostaglandins and scavenging of free radicals, to protect against gastroduodenal mucosal injury rather than inhibition or neutralization of gastric acid[7]. There is no study yet to investigate the effect of *Ginkgo biloba* extract on peptic ulcer. Presumably, the property of a free radical scavenger for *Ginkgo biloba* extract can protect

Chao JCJ *et al. Ginkgo biloba* extract and duodenal ulcer

561

duodenal ulcer from oxidative damage. Therefore, the purpose of this study was to investigate the effect of *Ginkgo biloba* extract on cytoprotective factors in rats with acetic acid-induced duodenal ulcer.

MATERIALS AND METHODS

Animals and duodenal ulcer operation

Male Sprague-Dawley rats (200-250 g) were purchased from the National Laboratory Animal Center (National Science Council, Taipei, Taiwan). The rats were housed in individual cages and had free access to food (powdered laboratory autoclavable rodent diet 5010, PMI Nutrition International Inc., Brentwood, MO), except for the fasting period. The light cycle was 12 hours and the room temperature was kept at 22-24℃. One hundred and forty-four rats were randomly divided into four groups: sham operation without ginkgo, sham operation with ginkgo, duodenal ulcer without ginkgo, and duodenal ulcer with ginkgo ($n=36$ per group). Rats with duodenal ulcer were induced by acetic acid[8]. Prior to operation, the rats were fasted overnight, anesthetized by intraperitoneal injection with 50 mg/kg body weight thiopental sodium (Abbott Australasia Pty.Ltd., Kurnell, Australia), and the abdomen was then opened. A plastic tube (4.5 mm in inner diameter) filled with 70 μL of 500 mL/L acetic acid was applied tightly to the surface of the duodenum for 15 s. Due to different tolerance to acetic acid in various layers of the duodenum, it only caused immediate necrosis in the mucosa and submucosa, and a part of muscular layers exactly within the area of acetic acid application without penetration or perforation to the surrounding organs. Normal saline was used in sham operation rats instead of acetic acid. After operation, the rats were allowed to recover from anesthesia. Operated rats received only water on the day of operation (day 0), and were fed with a normal chow diet *ad libitum* next day (day 1) before treatment. Body weight of the rats was routinely recorded. All protocols were conducted under the guidelines of Animal Care and Use Committee, Taipei Medical University.

Treatment and pathological observation

The next day after operation, the rats were intravenously (iv) injected with *Ginkgo biloba* extract solution (Cerenin®, Dr. Willmar Schwabe GMBH & Co., Karlsruhe, Germany) from the tail at a single dose of 0.5 mg/(kg· d) for 7 and 14 days. The dose of *Ginkgo biloba* extract was calculated from the clinical recommendation of 35 mg intravenous injection (5 mL injection solution) for 70 kg adults (Cerenin®). Each mL of the injection solution contained 3.5 mg *Ginkgo biloba* extract (240 mg/g flavonoids and 60 mg/g terpenoids), 30 mg of 960 mL/L ethanol, 40 mg sorbitol, and 0.1 mol/L NaOH. The injection volume was adjusted daily by body weight. Rats without ginkgo were intravenously injected with the same volume of vehicle solution without ginkgo from the tail. Four rats in each group were killed on day 1 before ginkgo treatment to identify the formation of duodenal ulcer, and sixteen rats in each group were sacrificed for both biochemical analyses (8 rats) and pathological examination (8 rats) after 7 and 14 d treatment, respectively. The duodenum (5 mm×5 mm) was excised, preserved in 40 mg/L paraformaldehyde, and stained with haematoxylin and eosin. Under light microscope at a magnification of ×100 or ×200, coded specimens were evaluated by a pathologist in a blinded fashion.

Semiquantitation of cell proliferation

Rats were intraperitoneally (ip) injected with bromodeoxyuridine (BrdU; Sigma-Aldrich Co., St. Louis, MO) 5 mg/kg body weight one hour before sacrifice for immunohistochemical analysis[9]. The duodenum (4 μm thick) was fixed in formalin and embedded in paraffin. The duodenum sections were deparaffinized in xylene, dehydrated by graded ethanol series, and placed in 0.01 mol/L phosphate buffered saline (pH 7.4). Antigen retrieval was performed by boiling the duodenum sections in 0.1 mol/L citrate buffer (pH 6.0) for 10 min to deactivate endogenous alkaline phosphatase activity. The tissue sections were then exposed to 3% H_2O_2 to block endogenous peroxidases, and followed by partial denaturation of double-stranded DNA by treatment with 1 mol/L HCl. The sections were incubated with monoclonal mouse anti-BrdU antibody (1:50 dilution; DAKO, Denmark) for 1 h, and incubated with biotinylated anti-mouse IgG for 30 min. The sections were stained by a streptavidin-biotin complex method using a commercial kit (LSAB2 kit/HRP, DAKO), and detected by diaminobenzidine. The number of cells in the proliferation zone was calculated by counting the cells between the first stained cells of the serosal side and the last stained cells of the mucosal surface of a crypt under light microscope to evaluate the healing of the mucosa[9]. The number of BrdU-labeled cells in the proliferation zone was counted by the number of positive cells from the serosal side to the mucosal surface of a crypt to evaluate DNA synthesis.

Prostaglandin E₂ concentration in duodenal mucosa

Prostaglandin E_2 (PGE$_2$) concentration in the duodenal mucosa was quantitated by ELISA using a commercial kit (DE2100, Research and Diagnostics Systems, Inc., Minneapolis, MN). The duodenal mucosa (100 mg wet weight) was homogenized with 1 mL of 150 mL/L methanol, and centrifuged at 8 000×g at 4℃ for 10 min. The supernatant was applied to a C_{18} Sep-Pak®minicolumn (Amersham Biosciences Ltd. Taiwan Branch, Taipei, Taiwan) at the flow rate of 0.5 mL/min. The column was washed with 2 mL petroleum ether followed by 2 mL of 150 mL/L methanol, and prostaglandin was eluted by 2 mL methyl formate. The elute was evaporated using nitrogen gas, and the residue was dissolved in 0.5 mL deionized water. The sample suspension or standards (100 μL) were added to a 96-well plate coated with goat anti-mouse polyclonal antibody, incubated with 50 μL prostaglandin E_2 conjugated to alkaline phosphatase and 50 μL mouse monoclonal anti-prostaglandin E_2 antibody at 2-8℃ for 18-24 h. After several washes, the samples were incubated with 200 μL p-nitrophenyl phosphate substrate at 37℃ for 1 h, and the reaction was terminated by 50 μL trisodium phosphate solution. The levels of prostaglandin E_2 were determined at 405 nm using an ELISA reader (Multiskan RC, Thermo Labsystems, Helsinki, Finland). Protein content in the duodenal mucosa was determined by the modified method of Lowry *et al.* using a Bio-Rad DC protein assay kit (Bio-Rad Laboratories, Hercules, CA)[10].

Superoxide dismutase activity in duodenal mucosa and erythrocytes

The activity of SOD was determined spectrophotometrically at 525 nm using a commercial kit (Bioxytech®SOD-525™ assay, Oxis International, Inc., Portland, OR). Duodenal mucosa (15-20 mg) was homogenized in 0.25 mol/L sucrose solution, and centrifuged at 8 500×g at 4℃ for 10 min. Blood samples (200 μL) were centrifuged at 2 500×g at 4℃ for 5 min. The erythrocyte pellet was suspended in ice-cold water. The mucosa supernatant and erythrocyte suspension were extracted with ethanol/chloroform (62.6∶37.5, *v/v*) for removal of hemoglobin interference. The samples were incubated with the chromogenic reagent (5,6,6a,11b-tetrahydro-3,9,10-trihydroxybenzo[c]fluorene) in alkaline condition (pH 8.8), and the absorbance was read at 525 nm within 1 min. The specific activity of SOD was expressed as unit/mg protein.

One SOD unit was defined as the activity that doubled the autooxidation rate in the absence of SOD.

Lipid peroxidation in plasma

Because of the limited amount of the duodenum specimen, lipid peroxidation was measured in the plasma. The concentration of lipid peroxides in the plasma was assessed colorimetrically at 586 nm using a commercial kit (Calbiochem 437634, Calbiochem-Novabiochem Cor., La Jolla, CA). The plasma (200 μL) was mixed with 650 μL of Reagent 1 (7.7 mM N-methyl-2-phenylindole in 750 mL/L acetonitrile and 250 mL/L methanol) and 150 μL of Reagent 2 (15.4 M methanesulfonic acid) at 45℃ for 40 min. The levels of MDA and 4-hydroxy-2(E)-nonenal (4-HNE), the end products derived from peroxidation of polyunsaturated fatty acids and related esters, were measured at 586 nm.

Statistical analysis

The data are expressed as mean±SD. The data were analyzed by two-way ANOVA to determine the main effects of duodenal ulcer and ginkgo using SAS (version 6.12, SAS Institute, Cary, NC). *Post hoc* multiple comparisons between two groups were performed by Fisher's least significant difference test. Statistical significance was assigned at the 0.05 level.

RESULTS

The total dose of ginkgo was 108.7±4.1 mg/d, 105.3±8.0 mg/d for 7 d treatment, and 106.2±4.7 mg/d, 114.8±3.5 mg/d for 14 d treatment in sham operation and duodenal ulcer rats, respectively. Duodenal ulcer rats for 14 d treatment had higher ginkgo administration ($P<0.05$) compared with other rats. However, the total dose of ginkgo did not significantly differ among other rats. The initial weight on day 1 was 217.3±19.6 g, 206.6±9.1 g, 214.7±15.9 g, and 202.7±16.9 g for 7 d treatment, and 221.8±11.4 g, 199.8±10.5 g, 200.2±18.6 g, and 212.6±7.5 g for 14 d treatment in sham operation rats without ginkgo, sham operation rats with ginkgo, duodenal ulcer rats without ginkgo, and duodenal ulcer rats with ginkgo, respectively. The initial weight did not significantly differ among the groups. Weight gain did not significantly differ among four groups during the first week (Figure 1). Duodenal ulcer rats without ginkgo (24.5±9.5 g) had significantly lower weight gain ($P<0.05$) compared with sham operation rats without ginkgo (32.5±8.4 g) and duodenal ulcer rats with ginkgo (34.0±4.5 g) during the second week. However, weight gain did not significantly differ between sham operation rats with and without ginkgo (25.2±7.7 g versus 32.5±8.4 g), and between sham operation rats without ginkgo and duodenal ulcer rats with ginkgo (32.5±8.4 g versus 34.0±4.5 g).

Figure 1 Weight gain of rats during the first and second weeks. Data are mean±SD (*n*=8). Values not sharing the same letter differ significantly ($P<0.05$) within the same week by Fisher's least significant difference test.

To identify the formation and healing of duodenal ulcer in rats after operation, gross morphological appearance magnified by ×100 or ×200 is shown in Figure 2. Compared with sham operation rats (Figure 2A), duodenal ulcer rats on day 1 before treatment had the discontinuous lining of the mucosal and submucosal layers, damage in the muscular layer, and serious inflammation with aggregation of the leukocytes (Figure 2B), which was similar to human duodenal ulcer in the pathology. The mean diameter of the ulcer damage was 2 mm under microscopic observation. After 7 d treatment, duodenal ulcer rats without ginkgo still had inflammation (Figure 2C). The mean diameter of the ulcer damage reduced to 1 mm. However, the inflammation almost recovered, and the microvilli proliferated in duodenal ulcer rats with ginkgo (Figure 2D). The mean diameter of the ulcer damage reduced to less than 1 mm. After 14 d treatment, the inflammation lessened and the microvilli increased proliferation in duodenal ulcer rats without ginkgo (Figure 2E). The mucosal healing and proliferation were more advanced in duodenal ulcer rats with ginkgo (Figure 2F). The diameter of the ulcer damage was undetectable in duodenal ulcer rats with and without ginkgo.

Cell proliferation of the duodenal mucosa was determined by anti-BrdU-immunohistochemical staining (Figure 3A). Duodenal ulcer rats had significantly higher number of total cells ($P<0.05$) in the proliferation zone than sham operation rats during the experimental period (Figure 3B). After 7 d treatment, duodenal ulcer rats with ginkgo (30.1±4.1) had significantly higher number of BrdU-labeled cells ($P<0.05$) in the proliferation zone compared with sham operation rats with (23.7±2.9) and without ginkgo (25.4±3.0) (Figure 3C). After 14 d treatment, duodenal ulcer rats (27.4±4.0 and 27.8±2.3 for those with and without ginkgo) had higher number of BrdU-labeled cells ($P<0.05$) in the proliferation zone than sham operation rats (22.4±3.5 and 20.8±0.5 for those with and without ginkgo). However, the number of both total and BrdU-labeled cells in the proliferation zone did not significantly differ between duodenal ulcer or sham operation rats with and without ginkgo during the experimental period.

The concentration of PGE_2 in the duodenal mucosa did not significantly differ among four groups after 7 d treatment (Figure 4). However, after 14 d treatment, duodenal ulcer rats with ginkgo (61.6±37.5 pg/mg protein) significantly increased PGE_2 concentration at least two-fold ($P<0.05$) compared with other rats (29.8±14.8 pg/mg, 28.0±25.2 pg/mg, and 26.9±11.9 pg/mg protein for sham operation rats without ginkgo, sham operation rats with ginkgo, and duodenal ulcer rats without ginkgo, respectively). Mucosal PGE_2 concentration did not significantly differ among other three groups.

The activity of SOD in the duodenal mucosa and erythrocytes did not significantly differ among four groups after 7 d treatment (Figure 5). After 14 d treatment, sham operation rats with ginkgo (21.0±6.9 U/mg protein) and duodenal ulcer rats without ginkgo (19.4±6.7 U/mg protein) significantly decreased the activity of SOD in the duodenal mucosa by 45% and 49% ($P<0.05$), respectively, compared with sham operation rats without ginkgo (38.1±18.9 U/mg protein) (Figure 5A). The activity of SOD in the duodenal mucosa did not significantly differ between duodenal ulcer rats with ginkgo (27.1±9.7 U/mg protein) and other rats. Duodenal ulcer rats without ginkgo (4.87±1.49 U/mg protein) significantly decreased the activity of SOD in the erythrocytes by 37% and 41% ($P<0.05$) compared with sham operation rats without ginkgo (7.78±2.16 U/mg protein) and duodenal ulcer rats with ginkgo (8.22±1.92 U/mg protein), respectively (Figure 5B). The activity of SOD in the erythrocytes did not significantly differ between sham operation rats with and without ginkgo (6.31±2.34 U/mg versus 7.78±2.16 U/mg protein), and between sham operation and duodenal ulcer rats with

Figure 2 Representative micrographs of duodenal mucosa stained by haematoxylin and eosin. A: sham operation rats on day 1 before treatment (×200), B: duodenal ulcer rats on day 1 before treatment (×100), C: duodenal ulcer rats without ginkgo after 7 d treatment (×100), D: duodenal ulcer rats with ginkgo after 7 d treatment (×200), E: duodenal ulcer rats without ginkgo after 14 d treatment (×100), and F: duodenal ulcer rats with ginkgo after 14 d treatment (×200).

Figure 3 Representative micrographs (×400) stained by anti-bromodeoxyuridine (anti-BrdU) immunohistochemical method (A), and quantitation of the number of total (B) and BrdU-labeled (C) cells in the proliferation zone from the duodenal mucosa of the rats. Data are mean±SD (*n*=8). The nuclei of BrdU-labeled cells were stained in brown. The number of total and BrdU-labeled cells was obtained from three individual crypts for each rat. Values not sharing the same letter differ significantly (*P*<0.05) within the same day by Fisher's least significant difference test.

ginkgo (6.31±2.34 U/mg versus 8.22±1.92 U /mg protein).

Sham operation rats with ginkgo (3.14±1.21 μmol/mL) and duodenal ulcer rats without ginkgo (2.92±0.90 μmol/mL) significantly increased lipid peroxides in the plasma by 85% and 72% (*P*<0.05), respectively, compared with sham operation rats without ginkgo (1.70±0.76 μmol/mL) after 7 d treatment (Figure 6). After 14 d treatment, sham operation rats with

ginkgo (3.52±0.99 μmol/mL) and duodenal ulcer rats without ginkgo (4.18±1.12 μmol/mL) significantly increased lipid peroxides in the plasma by 120% and 161% (*P*<0.05), respectively, compared with sham operation rats without ginkgo (1.60±1.10 μmol/mL). Duodenal ulcer rats with ginkgo after 7 (1.65±0.69 μmol/mL) and 14 d treatment (1.80±0.73 μmol/mL) significantly decreased lipid peroxides in the plasma by 43%

and 57% ($P<0.05$), respectively, compared with duodenal ulcer rats without ginkgo in the corresponding days. Lipid peroxidation in the plasma did not significantly differ between duodenal ulcer rats with ginkgo and sham operation rats without ginkgo during the experimental period.

perimental period. Data are mean±SD (n=8). Values not sharing the same letter differ significantly ($P<0.05$) within the same day by Fisher's least significant difference test.

DISCUSSION

Ginkgo biloba extract was administered by iv injection in this study. The precise dose of ginkgo was well controlled by iv injection into the rats, although oral administration was more convenient for humans. The dose of ginkgo administration was constant at 0.5 mg/(kg· d). However, the total dose was higher in duodenal ulcer rats for 14 d treatment, because weight gain was higher in duodenal ulcer rats with ginkgo after 14 d treatment.

Reactive oxygen species (ROS) could play an important role in the pathogenesis and aggravation of duodenal ulceration[3,11]. Certain forms of ROS such as H_2O_2 might act as signal transduction messengers to activate transcription factors NF-κB and AP-1, which bind to the promoter region of a large variety of genes that are directly involved in the pathogenesis of diseases[12]. Additionally, oxygen free radicals have been reported to trigger leukocyte adhesion and activation through modulating the expression of leukocyte adhesion molecules and CD markers[13]. Pathological results in our study showed that *Ginkgo biloba* extract could eliminate inflammation caused by duodenal ulcer probably because of its antioxidant property. *Ginkgo biloba* extract or its component exerted an anti-inflammatory effect by suppressing the production of active oxygen and nitrogen species[14,15]. Additionally, gross appearance found that more microvilli formation occurred in duodenal ulcer rats with ginkgo compared with those without ginkgo, indicating *Ginkgo biloba* extract could improve mucosal repair and proliferation. However, semiquantitation of cell proliferation demonstrated that only duodenal ulcer per se significantly increased numbers of total and BrdU-labeled cells in the proliferation zone of the duodenal mucosa. *Ginkgo biloba* extract did not influence these numbers in duodenal ulcer rats. It could be due to a small dose of BrdU (5 mg /kg, ip) and the short exposure time (1 h) to BrdU before sacrifice in our study compared with the administration of BrdU at 100 mg/kg (ip) 90 min prior to euthanasia in a previous study[16]. It can not be ruled out the possibility that duodenal ulcer rats with ginkgo increase numbers of total and BrdU-labeled cells in the proliferation zone compared with those without ginkgo after administration of BrdU at a higher dose for a longer incorporation time. Dissimilar to this *in vivo* study, our *in vitro* study showed that EGb 761 at 1 000 mg/L significantly decreased cell proliferation to 45% and 39% of the control group in human hepatocellular carcinoma HepG2 and Hep3B cells[17].

Prostaglandins E, F, and I have been found to exist in the mucosa and fluid of the gastrointestinal tract, and play important roles in modulating the mucosal integrity and various functions of the gastrointestinal tract[18-20]. Besides the antisecretory property of prostaglandins[21], several mechanisms of the gastroduodenal cytoprotective action for PGE$_2$ have been reported, including against disruption of gastric mucosal microvasculature[22], stimulation of mucus and bicarbonate secretion[23], elevation of blood flow[18,24], stimulation of calcium efflux[25], and stabilization of microtubules[25]. Although PGE$_2$ concentration in the duodenal mucosa did not significantly differ among duodenal ulcer rats without ginkgo, sham operation rats with and without ginkgo during the experimental period, duodenal ulcer rats with ginkgo significantly increased PGE$_2$ concentration in the duodenal mucosa by 2.3-fold compared with those without ginkgo after 14 d treatment. Similarly, a previous study found that PGE$_2$ concentration in the duodenal mucosa significantly increased by 2- or 3.2-fold, respectively, after H$_2$-blocker drug treatment with famotidine

(40 mg daily) or ranitidine (150 mg twice daily) in duodenal ulcer patients for 4 weeks[26]. The data suggest that *Ginkgo biloba* extract has similar effectiveness in increasing PGE$_2$ concentration in the duodenal mucosa to H$_2$-blocker drugs. Moreover, increased PGE$_2$ concentration in the duodenal mucosa may play an important role in duodenal cytoprotection to improve the repair of the duodenal mucosa.

Duodenal ulcer rats without ginkgo significantly decreased the activity of SOD in the duodenal mucosa and erythrocytes compared with sham operation rats without ginkgo after 14 days. Similarly, SOD activity markedly depleted in the ulcer edge of patients with duodenal ulcer compared with that in biopsies from the duodenal bulb of healthy control subjects, and increased after one month of anti-ulcer treatment[27]. However, SOD activity in erythrocytes and serum did not differ between patients with duodenal ulcer and healthy control subjects. The decreased activity of SOD might attribute to the increased consumption of SOD for the defense of superoxide radicals generated in the duodenal ulcer rats. After 14 d treatment, *Ginkgo biloba* extract significantly restored SOD activity in erythrocytes of duodenal ulcer rats, but did not affect SOD activity in duodenal mucosa. The previous study demonstrated that coadministration of SOD and catalase protected against gastric mucosa lesions induced by water immersion restraint stress in rats, and suggested that the protective effect of SOD and catalase could be due to their antioxidant activity to scavenge ROS[28]. *Ginkgo biloba* extract has been reported as a strong scavenger for superoxide anion[2]. It is assumed that *Ginkgo biloba* extract given by intravenous injection may directly compensate the utilization of SOD in erythrocytes for the defense of superoxide anion. Whereas the trend for increased SOD activity in the duodenal mucosa of duodenal ulcer rats with ginkgo was not obvious as observed in erythrocytes, probably because the amount of ginkgo reached to the duodenal mucosa was less than that in the circulation, and the treatment duration was not long enough to significantly raise SOD activity in the duodenal mucosa.

Duodenal ulcer rats without ginkgo significantly increased plasma lipid peroxides compared with sham operation rats without ginkgo during the experimental period, suggesting that duodenal ulcer may be accompanied by oxidative damage to the body. The decreased SOD activity in erythrocytes of duodenal ulcer rats without ginkgo might be attributed to the increased utilization of SOD for the protection against the increased lipid peroxides in plasma. *Ginkgo biloba* extract significantly decreased the elevated lipid peroxides in plasma of duodenal ulcer rats after 7 and 14 d treatment. Similarly, *Ginkgo biloba* extract has been demonstrated to act as an antioxidant and a free radical scavenger to reduce the increased lipid peroxides induced by gentamicin in rat plasma and kidney[29]. Unexpectedly, sham operation rats with ginkgo had lower SOD activity in the duodenal mucosa and higher lipid peroxides in plasma compared with those without ginkgo. In contrast with *Ginkgo biloba* extract as an antioxidant in previous studies[2,14,29], it might play a prooxidant role in sham operation rats. Flavonoids with phenol rings in *Ginkgo biloba* extract could be metabolized by peroxidase to form prooxidant phenoxyl radicals which, in some cases, were sufficiently reactive to cooxidize glutathione or NADH accompanied by extensive oxygen uptake and reactive oxygen species formation[30]. However, no report has directly pointed out the possibility of *Ginkgo biloba* extract as a prooxidant.

Overall, duodenal ulcer rats with ginkgo had less inflammation and more microvilli proliferation, and significantly reduced lipid peroxides in plasma compared with those without ginkgo after 7 d treatment. Additionally, duodenal ulcer rats with ginkgo tended to increase PGE$_2$ level in the duodenal mucosa and SOD activity in erythrocytes compared with those without ginkgo, but not statistically significant. After 14 d treatment, besides further improvement in the healing of duodenal ulcer observed by gross appearance and a decrease in plasma lipid peroxides, duodenal ulcer rats with ginkgo significantly increased weight gain, PGE$_2$ concentration in the duodenal mucosa, and SOD activity in erythrocytes. Changes in the level of plasma lipid peroxides seemed to be more sensitive and were accompanied by the repair of the duodenal mucosa in duodenal ulcer rats after *Ginkgo biloba* extract treatment. In conclusion, *Ginkgo biloba* extract can increase PGE$_2$ level, SOD activity, and reduce oxidative damage by the actions of cytoprotection and antioxidation to improve the repair of the duodenal mucosa in duodenal ulcer rats.

Abstract

AIM: Transfer and expression of insulin gene *in vivo* are an alternative strategy to improve glycemic control in type 1 diabetes. Hydrodynamics-based procedure has been proved to be very efficient to transfer naked DNA to mouse livers. The basal hepatic insulin production mediated by this rapid tail vein injection was studied to determine its effect on the resumption of glycemic control in type 1 diabetic mice.

METHODS: Engineered insulin cDNA was inserted into plasmid vectors under a CMV promoter, and transferred into STZ induced diabetic mice by hydrodynamic procedure. Glucose levels, body weight of treated mice, insulin levels, immunohistology of the liver, and quantity of insulin mRNA in the liver were assayed to identify the improvement of hyperglycemic complication after plasmid administration. *Sleeping Beauty*, a transposon system, was also used to prolong the insulin expression in the liver.

RESULTS: After plasmid administration, Plasma insulin was significantly increased in the diabetic mice and the livers were insulin-positive by immunostaining. At the same time the hyperglycemic complication was improved. The blood glucose levels of mice were reduced to normal. Glucose tolerance of the treated diabetic mice was improved. Body weight loss was also ameliorated. The rapid tail vein injection did not cause any fatal result.

CONCLUSION: Our results suggested that insulin gene could be efficiently transferred into the livers of diabetic mice via rapid tail vein injection and it resulted in high level of insulin expression. The basal hepatic insulin production mediated by hydrodynamics-based administration improved the glycemic control in type 1 diabetes dramatically and ameliorated diabetic syndromes. Hydrodynamics-based administration offers a simple and efficient way in the study of gene therapy for type 1 diabetes.

INTRODUCTION

Type 1 or insulin-dependent diabetes mellitus is resulted from autoimmune destruction of the pancreatic β-cells[1]. Due to severe deficiency of insulin, the key pancreatic hormone necessary for glucose homeostasis, patients with type 1 diabetes suffer from elevated blood glucose levels manifested as thirst, diuresis, overeating, ketoacidosis as well as weight loss. Development of long-term diabetic complications, such as nephropathy, retinopathy, neuropathy and macrovascular disease is also very dangerous and lethal. Currently, type 1 diabetic patients are treated with twice-daily insulin injection, which neither provides adequate glycemic control nor prevents the development of diabetic complications. Although oral and inhaled forms of insulin or insulin pump are used to achieve better glycemic control, these strategies need to be further improved[2].

Insulin gene therapy, an alternative strategy to improve glycemic control in type 1 diabetes, can restore endogenous insulin production by insulin gene delivery. Although regulated insulin expression has been developed recently, the slow kinetics of insulin secretion limits its application in clinical research. On the other hand, basal insulin production has been proved to be an effective and adjuvant strategy in insulin therapy[3]. The most intensely studied method for gene therapy utilizes viruses as a carrier to mediate long-term transgene expression, which is necessary for the chronic nature of diabetes, with improved safety profiles. Of the currently available gene delivery vehicles, only a few viral vectors, including lentiviral and adeno-associated viral (AAV) vectors meet these requirements. Except limited packaging size and the possibility of insertional mutagenesis following delivery of recombinant vectors, viral carriers usually require laborious procedures for preparation and purification[4,5]. All these shortcomings make the viral carriers inconvenient in studying the function of gene products or the practicability of gene expression cassettes.

One of the alternatives currently under development is the direct use of naked DNA that is routine in preparation and safe after administration. But naked plasmid has obstacles in diabetic gene therapy because of its less efficiency to transfect animal cells. Low level expression of insulin fails to reduce blood glucose levels significantly[6,7]. Liu and Zhang have developed a hydrodynamics-based procedure to mediate efficient expression of transgenes in the liver of mice by systemic administration of naked DNA[8,9]. The liver, a surrogate organ for insulin gene transfer in most preclinical tests *in vivo*, showed the highest level of gene expression among the organs expressing transgenes. This strategy has been proved to be a convenient way in studying gene function and gene therapy. We used the hydrodynamics-based procedure, a convenient and safe strategy for naked DNA transfer, in the study of diabetes gene therapy.

In this report we injected naked plasmid with insulin precursor cDNA into diabetic mice via hydrodynamics-based procedure. The basal insulin production and its effect on the reversal of diabetic manifestations were evaluated. *Sleeping*

Beauty[10], a TC-1 like transposon system, was also used to prolong the high level of insulin expression.

MATERIALS AND METHODS

Construction of plasmid vector

Engineered human proinsulin cDNA (mhINS) contained furin recognition sequences (Arg-X-Arg-Arg) at B/C and C/A junction regions. Such a genetical modification allowed proinsulin to be processed maturely by the ubiquitous protease furin in non-endocrine cells[11]. An expression cassette containing mhINS cDNA driven by a CMV promoter in plasmid pcDNA3-mhINS[12] (provided by Dr. Shen KT in Zhongshan Hospital) was recloned between two inverted reverse sequences in plasmid pT, a *Sleeping Beauty* transposon vector[10] (provided by Dr. Zoltan Ivics). Plasmid used for transfection was purified with a purification kit (Qiagen) according to the instructions.

Animal studies

Male ICR mice (from BK Company, weighing 25-30 g) were used in this study. All the mice were fed at room temperature with sufficient water and food, and monitored for body weight every 3 days. To induce diabetes, the animals received intraperitoneal injection of streptozotocin (STZ dissolved in a 100 mmol/l sodium citrate solution pH 4.5, 150 mM NaCl, immediately before administration) at the dose of 150 mg/kg body weight. The mice with blood glucose levels in the range of 20-30 mmol/l were selected and used 7 days after STZ treatment. Blood glucose levels were determined with Precision Plus Electrodes (Medisense, MA). Plasma insulin levels were measured by human insulin radioimmunoassay (RIA, Linco Research, St. Louis, MO). Blood samples were collected by a retro-orbital technique into Eppendorf tubes. Subsequently, separated plasma from each of two to three mice in each group was mixed to obtain enough volume of samples for insulin evaluation assays.

Plasmid administration

Administration of mhINS vectors into STZ-induced diabetic mice was carried out by intravenous coinjection of 80 µg of pT-mhINS and 8 µg of pCMV-SB (plasmid expressing transposase), or intravenous injection of 80 µg of pcDNA3-mhINS in 2-3 ml (one tenth of the body weight in grams) of Ringer's solution (147 mM NaCl, 4 mM KCl, 1.13 mM CaCl$_2$) in 7 seconds[9].

Glucose tolerance test

The mice were subjected to three hour fasting and injected intraperitoneally with 20% glucose at the dose of 2 g/kg body weight. Blood glucose was measured at 30-minute intervals before and after glucose infusion.

Identification of mhINS DNA and mRNA in livers

Genomic DNA prepared from livers of mice was used for PCR detection with primers specific for mhINS cDNA (forward, 5'-CGCAGCCTTTGTGAACCA-3; and backward, 5'-TCCACAATGCCACGCCT-3'). Total RNA from livers was reversely transcribed and the resulting pool of cDNA was subjected to PCR detection with the same primers above. The reaction mixture for PCR amplification was subjected to 30 cycles of denaturation (95℃, 30 seconds), annealing (63℃, 30 seconds), and extension (72℃, 30 seconds). The amplified products were 204 bp in length and identified by agarose-gel electrophoresis. For β-actin RT-PCR, the sequences of primers were 5'-CCTTCCTGTGCATGGAGTCCT-3' and 5'-GGAGCAATGATCTTGATCTTC-3'. The PCR conditions involved denaturation at 95℃ for 30 s, annealing at 55℃ for

30 s, and extension at 72℃ for 30 s for 30 cycles, and the PCR products were 202 bp in length. Here, β-actin RT-PCR was used as an internal control.

Quantitative RT-PCR analysis

On days 1, 7 and 14 after plasmid injection, we sacrificed the mice that had received pCMV-mhINS and pT-mhINS, and harvested the livers. The total RNA of the liver samples was isolated and the contaminated DNA was excluded with DNase I. Two micrograms of quantified RNA were first subjected to reverse transcription using an oligo(dT) primer and reverse transcriptase (RT, Gibco BRL, Rockville, MD, USA) to generate first-strand cDNA. To determine the levels of transgene-derived insulin mRNA in the liver, we performed quantitative real-time PCR analysis using an ABI PRISM 7000 system. Taqman Universal PCR MasterMix was used to provide critical components for PCR mixture. The primers and probe were as follows: forward primer, 5'-AACACCTGTGCGGCTCAGA-3'; backward, 5'-CGTTCCCCGCACACTAGGTA-3'; FAM labeled MGB probe, FAM-5'-CTGGTGGAAGCTCT-3'-MGB. The PCR process was at 50℃ for 2 min, at 95℃ for 10 min, then at 95℃ for 15 s and at 60℃ for 10 min for a total of 40 cycles. The length of expected products was 54 bp. The standard curve for mhINS plasmid was created. The quantity of insulin mRNA was expressed as pg/cDNA from 100 ng of total RNA.

Immunocytochemical analysis

For immunohistochemical (IHC) procedures, the tissues were fixed in 4% buffered paraformaldehyde. An antibody to human insulin (Linco Research) was used for immunostaining. The number of insulin-positive hepatocytes was counted on IHC sections from 3-4 animals.

RESULTS

Reduction of blood glucose in the diabetic mice treated with insulin precursor DNA

The expression constructs of human insulin precursor driven by CMV promoter are shown in Figure 1. Insulin precursor vectors were injected rapidly via tail vein into diabetic mice, and blood glucose of the mice was measured to determine the effect of insulin production after the naked vector delivery. As shown in Figure 2, the administration of insulin vectors resulted in a significant reduction in glucose concentration. In the eight animals co-transferred with pT-mhINS and pCMV-SB, their blood glucose levels were reduced to normal one day after plasmid injection, and three of them maintained the normal levels for two weeks. Glucose concentration was also reduced significantly one day after administration of the non-transposon vector pcDNA3-mhINS, but increased rapidly and reached pretreatment levels one week later. In contrast, Ringer's solution-treated animals remained the high glucose levels unchanged. The severe loss of body weight of the diabetic mice was ameliorated after delivery of pcDNA3-mhINS and pT-mhINS (Figure 3). Also, urination of the treated diabetic mice lessened dramatically. These results indicated that symptoms of diabetes were improved after hydrodynamics mediated insulin gene delivery. No diabetic mouse died from the rapid tail vein injection, which showed the safety of hydrodynamics-based DNA administration in the study of gene therapy for diabetes.

Insulin production in STZ-induced diabetic mice after insulin vector treatment

Insulin protein in mouse serum was measured by radioimmunology with human insulin polyclonal antibodies. Normal mice and STZ-induced diabetic mice treated with

Ringer's solution were used as controls. Insulin protein in pT-mhINS and pCMV-SB co-treated STZ mice was 97.2 μU/ml, 33.3 μU/ml, and 12.7 μU/ml one day, seven days and fourteen days after treatment, respectively. In pcDNA3-mhINS treated mice it was 113 μU/ml, 4.8 μU/ml, and 3.4 μU/ml one day, seven days and fourteen days after treatment, respectively (Table 1). Seven days after plasmid administration, insulin production was seven fold higher in serum of diabetic mice treated with transposon vector than that in serum of those treated with non-transponson vector, indicating transposon vector was more effective to mediate sustained basal insulin production.

Figure 1 Stucture of pcDNA3-mhINS, pT-mhINS, and pCMV-SB. CMV, CMV promoter; mhINS, engineered human insulin cDNA; IR, inverted repeat sequences of *Sleeping Beauty*.

Figure 2 Reduction of blood glucose in diabetic mice treated with insulin precursor DNA. Data were plotted as the mean mean±SEM. *P*<0.01(1d). Vector administration was at day 0.

Figure 3 Weight increment of the mice after the mhINS vector treatment. Vectors were administrated at day 0.

Table 1 Insulin production in STZ-induced diabetic mice after insulin vector treatment (mean±SD)

Serum insulin Level(μU/ml)	pCMV-mhINS	pT-mhINS+ pCMV-SB	Diabetic control	Normal control
1 day after treatment	113.1±20.6	97.2±14.4	5.2±0.3	10-50
7 days after treatment	4.8±1.3	33.3±10.2	-	-
14 days after treatment	3.4±0.2	12.7±4.6	-	-

PCR and RT-PCR detection for mhINS cDNA and mRNA in livers

Total DNA and RNA were extracted for PCR and RT-PCR to detect if mhINS vectors were transfected into the mice livers and transcripted into mRNA. The PCR and RT-PCR products of 204 bp fragments were amplified from all livers of mice administrated pcDNA3-mhINS and pT-mhINS, but not from controls. In RT-PCR detection with β-actin primers, 202 bp fragments were found in all hepatic RNAs (Figure 4).

Figure 4 PCR and RT-PCR detection for mhINS cDNA and mRNA in livers. A, mhINS cDNA PCR; B, mhINS mRNA RT-PCR; C, β-actin RT-PCR. The number above the photo shows DNA marker (1), positive control (2), negative control (3), livers of pT-mhINS treated mice 1 day (4) and 7 days (5) after administration, livers of pcDNA3-mhINS treated mice 1 day (6) and 7 days (7) after administration.

Quantitative real-time RT-PCR analysis for insulin mRNA in livers

To identify the difference of transcript levels of mhINS in the livers of diabetic mice treated with transposon and non-transposon vectors seven and fourteen days after injection, real-time RT-PCR was performed. The transcripts of mhINS in the livers of mice treated with transposon vector were more than those in the livers of mice treated with non-transposon vector seven days or fourteen days after delivery (Table 2). No mhINS transcripts were detected in the livers of negative control mice. To identify if the isolated RNA was contaminated by mhINS DNA, RNA isolated from the livers of plasmid-treated mice but not reversely transcribed was subjected to real-time PCR. Negative results suggested that the isolated RNA was not contaminated by mhINS DNA.

Table 2 Quantity of mhINS mRNA in mouse liver after plasmid infusion (mean±SD)

Quantity of mRNA(pg)	pCMV-mhINS	pT-mhINS+ pCMV-SB	Diabetic control
7 days after treatment	0.21±0.14	3.41±1.48	0
14 days after treatment	0.13±0.04	1.24±1.06	0

Expression of insulin protein in livers of treated diabetic mice

To confirm that treatment of the diabetic mice with mhINS vectors resulted in insulin expression in the liver, immunohistological staining of liver sections with antibodies against insulin was performed. As shown in Figure 5, insulin-positive cells were observed in all livers of mhINS vector-treated mice. In contrast, it was negative in the livers of Ringer's solution-treated mice. To provide more quantitative information, liver sections from three cases in each group were randomly observed 7 days and 14 days after plasmid administration and the number of insulin-positive hepatocytes were counted. There were more positive cells in the livers of mice treated with transposon vector as compared with those treated with non-transposon vector (Table 3).

Figure 5 The expression of insulin protein in the livers of the treated diabetic mice. One day after pT-mhINS and pCMV-SB treatment (A), pcDNA3-mhINS treatment (B), and Ringer's solution-treatment(C), mice were sacrificed and liver sections were stained with antibodies to human insulin.

Table 3 Insulin-positive cells in mouse liver after plasmid infusion (mean±SD)

Positive cells	pCMV-mhINS	pT-mhINS+ pCMV-SB	Diabetic control
7 days after treatment	6.3±2.3	19.0±5.7	0
14 days after treatment	2.3±0.9	9.3±2.4	0

Effects of plasma insulin on glucose tolerance in diabetic mice treated with insulin vectors

To assess whether or not hepatic products of insulin at basal levels had any therapeutic effect on blood glucose disposal, glucose tolerance experiments were performed in the treated diabetic animals. As shown in Figure 6, blood glucose levels in normal control mice moderately rose to about 12 mM after glucose infusion, and rapidly restored to normal within 1.5 h. In contrast, glucose infusion further exacerbated the severity of hyperglycemia in diabetic animals, resulting in higher glucose concentration (over 22 mM), which persisted for more than 2 hours before slow decline. Blood glucose levels of the diabetic mice treated with insulin vectors were moderately elevated to the same degree as that of the normal mice after glucose challenge and returned to pre-challenge levels within

2 hours. These results suggested that sustained expression of hepatic insulin at basal levels could significantly enhance glucose tolerance in type 1 diabetic animals.

Figure 6 Effects of plasma insulin on glucose tolerance in the diabetic mice treated with the insulin vectors. Blood glucose levels at 30 min intervals prior to and after glucose challenge were determined and plotted as a function of time. Data were obtained 2 days after insulin vector treatment. Data are the mean±SEM, n=2 or 3.

DISCUSSION

One of the difficulties in gene therapy for diabetes is the requirement of high production of insulin to reduce blood glucose levels. Viral vectors, such as adenovirus[13-15], AAV[16-18], and retrovirus[19] have been used. Productive transduction by retroviruses depends on cell division, which is a limiting factor for transducing postmitotic cells. In contrast, adenoviruses are effective for transducing non-dividing cells, but leaky expression of adenoviral proteins is immunogenic, consequently resulting in transient transgene expression. Recombinant AAV vectors have been widely used for gene transfer because of their inherently non-immunogenic nature and ability to stably transduce both dividing and non-dividing cells. Although rAAV is able to mediate stable transgene expression, efficient transduction of the liver by rAAV vector requires intraportal vein injection instead of peripheral intravenous infusion, and stable transgene expression is detected only in approximately 5% of liver cells. Naked plasmid vector, simpler, cheaper and more routine in preparation than viral vectors, is convenient in studying gene function and the practicability of gene expressing vectors. Hydrodynamics-based procedure can mediate naked DNA transfer to the liver most efficiently. It has been used in the study of transfer and expression of various genes, such as FIX[20], IL-10[21], LDL[22], HDV[23], hepatocyte growth factor[24], *etc*. The method was proved to be very efficient for delivery of these genes into the mouse liver. The peak level of gene expression could be gained 24 hours after injection[8,9]. Transaminase levels and liver histological results showed that rapid intravenous plasmid injection into mice could induce transient focal acute liver damage, which was rapidly repaired within 3 to 10 days. In the present study, we used hydrodynamics-based procedure to deliver insulin gene into STZ-induced type 1 diabetic mice. Insulin production was greatly improved after plasmid injection, and hyperglycemia was recovered to normal blood glucose levels. Most of all, no diabetic mice died from the procedure. These results indicated that hydrodynamics-based administration was a safe and very efficient way in the study of gene therapy for diabetes at the animal study stage.

Most preclinical tests of *in vivo* insulin gene transfer in the past chose the liver as a surrogate organ for insulin production[2]. One attractive feature of hepatic insulin gene delivery is that hepatocytes are capable of responding to

changes in blood glucose concentrations. In addition, the liver is a major insulin target organ for glucose homeostasis and helps to maintain blood glucose concentrations in a narrow physiological range. Another advantageous feature of hepatic insulin production is related to the observation that portal insulin levels are relatively higher than peripheral insulin concentrations, as pancreatic insulin is released directly to portal circulation. Insulin gene expression in the liver is likely to restore to some extent portal/peripheral insulin concentration gradient in type 1 diabetes. Finally, the liver is a relatively large organ with a robust capacity for protein synthesis, and even a small fraction of hepatocytes transduced will be able to secret sufficient amount of insulin for improving glycemic control in type 1 diabetes. Taken together, the liver is an excellent target site for insulin gene delivery. The limitation that the liver lacks pancreas-specific prohormone convertases PC2 and PC3 for insulin processing has largely been overcome by converting amino acid residues at B/C and C/A junction regions of the proinsulin polypeptide chain to a consensus furin recognition site[25,26]. So proinsulin synthesized in hepatocytes will be processed by ubiquitously expressed enzyme furin. Hydrodynamics-based administration can efficiently deliver foreign gene into the liver. In this study, furin-cleaved proinsulin gene was injected into diabetic mice via rapid tail vein. There was a high expression of insulin mRNA and protein in the liver of mice treated with mhINS plasmid vetors. The glucose disposal of diabetic mice was also improved. These results indicated that hydrodynamics-mediated insulin expression in the liver was effective to improve the glucose control in type 1 diabetic mice.

One limitation of non-β cell expression of insulin gene is the lack of regulated protein secretory pathway. To overcome this limitation, different approaches have been taken to control hepatic insulin gene expression in the liver. While considerable process has been made to achieve regulated insulin gene expression[2,27], there are several issues concerning the safety and potential toxicity of such systems. A slow kinetics in insulin production and secretion from the liver in these reports was life-threatening[28]. Sustained basal hepatic insulin production, another effective strategy in therapy of diabetes however, could be used as an adjuvant treatment to insulin therapy, and could confer profound therapeutic benefits to type 1 diabetes mellitus[29]. Basal insulin represents an important physiological phase of insulin secretion in the post-absorption phase. In addition to providing the basal requirement for hormones in glucose metabolism, basal insulin played a key role in preventing the development of ketoacidosis[3,18,26]. In the present study we transferred insulin expression plasmid controlled by a constitutive CMV promoter into STZ-induced diabetic mice. The results showed that non-regulated basal production of plasma insulin was significantly increased after plasmid administration. Blood glucose levels were reduced to normal and glucose tolerance was improved also. Weight loss was also ameliorated. Although the treated mice occurred hypoglycemia during fasting, controlling the dose of DNA injection could overcome it. Basal insulin production, when combined with twice-daily insulin injection, could achieve better glycemic control without the need of multiple daily insulin injections and excessive body weight gain, an inevitable consequence associated with intensive insulin therapy[30].

Unlike mammalian promoter, CMV promoter delivered *in vivo* is known to induce cytokine production and cytokine-mediated effects could subsequently attenuate the promoter activity and limit transgene expression[31,32]. We delivered mhINS under the promoter of rat liver pyruvate kinase gene (LPK) that has glucose response element. However, there was no difference in ameliorating hyperglycemia between two promoter-driven plamids (data not shown). Elongation factor promoter (EF) was also used to drive insulin expression. Though less DNA was required to normalize glucose concentration, there was no significant difference in prolonging the normalized state of glucose concentration between CMV and EF promoters (reported in another article). Some points would account for these results. A majority of DNA began to lose one day after injection and insulin expression declined below certain levels that can not significantly reduce blood glucose levels. So there was no significant difference in reduction of glucose level among CMV, EF and LPK promoters when the peak level expression of insulin was over. So how to stabilize DNA infused into hepatic cells and how to prevent gene silencing would be the most critical steps before hydrodynamics-based procedure can be used in gene therapy of diseases that need high levels of gene products.

Sleeping Beauty vector, one of mammalian transposon systems, was used in this study to prolong the high levels of insulin expression. *Sleeping Beauty* transposon could be efficiently inserted into mammalian chromosomes *in vivo* and might permit longer-term foreign gene expression with a single administration[33]. The results indicated that the effect of transposon vector on hyperglycemia excelled that of non-transposon vector. Although the feature of unspecific insertion made transposon system unsafe in the practicality of gene therapy, it was still valuable in the study of gene function for diabetes therapy. Other safer systems to prolong naked DNA expression have been developed recently, such as phage φ31 integration system[34], combination of hepatic control region and hepatic promoter, *etc*.[20,35-37]. These strategies, combined with hydrodynamics procedure, would be very valuable in the study of gene therapy for diabetes.

Although hydrodynamics-based procedure is unsuitable for clinical use, local gene transfer with such a high liquid pressure has been developed and is more practical[38-42]. So hydrodynamics-based administration could be an efficient, safe and convenient way in the study of gene therapy for diabetes, especially in study of the function of gene products and the practicality of gene expressing vectors.

In conclusion, hydrodynamics-based approach can transfer insulin cDNA efficiently into diabetic mice livers. High level expression of insulin protein can result in significant reduction of blood glucose levels and improve diabetic syndromes. This intravenous procedure could be a convenient and efficient way in study of gene transfer and expression in diabetic mice.

Abstract

AIM: To investigate the effect of NF-κB decoy oligodeoxynuleotides (ODNs) - modified dendritic cells (DCs) on regeneration of partial liver allograft.

METHODS: Bone marrow (BM)- derived DCs from SD rats were propagated in the presence of GM-CSF or GM-CSF+IL-4 to obtain immature DCs or mature DCs, respectively. GM-CSF-propagated DCs were treated with double-strand NF-κB decoy ODNs containing two NF-κB binding sites or scrambled ODNs. Allogeneic (SD rat to LEW rat) 50% partial liver transplantation was performed. Normal saline (group A), GM-CSF -propagated DCs (group B), GM-CSF+IL-4 - propagated DCs (group C), and GM-CSF+NF-κB decoy ODNs (group D) or scrambled ODNs -propagated DCs (group E) were injected intravenously into recipient LEW rats 7 days prior to liver transplantation and immediately after transplantation. DNA synthesis (BrdU labeling) and apoptosis of hepatocytes were detected with immunostaining and TUNEL staining postoperative 24 h, 48 h, 72 h and 84 h, respectively. Liver graft-resident NK cell activity, hepatic IFN-γ mRNA expression and recipient serum IFN-γ level at the time of the maximal liver allograft regeneration were measured with ^{51}Cr release assay, semiquantitative RT-PCR and ELISA, respectively.

RESULTS: Regeneration of liver allograft was markedly promoted by NF-κB decoy ODNs-modified immature DCs but was significantly suppressed by mature DCs, the DNA synthesis of hepatocytes peaked at postoperative 72 h in group A, group B and group E rats, whereas the DNA synthesis of hepatocytes peaked at postoperative 84 h in group C rats and 48 h in group D rats, respectively. The maximal BrdU labeling index of hepatocytes in group D rats was significantly higher than that in the other groups rats. NF-κB decoy ODNs-modified immature DCs markedly suppressed but mature DCs markedly promoted apoptosis of hepatocytes, liver-resident NK cell activity, hepatic IFN-γ mRNA expression and recipient serum IFN-γ production. At the time of the maximal regeneration of liver allograft, the minimal apoptosis of hepatocytes, the minimal activity of liver-resident NK cells, the minimal hepatic IFN-γ mRNA expression and serum IFN-γ production were detected in group D rats. The apoptotic index of hepatocytes, the activity

of liver- resident NK cells, the hepatic IFN-γ mRNA expression level and the serum IFN-γ level in group D rats were significantly lower than that in the other groups rats at the time of the maximal regeneration of liver allograft.

CONCLUSION: The data suggest that the augmented regeneration of partial liver allograft induced by NF-κB decoy ODNs-modified DCs may be attributable to the reduced apoptotic hepatocytes, the suppressed activity of liver-resident NK cells and the reduced IFN-γ production.

INTRODUCTION

Complete and prompt liver regeneration after living liver donation and transplantation could occur in both donor and recipient in most circumstances[1-5]. Particularly in the transplant recipients, rejection[6,7] and ischemic injury[8] could result in inadequate regeneration, leading to hepatic insufficiency or overt liver failure. Early recognition and correction of these complications maximize the chance of liver graft salvage and good outcome for the patient.

Liver regeneration may be regulated cooperatively not only by humoral factors such as hormones, growth factors and growth inhibitory factors, but also by the immune system. It has been reported that regenerating hepatocytes became sensitive to the cytotoxic activity of normal liver-resident NK cells from partially hepatectomized mice[9-15]. It has also been reported that during the acute phase of regeneration after partial hepatectomy in rats, NK cell functions were temporary suppressed, followed by their recovery at the termination of regeneration[14], suggesting that such a selective suppression of NK cell functions during the acute phase represents an important regulatory mechanism for liver regeneration in the presence of hepatic NK cells. These observations indicate that liver-resident NK cells may be involved in regulating the extent of hepatocyte regeneration.

A recent study revealed that NKT cells proliferated in the liver after administration of IL-12[16], were cytotoxic effector cells and the main antimetastatic lymphocyte population in the liver. NKT cells are thought to be responsible for the recognition and regulation of not only malignant cell proliferation but also benign cell proliferation, suggesting that NKT cells may be involved in the regulation of hepatocyte regeneration[17].

It is accepted that both donor and recipient DCs mediate the rejection of graft in organ transplantation. Several studies have shown that immature donor DCs, deficient in surface costimulatory molecules, could induce T-cell hyporesponsiveness[18-20] and prolong graft survival in unmodified hosts[21-24]. Other studies showed that DCs treated with NF-κB decoy oligodeoxynuleoides (ODNs)

containing specific NF-κB binding sites, which are maintained in an immature state, could induce tolerance of cardiac allograft[25,26]. Our recent study showed that NF-κB decoy ODNs-modified DCs could induce tolerance of rat liver allograft by promoting apoptosis of liver graft-infiltrating cells (GIC) in the portal areas and suppressing IFN-γ mRNA expression in the liver graft[27].

We hypothesize that the enhanced apoptosis of liver graft-infiltrating cells by NF-κB decoy ODNs- modified DCs can reduce the total number of liver-resident NK cells and suppress the cytotoxicity of NK cells to the regenerating hepatocytes, and consequently promote liver graft regeneration. In the present study we reported for the first time that NF-κB decoy ODNs-modified DCs could promote regeneration of partial liver allograft by suppressing hepatocyte apoptosis, liver-resident NK cell activity and IFN-γ production.

MATERIALS AND METHODS

NF-kB decoy ODNs

Double-stranded NF-κB decoy ODNs or scrambled ODNs (as a control for NF-κB decoy ODNs) were generated using equimolar amounts of single-stranded sense and antisense phosphorothioate-modified oligonucleotide containing two NF-κB binding sites (sense sequence 5'-AGGGACTTTCCGCTG-GGGACTTTCC-3', NF-κB binding sites bold lines and underlined)[25] and scrambled oligonucleotide (sense sequence 5'-TTGCCGTACCTGACTTAGCC-3')[28]. Sense and antisense strands of each oligonucleotide were mixed in the presence of 150 mM PBS, heated to 100℃, and allowed to cool to room temperature to obtain double-stranded DNA.

Propagation of bone marrow-derived DC populations

Bone marrow cells harvested from femurs of normal SD rats were cultured in 24-well plates (2×10^6 per well) in 2 ml of RPMI 1640 complete medium supplemented with antibiotics, 10% fetal calf serum (FCS) and 4.0 ng/ml recombinant rat GM-CSF to obtain immature DCs. In addition to GM-CSF, 10 ng/ml recombinant rat IL-4 was added to cultures to obtain mature DCs. To select plates, 10 μM NF-κB decoy or scrambled ODNs was added at the initiation of culture of DCs[25]. Cytokine-enriched medium was refreshed every 2 days, after gentle swirling of the plates, half of the old medium was aspirated and an equivalent volume of fresh, cytokine-supplemented medium was added. Thus, nonadherent granulocytes were depleted without dislodging clusters of developing DCs attached loosely to a monolayer of plastic-adherent macrophages. Nonadherent cells released spontaneously from the clusters were harvested after 7 days.

Liver transplantation

Eighty male LEW rats and eighty male SD rats weighing 250-300 g were used in all the experiments. Allogeneic liver transplantations were performed using a combination of SD rats with LEW rats. All operations were performed under ether anesthesia in sterile conditions. Orthotopic 50% partial liver transplantations were performed according to the method described in our previous study[29]. Normal saline (group A), 1×10^7 GM-CSF-propagated DCs (group B), 1×10^7 GM-CSF+IL-4 - propagated DCs (group C), and 1×10^7 GM-CSF+ NF-κB decoy ODNs or scrambled ODNs - propagated DCs (group D or group E) were injected intravenously through the penile vein into recipient LEW rats 7 days prior to liver transplantation and immediately after liver transplantation, respectively. Liver graft samples and blood samples ($n=8$) were harvested at 24 h, 48 h, 72 h and 84 h postoperatively. Part of the liver grafts was immediately used for isolation of NK cells.

Part of the liver graft tissues was immediately frozen in liquid nitrogen and kept at -80℃ for mRNA extraction and part of the liver graft tissues was preserved in 10% formalin for liver regeneration and apoptosis detection.

Liver allograft regeneration detection (BrdU labeling index)

Regeneration extent of liver allograft was indicated by BrdU labeling index of hepatocytes. The BrdU labeling index was determined as described previously. Briefly, BrdU administered intravenously at a dose of 50 mg/kg 30 min before death to measure DNA synthesis in the regenerative liver. Deparaffinized liver sections were incubated with anti-BrdU antibody for 60 min. Immunostaining for BrdU was performed by the avidin-biotin-immunoperoxidase method using ABC kit. A total of 1 000 hepatocytes were counted and the labeling index was calculated.

Apoptosis of hepatocytes

Apoptotic cells in tissue sections were detected with the *in situ* cell death detection kit. The liver graft tissue sections were dewaxed and rehydrated according to standard protocols. Tissue sections were incubated with proteinase K(20 μg/ml in 10 mM Tris/HCl, pH 7.4-8.0) for 15 to 30 min at 21-37℃. Endogenous peroxidase activity was quenched with blocking solution (0.3% H_2O_2 in methanol) for 30 min at room temperature before exposure to TUNEL reaction mixture at 37℃ for 60 min. After washed in stop wash buffer, POD (peroxidase) was added to react for 30 min at 37℃. DAB-substrate was used for color development, and the sections were counterstained with Harrs' hematoxylin. TUNEL staining was mounted under glass coverslip and analysed under light microscope.

Activity of liver graft-resident NK cells

Hepatic mononuclear cells (MNCs) were isolated by the sinusoidal lavage method of Bouwens and Wisse[30]. The cells were obtained by portal vein perfusion with 1% EDTA in PBS at 37℃ and a pressure of 50 H_2O, and washed. Then, 30 mL of perfused fluid was collected from the inferior vena cava, and the erythrocytes and granulocytes were separated by the Ficoll (density 1.077) at 400 g for 25 min at 25℃. NK activity was measured by the ^{51}Cr release method. After washed with PBS, RPMI 1640 medium containing 10% fetal bovine serum was added and the cell count was adjusted to 1×10^6/ml. Next, the cultured K562 cells were harvested by centrifugation, 50 to 100 μl of ^{51}Cr was added, and the mixture was incubated at 37℃ for 1 h. Also after the cells were washed with PBS, RPMI 1640 medium containing 10% fetal bovine serum was added and the cell count was adjusted to 1×10^6/ml. Then the target cells were placed in each well of a microplate. 1 N HCl was added to obtain maximum release and RPMI 1640 medium containing 10% fetal bovine serum was added to obtain spontaneous release (controls). Liver MNCs were added to the other wells at an effector /target ratio of 20. Centrifugation was performed for 5 min at 800 rpm, using a plate centrifuge, followed by incubation for 3.5 h in 5% CO_2. The culture supernatant was collected from each well and radioactivity was measured with a g-scintillation counter. NK cells activity was calculated as follows:

$$NK\ cell\ activity\ (\%) = \frac{Experimental\ release\ (cpm)-spontaneous\ release\ (cpm)}{Maximum\ release\ (cpm)-spontaneous\ release\ (cpm)} \times 100$$

Semiquantitative RT-PCR assay for IFN-gmRNA expression in liver graft

IFN-γ mRNA expression was determined by semiquantitative

reverse transcription-PCR amplification in contrast with house-keeping gene β-actin. Total RNA from 10 mg liver allograft tissue was extracted using Tripure™ reagent. First-strand cDNA was transcribed from 1 μg RNA using AMV and an Oligo (dT$_{15}$) primer. PCR was performed in a 25 μl reaction system containing 10 μl cDNA, 2 μl 10 mM dNTP, 2.5 μl 10×buffer, 2.5 μl 25 mmol.L^{-1} MgCl$_2$, 2 μl specific primer, 5 μl water and 1 μl Taq (35 cycles: at 95℃ for 60 seconds, at 59℃ for 90 seconds, and at 72℃ for 10 seconds). The primers[31, 32] used in PCR reactions were as follows: IFN-γ, 5' primer 5' -AAGACAACCAGGCCATCAGCA-3' , 3' primer 5' -AGCCACAGTGTGAGTTCAGTC -3' , to give a 547 bp product. β-actin, 5' primer 5' -ATGCCATCCTGCGTCTGG ACCTGGC-3' , 3' primer 5' -AGCATTTGCGGTGCACGAT GGAGGG-3' , to give a 607 bp product. PCR products of each sample were subjected to electrophoresis in a 15 g.L^{-1} agarose gel containing 0.5 mg.L^{-1} ethidium bromide. Densitometrical analysis using NIH image software was performed for semiquantification of PCR products, and mRNA expression was evaluated by the band-intensity ratio of IFN-γ to β-actin, and presented as percent of β-actin (%).

Statistical analysis

Statistic analysis of data was performed using *t*-test, *P*<0.05 was considered statistically significant.

RESULTS

Augmented regeneration of partial liver allograft by NF-**k**B decoy ODNs-modified DCs

DNA synthesis by regenerating hepatocytes in the liver graft is shown in Figure 1. The BrdU labeling index of hepatocytes in liver graft peaked at postoperative 72 h in group A, group B and group E rats, whereas the BrdU labeling index of hepatocytes in liver graft peaked at postoperative 96 h in group C rats and 48 h in group D rats, respectively. The maximum BrdU labeling index of hepatocytes was 28.07±4.53% for group A rats, 34.46±6.72% for group B rats, 19.81±3.65% for group C rats, 48.62±9.07% for group D rats and 35.12±6.37% for group E rats, respectively. The maximum BrdU labeling index of hepatocytes was significantly higher in group D rats but significantly lower in group C rats than that in the other groups rats (*P*<0.01 or *P*<0.001). The data suggested that regeneration of partial liver allograft was promoted by NF-κB decoy ODNs-modified DCs.

Suppression of apoptosis of hepatocytes by NF-**k**B decoy ODNs-modified DCs

Some studies showed that liver regeneration was a process involving cell proliferation and inhibition of apoptosis[33-35]. To determine the augmented regeneration of liver allografts induced by NF-κB decoy ODNs-treated DCs was associated with the inhibited apoptotic death of hepatocytes, apoptotic activity in the liver graft at the time of maximal liver allograft regeneration was examined by TUNEL staining analysis. TUNEL staining of the liver graft sections revealed that the apoptosis index of hepatocytes was 13.07±3.27% for group A rats, 9.32±2.15% for group B rats, 17.76±3.89% for group C rats, 5.42±1.76% for group D rats and 9.75±2.53% for group E rats, respectively. The apoptosis index of hepatocytes was significantly lower in group D rats but significantly higher in group C rats than that in the other groups rats (*P*<0.05 or *P*<0.01 or *P*<0.001). These data strongly suggested that the augmented regeneration of the partial liver allograft induced by NF-κB decoy ODNs-modified DCs might be associated with the significantly suppressed apoptotic death of hepatocytes.

Figure 2 Suppression of apoptosis of hepatocytes in partial liver allografts by NF-κB decoy ODNs-modified DCs (×400). Apoptosis of hepatocytes in the liver allografts from group C rats (A) and group D rats (B).

Suppression of activity of liver allograft-resident NK cells by NF-**k**B decoy ODNs-modified DCs

Activity of the liver graft-resident NK cells at the time of the maximal liver allograft regeneration was measured with ^{51}Cr release assay. A certain degree of activity of liver graft-resident NK cells was measured in group A rats. Activity of the liver graft-resident NK cells was partially suppressed by administration of immature DCs (group B and group E) but was significantly elevated by administration of IL-4 stimulated

mature DCs (Group C), whereas the activity of the liver graft-resident NK cells was significantly suppressed by administration of NF-κB decoy ODNs-modified DCs (group D). The activity value of the liver graft-resident NK cells was 36.47±6.32% for group A rats, 21.58±4.61% for group B rats, 52.93±7.73% for group C rats, 8.43±2.18% for group D rats, and 23.06±5.27% for group E rats, respectively. The activity of the liver graft-resident NK cells was significantly lower in group D rats but markedly higher in group C rats than that in the other groups rats ($P<0.001$). The results suggested that the augmented regeneration of the partial liver allograft induced by NF-κB decoy ODNs-modified DCs might be associated with the markedly suppressed activity of the liver allograft-resident NK cells.

Suppression of IFN-γ production by NF-κB decoy ODNs-modified DCs

To determine the relationship of specific immunoregulator cytokine production to the regeneration of partial liver allograft, IFN-γ mRNA expression in the liver graft and serum level of IFN-γ at the time of the maximal liver allograft regeneration were examined by RT-PCR assay and ELISA(as shown in Figure 3 and Figure 4), respectively. A certain level of hepatic IFN-γ mRNA expression and a certain serum level of IFN-γ were detected in group A rats. Hepatic INF-γ mRNA expression and serum INF-γ production were partially down-regulated by administration of immature DCs (group B and group E) but were significantly up-regulated by administration of IL-4 stimulated mature DCs (Group C), whereas the hepatic INF-γ mRNA expression and serum INF-γ production were significantly suppressed by administration of NF-κB decoy ODNs-modified DCs (group D). The hepatic INF-γ mRNA expression level and the serum INF-γ level were markedly lower in group D rats but markedly higher in group C rats than that in the other groups rats. The results suggested that the augmented regeneration of the partial liver allograft induced by NF-κB decoy ODNs-modified DCs might be associated with the markedly suppressed hepatic IFN-γ mRNA expression and serum INF-γ production.

DISCUSSION

Our and other studies have shown that NF-κB decoy ODNs - modified immature DCs, which are stably deficient in surface costimulatory molecules and allosimulatory capacity, could inhibit alloantigen-specific T cell response and prolong cardiac and liver allograft survival in unmodified recipients[25-27]. NF-κB also has been found to be an important transcriptional regulator of liver regeneration[36-39]. NF-κB could prevent hepatocytes from undergoing apoptosis during development and liver regeneration, and inhibition of NF-κB activation could induce apoptosis but not proliferation of hepatocytes. Whether the immature DCs modified with NF-κB decoy ODNs, which inhibit NF-κB activation, can interfere with the liver allograft regeneration is unknown. To study the effect of NF-κB decoy ODNs-modified DCs on hepatic regeneration after liver transplantation, we measured the BrdU labeling index of hepatocytes in the partial liver allograft. Uchiyama *et al*[6] demonstrated that DNA synthesis in liver was slower after an orthotopic transplantation than after a partial hepatectomy. In our partial liver transplantation model, the BrdU labeling index of hepatocytes peaked at 72 h after a allogeneic transplantation, in contrast to the maximum DNA synthesis at 24 h that has been documented after a partial hepatectomy[40]. In the present study immature DCs or mature DCs were administered to recipient rats 7 days prior to liver transplantation and immediately after liver transplantation to detect whether NF-κB decoy ODNs-modified DCs could improve the delayed liver graft regeneration. Our results showed that partial liver graft DNA synthesis peaked earlier in group D rats (pretreatment with NF-κB decoy ODNs-modified immature DCs) but slower in group C rats (pretreatment with mature DCs) than that in the other groups rats. The maximum BrdU labeling index of hepatocytes in group D rats was significantly higher than that in the other groups rats, whereas the maximum BrdU labeling index of hepatocytes in group C rats was significantly lower than that in the other groups rats. In the present study, we also found that pretreatment with NF-κB decoy ODNs-modified DCs could reduce apoptosis of hepatocytes in the liver graft, however, pretreatment with mature DCs could promote apoptosis of hepatocytes in the liver graft. *In situ* TUNEL staining of the liver graft sections revealed that the maximum apoptosis of hepatocytes was detected in group C rats and the minimum apoptosis of hepatocytes was detected in group D rats. Our results suggested that NF-κB decoy ODNs-modified DCs could suppress apoptosis of hepatocytes and promote partial liver allograft regeneration.

The mechanisms by which NF-κB decoy ODNs-modified DCs promote regeneration of partial liver allograft remain to be clarified. In the present study, we found that the augmented regeneration of liver graft induced by NF-κB decoy ODNs-

modified DCs might be associated with the reduced activity of liver- resident NK cells and the decreased IFN-γ production. A negative correlation was observed between liver regeneration and immune reaction (NK cell activity) in other studies[11,12], for the liver-resident and spleen-resident NK cells showed specific cytotoxicity against regenerating hepatocytes. Previous studies have shown that the liver grafts contained large numbers of NK cells and NK like cells with early lymphocyte activation before transplantation, and there was an influx of recipient NK and NK-like cells into the liver graft immediately after revascularization[41] and their cytotoxic activity was significantly augmented in the rejected liver allograft[42,43]. Other experimental studies have demonstrated that FasL expression on activated NK cells was augmented[44,45], and FasL ligation to Fas expressed on hepatocytes could mediate hepatocytes apoptosis[46,47]. Moreover, NK cells produce IFN-γ, which is involved in the aggravation of fulminant hepatitis. Thus, a decrease in NK cell activity may lead to reduction of IFN-γ. Although the definite role of NK cell activity and IFN-γ in liver regeneration is to be clarified, a rapid and profound suppression of a variety of spontaneous functions of NK cells in the liver or blood at the initiation phase of liver regeneration has been shown, including the rapidly decreased NK cell numbers and NK cell activity[11,12]. Vujanovic *et al*[14] found that depletion of NK cells by specific antibody accelerated rat liver regeneration after 70% partial hepatectomy. Tanigawa and Tamura[11,12] also found that FK506 and augmenter of liver regeneration promoted liver regeneration by reducing NK cell activity. Liu *et al*[9] recently suggested that the enhanced liver regeneration by oral ursodesoxycholic acid was mediated by suppression of NK cell activity in partially hepatectomized rats, and interleukin-2, a potent inducer of allograft rejection, could completely or partially block the decrease in NK activity and the increase in hepatocyte mitotic index. IFN-γ is secreted predominantly by activated T lymphocytes and activated NK cells interact *in vitro* in a complex network of mediators with other immune cytokines. IFN-γ is a potent stimulus for monocytes and macrophages that increases their expression of class II MHC antigens and Fc receptors. It also enhances TNF-α secretion. IFN-γ is also known to control the expression of mitochondrial transcription factor A, a nuclear gene responsible for mitochondrial metabolism. Moreover, IFN-γ could inhibit liver regeneration by stimulating MHC class II antigens expression by Kupffer cells in the regenerating liver[48]. These MHC class II antigen-positive Kupffer cells act as antigen-presenting cells and present hepatocyte as antigen, the so-called abnormal "self", to helper and cytotoxic T cells. Both types of T cells, in turn, may suppress hepatocyte proliferation. In this respect, a synergistic effect was also observed with the combination of IL-2 and IFN-γ. A recent study demonstrated that administration of IFN-γ inhibited liver regeneration by decreasing the mitochondrial transcription factor A expression[10]. These data suggested that augmentation of NK cell activity and IFN-γ production could inhibit liver regeneration. In the present study, we found that liver allograft-resident NK cell activity and hepatic IFN-γ mRNA expression and serum INF-γ production at the time of the maximal liver allograft regeneration were significantly suppressed by pretreatment with NF-κB decoy ODNs-modified immature DCs, whereas liver allograft-resident NK cell activity and hepatic IFN-γ mRNA expression and serum INF-γ production at the time of the maximal liver allograft regeneration were significantly elevated by pretreatment with mature DCs. The results suggested that there was a negative relationship between liver allograft regeneration and NK cell activity and IFN-γ production in the present study.

The mechanisms by which NF-κB decoy ODNs-modified immature DCs suppress the activity of liver allograft-resident NK cells and IFN-γ production after liver transplantation are

still to be clarified. In our previous study we found *in vitro* and *in vivo* evidences that the stably immature NF-κB decoy ODNs-treated DCs could suppress T cell allostimulatory ability, promote apoptotic death of live graft-infiltrating lymphocytes, and consequently suppress Th1 immunostimulatory cytokines such as IL-2 and IFN-γ mRNA expression in the liver graft[27]. We hypothesized that the enhanced apoptosis of liver graft-infiltrating lymphocytes by NF-κB decoy ODNs-modified DCs could reduce the total number of the activated liver-resident NK cells and suppress the NK cell cytotoxicity to the regenerating hepatocytes. At the same time, the enhanced apoptosis of liver graft-infiltrating lymphocytes could decrease IFN-γ mRNA expression and IFN-γ production in the liver graft.

In summary, pretreatment with NF-κB decoy ODNs-modified immature DCs can suppress liver allograft-resident NK cell activity and IFN-γ production. The suppressed liver allograft-resident NK cell activity and IFN-γ production, in turn, may suppress hepatocyte apoptosis and promote regeneration of partial liver allograft.

Abstract

AIM: To improve the technique of tissue microarray (tissue chip).

METHODS: A new tissue microarraying method was invented with a common microscope installed with a special holing needle, a sampling needle, and a special box fixing paraffin blocks on the microscope slide carrier. With the movement of microscope tube and objective stage on vertical and cross dimensions respectively, the holing procedure on the recipient paraffin blocks and sampling procedure of core tissue biopsies taken from the donor blocks were performed with the refitted microscope on the same platform. The precise observation and localization of representative regions in the donor blocks were also performed with the microscope equipped with a stereoscope.

RESULTS: Highly-qualified tissue chips of colorectal tumors were produced by a new method, which simplified the conventional microarraying procedure, and was more convenient and accurate than that employing the existing tissue microarraying instruments.

CONCLUSION: Using the refitted common microscope to produce tissue microarray is a simple, reliable, cost-effective and well-applicable technique.

INTRODUCTION

Tissue microarray (TMA, tissue chip) is one of the most important biochip technologies, following the gene chip and protein chip. This technology was first illustrated by Kononen *et al*[1] in the magazine of *Nature Medicine* in 1998, who then has been working with the National Human Genome Research Institute. Illuminated by the idea of DNA microarray (gene chip), Kononen *et al* proposed a new method of tissue microarray to improve the conventional process of immunostaining and fluorescent *in situ* hybridization(FISH) of individual tissue sections, which was laborious, low-efficient, vulnerable to various factors affecting the experiments and poor comparability.

TMA technology is sharply distinguished from the methods illustrated by Battifora *et al*[2] (1986) and Wan *et al*[3] (1987), which involved manually randomized rearrangement of tissue specimens. The difference lies in that the spots on TMA chips are minute (0.6 mm-2.0 mm in diameter), the quantity is huge (up to 1000 arrays at present), the shape is regular and the arrays are ordinal. The results obtained from TMAs are more scientific and comparable while the research is more informative, efficient and requires less consumption of reagents. Besides, it paves the way to the standardization of inspection and automation of analysis, which eventually makes the molecular pathological research step forward on the way of standardization and advancement in technolog[4-7].

Nevertheless, the current facilities of tissue microarrays are not advanced as expected but are costly. Moreover, it is not convenient to observe and locate the exact sites in the donor tissue blocks, or to install, adjust and replace the holing and sampling needles. Thus, the whole procedure takes much time that restricts the wide application of this particular technology[8,9]. To make up the inadequacy, we proposed a new methodology of TMA in the following section, which is convenient, up-to-date and well applicable.

MATERIALS AND METHODS

Technical design

The key techniques of TMA included high-adhesive glass slide preparation, reliable tissue specimen acquisition, tissue core arrangement, fine sectioning and section transferring techniques, as well as tissue staining and molecular pathological technology. The core technology was the acquisition of reliable tissue specimen and arrangement of tissue cores, which involved tissue fixation, collection, dehydration, embedding, tissue array design and sampling procedures, especially the exact location of needed tissue, instruments and methods of sampling and puncture, *etc*. To avoid the inadequacy of the current TMA method, we proposed a new method for fabrication of TMAs through re-equipping the common microscope. With the precise mechanical controls and sampling site observation of the microscope, the new procedure simplified the holing, sampling and inserting process, increased reliabilities, and reduced costs and was ready for wide application.

Equipments and articles

Following equipments and articles were required: a refitted common light microscope; a set of holing, sampling needles and related components (China patent No. 03113734.2), which were installed in the objective holde; a special paraffin-fixing box (China patent No. 03113733.4) placed on the slide carrier; turn buckles and screw nuts fitted by the microscope pillar for controlling the moving range of object stage or the lens; the buckles for fixing glass slide carrier; sufficient paraffin-

embedded donor and recipient blocks; a temperature controlling oven; adhesive-coated glass slides; a tissue sectioning and transferring system as well as instruments, equipments and reagents of routine staining and molecular pathology. A stereomicroscope, a scanning apparatus and a computer automation analysis system were needed if available.

Tissue sample acquisition

This method could be applied in fabrication of paraffin embedded tissue microarrays. We took surgically or endoscopically sectioned fresh tissue, and banked paraffin-embedded tissue blocks as the specimen. The acquisition procedure included tissue fixation, collection, dehydration, hyaline and paraffin embedding, which were basically not different from the routine ones. However, to ensure the quality of TMA, procedures such as the use of fixation solutions and fixing time should be standardized and mRNA in the specimen should be preserved as much as possible.

Paraffin TMA block construction

This was one of the key techniques in the new procedure. Illustrated in Figure 1(A, B, C, D), the basic process included holing in the recipient blocks, location on the donor blocks, tissue core sampling and inserting. A. Holing A recipient block is fixed in the paraffin-fixing box, and the holing needle is tuned to the working place, and punched into the exact site of the recipient block and then is drawn back with adjustment of the rotating screw. Then the core needle is pressed to squeeze out the paraffin in the needle. B. Location A donor block is fixed in the paraffin-fixing box, and the stereomicroscope len is tuned to the working place, then the exact sampling site is observed and fixed in the center part of the microscopic vision field. C. Sampling The sampling needle is tuned to the working place, and inserted into the selected site of donor block, and retrieved with the adjustment of rotating screw. D. Inserting With the microscope stage moving, the recipient block moves under the sampling needle. When the sampling needle moves exactly above the recipient hole, the core needle is pressed to squeeze out the tissue core and then inserted it into the recipient hole.

Figure 1 Procedures of paraffin-embed tissue micro-arraying. (1. holing needle, 2. stereomicroscope lens, 3. sampling needle, 4. paraffin block-fixing box, 5. recipient paraffin block).

Sectioning, transferring and staining or molecular pathological detecting

After insertion of all the samples, the recipient block was taken out from the fixing box and heated up to 58-65℃ and the tissue core was flattened by a glass slide and then cooled down. The next procedures were sectioning, tissue slice transferring and routine staining (HE) or PCR, immunofluorescent *in situ* hybridization, *etc.* (Firgures 3-4).

Figure 2 Defining accurate sampling sites in donor block under stereomicroscope. (1. Paraffin donor block and paraffin embedded tissue under stereomicroscope, 2. Routine section and HE staining of paraffin embedded donor tissue under stereomicroscope, 3. Regions of stroma, less cells or areas with no tissue, 4. Sampling locus.).

Figure 3 Pictures of paraffin-embedded tissue core arrangement (A), tissue spot arrays on slide (B) and magnified (X8) picture of selected array spots (C).

Computer imaging scan and data analysis

High-throughput digital imaging scanning and processing systems, as well as computer database programs such as Access, Excel were used to examine each core under microscope simultaneously. Data were analyzed with clinical information.

RESULTS

Employing the above method, high-quality tissue chips of colorectal tumors were successfully produced. Figure 3A is an image of the paraffin embedded tissue core arrays, which was 24 mm×35 mm in size. Every 3 core-specimens were obtained from each paraffin-embedded biopsy specimen, resulting in 111 cores from 35 colorectal tumor biopsy specimens (including colorectal adenocarcinoma, adenoma, non-adenoma polyps) and 2 normal colorectal tissue specimens. Each core was 1.3 mm in diameter and 0.7 mm in spacing.

The tissue micro-array of colorectal tumors on a glass slide (HE staining) is displayed in Figure 3B. The blank spot (dot array) on the left-hand corner was the location mark, and the blank spot in the center part was lost during sectioning and

Figure 4 Photographs of different tissue array elements stained with HE(A) and immunohistochemistry (B: P53, C: PCNA).

Table 1 Comparison of gene, protein and tissue chips

	Gene chip	Protein chip	Tissue chip
Substrate	Definitive DNA or RNA (Oligo or cDNA)	Definitive proteins (antigens\ antibodies, *etc.*)	Many tissue samples
Probes	Labelled DNA or RNA (Cy3 and Cy5 -tyramide)	Labelled antigens or antibodies	Specific antigens or antibodies, as well as labelled DNA or RNA sequences
Target material	Various sequences of DNA or RNA	Multiple kinds of proteins	Morphology and DNA, RNA and proteins
Superiorities	Analyzing numerous genes simultaneously in the same sample	Analyzing numerous proteins simultaneously in the same sample	Profile of genes or proteins in numerous tissues or populations
Applications	Large-scale, parallel analysis of genetic alterations, functions and drug researches at DNA and RNA level	Large-scale, parallel analysis of concentrations, functional activities or interactions of proteins	Large-scale, parallel *in situ* analysis of DNA, RNA and proteins associated with clinical endpoints in hundreds of cell types or tissues at one time

staining, which made a rate of 0.8% non-evaluable core biopsy sections. The selected spots in Figure 3B were magnified (X8) in Figure 3C under a stereoscope and the dot arrays were in good order, sharp bordered, not crushed or deformed. All the arraying tissue specimens were representative of the interest regions, which coincidently met the research demands.

Good staining quality was also attained on the same array sites in different slides stained with HE, immunohistochemistry and others respectively. The results were more comparable and sensitive on the chip slide as shown in Figure 4. Further detailed analyses would be reported soon.

DISCUSSION

As one of the three most important biochip technologies, tissue microarray has been accepted as a large-scale, parallel molecular analysis just like gene and protein chips[3-6,10-15]. The results were more scientific, comparable, informative and efficient, and it needed less consumption of reagents[16-23]. The difference lies in that the dot arrays of tissue chip were specimens from hundreds of different tissues and could show the features of morphology and expressions of DNA, RNA or proteins *in situ* associated with clinical endpoints at the same time. And the procedure was less complex and the results were more clinically applicable. Thus TMA is more feasible in the functional researches of gene and protein, especially in researches of gene or protein profiles in different tissues or populations. Therefore TMA has become one of the most

important methods in functional genomic and proteinomic researches in the post-genomic era and, it has been expected to have wide applications in molecular pathology, drug discovery, monitoring of hygiene and environment, as well as national defense researches (Table 1)[24,25].

However, the present technology of TMA is still not satisfactory. On the one hand, the instruments were not very advanced but costly. On the other hand, the present procedure took time and was not convenient to observe and locate the exact sites in donor tissue blocks[8,9,26-32]. The new method to produce tissue microarray with refitted common microscope we presented here has the following advantages. (1) With the precise mechanical control of common microscope, the holing and sampling procedures in the paraffin recipient block and donor block are simpler and more accurate. (2) The punching procedure of holing and sampling needles is controlled by the adjustment of microscope stage or lens regulating screw, which frees us from direct finger operation and avoids needle gliding or trembling. This method is less laborious and easier and more accurate to control the holing and sampling depth. (3) The working place of holing and sampling needles and object lens changes with the rotation of objective holde and thus is easier to replace the needles and more convenient to apply the single-use holing and sampling needles in order to maintain a higher accuracy. (4) With this new method, the sampling sites can be easily and accurately observed and located under a microscope or a steromicroscope and thus spares the efforts of marking the regions to punch on the face of the donor block and without

eyeballing, as is the case with the Beecher's instruments. (5) The whole process of holing, locating and sampling is performed with the same instrument on the same platform and thus spares uses of other platforms and instruments.

As TMA involves a number of related technologies and sciences, including engineering, surface physics and chemistry, pathology, molecular biology and information science, to produce high-quality tissue biochips, consideration should be also taken into the design of arrays, the qualities of holing and sampling needles, sectioning and transferring techniques, staining and other molecular pathological techniques. To improve the density and precision of arrays, the needles should be more minute in diameter and sharper in point. The arrangement of arrays should be in accordance with the research objectives and the computer imaging, and statistical tools should be provided for efficient management of a large amount of data generated from this high-throughput approach[33-35].

Abstract

AIM: This study was designed to compare the levels of v5 and v6 splice variants of CD44 evaluated using ELISA test in the serum of patients with colorectal cancer in different stages of progression of the disease estimated in pT stage according to WHO score, histopathological grade of malignancy and some clinicopathological features.

METHODS: The serum obtained from 114 persons with colorectal adenocarcinomas was examined using ELISA method. pT stage and grade of malignancy of the tumour were examined in formalin fixed and paraffin embedded materials obtained during operation.

RESULTS: Only the level of CD44 v5 in the serum of patients before operation with G2 pT4 tumour was lower than that in other probes and the difference was statistically significant. We did not find any other correlations between the level of v5 and v6 CD44 variants and other evaluated parameters.

CONCLUSION: The level of CD44 v5 and v6 estimated by ELISA test in the serum can not be used as a prognostic factor in colorectal cancer.

INTRODUCTION

Neoplasmal diseases are the second, or according to some authors, the third cause of deaths all over the world just after the cardiovascular and infectious diseases, and just before communication accidents. Colorectal cancers are among other neoplasms on the third place in morbidity and mortality after the breast and lung and bronchus cancers in women and prostate and lung and bronchus cancers in men. According to American National Cancer Institute, 105 500 persons had a colon cancer and 42 000 rectum cancer in 2002 in the United States of America. Colorectal cancer is also the third cause of death among all neoplasmal diseases. It is estimated that over 57 000 persons died in 2003 in the United States due to colon cancer[1]. According to World Health Organization data in 1990, over 437 000 persons died and 783 000 became ill due to colorectal cancer. The incidence of this disease has been rising, and is more frequent in developed countries. The survival rate after radical operative treatment and chemo- or radiotherapy is still unsatisfactory. The 5-year survival after radical treatment was about 60% in the Unites States and Western Europe, whereas it was only about 40% in Eastern Europe[2]. The recurrence of the disease is dependent on the progression of neoplasmal metastases to lymph nodules and distal organs and is the most common cause of death[3-6]. The routine examinations of specimens with the estimation of the pT according to WHO score as well as the histopathological grade of malignancy, clinical evaluation and even the changes in CEA levels in the serum evaluation are still insufficient to determine the precise prognosis about recurrence of the disease and survival rate. This is the reason, why a lot of medical investigations are concerned with understanding these problems and determining the prognostic factors in colorectal cancers, *i.e.* mutations of c-Ki-ras, C-Myc, APC, p53, DCC and other genes, CD44 protein in the tumour tissues and CEA and CA19.9 in the serum[6-14]. The aim of this study was to determine if there were any differences between levels of variant 5 and 6 glycoprotein CD44 according to pT stage and histopathological grade of malignancy as well as some clinical features.

MATERIALS AND METHODS

Patients

One hundred and fourteen patients with colorectal adenocarcinoma were operated at the 2nd Department of General and Gastroenterological Surgery of Medical University of Bialystok, Poland in 1997-2001. There were 68 (59.65%) men and 46 (40.35%) women. The median age was 65 years (range: 32-87 years). The diagnosis was made based on clinical symptoms and endoscopic examination as well as histopathological study of tissue samples. Other types of cancer and polyps were excluded from the investigation. Fifty-nine cases (51.75%) of tumours were localized in the rectum and sigmoid colon and the rest, fifty-five cases (48.25%) were localized in other parts of the large bowel. Twelve tumours were inoperable. All the patients were divided into 6 groups according to the grade of malignancy and pT stage (Table 1, Table 2). The patients had not any preoperative chemo- or radiotherapy. All the patients were monitored after operation. Thirty-one (27.19 %) of the controls died due to the recurrence of the disease (Table 3).

Tissue and serum samples

Tumour tissues were obtained during the operation. They were typically prepared and paraffin embedded sections were examined to estimate pT score and malignancy grade in G1-G3 score. The blood was collected from these patients before (sample A) and 10 days after the operation (sample B). The blood was centrifuged at 4℃ and the serum samples were

stored at -80℃ until examination. The level of v5 and v6 variants of CD44 protein in the serum samples was estimated by ELISA test using kits for SCD44var(v5) and SCD44var(v6) ELISA (Bender MedSystem) according to the manufacturer's protocol. The values of levels obtained in our examination are presented in Table 4.

Statistical analysis

χ^2 Pearson, χ^2 NW, NIR and *U* Mann-Whithney tests were used to analyse the correlation between CD44v5 and CD44v6 expressions before (v5A, v6A) and after the operation (v5B, v6B), and such features as sex, age, location of the tumour in the large bowel (sigmo-rectal or the rest of the colon), the clinical stage according to pT stage and the grade of malignancy as well as the time of survival and the presence of recurrence. Student *t* test was used to analyse correlation between control and tested groups. *P* values less than 0.05 were considered to be statistically significant.

RESULTS

The level of CD44 v5 splice variant in the serum obtained from patients with colorectal adenocarcinoma evaluated by ELISA test before operation was lower in G2 pT4 stage of tumour than those in others probes and the difference was statistically significant. But there were not any other statistically significant correlations with clinicopathological features like sex, age, location of the tumour, pT stage and the grade of malignancy estimated in 3-stage score from G1 to G3. There were not any other differences between levels of that variant before and after operation as well.

The level of CD44 v6 evaluated in the serum obtained from patients did not correlate with any clinical and histopathological features. Also, there was not any statistically significant difference between its levels before and after operation.

The level of both v5 and v6 CD44 variants in the serum did not correlate with the recurrences of cancer and mortality (Table 4).

DISCUSSION

CD44 described at first by Dalchau in 1980 is a molecule which can take part in carcinogenesis and formation of metastases in lymph nodes and distal organs[15]. It is a cell surface transmembrane glycoprotein which occurs in both healthy and neoplasm cells. The gene which codes for CD44 consists of 20 exons, and 10 of them can be combined, so there are a lot of its variants. It can also be modified just after the process of translation. The most common molecule with a molecular weight 85-90 kd is called standard molecule and is the main surface receptor of hyaluronic acid. It also takes an active part in intracellular communication and interactions between the cell and the extracellular matrix. It is responsible for T lymphocyte and natural killer cell activation, aggregation and B and T cell migration. It also induces the tumour necrosis factor and interleukin 1 release. So it is described as a main factor in the formation of metastases, however the precise mechanism of its function is still unknown[16-19]. Examinations of standard CD44 molecule in tumour tissues and in neoplasm lymph nodes showed its higher expression[6,20-23]. The examinations of some isoforms of CD44 in cancer and lymph nodes tissues showed the same results, but the number of examined patients was small[24-26]. Especially v5 and v6 CD44 splice variant expression was higher in tumour tissues and depended on cancer progression[6]. Elevated levels of sCD44v6 in malignant ascites was also described[27]. Some publications about expression of v6 CD44 and v8-10CD44 isoform in the serum of patients with colorectal cancer did not show any correlation with pathological features and metastases[28-30]. The same results of examination concerned with CD44 v5 and v6 were presented in this study. The lack of correlation between expression of v5 and v6 variants of CD44 and clinico-pathological features could depend on the absence of these molecules in the soluble form in the serum.

In conclusion, there is no association between CD44v5 and v6 expression estimated in the serum and any clinico-pathological features in patients with colorectal adenocarcinomas. Due to the short time of observation it is not implicated as a prognostic factor in colorectal cancer and it demands further investigations.

Abstract

AIM: Anaemia caused by acute upper gastrointestinal bleeding is treated with blood transfusion or iron, but patients usually face a two-month recovery period from post-haemorrhage anaemia. This prospective, randomised, open, pilot study was designed to investigate whether recombinant human erythropoietin (Epoetin) therapy accelerate haematocrit increase in the post-bleeding recovery period.

METHODS: We studied hospitalised patients admitted because of acute ulcer bleeding or haemorrhagic gastritis, who had a haematocrit of 27-33% and did not receive blood transfusions. One day after the endoscopic confirmation of cessation of bleeding, they were randomised either to erythropoietin (20 000 IU Epoetin alfa subcutaneously, on days 0, 4 and 6) plus iron (100 mg im, on days 1- 6, (G_1) or iron only (G_2). Haematocrit was measured on days 0, 6, 14, 30, 45, and 60, respectively.

RESULTS: One patient from G_1 and two from G_2 were lost to follow-up. Therefore, 14 and 13 patients from G_1 and G_2 respectively were analysed. Demographic characteristics, serum iron, ferritin, total iron binding capacity, reticulocytes, and haematocrit were not significantly different at entry to the study. Median reticulocyte counts were significantly different between groups on day six (G_1: 4.0, 3.0-6.4 vs G_2: 3.5, 2.1-4.4%, P=0.03) and median haematocrit on day fourteen [G_1: 35.9, 30.7-41.0 vs G_2: 32.5, 29.5-37.0% (median, range), P=0.04].

CONCLUSION: Erythropoietin administration significantly accelerates correction of anemia after acute ulcer bleeding. The haematocrit gain is equivalent to one unit of transfused blood two weeks after the bleeding episode.

INTRODUCTION

Following an episode of acute gastrointestinal bleeding from peptic ulcer disease, patients face a two-month recovery period from post haemorrhage iron deficiency anaemia. If haematocrit is lower than 25%, corresponding to a haemoglobin value of 8 g/dl, patients are usually treated with blood transfusion supplemented with iron replenishment therapy. However, when haematocrit is higher than 30%, it slowly recovers with iron administration alone. During this recovery period patients are unable to work and face health-related reduced quality of life, because of iron deficiency anaemia, at least until haematocrit is increased to more than 35%. Therefore, shortening the recovery phase from post-haemorrhage anaemia is of clinical importance.

Erythropoietin is a glycoprotein hormone, synthesized predominantly in the kidney, that promotes the differentiation of erythroid progenitor cells and therefore it regulates the production of red blood cells. In addition, it stimulates the synthesis of haemoglobin[1]. In the recent years, recombinant human erythropoietin (r-HuEPO, Epoetin Alfa) has become readily available and permitted the clinical investigation and application of this hormone to the treatment of anaemia. Epoetin Alfa has been shown to accelerate erythropoiesis and reduce the requirement for blood transfusion in patients undergoing gynaecologic surgery[2] and those with anaemia because of chronic renal failure[3], inflammatory bowel disease[4], or human immunodeficiency virus infection[5]. The success of Epoetin Alfa in treating anaemia in the post surgical recovery period[6] suggests that it may be of benefit as an adjuvant therapy in treating the post haemorrhage anaemia due to peptic ulcer bleeding. The aim therefore of the present pilot study was to investigate whether adjuvant therapy with erythropoietin could be of benefit to this patient population, by accelerating an increase of the haematocrit during the recovery period from anaemia.

MATERIALS AND METHODS

Patients

Over a two-year period (1998-1999), 30 hospitalised adult patients admitted to our departments because of acute gastrointestinal bleeding from peptic ulcer or haemorrhagic gastritis were invited to participate in this prospective, randomised open pilot study. Patients included in the study fulfilled the following criteria. They did not require blood transfusion for resuscitation. They also had a stable haematocrit value at between 30-33% for men (normal range: 39-49%) and 25-30% for women (normal range: 33-43%) after confirming the cessation of the bleeding episode by endoscopy performed on the third day of hospitalisation. All patients should have a clean-based ulcer or red spot, indicating a low (<3%) rebreeding rate[7]. Exclusion criteria were any known causes of anaemia including haematologic diseases, cancer, gastric surgery, or intention to use non-steroidal anti-inflammatory drugs following hospital discharge. Women of childbearing age, those with uncontrolled hypertension or seizure history and patients with severe chronic diseases were also excluded from the study.

Patients gave written informed consent to the study, after full explanation by the investigators. The study protocol was approved by our institution review board on human studies.

Methods

Study design Patients eligible to enter the study had haematocrit determinations on the second and third day of hospitalisation. If haematocrit had not changed by more than 1%, they were randomised according to a computer-generated randomisation list to Epoetin plus iron or iron therapy alone. Neither patients nor investigators were blinded to the therapy.

All patients were treated with intramuscular injections of 332 mg/2 ml ferric hydroxide polymaltose complex, corresponding to 100 mg of Fe^{3+}, (Ferrum Hausmann®, Vifor, St. Gallen, Switzerland). Injections were given on days one to six. The total quantity of injected Fe^{3+} was 600 mg. Those randomised into the Epoetin group received adjuvant therapy with 20 000 IU of recombinant human erythropoietin (Epoetin Alfa, Eprex®, Cilag, Switzerland) given subcutaneously on days zero, four and six. The total quantity of Epoetin given was 60 000 IU. Patients were also treated with 20 mg of omeprazole twice daily, iv, for peptic ulcer bleeding over the initial 3-5 days of hospitalisation. They then resumed a normal diet and received 20 mg of omeprazole/day, orally, for one month. In those patients who were *H pylori* positive, eradication therapy was scheduled after completing follow-up, *i.e.*, two months after the bleeding episode.

Haematocrit and reticulocytes (normal value: 0.5-1.5%) were measured on days 0, 6, 14, 30, 45 and 60, respectively. Serum iron (normal values: 50-160 μg/dl), ferritin (normal values: 12-300 μg/dl) and total iron binding capacity (TIBC) (normal values: 250-400 μg/dl) were measured on days 0, 14, 30 and 45 from randomisation.

Statistical analysis

Data were analysed by the statistical packages SPSS 10.0.0 (SPSS Inc., Chicago, Illinois, USA) and Statgraphics Plus 4.0 (Manugistics Inc., Statistical Graphics Corp., Rockville, USA). Numerical data were assessed by the non-parametric Mann-Whitney two-sided *U*-test and the Kruskal-Wallis *t* test used for two- and multiple-sample comparison analysis, respectively.

Results in the text and table are presented as median with ranges. Data in figures are presented as box-and-whisker plots. The box includes 50% of the results falling between 25th and 75th percentile (interquartile distance). The median value is represented as a horizontal line inside the box. Outliers, *i.e.*, points more than 1.5 times the interquartile range from the end of the box are shown as open circles. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Over the two-year study period, 30 adults fulfilling the inclusion criteria were randomised into the two treatment arms. Demographic and laboratory characteristics were not significantly different between the two groups at entry to the study (Table 1). Three patients were lost to follow up. Therefore, 14 patients in the Epoetin-iron treatment group and 13 patients in the iron treatment group were available for analysis.

Serum iron levels significantly increased over the study period within each group (Figure 1), but they were not significantly different between treatment groups anytime during the study period (Mann-Whitney *U* test>62, *P*>0.67). All the patients had normal serum ferritin levels during the study period. Ferritin did not significantly change over time either in the Epoetin-iron treatment group (Kruskal-Wallis T=0.07, *P*=0.1) or the iron treatment group (Kruskal-Wallis T=7.47, *P*=0.06). There was not any significant difference of

ferritin levels between treatment groups anytime during the study (Mann-Whitney *U* test>46.5, *P*>0.14). Similar results to ferritin were obtained for TIBC, which did not significantly change over time either within the Epoetin-iron (Kruskal-Wallis T=2.87, *P*=0.41) or the iron treatment group (Kruskal-Wallis T=3.50, *P*=0.32). In addition, there was not any significant difference of TIBC between treatment groups anytime during the study (Mann-Whitney *U* test>58.5, *P*>0.22).

Table 1 Demographic and laboratory data (median, range) of patients included in each treatment arm

	Epoetin+Iron (G$_1$, n=15)	Iron (G$_2$, n=15)	[a]*P*-value
Male/female	10/ 5	10/ 5	
Age (years)	62, 36-70	58, 35-71	0.54

[a]Mann-Whitney two-sided *U*-test, [b]at entry to the study.

Figure 1 Box-and-whisker plots showing a progressive increase of serum iron levels over the recovery period from peptic ulcer bleeding of patients treated with either Epoetin alfa plus iron (G$_1$, dashed whiskers) or iron only (G$_2$, open whiskers). There were not any statistically significant differences between treatment groups anytime during the study (two-tailed Mann-Whitney *U* test>62, *P*>0.67).

Figure 2 Box-and-whisker plots showing percent reticulocyte counts over the recovery period from peptic ulcer bleeding of patients treated with Epoetin alfa plus iron (G$_1$, dashed whiskers) and those treated with iron only (G$_2$, open whiskers). On day six patients in G$_1$ had significantly different (higher) median percent reticulocyte counts as compared with G$_2$ (two-tailed Mann-Whitney *U* test=46.5, *P*=0.03).

There was a brisk increase of reticulocyte counts in both groups on the sixth day of the study. This was the only date when there was a significant difference between the treatment groups in favour of the Epoetin-iron group (median: 4.0% *versus* 3.5%,) (Mann-Whitney U test=46.5, $P<0.03$) (Figure 2). Following the sixth day of the study, the reticulocyte counts were progressively decreased in both groups. Haematocrit increased over the study period within each group (Figure 3), but it was significantly different between treatment groups (higher in the Epoetin-iron group) only on the fourteenth day of the study (median: 35.85% *versus* 32.5%, range: 30, 7-41 *versus* 29, 5-37) (Mann-Whitney U test=49, $P=0.041$) (Figure 3). Epoetin therapy was not associated with any side effects in our study.

Figure 3 Box-and-whisker plots showing haematocrit values over the recovery period from peptic ulcer bleeding of patients treated with Epoetin alfa plus iron (G_1, dashed whiskers) and those treated with iron only (G_2, open whiskers). On day fourteen patients in G_1 had significantly different (higher) haematocrit values as compared with G_2 (two-tailed Mann-Whitney U test=49.0, $P=0.041$).

DISCUSSION

Acute upper gastrointestinal bleeding is a major cause of hospitalisation. Data from the USA and UK indicate that the overall incidence of acute upper gastrointestinal bleeding was about 100 hospital admissions per 100 000 adult population per year[8,9]. In about 50% of these patients, the causes of bleeding were peptic ulcer or erosive-haemorrhagic gastritis. There are no guidelines dictating when patients with acute peptic ulcer bleeding should undergo transfusion. However, common sense dictates that stable patients, *i.e.*, those who did not continue to bleed and had a low risk of rebleeding[10], as confirmed by emergency endoscopy, or a haematocrit higher than 25% should avoid blood transfusion[11]. Hui and co-authors have recently shown that patients under the age of 60 admitted because of bleeding duodenal ulcer, having no stigmata of haemorrhage on emergency endoscopy and no concurrent serious medical illness might be discharged within 24 hours of endoscopy if haematocrit was above 30% and there were no clinical signs of circulatory instability[12]. One might therefore, argue that our patients were candidates for early discharge. However, the prolongation of hospitalization in our study was only due to study practicalities, since the Epoetin-iron therapy could be safely administered on an outpatient basis.

Avoiding blood transfusion is wise in this group of patients. There is a worldwide concern of blood born transmission of infectious agents, and the risk of significant reduction in the blood donor pool with the planned introduction of testing for prior disease. The risk of infection per blood unit transfused was estimated by mathematical models to 1:676 000 for HIV, 1:103 000 for HCV and 1:63 000 for HBV infection[13,14]. Transmission of hepatitis A or G virus was rare[14] and occurred primarily in the window period[15]. The most common infectious agents transmitted were cytomegalovirus[16] and *Yersinia enterocolitica*[17]. The immunologic risks ranged from mild febrile nonhaemolytic reactions to fatal haemolytic ones[18]. In addition, transfusion-associated graft-versus-host disease might be seen in immunocompetent patients[18, 13].

Hospitalised patients for acute upper gastrointestinal bleeding may avoid blood transfusions, but following their discharge from the hospital they face a two-month recovery period from acute post haemorrhage anaemia. Symptoms experienced by anaemic patients included cold skin, dizziness, palpitations, or depression, which substantially affect patients' quality of life. Identifying patients most likely to benefit from blood conservation is not always easy. There was a recent debate about the threshold for transfusion at which the benefits outweigh the risks[18]. No doubt even elderly patients might tolerate haematocrit of about 20-22%, especially those with megaloblastic anaemia. However, patients having haematocrit of about 30% at discharge might feel unable to work until haematocrit recovers to about 35%. It is therefore of clinical importance to improve the functional status of the anaemic patients by shortening the recovery period from iron deficiency anaemia.

Recombinant human erythropoietin (Epoetin Alfa) has been shown to accelerate erythropoiesis in certain anaemia states[3-5,18]. It has also been used perioperatively in gynaecologic surgery[2,6] and in a few cases of Jehovah' s Witness hospitalised for acute gastrointestinal bleeding[20-22,25]. Epoetin Alfa may therefore allow a lower value of haematocrit to be accepted, above which one would not transfuse. Our data agree with published studies showing an increase of haematocrit in the erythropoietin treated anaemic patients between one and two weeks post treatment[2,6,23,24]. They also showed that patients with post haemorrhage anaemia treated with erythropoietin plus iron had a higher median haematocrit (35.9%) two weeks after the bleeding episode compared with controls treated with iron only (32.5%). This gain of 3.4% of haematocrit corresponds to one unit of transfused blood.

We used an adequate iron dose to replenish iron stores, as it was shown by normal ferritin and serum iron levels in all patients throughout the two-month study period. This is essential for patients treated with recombinant human erythropoietin, because it stimulates erythropoiesis and may quickly exhaust iron stores. We selected the intramuscular iron formulation to avoid dark-stained stools that might be mistaken for recurrence of bleeding. However, since oral iron is preferred to intramuscular injections, further studies are needed to investigate whether oral iron therapy may have the same beneficial result simplifying the therapeutic regime of iron-Epoetin, and avoiding possible side effects of iron injections.

Various doses of Epoetin have been used to stimulate erythropoiesis ranging from 50 to 600 IU/kg. In the study of Rutherford *et al*[24] higher doses of Epoetin were associated with quicker stimulation of erythropoiesis, indicated by a significant increase of haematocrit by the sixth day. Our patients were treated with a lower dose of Epoetin (300 IU/kg), which may explain why they had a later response (day 14).

Our pilot study has demonstrated that patients who have been treated with Epoetin Alfa in addition to iron have accelerated response in terms of erythropoiesis. However, Epoetin is an expensive drug, the cost per treatment was 2.5 Euro for iron and 533.5 Euro for the Epoetin regime in our study. A larger study with a different design should address the secondary end-points of symptom scores and quality of life changes and also the socio-economic consequences like the time lost from work and the time of resumption of activities. The usefulness of Epoetin as a blood conserving adjuvant therapy should also be tested in the high-risk subgroup of

haemodynamically unstable patients who need transfusions. This has been suggested by case reports of severe GI bleeding in Jehovah' s Witnesses who refused blood transfusions[20,21,25].

Abstract

AIM: To determine the mutational characterization of P-type ATP7B gene and to explore the correlation of ATP7B genotype to phenotype in Chinese patients with Wilson disease (WD).

METHODS: Seventy-five patients with WD from 72 no-kinship families, 44 males and 31 females, were enrolled in this study. The age of onset ranged from 4 to 39 years, ≤18 years in 72 patients. Some exons of ATP7B gene mutations were analyzed in patients with WD by using biochemical methods, polymerase chain reaction-single strand configuration polymorphism (PCR-SSCP) and DNA sequence analysis. A total of 778 coding regions were identified with restriction enzyme Msp I. The activity of Cu-ATPase was assessed by measuring inorganic phosphorus.

RESULTS: Sixty-six of 75 patients (88%) had with hepatic manifestations, 39 of them had only hepatic manifestations, 27 patients had hepatic and neurological manifestations or other symptoms at the same time (16 patients had associated neurological manifestation, 3 patients had osteopathy, 8 patients had other symptoms). Eight of the 75 patients (10.7%) had only neurological symptoms, one patient (5 years old) had no symptom. Twelve changing patterns were detected in ATP7B gene by DNA sequencing, including seven mutations (R778L, C656X, G943D, V1140A, V1106I V1216M and 1384del17), six polymorphisms (IVS4-5t/c, A2495G, C2310G, IVS18+6c/t and IVS20+5a/g). R778L occurred in 49/66 patients (74%) with hepatic manifestations, homozygosis of R778L in 16 patients, heterozygosity of R778L in 33 patients. V1106I mutation of ATP7B gene occurred in 2 patients with delaying onset of clinical symptoms. Cu-ATPase activity of three patients with known mutations (R778L/ V1106I/A2495G, R778L/V1216M and R778L/R778L) were determined, and the activity of Cu-ATPase was decreased by 44.55%, 88.23% and 69.49% respectively.

CONCLUSION: 1384del17bp is a novel mutation found in

WD patients. R778L is the most common mutation of ATP7B gene. There is a correlation between R778L and hepatic manifestations in WD patient.

INTRODUCTION

Wilson disease (WD), or hepatolenticular degeneration, is an autosomal recessive disorder of copper metabolism caused by ATP7B gene mutation. The clinical manifestations of copper accumulation produced by enzyme deficiency usually presented after birth, but rarely occurred before 5 years old. Patients with WD most often present with either progressive liver degenration or neurologic symptoms, or both. Three major clinical patterns of live disease in WD are hepatic cirrhosis, chronic active hepatitis and fulminant hepatic failure. Neurological manifestations are bradykinesia, rigidity, tremor and dyskinesia, *etc*. Copper-transporting P-type ATP7B gene has been identified as a defective gene in WD. The WD locus (ATP7B, OMIM#277900), consisting of 21 exons, has been isolated by using YAC mapping on 13q14.3[1]. Mutation screening in WD patients has led to the detection of at least 200 disease-specific mutations (HGMD). The published data suggest that some mutations appear to be population specific, while others are common to many populations. Arg778Leu has been identified as the most common mutation in the Asian population, accounting for 28-44% of WD chromosomes. The codon H1069Q mutation has been reported to have a high allele frequency in the eastern and northern European populations. This study was to investigate the mutational characterization of P-type ATP7B gene and to explore the correlation between genotype and phenotype in Chinese patients with WD.

MATERIALS AND METHODS

Subject

Seventy-five patients with WD from 72 no-kinship families, 44 males and 31 females, were enrolled in this study. All WD patients were from the Neurological Clinic in Xinhua Hospital and Shanghai Children' s Medical Center, Shanghai Second medical University. The age at onset of symptoms was 4 to 39 years, ≤18 years in 72 patients. The diagnosis of WD was confirmed by serum ceruloplasmin (or cupper oxides activity), urinary copper of 24 h, liver and/or brain imaging features (CT or MRI).

Polymerase chain reaction (PCR)

DNA was isolated from peripheral blood. Some exons (3, 5, 7, 8, 10, 12, 15, 16, 17, 18 and 19) were amplified by PCR with the primers previously reported[2]. Reactions were carried out in 50 μl [H_2O 33 μl, buffer (10×) 5 μl, dNPT (10 mmol/L)

4 µl, primer (12.5 µmol/L) 4 µl, Taq DNA polymerase 2 units]. Amplification was performed 35 cycles, 94℃ for 40 s, each cycle was at 58-65℃ for 1min, at 72℃ for 1 min, degeneration at 94℃ for 5 min and a final extension at 72℃ for 10 min.

Single strand configuration polymorphism (PCR-SSCP) and sequencing

Five µl of PCR product and equivalence denaturing solution were degenerated at 95℃ for 10 min, then they were placed directly on ice. Six µl was added into a gel, using the auto-electrophoresis system (Pharmacia Biotech). Exons exhibiting an irregular shift by SSCP were subjected to direct sequencing for mutation identification. Before direct sequencing, PCR products were purified from agarose gel, using the Quike kit. Direct sequencing was performed using the ABI PRISM™ 377 DNA sequencer (PE Applied Bisytems).

Restriction-enzyme analysis

The CGG to CTG transition at exon 8 splice acceptor site was recognized by Msp I restriction-endonuclease. In normal exon 8, PCR product (296 bp) was amplified into two products of 256 bp and 40 bp. R778L would not be recognized, and PCR product (296 bp) was not digested.

Cu-ATPase activity

Ten ml peripheral venous blood was put in a heparinization bottle, lymphocytes were collected, and then split and membrane was collected[3]. Cu-ATPase was assessed by a kit made in Nanjing Jiancheng Biotechnology Company, and protein was quantified by UV/spectrophotometer (PE).

RESULTS

Clinical features

Sixty-six of 75 patients (88%) had hepatic manifestations, 39 of them had only hepatic manifestations (Table 1), and 27 patients of them had hepatic manifestations and other symptoms at the same time. Among the 27 patients who had both hepatic and other symptoms, 16 patients were associated with neurological manifestations, 3 patients with musculoskeleton symptoms, 8 patients with other symptoms (hemolytic anemia

or renal lesions). Eight of the 75 patients had only neurological symptoms, one patient had no symptom identified by family screening and microsatellite DNA analysis[4].

Table 1 Clinical manifestations of WD patients

Clinical manifestation	Patient No. (%)
Cirrhosis, chronic active hepatitis	66(88)
Enlargement	25(33)
Rigidity, tremor, ataxia, dyskinesia, dysarthria,	24(32)
Behavioral disturbances, psychosis	4(5)
K-F rings	49(65)
Hemolysis, petechia	6(8)
Hematuria, proteinuria	6(8)
Amenorrhea, menoxenia, hairiness	5(7)
Degenerative joint disease	3(4)

Analysis of mutated genes

Twelve changing patterns were detected in ATP7B gene by DNA sequencing, including five missense mutations (R778L, G943D, C656X,V1140A, V1106I and V1216M), one deletion (1384del17) (Figures 1 and 2) and six polymorphisms (IVS4-5t/c, 2495A>G, C2310G, IVS18+6c/t and IVS20+5a/g) (Table 2). With restriction-enzyme analysis and sequencing in exon 8, R778L and L/L770 were identified in 54/75 WD patients, 16 patients showed homozygous, and 38 patients heterozygous.

Correlation between genotype and phenotype

In 66 patients with hepatic manifestations, 49 patients (74%) carried R778L (arginine to leucine) mutation and L/L770 polymorphism (2310 site C to G). V1106I mutation occurred in two WD patients with later onset of illness and had presenting neurological manifestations when they were 39 and 48 years old respectively.

Cu-ATPase activity

Cu-ATPase activity was determined in 3 patients with known mutations (R778L/V1106I, R778L/V1216M and R778L/R778L), activity of cu-ATPase was decreased by 44.55%, 88.23% and 69.49% respectively, compared with normal value.

Figure 1 Family analysis of patient 038. A: Patients father carrying 1384Del17bp (ATP7B genes position 1 384-1 400 bp deletion). B: Msp I digested PCR product of ATP7B gene exon 8 of patients mother shows that she was R778L carrier. C and D: Patients genotypes are R778L/1384Del17 bp, 1384Del17 bp from his father and R778L from his mother.

21	IVS21+3		4398+3 t→g

DISCUSSION

Wilson disease is an autosomal recessive disorder in copper transport. Disturbance of copper metabolism leads to accumulation of copper resulting in tissue damage, principally in the liver and brain. The disorder manifests as progressive liver degeneration, which is one of the important causes of chronic liver disease in childhood, although it is rare. Without early intervention, WD has a higher mortality and morbidity. ATP7B gene for WD is distributed worldwide, and has been demonstrated in almost all races. Epidemiological survey indicated that the prevalence of the disease was 1/30 000 live births, with a corresponding gene frequency of 0.3-0.7%, and a heterozygote carrier frequency of 1%[5]. The prevalence of the disease is high in China.

There was a correlation between the age of onset and initial manifestations. Initial clinical feature was diverse. The age of onset ranged from 6 years to 15 years old in most patients with WD. In this group of patients, 72 patients were ≤ 18 years old, accounting for 96%, and 61 patients (81%) were ≤12 years old. In a large series of patients, the initial clinical manifestations were found to be 42% in liver, 34% in neurological system, 10% in psychiatric system, 12% in hematological system, 1% in kidney. Less commonly, patients had skeletal or other symptoms[5]. In our patients, the initial clinical manifestations were found to 52% in liver (Cirrhosis, chronic active hepatitis), 21% in neurological system, 33% in saliva enlargement of spleen, 8% in kidney. Skeletal symptoms cccirred in 3 patients (4%).The subjects in this study were most pediatric patients, it might be responsible for higher percentage of liver impairments in this study, compared with that in other reports.

To date, at least 200 different mutations have been identified in WD chromosomes. Some mutations appear to be population specific. H1069Q has been identified as the most common mutation in the eastern and northern European populations[6-10]. Caca *et al* reported that an allele frequency of H1069Q was 63% in 82 WD patients, homozygous in 32 patients (39%), heterozygous in 39 patients (48%)[11]. The H1069Q mutation was found in 27/42 WD patients (64.3%) from 39 Hungarian families, homozygous in 9, heterozygous in 18[12]. The R778L has been reported to have a high allele frequency in the Oriental populations, such as Japanese, Korean, and Chinese. The allele frequency of R778L was 37.9% in Korean patients with WD[13,14], 27% in Japanese WD[15-19] and 28-44% in Chinese[20-30]. In this study all the 75 WD patients were Han people. The R778L mutation was identified in 68/144 alleles with an allele frequency of 45.6%, in 54 WD patients (72%), homozygous in 16 patients, heterozygous in 38 patients. The average age of the patients was 9.5 years in homozygous, 10.7 years in heterozygous, there was no significant difference

between two groups. In our patients, we did not detect the H1069Q mutation, the most common WD mutation found in the European population. Our data showed that patients had clinical manifestations at preschool age or school age, liver impairment was the most common clinical manifestation, and allele frequency of the R778L was higher in patients with liver impairment. It is suggested that there might be a correlation between R778L mutation and liver impairment at initial evaluation.

The V1106I mutation was identified in two WD patients with late onset of phenotypes. One patient had neurological manifestations (tremor, and dysarthria) at the age of 39, progressing slowly. She was diagnosed as WD based on the decreased activity of Cu-ATPase and serum ceruloplasmin, Kayser-Fleischer rings, and increased urinary copper excretion. Treatment with oral D- penicillamine initiated at 9 months after diagnosis was made, showed clinical improvement. The genotype of the patient (014) was V1140A/V1106I. The other patient (026) having a past history of chronic hepatitis had psychiatric symptoms at the age of 48 years. Tremor gradually appeared and became progressively worse. After oral D- penicillamine clinical symptoms were remitted. Her genotype was R778L/V1106I. The other mutation did not detected by sequencing in exons 1 to 21 in these two patients. The results of family analysis of patient (038) with 1384De117bp/R778l genotype demonstrated that 1384De117bp was originated paternally and R778L maternally. R778L/V1216M (033) was found in one patient. G to A mutation at position 3646 occurred in exon 17 of ATP7B. The results demonstrated that the activity of Cu-ATPase was significantly decreased in lymphocytic membrane by 44.55% in patients with R778L/V1106I genotype, 88.23% in patients with R778L/V1216M genotype, 69.49% in patients with R778L/R778L (034) genotype. It can be presumed that the decreased degree of Cu-ATPase is correlated with the severity of clinical manifestations and genotypes.

Abstract

AIM: Stress induces gastric ulceration in human and experimental animals. People tend to smoke more cigarettes when under stress. Nitric oxide (NO) and nicotine have opposing effects on gastric integrity. The present study examined the possible therapeutic benefit of NO in nicotine-treated rats with stress-induced gastric ulceration.

METHODS: Rats drank a nicotine solution while control rats drank tap water for 20 days. The alkoloid was then replaced by water with or without supplementation of isosorbide dinitrate (NO donor) for an additional 10 days. Isosorbide dinitrate was given twice shortly before experiments (acute) or three times daily by oral gavages for 10 days after the rats stopped drinking nicotine solution. At the end of experiments, ulcer index, gastric adhesion mucus content and MPO activity were measured and analysed.

RESULTS: Nicotine treatment decreased gastric mucus content and intensified stress-induced gastric ulcer. A higher ulcer index persisted even after the rats stopped drinking nicotine solution for 10 days. Acute NO donor showed no benefit on both mucus and ulcer index in nicotine treatment or/and stress condition. Chronic NO donor treatment reversed the worsening action of nicotine in stomach. Stress increased gastric mucosal myeloperoxidase (MPO) activity, which was antagonized by chronic NO treatment. However, nicotine was unlikely to change mucosal MPO activity.

CONCLUSION: The intensifying action of nicotine on stress-induced gastric ulceration persists for 10 days after cessation. Nicotine treatment significantly decreases gastric mucus content that can be restored by chronic NO donor treatment. The present study suggests that NO antagonizes the ulcerogenic action of nicotine through a cytoprotective way.

INTRODUCTION

Stress is well associated with cigarette smoking. It has been reported that cigarettes help alleviate the feelings of stress which may underlie the tendency to smoke more cigarettes when under stress. However, smoking also further enhances stress levels because stress level has been shown to decline after smoking cessation[1]. Hence, the vicious cycle of stress and smoking perpetuates. Clinical study and experiments have demonstrated that stress is a risk factor for gastrointestinal tract diseases[2-5] and peptic ulcer disease is more common in smokers than in non-smokers. Although Western and traditional Chinese medicine[6] have demonstrated efficacy in the treatment of peptic ulcer disease, peptic ulcers in smokers heal slowly and relapse frequently[7].

Since nicotine accumulates in gastric juice, nicotine is thought to be the major culprit in cigarette smoking causing the detrimental effects of smoking in gastric ulceration[7]. Nicotine also stimulates the central nervous system and chronic nicotine intake intensifies stress-induced gastric mucosal damages in rats[8,9]. The interaction between stress and nicotine has been reported to work synergistically to intensify gastric ulceration[10,11]. Smoking cessation could reduce the incidence and recurrence rate of peptic ulcer but only in people who were light smokers. However, in heavy smokers, smoking cessation did not reduce the incidence and recurrence rate of peptic ulcer. To treat peptic ulcer disease in these former smokers, more studies are needed to provide insights in to the restoration of the normal gastric integrity and the prevention of disease recurrence. Since gastric mucosal prostaglandin, nitric oxide (NO) and gastric adhesion mucus content[12] could contribute significantly to maintaining normal gastric integrity, *i.e.,* cytoprotection, while neutrophil infiltration had an ulcerogenic effect[13], these important parameters were, therefore, the focus of the present study.

In support of the role of prostaglandin, aspirin which inhibits prostaglandin synthesis has been shown to induce gastric mucosal damage. However, in the presence of an NO releasing compound, the ulcerogenic action of aspirin is abolished[14]. In animal experiments, chronic nicotine treatment has been shown to markedly reduce gastric mucus content[15], while other studies demonstrated that NO enhanced gastric mucus production[16,17]. Inhibition of NO synthesis intensifies, while L-arginine (an NO substrate) reduces gastric ulceration in rats induced by cold-restraint stress[18]. These studies suggest that NO may provide a therapeutic benefit to reverse the detrimental effects of nicotine, especially in heavy smokers. In this study, we used the cold-restraint stress-induced gastric ulceration model to evaluate the role of NO in restoring normal gastric integrity after chronic nicotine insult.

MATERIALS AND METHODS

General

In present study, we used male Sprague-Dawley rats (weighing 155-180 g). The animals were fed with a conventional pellet diet. Three rats were housed per cage and kept at room temperature ($22\pm1\ ^\circ\mathrm{C}$) with humidity of 65-70%. The rats were randomly assigned to tap water control group and nicotine group. In the nicotine group, the animals drank a nicotine solution [tap water containing nicotine bitartrate (50 µg/ml)

(Sigma)] for 20 days. NO donor was given to some nicotine-treated rats twice at 1 hour and at 10 min before experimentation. In the second experiment, rats drank the nicotine solution for 20 days and then the solution was replaced by tap water. NO donor was administered to some nicotine-treated rats for an additional 10 days. Solid food was withdrawn 48 hours before the start of experimentation. The animals were kept in fasting cages and allowed to drink a solution containing 8% sucrose in 0.2% NaCl (w/v). In the nicotine-treated group, rats were given the 8% sucrose/0.2% NaCl solution containing the same concentration of nicotine.

NO donor

Isosorbide dinitrite (Sigma) was used as an NO donor[19] and administered at a dose of 10 mg/kg body weight. Isosorbide was freshly prepared. For acute treatment, the rats were given isosorbide by oral gavages twice at 1 hour and at 10 minutes before experimentation. In chronic experiments, NO donor was administered by oral gavages every 5 hours, three times daily for 10 days simultaneously after quitting nicotine.

Cold-restraint stress induced gastric ulcer

Rats were starved for 48 hours, and the drinking solution was removed 1 hour before starting experiments. For cold-restraint stress, the rats were restrained in individual close-fitting tubular wire-mesh cages at 4℃[12] and the no stress control group was kept in starvation cages at 22℃. At the end of 2 hours, all the rats were sacrificed.

Gastric ulcer index

An observer who was unaware of the treatment regimen determined the severity of gastric mucosal lesions. The lesions were examined under an illuminated magnifier (3X). Lesion size (mm) was measured along its greatest length and in the case of patches, five such lesions were considered the equivalent of a 1 mm ulcer. The sum of the lesion lengths in each group of animals was divided by its number and expressed as the mean gastric hemorrhagic lesion index[8].

Gastric adhesion mucus content

Gastric adhesion mucus content was determined by the Alcian blue method[12,20]. The stomachs were removed, opened, and immediately soaked in Alcian blue solution for 2 hours. The Alcian blue dye complex attached to the gastric wall mucus and was separated from gastric wall by vortexing and subsequent extracting with magnesium chloride. The extracted solution was quantitated spectrophotometrically at 598 nm. The mucus content was correlated with the amount of Alcian blue per gram wet weight of glandular tissue.

Gastric mucosal myeloperoxidase activity (MPO)

MPO activity was measured as previously described[21-24]. Firstly, the gastric mucosa was scraped after examination of ulcer index. The scrapings were then homogenized in ice-cold phosphate buffer. Hexadecyltrimethyl ammonium bromide (0.5% HTAB) (Sigma) was added to this phosphate buffer (50 mM, pH 6.0) to release MPO from the primary granules of neutrophils. Homogenates were then centrifuged and the supernatants were aspirated and mixed with *o*-dianisidine hydrogen peroxide reagent (Aldrich Chemical Co.) and absorbance at 460 nm was measured with a spectrophotometer. One unit of MPO activity was defined as that degrading 1 μmol of peroxide per minute at 25℃ per g protein of gastric mucosa.

Statistics

All values in present study indicated mean±SD and were analyzed using the two-tailed Student's *t* test. Differences between groups exposed to the same experimental conditions were analysed by the χ^2 test. The *P* value less than 5% was considered as statistically significant.

RESULTS

Effects of nicotine and acute NO treatment on stress-induced gastric ulceration

As summarized in Table 1A, only petechiae were found in the stomach of animals in the non-stressed control group and the mean ulcer index were unaffected by tap water, nicotine or acute NO donor treatments. Cold-restraint stress induced haemorrhagic ulcers in the glandular mucosa with a 100% incidence as indicated by the mean ulcer index in all stressed animals, whether given tap water, nicotine with or without NO donor (Table 1B). Treatment with nicotine for 20 days intensified stress-induced gastric ulceration significantly but had no effect on non-stressed group. Acute NO administration twice shortly before cold-restraint stress in nicotine-treated animals failed to reduce the ulcerogenic effect of nicotine (Table 1B).

Interestingly, nicotine treatment alone in the non-stressed group significantly reduced the gastric adhesion mucus content as compared to tap water control group, while acute NO treatment failed to reverse the effect of nicotine (Table 1A). When animals were subjected to stress, the adhesion mucus content was reduced to 50% of that of non-stressed group. Nicotine treatment further reduced the adhesion mucus content in stressed animals and acute NO treatment did not reverse the effects of nicotine (Table 1B).

Table 1 Effects of nicotine and acute nitric oxide treatment on gastric ulceration and adhesion mucus content in rats

Experimental group	No. of rats with lesions	Ulcer index (mm)	Adhesion mucus content (μg/g wet glandular tissue)
A. No stress (unrestrained at 22℃ for 2 hours)			
Tap water	2 (7)	0.04±0.03	382±38
Nicotine alone	3 (8)	0.05±0.03	283±27[a]
Nicotine + NO (acute)	2 (8)	0.06±0.04	276±28[a]
B. Stress (restrained at 4℃ for 2 hours)			
Tap water	8 (8)[c]	6.0±0.7	200±17[b]
Nicotine alone	8 (8)[c]	19.0±1.7[ad]	152±14[ab]
Nicotine+ NO (acute)	7 (7)[c]	17.8±1.7[ad]	143±15[ab]

Values are mean±SD. Number of rats in each group is shown in parentheses. Lesions: Only petechiae in stomach were seen in non-stressed condition. Both petechiae and haemorrhagic ulcer in stomach were observed in stressed condition. Tap water: Rats drank water as control. Nicotine alone: Rats drank nicotine water (50 μg/ml) for 20 days. Nicotine + NO (acute): Rats drank nicotine water (50 μg/ml) for 20 days. Rats were given NO donor 60 min and 10 min twice by oral gavages before stress. [a]*P*<0.05 when compared to its own tap water control in A or B. [b]*P*<0.05, [c]*P*<0.01, [d]*P*<0.001 when compared to the corresponding control in A.

Effects of nicotine and chronic NO treatment on stress-induced gastric ulceration

To mimic the early effects of quitting smoking, animals were given nicotine solution for 20 days and nicotine was replaced by tap water for an additional 10 days and this treatment group was designated as quit nicotine. In the absence of cold-restraint stress, only petechiae but no ulcers were detected in the stomach in all groups: tap water control, quit nicotine cessation with or without chronic NO treatment (Table 2A). Interestingly, the adhesion mucus content was reduced even 10 days after nicotine cessation and chronic NO treatment for 10 days

restored the adherent mucus content to that of tap water control group (Table 2A). Hence, the damaging effect of nicotine on adhesion mucus content persisted even after nicotine cessation but could be reversed by chronic NO treatment.

As shown in Table 2B, cold-restraint stress induced haemorrhagic ulcers in the glandular mucosa in all treatment groups: tap water, quit nicotine with or without chronic NO treatment. The effects of nicotine persisted even after nicotine cessation as indicated by the increased gastric ulcer index in the quit nicotine group as compared to the tap water control group. Consistent with the protective effect of chronic NO treatment in restoring adhesion mucus content in non-stressed animals (Table 2A), the mean ulcer index induced by stress was reduced by NO treatment after nicotine cessation to the level of the tap water control group (Table 2B). In addition, chronic NO treatment after nicotine cessation in stressed animals also restored the mucus content to that of the tap water control group (Table 2B).

Table 2 Changes of ulcer index and adhesion mucus content after quit nicotine intake alone or with chronic nitric oxide donor (NO) treatment

Experimental group	No. of rats with lesions	Ulcer index (mm)	Adhesion mucus content (μg/g wet glandular tissue)
A. No stress (unrestrained at 22℃ for 2 hours)			
Tap water	2 (7)	0.03±0.02	391±39
Quit nicotine	3 (8)	0.04±0.02	278±29[a]
Quit nicotine+NO (chronic)	2 (7)	0.04±0.03	386±37
B. Stress (restrained at 4℃ for 2 hours)			
Tap water	8 (8)[c]	6.2±0.7[d]	190±18[d]
Quit nicotine	8 (8)[c]	9.0±0.9[ad]	142±16[c]
Quit nicotine+ NO (chronic)	7 (7)[b]	5.8±0.8[d]	210±19[d]

Values are mean±SD. Number of rats in each group is shown in parentheses. Lesions: Only petechiae in stomach were seen with non-stressed condition. Both petechiae and haemorrhagic ulcer in stomach were observed in stressed condition. Tap water: Rats drank water as control. Quit nicotine: Rats drank nicotine (50 μg/ml) for 20 days, then, nicotine was replaced by water for another 10 days. Quit nicotine + NO (chronic): Rats drank nicotine (50 μg/ml) for 20 days, then, nicotine was replaced by water, and rats were given NO donor three times daily by oral gavages for 10 days before experiment. [a]$P<0.05$ when compared to its own tap water control in A or B. [b]$P<0.05$, [c]$P<0.01$, [d]$P<0.001$ when compared to the corresponding control in A.

Effects of nicotine and NO on gastric mucosal MPO activity

Since gastric ulcer formation was associated with MPO activity, we next measured gastric MPO activity. As shown in Table 3, the gastric mucosal MPO activity in non-stressed tap water control group was used as a baseline for comparison with other treatment groups. Cold-restraint stress alone induced MPO activity significantly. Although nicotine treatment intensified stress-induced gastric ulceration (Table 1B), the MPO activity was not further increased by nicotine treatment in stressed animals and was slightly but not significantly reduced by acute NO treatment (Table 3). After nicotine cessation, the higher MPO activity was maintained in stressed animals but was significantly suppressed by chronic NO treatment.

DISCUSSION

Gastric ulceration is resulted from an imbalance of gastric defensive and aggressive factors. The adherent mucus layer could provide a defensive barrier against self-digestion by gastric acid and pepsin[25,26]. In a water immersion restraint stress model, gastric ulcer formation was associated with MPO activity[13]. Because MPO is mainly produced by neutrophils, MPO activity is considered as an index for the evaluation of neutrophil infiltration[13]. Since activated neutrophils produce many enzymes and free radicals that damage the gastric mucosa, neutrophil is considered as an aggressive factor in ulcer formation. Chow *et al.*[27] reported that cigarette smoking significantly potentiated the formation of gastric mucosal lesions and enhanced gastric mucosal MPO activity. Reduction of NO production was well associated with enhancement in both neutrophil infiltration and gastric ulcer formation in water immersion restraint stress model[28].

In the cold-restraint stress model, gastric ulcer formation was mainly due to gastric hypermotility, which could lead to mucosal over friction[29]. Hence, the gastric mucus layer is extremely important and the mucus is generally believed to contribute to a cytoprotective action. Gastric mucus originates from the goblet cells and NO plays a critical role in the maintenance of goblet cell functions. NO donors could increase mucus release from gastric mucosal cells in rats[30] and enhance mucus gel thickness in the rat stomach[16]. Tobacco smoking has been reported to suppress NO release[31-33] which might be explained in part by nicotine-induced damage of endothelial cells and lower NO synthesis[34].

In the present study, we examined the effects of nicotine and NO in cold-restraint stress. To mimic the nicotine intake in heavy smokers, animals were given drinking water containing 50 μg/ml of nicotine, a concentration reported to be comparable to the nicotine intake in heavy smokers[8, 35]. This concentration of nicotine in drinking water has been previously shown to intensify cold-restraint stress-induced gastric ulceration[8,9,29]. Our data suggest that chronic nicotine treatment could significantly reduce the gastric mucus content and this latter effect persisted for even 10 days after nicotine cessation. Reduction of the gastric mucus content could lead to weakening of the gastric defensive capability which underlies the intensifying effect of nicotine on stress-induced gastric ulceration. Our results confirmed the previous observations that chronic nicotine administration could reduce the gastric mucus content[36,37].

Table 3 Change in mucosal MPO activity after nicotine intake and nitric oxide donor (NO) treatment

	Tap water +no stress	Tap water +stress	Nicotine +stress	Nicotine +stress +NO (acute)	Quit nicotine +stress	Quit nicotine +stress +NO (chronic)
MPO (u/g protein):	6.3±0.7	9.3±1.1[a]	9.1±1.0[a]	7.9±0.9	9.4±1.2[a]	5.7±0.9[b]

Values are mean±SD. Each group had 8 rats. Stress: restrained at 4℃ for 2 hours. Tap water: Rats drank water (control). Nicotine: Rats drank nicotine 50 μg/ml for 20 days. Quit nicotine: Rats drank nicotine (50 μg/ml) for 20 days, then, nicotine was replaced by water for another 10 days. NO (acute): Rats drank nicotine (50 μg/ml) for 20 days, the rats were then given NO donor 60 and 10 min by oral gavages before stress. NO (chronic): Rats drank nicotine (50 μg/ml) for 20 days, then, nicotine was replaced by water, the rats were given NO donor three times daily by oral gavages for 10 days before experiment. [a]$P<0.05$ *vs* its own corresponding group in tap water + no stress control. [b]$P<0.05$ *vs* its own corresponding group in tap water +stress control.

Although nicotine intensified stress-induced gastric ulceration which was associated with enhanced MPO activity, nicotine had no additive effect on MPO activity, suggesting that the potentiating effect of nicotine is unrelated to gastric mucosal neutrophil infiltration. Acute NO donor treatment had no protective effect on animals subjected to chronic nicotine treatment and stress, while chronic NO donor treatment for 10 days after nicotine cessation could sufficiently restore the normal gastric mucosal integrity and increase the mucus content. Similarly, acute NO donor treatment did not significantly affect MPO activity in animals subjected to nicotine and stress. However, after nicotine cessation, the MPO activity was significantly reduced by chronic NO treatment in stressed animals. These results suggest that prolonged NO therapy may be necessary to restore the normal mucus layer and reduce MPO activity. Nevertheless, our data demonstrate that NO has a gastric mucosal cytoprotective activity and suggest that the protective role of NO in restoring the gastric mucosal integrity may be mediated via suppression of neutrophil infiltration and MPO activity. Our results are of clinical significance, and suggest that prolonged NO therapy may help to restore gastric mucosal integrity in heavy smokers, especially after they have stopped smoking.

Abstract

AIM: Only a minority of patients carrying a defined viral aetiologic agent develop cirrhosis and ultimately hepatocellular carcinoma (HCC), the mechanism underlying the worsening is still undefined. Experimental infection by *Helicobacter hepaticus* in mice causes chronic hepatitis and HCC and recently, more *Helicobacter* species (*Helicobacter* spp.) have been detected in the liver of patients suffering from cholestatic diseases and HCC arising from non-cirrhotic liver. We investigated whether *Helicobacter* spp. sequences could be detected in the liver of patients with cirrhosis and HCC compared to subjects with metastasis to liver from colon cancer.

METHODS: Twenty-three liver samples from patients operated upon for HCC superimposed on hepatitis C virus (HCV)-related cirrhosis and 6 from patients with resected metastases from colorectal cancer, were tested by polymerase chain reaction for presence of genomic 16S rRNA of *Helicobacter* genus using specific primers. DNA sequencing and *cag A* gene analysis were also performed.

RESULTS: Genomic sequences of *Helicobacter* spp. were found in 17 of 20 (85%) liver samples from patients with HCC and in 2 of 6 samples from patients with liver metastasis. In three samples of the first group the result was uncertain. *H pylori* was revealed in 16 out of 17 positive samples and *Helicobacter pullorum* in the other.

CONCLUSION: *Helicobacter* spp., carcinogenic in mice, were found at a higher frequency in the liver of patients with HCV-related cirrhosis and HCC than those in patients without primary liver disease.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fourth cause of cancer death worldwide[1]. This tumor often follows chronic liver inflammation and longstanding cirrhosis. Cirrhosis of the liver is a diffuse process, characterised by fibrosis and nodule formation, which stems from hepatocellular injury. The cellular necrosis might originate from viral, toxic, metabolic and autoimmune sources[2]. Moreover, hepatitis B and hepatitis C viruses (HBV and HCV) are well-known etiologic factors for liver cirrhosis, and have been classified by the International Agency for Research on Cancer (IARC) as type I liver carcinogens. Both viruses are highly prevalent in the adult population in Italy[3,4]. Both viral and host characteristics have been reported to influence the outcome of HBV or HCV infection and the development of cirrhosis, but they do not explain all the epidemiological variations of the disease. For instance, in the case of HCV, the viral genotype 1b[5] has been repeatedly connected with severity of liver outcome, although in other reports this issue has been debated[6]. Host characteristics also play an important role in the pathogenesis of liver disease. For example, HLA class II haplotype DR5 has been shown to protect patients from the development of cirrhosis[7].

Chronic inflammation *per se* is known to be a factor of progression towards cancer[8], though HCV in itself does not appear to foster a strong inflammatory mechanism[9]. It is thus not yet clear what factors most influence the outcome of the liver disease. Searching for other noxae has therefore become mandatory. A new infectious agent, *Helicobacter hepaticus* (*H. hepaticus*), that causes chronic active hepatitis and associated liver tumors in A/J Cr mice, has been described by Ward *et al*[10]. Recently, other *Helicobacter* species (*Helicobacter* spp.), including *Helicobacter pylori* (*H pylori*), bacteria associated with the pathogenesis of gastric[11-14] and extradigestive manifestations[15,16], have been detected in the liver of persons suffering from cholestatic diseases and HCC arising from non-cirrhotic liver[17,18]. We have previously reported a high frequency of *H pylori* and *Helicobacter pullorum* (*H.pullorum*) sequences detected by the polymerase chain reaction (PCR), in the liver of patients with cirrhosis and superimposed HCC[19].

To demonstrate a role of the bacteria as a co-factor in the development of end-stage of liver disease in humans, it is fundamental to evidence whether *Helicobacter* occurs at the same frequency in the liver of patients without primary liver disease. The present study investigated whether *Helicobacter* spp. genomes could be detected in liver specimens from patients without any diagnosis of chronic active hepatitis, cirrhosis or HCC, compared with specimens from HCC patients. Therefore, we analysed liver samples from subjects operated upon for metastasis to the liver from colon cancer and, the presence of *Helicobacter* was assayed by molecular methods.

MATERIALS AND METHODS

Liver samples were obtained during the surgical excision for cure from 23 patients operated upon for HCC superimposed

on hepatitis C virus (HCV)-related cirrhosis and from 6 patients suffering from metastatic cancer to the liver, in whom surgery might obtain remission of the disease. All samples were immediately frozen in liquid nitrogen and stored at -80℃ prior to testing. The architectural pattern and histologic grade of tumor differentiation of HCC were recorded in accordance with World Health Organisation (WHO) proposals[20]. HCV infection was demonstrated by means of an ELISA (Axsym System, Abbott Diagnostics) and an RIBA (RIBA II, LIA, HCV3, Sorin, Saluggia, Italy), and confirmed through detection of circulating HCV-RNA in a PCR.

DNA extraction from liver tissues

Approximately 3 mm³ of tissue was cut and incubated with 0.4 mg/ml proteinase K (Sigma, St Louis) in 0.5 ml extraction buffer (10 mM Tris- HCl, pH 7.5; 1 mM ethylene diamine tetra acetate or EDTA, pH 8; 0.25M sodium chloride; 0.2% sodium dodecyl sulphate or SDS) at 56℃ on an agitator until total tissue digestion, the proteinase K was inactivated by boiling it for 10 min. The mixture was centrifuged at 14 000 rpm (Eppendorf centrifuge 5415 C) at room temperature, and to the supernatant, 1 volume of phenol/chloroform (1:1 ratio, equilibrated with 0.1 M phosphate buffered saline, pH 7.5) was added. After vortexed and centrifuged at 14 000 rpm, the aqueous phase was precipitated with 2 volumes of 100% ethanol containing 10% volume of 3M sodium acetate, pH 4.8 at -80℃ for 20 min or at -20℃ overnight. After two washes with 75% ethanol, the pellet was dried and resuspended in 300 μl TE buffer (10 mM Tris-HCl, pH 7.5, 5 mM EDTA, pH 8) for further use.

Nested-PCR

Amplification of 16S rRNA gene Samples were amplified by *Helicobacter* genus-specific 16S ribosomal RNA(16S rRNA) primers (designated Heli, Table 1) that could identify genomic sequences of 26 species of *Helicobacter*.

First amplification step Genomic DNA was amplified in a total volume of 50 μl containing PCR buffer (1X), 200 μM dNTP, 4 mM Mg²⁺, 0.2 μM primers (Heli-nest-S and Heli-nest-R, Table 1), 1 U *Taq* DNA polymerase (GibcoBRL, USA) and 1 μg of total DNA. The reaction mixture was initially denatured for 2 min at 94℃ then amplified for 35 cycles as follows: denaturation for 30 s at 94℃, primer annealing for 30 s at 55℃ and extension for 1.5 min at 72℃. A final extension step was done for 5 min at 72℃ (Thermocycler HYBAID–OmniGene TR3 5M2-UK). An amplification product of 1 300 bp by the forward and reverse primers was expected.

Second amplification step PCR was repeated as above with minor alterations: 1 μl of amplicon was used from the first amplification step, the annealing temperature was brought to 60℃, extension time lasted 30 s for 35 cycles and Heli-R/Heli-S primers (Table 1) were used. The expected size of the amplicon was 480 bp.

Amplification of cag A gene

Samples generating a positive result from the Nested-PCR were subsequently analysed with a different pair of primers (CagA, Table 1). The CagA-1 and CagA-2 primers used (Table 1) amplified a 290 bp product from the 128 KDa Cag A protein, typical of *H pylori*[21]. Fifty microliter of reaction mixture was prepared containing PCR buffer (1X), 2 mM of Mg²⁺, 200 μM dNTP, 0.2 μM primers, 1 U of *Taq* DNA polymerase and 1 μg of DNA. Amplification consisted of an initial denaturation for 2 min at 94℃ then amplified for 50 cycles as follows: for 30 s at 94℃, for 30 s at 61℃ and for 1 min at 72℃. Extension was continued for another cycle for 5 min at 72℃. The PCR products were analysed on a 2% agarose gel. Positive

and negative controls were included. VCS Hae III and VCS Hinf I were used as DNA size standard for amplification with Heli primers and Cag A primers, respectively.

Southern blot hybridisation

For this purpose, 10 μl of the amplified DNA samples was electrophoresed on a 1% agarose gel. The samples were then transferred to nylon hybond N+ membrane (Amersham Pharmacia Biotech Inc., UK) treated with denaturing agent (0.5 M sodium hydroxide, 1.5 M sodium chloride). The membrane was then neutralised with 5X SSC (0.75M sodium chloride and 0.075M sodium acetate) for 1 min. The membrane was prehybridised in buffer (5X SSPE (0.6 M NaCl, 40 mM NaH₂PO₄, 4 mM EDTA), 0.5% SDS, 5X Denhardt' s solution, 0.02 mg/ml Salmon sperm) at 65℃ for 4 h. A freshly denatured probe, amplified from *H. pullorum* DNA and labelled with P ³² (Rediprime™ II, random labelling system, Amersham Pharmacia Biotech Inc., UK) according to the manufacturer' s instructions, was purified using Microspin™ S-400 (HR Columns, Amersham Pharmacia Biotech Inc., New Jersey, USA). Hybridisation was performed overnight at 65℃ in hybridisation solution containing blocking reagent (5X SSPE, 0.5% SDS, 5X Denhardt' s solution) and the DNA probe. The nylon membrane was then washed in 2X SSC, 0.1% SDS for 15 min at RT, 2X SSC, 0.1% SDS for 15 min at 65℃, 1X SSC, 0.1% SDS for 15 min at 65℃ and 0.5X SSC, 0.1% SDS for 10 min at 65℃. The bound probes were finally detected by autoradiography after 4 h at RT (Kodak scientific imaging film, X-OMAT/AR, Rochester, New York).

Sequencing of DNA

PCR-amplified *Helicobacter* genus-specific PCR products were run on a 2% agarose gel, purified using the QIAquick gel extraction kit (QIAGEN, Germany) and sequence analysis was performed with an Applied Biosystems DNA sequencer (Perkin-Elmer, Applied Biosystems, Warrington, Great Britain) following the procedure of the manufacturer, using the ABI PRISM 310 big dye terminator cycle sequencing kit. The sequences were entered, aligned and compared with known *Helicobacter* species using the BLAST programme (Genetics Computer Group, Madison, Wis.).

RESULTS

Screening for Helicobacter genus

We found DNA sequences typical of *Helicobacter* spp. in 17 of 20 (85%) livers from patients operated for HCC using *Helicobacter* genus-specific 16S rRNA primers. Three samples (15%) were negative, while in the remaining 3 out of 23, the results were uncertain. Two of 6 liver samples obtained from 6 patients whose livers were resected for metastasis due to colon cancer, contained sequences typical of *Helicobacter* spp.

The 480 bp product obtained in the second round of the nested-PCR with Heli primers is shown in Figure 1. The liver samples with a positive result by this method were all positive

by Southern blot hybridisation using P [32]-labelled probe generated from *H.pullorum* DNA (data not shown). These results confirmed the presence of *Helicobacter* gene sequences in the liver samples analysed from patients with cirrhosis and HCC.

Figure 1 Agarose gel (2%) showing PCR products obtained with *Helicobacter* genus-specific 16S ribosomal RNA primers. Lane 1 negative control (DEPC-treated water). Lanes 3 and 4 liver samples from patients with metastatic liver cancer. Lanes 2, 5, 6, 7, 8 and 9 positive liver samples. Lane 10 positive control (*H. hepaticus* DNA). MW molecular-weight marker (VCS Hae III).

Type I H pylori identification

The patients whose liver samples gave a signal typical for *Helicobacter* genus with Heli primers (Table 1), were analysed with primers specific for the amplification of a 290 bp stretch of the *cag A* gene[21]. The bands amplified corresponded to the expected size (Figure 2).

Overall, 16 out of 17 (94%) liver tissues from patients who were positive when tested for *Helicobacter* genus, were also found to be positive when tested for the presence of a sequence that was typical only for type I *Helicobacter pylori*, *i.e.*, the *cag A* gene.

Figure 2 Analysis of cagA-specific PCR products from *Helicobacter* genus positive liver samples of patients with cirrhosis and HCC. The 290 bp fragments were examined on 2% agarose gel electrophoresis. Lane 1 negative control (DEPC-treated water). Lanes 2 to 6 *Helicobacter* genus positive liver samples. Lanes 7 and 8 positive controls (cagA-cDNA). MW molecular-weight marker (VCS Hinf I). Lanes 2, 3, 5, and 6 positive for amplified cagA fragment. Lane 4 negative for cagA.

Presence of H pylori confirmed after DNA sequencing

The *Helicobacter* positive DNA fragments were sequenced. Comparison of DNA sequences of the genomic 16S rRNA amplicons with those of known *Helicobacter* spp. was performed using sequence alignment with the BLAST programme. The presence of *H pylori* and *H. pullorum* sequences was thus confirmed in these liver samples.

DISCUSSION

Despite the profound impact of HCC on human health worldwide[22], its pathogenesis remains uncertain. Thanks to the availability of very efficient vaccines that could prevent

HBV infection, WHO has sought to eradicate HBV infection and hence its long-term consequences such as HCC. However, in most industrialised countries, it has been shown that neither HBV nor *Schistosoma* infections play a major role in the development of HCC, instead, the majority of patients carry HCV. This virus does not integrate into host DNA, and it is likely that the mechanism of carcinogenesis differs from that of HBV. Therefore, the need to clarify the pathogenic mechanisms by which HCV may lead to liver cancer has become of prime importance.

Since the currently known risk factors cannot explain all aspects of its progression to HCC, other causal mechanisms should be explored[23]. From an epidemiological aspect, several studies have evidenced a high seroprevalence of *H pylori* among cirrhotic subjects[24-26], but these data have not been ubiquitarily confirmed[27]. Part of these differences might be explained by geographical and clinical differences in the population studied and the study-design[23]. Experimentally, Ward *et al.* have fulfilled Koch's postulates as far as the association of *H. hepaticus* with chronic active hepatitis and HCC in mice was concerned[10]. Whether *Helicobacter* spp. could act as a cofactor in the progression towards cirrhosis and carcinogenesis in humans with viral hepatitis, is still under review[23].

Chronic hepatitis is an inflammatory disease and each inflammatory process is characterised by increased levels of pro-inflammatory cytokines such as interleukins 1, 6 (IL-1, IL-6), tumor necrosis factor (TNF) and by the presence of lympho-mono cellular infiltrate and lymphoid follicle formation[28]. Viruses, such as HCV, are only capable of limited inflammation, due to shedding IL-1 receptor in circulation, thereby limiting the possibility of IL-1 binding to cellular receptors[23]. Helicobacters, on the other hand, are strong inducers of the inflammatory cascade[29], infection with them could lead to the accumulation of extraordinary number of lymphocytes and polymorphonuclear cells in the infected tissue. IL-1 gene cluster polymorphisms, thought to enhance IL-1β production, confer an increased risk of cancer in patients infected with *H pylori*[30]. Furthermore, Meyer-ter-Vehn *et al* have recently shown that strains of Cag-A-expressing *H pylori* could activate the ERK/MAP kinase cascade, resulting in Elk-1 phosphorylation and increased *c-fos* transcription. Proto-oncogene activation might represent a crucial step in the pathomechanism of *H pylori*-induced neoplasia. It has been shown that several *Helicobacter* spp. could also secrete a liver-specific toxin that causes hepatocyte necrosis in cell culture, and might therefore also be involved in damaging liver parenchyma *in vivo*.

The possibility that *Helicobacter* spp. could infect the biliary tract and the liver of humans has been reported by several studies in different settings. Fox *et al* have shown the presence of *Helicobacter* spp. in the bile of Chileans with chronic cholecystitis. Avenaud and coworkers have demonstrated by PCR the presence of genomic sequences of *Helicobacter* spp. in the liver of 8 patients with HCC without primary diagnosis of cirrhosis, a further analysis by sequencing revealed that these species were *H pylori* and *Helicobacter felis*[18]. Similarly, we have reported the presence of the cagA gene sequences obtained from the liver tissue of cirrhotic patients with HCC [19]. Furthermore, Nilsson *et al* have identified *H pylori* and *Helicobacter* spp. in human liver samples from patients suffering from primary sclerosing cholangitis and primary biliary cirrhosis[17] and recently in liver samples of patients with cholangiocarcinomas or HCC.

Of great interest is the fact that the gene sequence obtained from positive *Helicobacter* spp. specific 16S rRNA PCR was usually most analogous to *H pylori*. This encourages the speculation that the presence of *Helicobacter* DNA in human

liver tissue might reflect the transport of *H pylori* of gastric origin or its DNA to the liver. Studies have also indicated that intestinal *Helicobacter* might be implicated in hepatobiliary disease[17]. Recently, for the first time, the culture of a *Helicobacter* strain from the human liver has been described. So far, few studies have been reported regarding the presence of *Helicobacter* spp. genomes in liver tissues from patients not suffering from primary chronic liver diseases.

We now report the infrequent presence of genomic sequences of *H pylori* in liver parenchyma of patients operated upon for metastasis to the liver arising from colon cancer. In contrast, the presence of genome of *Helicobacter* spp. was found with a higher frequency in the liver from patients with HCV-related cirrhosis and HCC. This finding lends support to the hypothesis that co-infection with *H pylori* or *Helicobacter* spp. might amplify the chronic inflammation of the parenchyma, thereby leading to cirrhosis and HCC[23]. To date, we do not know whether bacterial infection of the liver could play a pathogenic role in the development of human HCC, analogous to what has been observed in the mouse model, and the question awaits clarification.

Abstract

AIM: *Helicobacter pylori* causes chronic gastritis, peptic ulcer, gastric cancer and MALT-lymphoma. Different genotypes of *Helicobacter pylori* are confirmed from diverse geographic areas. Its association with bleeding peptic ulcer remains controversial. The aim of this study was to investigate the *Helicobacter pylori vacA* alleles, *cagA* and *iceA* in patients with bleeding peptic ulcer.

METHODS: We enrolled patients with bleeding, non-bleeding peptic ulcers and chronic gastritis. Biopsy specimens were obtained from the antrum of the stomach for rapid urease test, bacterial culture and PCR assay. DNA extraction and polymerase chain reaction were used to detect the presence or absence of *cagA* and to assess the polymorphism of *vacA* and *iceA*.

RESULTS: A total of 168 patients (60.4%) (25 patients with chronic gastritis, 26 patients with bleeding gastric ulcer, 51 patients with non-bleeding gastric ulcer, 26 patients with bleeding duodenal ulcer, and 40 patients with non-bleeding duodenal ulcer) were found to have positive PCR results between January 2001 and December 2002. Concerning genotypes, we found *cagA* (139/278, 50%), *vacA* s1a (127/278, 45.7%), and *ice* A1 (125/278, 45%) predominated in all studied patients. In patients with bleeding peptic ulcers, *vacA* s1a and m1T were fewer than those in patients with non-bleeding peptic ulcers (37/106 *vs* 69/135, *P*=0.017, and 4/106 *vs* 21/135, *P* =0.002).

CONCLUSION: In patients with peptic ulcers, *H pylori vacA* s1a and m1T prevent bleeding complication.

INTRODUCTION

Helicobacter pylori (*H pylori*) infection has been closely linked to chronic gastritis, peptic ulcer, gastric cancer and MALT-lymphoma[1]. It is one of the most common bacterial infections of humans[2]. It remains to be answered why only a minority of *H pylori* carriers develop peptic ulcer disease. Host factors, *H pylori* strain variability, environmental factors, and NSAID play a role in the pathogenesis of peptic ulcer disease[3-5]. The clinical outcome of *H pylori* infection is supposed to be linked to certain strains, *e.g.* vacuolating cytotoxin (*vacA*) and the cytotoxin-associated gene (*cagA*)[6,7].

In patients with peptic ulcer disease, only a minority of them present with peptic ulcer hemorrhage. The incidence of peptic ulcer hemorrhage in patients with pre-existing peptic ulcer disease is less than 1% per year[8]. Whether *H pylori* increases the risk of ulcer bleeding is controversial. Wu *et al* confirmed that *H pylori* increased the risk of peptic ulcer bleeding[9]. Cullen *et al* had a similar finding (OR 2.8)[10]. In addition, eradication of *H pylori* infection could decrease the chance of peptic ulcer bleeding[11,12]. The above evidences strongly support the link of *H pylori* to peptic ulcer bleeding. However, the prevalence of *H pylori* has been found to be lower in bleeding ulcer patients than in non-bleeders[13]. The most likely explanation is the use of NSAIDs in the absence of *H pylori* infection in these patients. Another reason may be false negative results in these patients[14,15]. If we excluded the usage of NSAIDs in patients with duodenal ulcer bleeding, the prevalence of *H pylori* infection was 97%[16].

Controversy exists concerning relationship of genotypes of *H pylori* with peptic ulcer bleeding. So far, there are only few reports concerning this topic[17,18]. Although *H pylori* infection is very common, geographic distribution of different subtypes exists[19,20]. Therefore, it is interesting to investigate the genotypes in patients with peptic ulcer bleeding. The aim of this study was to determine the genotypes of *H pylori* in bleeding ulcer patients in Taiwan.

MATERIALS AND METHODS

Between January 2001 and December 2002, patients with non-bleeding peptic ulcers (gastric ulcer or duodenal ulcer, at least 5 mm in diameter), bleeding peptic ulcers (spurting or oozing hemorrhage, non-bleeding visible vessel, blood clots or pigmented spots at the ulcer base) or chronic gastritis were invited to enter the study. There was no past history of upper gastrointestinal bleeding (hematemesis or melena) in patients with non-bleeding peptic ulcer in this study. Patients with pregnancy, bleeding tendency (platelet count less than 50 000/mm³, prothrombin time less than 30%, or taking anti-coagulants), gastric malignancy, age under 10, or over 90 years, anti- *H pylori* therapy 4 weeks prior to enrollment, and inability to cooperate were excluded from the study. The study was approved by the Clinical Research Committee of the Veterans General Hospital, Taipei.

Endoscopic examination and biopsy were performed after informed consent was obtained. We took three specimens from the antrum, one for rapid urease test, another for bacterial culture and the third for DNA extraction and PCR assay. Lysates of biopsied gastric mucosa were used for PCR assay. DNA of gastric biopsy specimens was extracted according to the method described by Boom[21]. Briefly, biopsy specimens

were homogenized in guanidinium isothiocyanate, using a sterile micropestle. DNA was extracted, washed and eluted in 100 μl of 10 mM Tris-HCL (pH 8.3). Two μl of the eluted DNA was used for each PCR reaction.

The oligonucleotide primers for PCR amplification of specific segments are shown in Table 1[5,22-25]. For *vacA* evaluation, the PCR program comprised 35 cycles of denaturation at 94℃ for 1 min, annealing at 56℃ for 2 min, extension at 72℃ for 1 min, and one final extension at 72℃ for 10 min. For *cagA*, amplification was performed with 35 cycles of denaturation at 94℃ for 1 min, annealing at 56℃ for 2 min, extension at 72℃ for 1 min, and one final extension at 72℃ for 5 min. For *iceA* amplification, amplifications were performed with 40 cycles of denaturation at 95℃ for 30 s, annealing at 50℃ for 45 s, extension at 72℃ for 45 s and one final extension at 72℃ for 10 min.

The association between *H pylori* genotypes and clinical diseases was determined using χ^2 test and Yates' correction or Fisher's exact test when appropriate. A *P* value less than 0.05 was considered statistically significant.

RESULTS

A total of 278 patients with bleeding or non-bleeding peptic ulcers and chronic gastritis (200 males and 78 females, mean age: 62.1 years, 95% CI: 60.1-64.1 years) fulfilling the admission criteria, were included in this study. A total of 168 patients (60.4%) were found to have a positive urease test. A total of 168 patients (60.4%) (25 patients with chronic gastritis, 26 patients with bleeding gastric ulcer, 51 patients with non-bleeding gastric ulcer, 26 patients with bleeding duodenal ulcer, and 40 patients with non-bleeding duodenal ulcer) were found

to have positive PCR results. The ages of patients with bleeding gastric ulcer (mean: 67.8 yr, 95% CI: 62.8-72.8), non-bleeding gastric ulcer (mean: 63.5 yrs, 95% CI: 59.8-67.2), bleeding duodenal ulcer (mean: 65.5 yrs, 95% CI: 59.2-71.8) were greater than those of patients with non-bleeding duodenal ulcer (mean: 54.6 yrs, 95% CI: 49.5-59.7, $P<0.01$) and chronic gastritis (mean: 51.2 yrs, 95% CI: 42.8-59.6, $P<0.01$).

In patients with bleeding gastric ulcer, there were blood clots inside the stomach in 8 patients, coffee grounds in 8 patients, and clear fluid in 10 patients. In patients with bleeding duodenal ulcers, there were blood clots inside the stomach in 8 patients, coffee grounds in two patients and clear fluid in 16 patients.

In patients with bleeding peptic ulcers, 52 (49.1%) were found to have positive PCR for *H pylori*. It was lower than that in those with non-bleeding peptic ulcers (91/135, 67.4%, $P=0.006$) and chronic gastritis (25/37, 67.6%, $P=0.008$).

The genotypes in patients with chronic gastritis, duodenal ulcers and gastric ulcers are described in Table 2. There was no statistical difference among variables in different groups.

Concerning genotypes, we found *cagA* (139/278, 50%), *vacA* s1a (127/278, 45.7%), and *ice* A1 (125/278, 45%) predominated in all studied patients. In patients with bleeding peptic ulcers, *vacA* s1a and m1T were fewer than those in patients with non-bleeding peptic ulcers (37/106 *vs* 69/135, $P=0.017$, and 4/106 *vs* 21/135, $P=0.002$, Table 3).

DISCUSSION

H pylori is a world-wide infective agent ranging from 25% in developed countries to more than 80% in the developing world[26,27]. However, not all individuals infected with *H pylori* develop gastric illness and this may be related to various factors such as environmental factors, host genetic factors, and bacterial virulent ability[28,29].

This study determined using PCR the *cagA*, *vacA* and *iceA* status of 278 patients presenting for endoscopy by examining biopsy specimens from the antrum of each patient. Of them, 168 patients (60.4%) were found to have positive PCR. In this study, predominance of *vacA* s1a was found in patients with bleeding and non-bleeding peptic ulcer and chronic gastritis. Our finding was similar to those reported by other authors[25,30,31]. In Hong Kong and Korea, a low incidence of *vacA* s1a subtype was found[32,33].

The previous Taiwan reports gave no data concerning *vacA* s1c[25,30]. *VacA* s1c was frequently found (93/278, 33.5%) in this study. In patients with bleeding peptic ulcers, *vacA* s1c was less than that in patients with non-bleeding peptic ulcers (26% *vs* 38%), but it did not reach statistical significance. The incidence of *vacA* s1c in this study was similar to the reports of Hong Kong[32], Korea[33], and Japan[34], but different from those in Western world[19,20]. In contrast, *vacA* s1b and s2 were rare. Our findings were compatible with that in mainland China[31].

Concerning the m-region of *vacA*, m1 strains predominated in most Western reports[19,20,27]. However, there were only 2% m1 subtypes in patients with bleeding peptic ulcers and none in patients with non-bleeding peptic ulcers in this study. We used a modified primer (m1T)[25] and some peptic ulcer patients (bleeding: 3.8%, non-bleeding: 15.6%) with *H pylori* infection contained this genotype. m2 strains predominated (33% in patients with non-bleeding peptic ulcers, 25% in bleeding peptic ulcers) in this study. Our finding was consistent with reports from Taiwan[25,30], Hong Kong[32], and mainland China[31]. In contrast, Japan and Korea had a much lower incidence of m2 strains[24,33]. This indicates a great variation in the *vacA* region in Taiwan, particularly in the mid-region locus. *H pylori* may have a different geographic evolution in Taiwan

even compared with other East Asian countries.

IceA1 has been suggested to be related to peptic ulcer disease[23,35]. But, this finding was doubted by other authors and us[24,32,33]. In this study, we found *iceA1* was the predominant subtype and showed no difference between patients with bleeding and non-bleeding peptic ulcers. *IceA1* is the predominant subtype of *ice* in the East Asia, while *iceA2* is the predominant subtype in the USA and Columbia[24].

Certain genotypes (*e.g. cagA, vacA* s1a) have been closely related to severe clinical outcomes and response to anti- *H pylori* therapy[36-38]. However, these findings are not supported by other studies[24,25,29-32,34]. The association between *H pylori* infection and peptic ulcer bleeding is less clear, but a strong argument for the etiological role is the fact that eradication of *H pylori* decreased recurrence of bleeding[39]. Stack *et al* recently found that *cag* A positive *H pylori* was associated with an increased risk of ulcer bleeding[17]. However, Illies *et al* found that presence of *cagA* antibody was similar both in patients with bleeding and in non-bleeding controls[18]. In this study, there was no difference of *cagA* between patients with non-bleeding and those with bleeding peptic ulcers. However, there were fewer *vacA* s1a and m1T in patients with bleeding peptic ulcers than in patients with non-bleeding peptic ulcers.

In conclusion, in patients with bleeding peptic ulcers, *H pylori vacA* s1a and m1T are less than those in patients with non-bleeding peptic ulcers.

Abstract

AIM: To explore the abnormal function of platelets and the role of angelica sinensis injection (ASI) in patients with ulcerative colitis (UC).

METHODS: In 39 patients with active UC, 25 patients with remissive UC and 30 healthy people, α-granule membrane protein (GMP-140) and thromboxane B_2 (TXB_2) were detected by means of ELISA, 6-keto-PGF_{1a} was detected by radioimmunoassay, platelet count (PC) and 1 min platelet aggregation rate (1 min PAR) were detected by blood automatic tester and platelet aggregation tester respectively, and von Willebrand factor related antigen (vWF:Ag) was detected by the means of monoclonal -ELISA. The 64 patients with UC were divided into two therapy groups. After routine treatment and angelica sinensis injection (ASI) + routine treatment respectively for 3 weeks, all these parameters were also detected.

RESULTS: The PC, 1 min PAR and levels of GMP-140, TXB_2, and vWF:Ag in active UC were significanrly higher than those in remissive UC and normal controls ($P<0.05$-0.01).Meanwhile, 1 min PAR and levels of GMP-140, TXB_2, and vWF:Ag in remissive UC were still significantly higher than those in normal controls ($P<0.05$). Furthermore, 6-keto-PGF_{1a} level in active and remissive UC was remarkably lower than that in normal control ($P<0.05$-0.01). These parameters except 6-keto-PGF_{1a} were significantly improved after the treatment in ASI therapy group ($P<0.05$-0.01), whereas they all were little changed in routine therapy group ($P>0.05$).

CONCLUSION: Platelets can be significantly activated in UC, which might be related with vascular endothelium injury and imbalance between TXB_2 and 6-keto-PGF_{1a} in blood. ASI can significantly inhibit platelet activation, relieve vascular endothelial cell injury, and improve microcirculation in UC.

INTRODUCTION

Although the pathogenesis of ulcerative colitis (UC) still remains unknown, clinical observations have found that increased platelet number and platelet activation are notable characteristics of UC[1-6]. Reseaches revealed that the extract of platelets from patients with UC could induce intense inflammatory reaction for a few hours after they were injected into the skin of healthy people while the extracts of neutrophils and basophils had no such effect, suggesting that platelet was an important inflammatory cell, and could directly cause inflammation response[7,8]. Moreover, recent investigations indicated that the high blood coagulative state in patients with UC was closely related with the abnormal function of platelets, which resulted in high a probability of microvascular thrombosis and microcirculation dysfunction, main causative factors for UC[9,10]. More and more studies suggested that the role of platelets might represent a previously unrecognized component of UC pathogenesis and that antiplatelet drugs may provide new therapeutic possibilities in the management of UC[7,8,11-19].

The principal ingredient of ASI is sodium ferulate (SF), possesses various pharmacological effects on platelet function and blood circulation including regulating activity of platelets, inhibiting aggregation and liberation of platelets, improving microcirculation and decreasing consistency of blood[20-25]. Moreover, ASI almost has no toxicity[20]. So we presume that ASI might contribute to the treatment of UC. The aim of this study was to further explore the abnormal function of platelets and their mechanism in 64 patients with UC. At the same time, changes of the parameters related to platelet activation as well as clinical symptoms were observed before and after the treatment with ASI to investigate the effects of ASI on the abnormal function of platelets.

MATERIALS AND METHODS

Patients and grouping

A total of 64 patients with UC were recruited from Renmin Hospital of Wuhan University and Zhongnan Hospital of Wuhan University between January, 2000 and March, 2003. The diagnosis of UC was established according to the criteria reported in the literature[15]. According to the evaluating criteria of Jones standards for UC phase[26], 39 cases were evaluated as active UC (16 males, 23 females, aged 29 to 65, mean age 46.3 years, average disease course 10.6 months), 25 cases were evaluated as remissive UC (11 males, 14 females, mean age 43.6 years, average disease course 18.8 months). Thirty healthy volunteers without administration of antiplatelet medicine in recent 1 month (19 males, 11 females, mean age 42.8 years) were also enrolled in the study as normal control group. All the patients and healthy volunteers had no smoking history and administration of antiplatelet medicine. The 64 patients were randomly divided into routine therapy group and ASI therapy group according to the age. Among the 33 cases in routine therapy group and the 31 cases in ASI therapy group, 31 cases and 30 cases completed the experiment respectively. All groups showed comparable characteristics in sex and age.

Measurement of observed parameters

Venous blood samples 2 ml from the 64 patients without breakfast in the morning were obtained 24 hours after admission. At the same time, 2 ml blood sample was obtained from the 30 healthy volunteers under the same conditons. After mixed with 5% EDTA-Na$_2$ (v/v), an anticoagulant, the blood samples were quickly centrifuged at 3 000×g for 5 min. After separated from plasma, the blood samples were stored at -40℃ until detection for α-granule membrane protein (GMP-140), thromboxane B$_2$ (TXB$_2$), 6-keto-prostaglandin F$_{1a}$ (6-keto-PGF$_{1a}$) and von Willebrand factor related antigen (vWF:Ag). GMP-140 and TXB$_2$ were detected by using the ELISA kits, 6-keto-PGF$_{1a}$ was detected by the radioimmunoassay kit, and vWF:Ag was detected by the monoclonal-ELISA kit following the manufacturer's instructions. All the above detection kits were purchased from Institute of Thrombosis and Coagulation, Medical College of Suzhou University in China. At the same time, platelet count (PC) and 1 min platelet aggregation rate (1 min PAR) were measursed by a blood automatic tester (Beckman Co. USA) and a platelet aggregation rate tester (Wuxi Second Electronic Apparatus Factory) respectively using another venous blood sample obtained from all the subjects under the same conditon. After the treatments for 3 weeks, venous blood samples from 64 patients were obtained again and all the observed parameters were detected for the second time.

Treatment

After admission, the 33 patients in routine therapy group received routine treatment for 3 weeks including having semifluid diet, correctting the disorder of liquid and electrolyte and 2 g/day Etiasa, modified-release microgranules in sachets produced by Laboratoires Ethypharm, 2-3 times a day. Based on the above routine treatment, 40 ml ASI produced by Pharmaceutical Factory of Zhongnan Hospital of Wuhan University was added to 250 ml 10% glucose iv. drop once a day for 3 weeks for the 31 patients in ASI therapy group.

Statistical analysis

Experimental results were expressed as mean±SD. Statistical differences between groups were determined by ANOVA followed by Student's *t* test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Change of all observed parameters in patients with UC

Compared with normal group, 1 min PAR and levels of GMP-140, TXB$_2$, and vWF:Ag in UC group and in remissive UC group and active UC group were all significantly increased while 6-keto-PGF$_{1a}$ level was remarkably decreased (*P*<0.05-0.01). Meantime, PC in active UC group was obviously higher than that in normal group (*P*<0.01), whereas there was no significant difference in PC between remissive group and normal group (*P*>0.05). Furthermore, PC, 1 min PAR and levels of GMP-140, TXB$_2$, and vWF:Ag in active UC group were also significantly elevated compared with remissive group (*P*<0.05), while 6-keto-PGF$_{1a}$ was little changed (*P*>0.05) (Table 1).

Effects of ASI on abnormal function of platelets in patients with UC

After the treatment for 3 weeks, all observed parameters had no obvious changes compared with those before the treatment in the routine therapy group (*P*>0.05), whereas the elevated PC, 1 min PAR and levels of PC, GMP-140, TXB$_2$, and vWF: Ag were significantly decreased in the ASI therapy group compared with those before the treatment (*P*<0.05-0.01), while 6-keto-PGF$_{1a}$ level was still little changed (*P*>0.05) (Table 2).

DISCUSSION

Recent investigations indicate that platelets not only involve the increased incidence of systemic thromboembolism and a procoagulant blood state in UC but exhibit several proinflammatory properties including release of inflammatory and coagulant mediators such as platelet activated factor, thromboxane, thrombocytin (5-HT), platelet factor 4, platelet beta-thromboglobulin, platelet –derived growth factors, and recruitment, chemotaxis and modulation of the activity of other inflammatory cells[7-12, 27-31]. Moreover, platelet activation in UC might be responsible for the secondary activation of polymorphonuclear leukocytes (PMN) and increased the production of reactive oxygen species by PMN, which could account for the increase in PMN-mediated tissue injury associated with UC[32]. In addition, Danese and his coworkers found that activated platelets in UC expressed enhanced levels of CD40 ligand and interacted with CD40-positive human intestinal microvascular endothelial cells, which could produce

proinflammatory mediators, up-regulate cell adhesion molecule expression and secrete chemokines such as IL-8, a very important proinflammatory interleukin in UC. Meantime, the expression of functional IL-1R and IL-8R on the surface membrane of platelets in UC was found to be significantly increased[33,34].

GMP-140, a membrane glycoprotein, is mainly located in α-granule membrane of normal platelets. Only when platelets were activated and the granule were releasod, GMP-140 was expessed on the platelets surface and released into blood. Therefore, GMP-140 was commonly considered as the specific marker of platelet activation[4,35]. Furthermore, investigations have proven that GMP-140 could aggravate inflammatory response in UC by adhesion of leukocytes, facilitate diapedesis and induce proinflammatory cytokine production from monocytes such as MCP-1, IL-8[35]. At the same time, TXB_2 in blood and PRA have been found to be classic markers of platelet activation[4,5,12]. In our study, 1 min PAR and levels of GMP-140 and TXB_2 in blood of patients with UC were significantly increased compared with those in normal controls. Meatime, these parameters in patients with active UC were much higher than those in patients with remissive UC. These results suggested that platelets in circulation were obviously activated in UC and degree of the platelet activation was parallel to the severity of UC. Our study also indicated that the number of activated platelets in active UC was remarkably increased compared with those in remissive UC and normal controls. So, numerous activated platelets took part in the inflammatory response.

Our study revealed the mechanisms underlying the activation of platelet in UC might be as follows: The intestine mucosal vascular endothelial cells might be damaged and the collagen was exposed, thus activating the platelets in circulation because vWF:Ag, a macromoleculear glycoprotein mainly synthesized by vascular endothelial cell, was significantly increased in patients with UC in this study, which could sensitively reflect the injury of vascular endothelium. The parallel change between vWF:Ag and GMP-140 in this study also supported the hypothesis. Thromboxane A_2 (TXA_2), a strong vasoconstrictor, can intensely promote aggregation and activation of platelets while the effect of prostaglandin I_2 (PGI_2), a vasodilationor, on platelet is just on the contrary. In normal situation, TXA_2 and PGI_2 are in dynamic balance and their stable metabolites are TXB_2 and 6-keto-PGF_{1a}. In our study, significantly increased TXB_2 and remarkably decreased 6-keto-PGF_{1a} in patients with UC showed the obvious imbalance between TXA_2 and PGI_2, thus promoting platelet activation as well as resulting in dyfunction of microcirculation. The above results demonstrated that inhibition of platelet activation and improvement of microcirculation shuld be involved in the treatment for UC.

Numerous investigations have demonstrated that SF, a ASI' s principal ingredient, is not only a inhibitor of TXA_2 synthetase and cyclooxygenase-2, a crucial synthetase for arachidonic acid (AA) metabolism, but depresses the activity of phospholipase A_2, thus preventing the release of AA from phospholipid of cell membrane and effectly reducing the production of AA metabolites including TXA_2 and PGE_2[36-40]. Meantime, SF could compensativly promote the synthesis of 6-keto-PGF_{1a} during AA metabolism[41]. As a result, ASI could partly correct the imbalance between TXA_2 and 6-keto-PGF_{1a} in UC. Moreover, SF could directly inhibit 5-HT liberation and MDA synthesis from platelets[7,41]. In addition, SF could reduce the content of fibrinogen in blood, increase the charges on cell membrance, thus inhibiting the cell aggregation, lowering the blood consistency. SF could prolong plasma prothrombin time (PPT) and reduce the weight and length of thrombus, thus ameliorating microcirculation[20].

In our study, PC, 1 min PAR, and levels of GMP-140, TXB_2, and vWF:Ag were significantly decreased after 3 weeks treatment while 6-keto-PGF_{1a} level was little changed compared with those before treatment in the ASI group. At the same time, there was no significant difference in all observed parameters before and after the treatment in the routine therapy group. Furthermore, clinical symptoms such as abdomen pain, diarrhea, occult blood, fever in the patients of ASI group were relieved and controlled more quickly than those in the patients of routine therapy group. The above results suggested that ASI remarkably inhibited the activation of platelets, attenuated the injury of vascular endothelial cells as well as improved the microcirculation in patients with UC, thus contributing to relieve the inflammatory response in UC. The protective effect of ASI on vascular endothelial cell might be related with SF' s strong anti-oxidation property[2,3,20,42-44].

In summary, the results of this study have shown that ASI can significantly inhibit platelet activation, relieve vascular endothelial cell injury in UC. ASI in combination with the well-established drugs may contribute to an optimal treatment for UC.

Abstract

AIM: To study the effects of Kupffer cell-conditioned medium (KCCM) derived from lipopolysaccharide (LPS) treatment on proliferation of rat hepatic stellate cells (HSC).

METHODS: HSC and Kupffer cells were isolated from the liver of Wistar rats by *in situ* perfusion with pronase and collagenase and density gradient centrifugation with Nycodenz and cultured. KCCM was prepared and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay was used to detect HSC proliferation. The content of type IV collagen and laminin secreted by HSC in the HSC-conditioned medium was determined by radioimmunoassay. TGF-β_1 production in the KCCM was detected by enzyme-linked immunosorbent assay (ELISA).

RESULTS: HSC and Kupffer cells isolated had high purity. One microgram per mililiter LPS-activated KCCM and unstimulated KCCM could significantly promote HSC proliferation [0.132±0.005 and 0.123±0.008 *vs* control group (0.100±0.003), $P<0.01$], and there was a difference between them ($P<0.05$). Ten microgram per mililiter LPS-activated KCCM (0.106±0.010) was unable to promote HSC proliferation ($P>0.05$). Adding anti-TGF-β_1 antibodies could suppress the proliferation promoted by unstimulated KCCM and LPS (1 μg/ml)-activated KCCM (0.109±0.009 *vs* 0.123±0.008, 0.115±0.008 *vs* 0.132±0.005, $P<0.01$). LPS (1 μg/ml or 10 μg/ml) could not promote HSC proliferation immediately (0.096±0.003 and 0.101±0.004 *vs* 0.100±0.003, $P>0.05$). There was a parallel behavior between HSC proliferation and increased ECM level. One microgram per mililiter LPS-activated KCCM contained a larger amount of TGF-β_1 than unstimulated KCCM.

CONCLUSION: The technique for isolation of HSC and Kupffer cells described here is simple and reliable. KCCM stimulated by LPS may promote HSC proliferation and collagen accumulation, which are associated with hepatic fibrogenesis.

INTRODUCTION

Hepatic fibrosis is now regarded as a common response to chronic liver injury. Regardless of its nature (viral infections, alcohol abuse, and metal overload), it is also characterized by excessive deposition of extracellular matrix components[1-3]. Hepatic stellate cells (HSC) are a major source of extracellular matrix in normal and pathological conditions[4-6]. During fibrogenesis, HSC undergoes a process of activation, developing a myofibroblast-like phenotype associated with increased proliferation[7-9] and collagen synthesis[10,11]. As the data suggest, a paracrine mechanism may prevail over the stimulation of HSC proliferation and collagen synthesis *in vivo*[12,13].

Lipopolysaccharide (LPS) is a critical component of the cell membrane of gram-negative bacteria and can mediate pathophysiological alterations during endotoxaemia. Systemic exposure to LPS could result in a cascade of events involving cellular and soluble mediators of inflammation, leading to injury to organs, including liver[14,15]. Because LPS is known to activate Kupffer cells to release various kinds of cytokines[16-18], there may be a chain of events to cause hepatic fibrosis.

The aim of this study was to evaluate whether paracrine stimuli derived from LPS-activated Kupffer cells could induce HSC proliferation and collagen synthesis or LPS could stimulate HSC proliferation immediately.

MATERIALS AND METHODS

Materials

Pronase E, collagenase type IV, deoxyribonuclease I, MTT, Nycodenz [(5-*N*-2, 3-dihydroxypropylaceta-mido)-2, 4, 6-tri-iodo-N, N' bis -(2, 3–dihydroxypropyl) isophthalamide] and lipopolysaccharide (LPS, Escherichia coli, serotype 0111: B4) were obtained from Sigma. All immunocytochemical reagents, including rabbit antihuman desmin and rabbit antihuman lysozyme, were purchased from Maixin Co. (Fuzhou, China). Culture media, Dulbecco' s modified Eagle' s medium (DMEM) and PRMI1640 were purchased from GIBCO (Grand Island, NY). Newborn bovine serum and fetal bovine serum were purchased from Sijiqing Co. (Hangzhou, China).

Methods

HSC and Kupffer cell isolation and culture[19-25] HSC and Kupffer cells were isolated from rat livers by the pronase-collagenase method. Briefly, after the rat (male Wistar rats ranging from 350 g to 450 g of body weight) was anesthetized with sodium pentobarbital (40 mg/kg body weight, ip), the abdomen was opened and the portal vein was cannulated with 16-gauge cannula. The liver was perfused *in situ* for 15 min with Ca^{2+}/Mg^{2+}-free Hank' s balanced salt solution (pH 7.4, 37℃) at a flow rate of 15 mL/min, and was then perfused with Hank' s balanced salt solution (pH 7.4, 37℃) containing 0.1% pronase E and 0.05% collagenase type IV for an additional 30 min at a flow rate of 30 mL/min. After perfusion, the liver was removed, cut into small pieces, and incubated in a bath of Hank' s balanced salt solution containing 0.02% pronase E and 0.05% collagenase type IV and 0.001% deoxyribonuclease at 37℃ for 20 min. After passing through a filter (mesh size 74 μm), cells were washed twice with Hank' s balanced salt

solution and HSC were obtained by centrifugation over 12% (wt/vol) Nycodenz gradient for 18 min at 1 450 g. After centrifugation, HSC were collected from the interface, washed with Hank's balanced salt solution, and resuspended at a concentration of 1×10^5 cells/ml, in DMEM supplemented with 20% newborn bovine serum, 2 mmol/L glutamine, and 1% antibiotic solution. Kupffer cells were synchronously collected under the interface, washed with Hank's balanced salt solution, and resuspended at a concentration of 1×10^6 cells/ml, in PRMI 1640 supplemented with 10% fetal bovine serum, 2 mmol/L glutamine, and 1% antibiotic solution. Cells were then cultured at 37℃ in a humidified atmosphere containing 5% CO_2. The media of Kupffer cells were replaced 6 h after seeding and at every 48 h thereafter. Impurities caused by some endothelial cells were removed during the first medium change. The media of HSC were replaced 24 h after seeding and at every 48 h thereafter. Primary culture of HSC were allowed to grow to confluence 14 d after seeding, subcultured by trypsinization (0.125% trypsin) and then cultured in 96-well culture plates at a concentration of 1×10^5 cells/ml. HSC and Kupffer cells were identified by immunocytochemistry[26]. HSC were also identified by vitamin A typical fluorescence at 328 nm excitation wavelength.

Preparation of Kupffer cell-conditioned medium (KCCM)
After a 72 h recovery period from isolation, the primary Kupffer cells were cultured in the presence or absence of 1 µg/ml or 10 µg/ml of LPS. Conditioned medium was collected after 48 h of culture and filtered with a 0.45 µm membrane filter, and stored at -70℃ until use.

Modulation of HSC proliferation by KCCM or LPS
HSC were placed in 96-well plates and cultured for 48 h in the presence or absence of KCCM or LPS (1 µg/ml or 10 µg/ml). The HSC, with addition of KCCM, were cultured in the presence or absence of rabbit anti-human TGF-β_1 immunoglobulin. Conditioned media were collected and stored at -70℃ until use. The remaining cells were added with 180 µl media and 20 µl MTT (5 g/L) at 37℃. The media were removed 4 h later and formazan product was dissolved with 100 µl/well of dimethyl sulphoxide (DMSO). After a few minutes at room temperature, to ensure that all crystals were dissolved, the optic-metric density (OD) was read on an ELISA reader at test wavelength of 570 nm and referent wavelength of 630 nm.

Modulation of collagen type IV and laminin secretion by KCCM or LPS
The amount of type IV collagen and laminin, the most abundant type of ECM in early liver fibrosis, secreted by HSC in the HSC-conditioned medium was measured by radioimmunoassay.

Characterization of stimulatory factor in LPS-activated KCCM
TGF-β_1 production in the culture supernatant was measured by ELISA.

Statistical analysis
Data were expressed as mean±SD. Differences between any two groups were determined by new Duncan test and *t*-test. $P<0.05$ was considered statistically significant.

RESULTS
Isolation and culture of HSC and Kupffer cells
The HSC isolated with the aforementioned Nycodenz cushion ranged from 5×10^6 to 1×10^7 cells per liver, and Kupffer cell ranged from 3×10^6 to 5×10^6 cells per liver. The cell viability determined by trypan blue exclusion test varied considerably,

but was usually higher than 80%. HSC were identified by their typical dark-light microscopic appearance due to abundant vitamin A-containing vacuoles which showed intense fluorescence upon irradiation at 328 nm, and by positive immunocytochemical staining for desmin. Kupffer cells were identified by positive immunocytochemical staining for lysozyme. The initially isolated Kupffer cells were spherules with refraction which were much smaller than hepatocytes and HSC. Kupffer cells adhered to plates and some spread their pseudopods 4 h after seeding. During the first 24 h of HSC culture, the cells rounded up and flattened out. The major fraction contaminating nonadherent lymphocytes and endothelial cells, was removed with the first change of medium. After 2 to 3 d in culture, HSC developed a characteristic stellate shape. Lipid droplets had visible round nuclei and decreased with the time of culture. Confluence was reached on about the 14th day.

Effect of KCCM or LPS on HSC proliferation
When cells were cultured in the presence of 1 µg/ml or 10 µg/ml LPS, HSC proliferation was not observed ($P>0.05$). When cells were cultured in the presence of unstimulated KCCM and 1 µg/ml LPS-activated KCCM, HSC proliferated remarkably ($P<0.01$), and there was a difference between the two groups. Ten µg/ml LPS-activated KCCM could not promote HSC proliferation ($P>0.05$). In addition, HSC proliferation promoted by unstimulated KCCM and 1 µg/ml LPS-activated KCCM was suppressed partly in the presence of anti-TGF-β_1 antibodies ($P<0.01$), but there was a difference compared with control group ($P<0.01$) (Table 1).

Table 1 Effect of KCCM or LPS on HSC proliferation (mean±SD, *n*=12)

Treatment	A
LPS (1 µg/ml)	0.096±0.003
LPS (10 µg/ml)	0.101±0.004
KCCM1 (unstimulated)	0.123±0.008[c]
KCCM2 (1 µg/ml LPS-activated)	0.132±0.005[a]
KCCM3 (10 µg/ml LPS-activated)	0.106±0.010[d]
KCCM1 + anti-TGF-β_1 antibodies	0.109±0.009[b]
KCCM2 + anti-TGF-β_1 antibodies	0.115±0.008[d]
KCCM3 + anti-TGF-β_1 antibodies	0.106±0.010
Control group	0.100±0.003

[a]$P<0.01$ *vs* control group; [b]$P<0.01$ *vs* unstimulated KCCM group; [c]$P<0.05$, [d]$P<0.01$ *vs* 1 µg/ml LPS-activated KCCM group.

Effect of KCCM or LPS on collagen type IV and laminin secretion by HSC
When HSC were cultured in the presence of 1 µg/ml or 10 µg/ml LPS, the amount of collagen type IV secreted by HSC was 29.17±1.36 µg/L and 30.53±0.97 µg/L, respectively, and there was no difference between them ($P>0.05$). The amount of laminin was 56.61±2.39 ng/ml and 57.12±2.00 ng/ml respectively without statistical difference ($P>0.05$). When HSC were cultured in the presence of unstimulated KCCM and 1 µg/ml LPS-activated KCCM, collagen type IV and laminin secreted by HSC were markedly enhanced by LPS-stimulated KCCM (42.39±1.74 µg/L and 69.40±1.86 ng/ml), but were only slightly enhanced by unstimulated KCCM (37.99±1.41 µg/L and 63.54±2.25 ng/ml). Furthermore, this enhanced secretion was partly blocked in the presence of anti-TGF-β_1 antibodies. Ten microgram per mililiter LPS-activated KCCM could not promote collagen type IV and laminin secretion (31.12±0.84 µg/L and 56.34±2.17 ng/ml, $P>0.05$) (Table 2).

Table 2 Effect of KCCM or LPS on collagen type IV and laminin secretion by HSC (mean±SD, $n=6$)

Treatment	Collagen type IV (μg/L)	Laminin (ng/ml)
LPS (1 μg/ml)	30.53±0.9	57.12±2.00
LPS (10 μg/ml)	29.17±1.36	56.61±2.39
KCCM1 (unstimulated)	34.41±1.22[c]	62.00±2.23[c]
KCCM2 (1 μg/ml LPS-activated)	42.39±1.74[a]	69.40±1.86[a]
KCCM3 (10 μg/ml LPS-activated)	31.13±0.84[d]	56.34±2.17[d]
KCCM1+anti-TGF-β_1 antibodies	32.18±1.71[b]	58.87±2.31[b]
KCCM2+anti-TGF-β_1 antibodies	36.26±0.91[d]	65.25±1.95[d]
KCCM3+anti-TGF-β_1 antibodies	30.76±1.88	56.16±2.62
Control group	30.34±1.02	57.56±1.56

[a]$P<0.01$ vs control group; [b]$P<0.01$ vs unstimulated KCCM group; [c]$P<0.05$, [d]$P<0.01$ vs 1 μg/ml LPS-activated KCCM group.

Figure 1 Effect of KCCM or LPS on ECM secretion by HSC.

Stimulatory factor assay

The concentration of TGF-β_1 in LPS-activated KCCM was markedly higher (0.941±0.114) than that in unstimulated KCCM (0.465±0.075).

Table 3 TGF-β_1 in LPS-activated and unstimulated KCCM (mean±SD, $n=6$)

Group	TGF-β_1(OD)
KCCM1(unstimulated)	0.465±0.075[a]
KCCM2(1 μg/ml LPS-activated)	0.941±0.114[a]
KCCM3(10 μg/ml LPS-activated)	0.669±0.093[a]
Control group	0.089±0.010

[a]$P<0.01$ vs control group.

DISCUSSION

It has been recognized that HSC are the major source of extracellular matrix in normal and pathological conditions[1,5,9]. HSC activation during fibrogenesis, as a result of injury, is a dynamic process, which leads from a quiescent state to a myofibroblast-like phenotype with increased production of extracellular matrix and enhanced proliferation. Therefore, HSC play a central role in hepatic fibrogenesis. Previous studies have shown that the functions of adjacent cells were influenced by mediators released from Kupffer cells, such as protein synthesis in hepatocytes[27] and sinusoidal endothelial cell functions[28]. Several investigators have already evaluated the role of Kupffer cells in stimulating HSC, although the results were conflicting[29]. Endotoxemia has been found in patients with chronic liver disease, such as hepatic cirrhosis and hepatitis[30,31]. Endotoxemia and hepatocytic damage could affect each other, but there is no evidence to show whether endotoxemia could promote HSC activation. So the relation between LPS and HSC was studied to demonstrate the possible mechanism in the fibrogenesis of endotoxemia.

We established an *in vitro* model of HSC and Kupffer cell-conditioned medium. The primary HSC grew very slowly and confluence was reached on about the 14th day in culture. The subcultured HSC grew much faster than the primary HSC, and lipid droplets decreased and even disappeared, which accorded with previous studies. In this study, Kupffer cells and HSC were cultured with LPS (1 μg/ml or 10 μg/ml), and Kupffer cell-conditioned medium was cultured with HSC. This mimiced the process that intestinal LPS affected liver cells *in vivo* when endotoxemia occurred. We measured HSC proliferation after HSC were cultured with LPS directly or indirectly to evaluate the degree of HSC activation. Our data showed that unstimulated KCCM could promote HSC proliferation. When HSC were cultured in the presence of 1 μg/ml LPS-activated KCCM, HSC proliferated more remarkably than the former. It was suggested that the primary Kupffer cells could secret some factors and LPS could stimulate synthesis and secretion of these factors by Kupffer cells. When HSC were cultured in the presence of LPS directly, HSC proliferation could not be observed. Our results indicated that LPS affected HSC indirectly. Ten μg/ml LPS-activated KCCM could not promote HSC proliferation. It is difficult to assess and explain the reason why high concentration LPS could not activate HSC. One possibility was that high concentration LPS might decrease or suppress Kupffer cells to secrete cytokines, which could stimulate HSC proliferation. The other possibility was that cytokines secreted by Kupffer cells did not decrease, but Kupffer cells could secrete some other cytokines and counteract the promotion. So HSC did not undergo proliferation.

Overload ECM synthesis could lead to hepatic fibrosis. In our study, we measured the relative concentration of collagen type IV and laminin in HSC-conditioned media. Our results showed that there was a parallel behavior between increased HSC proliferation and increased ECM level. It was suggested that HSC proliferation was the direct reason of the overload ECM synthesis, which was probably related with the increased cell number and capability of single HSC to secret ECM.

TGF-β_1 is the most powerful cytokine to promote fibrosis. During the period of HSC activation, TGF-β_1 was a very important initiation factor[32]. In our study, HSC proliferation and ECM production by unstimulated KCCM and 1 μg/ml LPS-activated KCCM were suppressed partly in the presence of anti-TGF-β_1 antibodies, suggesting that HSC proliferation might be related with TGF-β_1 and some other cytokines, because anti-TGF-β_1 antibodies could completely not suppress the effect of proliferation. Our results suggested that Kupffer cells could be activated by a moderate concentration of LPS and probably release some soluble mediators, such as TGF-β_1, presented in the LPS-activated Kupffer cell-conditioned medium, which activated HSC from a quiescent state to a myofibroblast-like phenotype. It is clear that the stimulatory effect on both HSC proliferation and collagen synthesis is the main feature of liver fibrosis. It is easy to measure cytokines contained in LPS-activated KCCM by ELISA. Our results showed that moderate concentration of LPS-activated KCCM contained larger-activated KCCM and approve the above deducibility, *i.e.*, a high concentration of LPS might promote Kupffer cells to secrete a smaller amount of TGF-β_1 than 1 μg/ml LPS, and secret other cytokines to counteract the effect of TGF-β_1.

In conclusion, LPS plays a role in the stimulation of HSC proliferation and collagen synthesis. Kupffer cells cultured in

the presence at a moderate concentration of LPS can release products, which stimulate HSC proliferation and collagen accumulation. These *in vitro* observations presumably mimic some profibrogenic situations *in vivo*, whereas HSC are activated in the presence of LPS.

Abstract

AIM: To determine the perigastric lymph node involvement in periampullar tumors, in an attempt to optimize the surgical treatment of pylorus- preserving pancreatoduodenectomy.

METHODS: We retrospectively investigated the frequence of lymph nodes involvement in perigastric regions. Distribution and number of involved lymph nodes were exambined from 112 patients with carcinoma of pancreas, 59 patients with distal bile duct carcinoma, and 41 patients with carcinoma of the papilla of Vater.

RESULTS: The frequency of lymphatic spread of carcinoma in pancreas; distal bile duct and papilla of Vater was 18.7%, 1.9%, 2.5% respectively. With regard to the mode of lymphatic spread in perigastric region, Infrapyloric nodes of carcinoma of the head of pancreas predominated over others, in carcinomas of the distal bile duct and the papilla of Vater, the left gastric artery, and the greater curvature lymph nodes was the only sole sites, respectively.

CONCLUSION: Understanding perigastric lymphatic involvement in periampullary tumors may be helpful for choosing the appropriate surgical approaches to pancreatoduodenectomy with preservation of pylorus.

INTRODUCTION

Since the first pancreaticoduodenectomy was successfully performed, there have been many controveries[1-3] among surgeons about the preservation of pylorus during pancreatoduodenectomy is the adequate strategy in periampullar malignant tumors. Usually the decision of pylorus-preserving is decided by the presence or absence of positive lymph node involvement in the perigastric lymph nodes. The goal of our study is to determine the perigastric lymph node involvement in periampullary tumors and to perform appropriate surgical

procedures for "periampullary tumors".

MATERIALS AND METHODS

Materials

Speciments obtained from 112 patients with carcinoma of the pancreas of head including 23 cases of small carcinoma of pancreas, 51 patients of carcinoma of distal bile duct, 41 cases of carcinoma of the papilla of Vater. They all underwent consecutive resection at our Department of Surgery between January 1990 to December 2000. The 112 patients with carcinoma of pancreas were composed of 79 men and 33 women with a mean age of 67 years (range 41 to 73 years). The 51 patients with carcinoma of the distal bile duct were composed of 39 men and 12 women averaging at age of 61 years (range 39-81 years). The 41 patients with carcinoma of the papilla of Vater were composed of 27 men and 14 women averaging at age of 69.4 years (rang 47-79 years).

Methods

Patients with periampullar malignant tumors received radical operation. Primary group (N1) and secondary group (N2) lymph nodes were cleared together with neighboring connective tissue. The tertiary group(N3) lymph nodes with neighboring connective were appropriatelytely cleared (Figures 1A and 1B).

Figure 1 A and B Ranges of lymphatic and neighboring connective tissue dissection in periampullary malignant tumors. In Figure 1A n1, n2 and n3 (N07) nodes were cleared with neighboring connective tissue, In Figure 1B n2 nodes (N016) and connective tissue around the major vessels including aorta and inferior vein were cleared.

Immediately after operation The tumor locations were determined by close observation of the resected specimens. Lymph nodes macroscopically identified were separated from the fresh surgical specimen with the surrounding fatty tissues, in which small lymph nodes might be contained. Both the nodes and fatty tissues were embeded and cut into 5 μm sections and examined microscopically. Based on the guidelines of the General rules for Surgical and Pathological studies on Cancer of Pancreas by the Japanese society of Pancreatic Surgery[3] (4rd edition, 1996), General Rules for Surgical and Pathological studies on cancer of Biliary Tract by the Japanese Society of Biliary Surgery (4rd edition 1997), perigastric lymph nodes were classified as right cardiac lymph nodes, left cardiac lymph nodes, lesser curvature lymph nodes, great curcature lymph nodes, suprapyloric lymph nodes, infrapyloric lymph nodes. Metastatic lymph nodes of carcinoma were confirmed by microscopic examination and the percentage of positive lymph nodes was calculated using the formula: [the number of sites positive for carcinoma metastasis]/[the number of sites dissected actually].

RESULTS

The number of dissected lymph nodes in each case range between seven and 19(mean 12) in patients with carcinoma of the pancreas of head,between 4 and 15(mean 9.7) in those with carcinoma of the distal bile duct,and between 3 and 16(mean 10.4) in those with carcinoma of the papilla of Vater.

The frequency of lymph node involvement was 18.7% of the patients with advanced carcinoma of the pancreas of head had perigastric lymph node involvement,5.6% patients with small carcinoma of pancreas had perigastric node involvement localized to the number 5 and 6, 1.9% patients with carcinoma of the distal bile duct had perigastric lymph node involvement in N_07, 1.2% patients with carcinoma of the papilla of Vater had perigastric lymph node involvement only identified in N_04. Pathological metastatic rates to perigastric regional lymph nodes in resected cases of carcinoma of periampulla are shown in Table1.

Table 1 Perigastric lymph node involvement in patients with carcinoma of periampulla

Carcinoma of pancreas			Carcinoma of distal bile duct			Carcinoma of papilla of Vater		
No	%	I/II	No	%	I/II	No	%	I/II

I/II[the number of the sites positive for carcinoma metastasis]/[the number of sites dissected actually].

DISCUSSION

In this current study, periampulla cancer, includes three categories,namely carcinoma of ampulla, carcinoma of distal common bile duct, carcinonoma of pancreatic head.

Standard whipple operation for the treatment of resectable tumors of the periampullary region involves a radical pancreatoduodenectomy with an extensive gastric resection. The modified Whipple operation aims to preserve the stomache, pylorus and proximal duodenum so as to decreas postgastrectomy complications and improve the patient's quality of life. However, there were still many postoperative complications after pylous-preserving pancreatoduodenectomy (PPPD)[4,5]. In addition, in malignant periampullary tumor the patient's quality of life after resection depended more on recurrence of malignant diseases than on physiologic alterations related to the resection and reconstruction[6,7]. There might exist two kinds of recurrence after PPPD, one was the possibility of cancerous infitration of duodenal and gastric margins through lymph vessels[8], the other was the perigastric region node involvement. Individual lymph nodes have been histologically proved metastasis to perigastric region. According to our investigation, the rate of metastasis to perigastric lymph nodes in patients with carcinoma of pancreas was 18.7%. In those with other types of periampullary carcinomas, such as carcinoma of the ampulla, distal bile duct, the rate was 1.9% and 1.2% respectively. The involved sites were extremely limited[9-14]. So far as carcinoma of the pancreas of head concernd even small carcinoma of pancreas has a higher perigastric lymph node involvement[15,16].

The presence of metastatic cancer in lymph nodes excised during pancreatoduodenectomy is generally accepted as an evidence of a surgically incurable disease, and lymph node dissection may therefore be considered as a prognostic factor. PPPD could not remove peripyloric or celiac lymph nodes. The expected 5-year survival rate after PPPD without perigastric lymph node clearance range from 30% to 50% in patients with carcinoma of the ampulla of Vater or the distal bile duct[9,17,18]. However, impact on the negative survival of metastatic lymph nodes of carcinoma of pancreatic head has been observed in many studies and was associated with high rates of local and regional recurrence after PPPD[19,20].Taking all these into account, we hold that PPPD may be acceptable for carcinoma of the ampulla of Vater, distal bile duct. It may be indicated for carcinoma of pancreas of head if perigastric node involvement is not observed.

The mast cell is an enigmatic cell type whose physiological function has preoccupied large numbers of investigators for decades[1]. Some have concluded that the absence of mast cells is incompatible with life, at least in humans, because no human conditions have been documented where these cells are absent from the body. On the other hand, mice harboring specific mutations in certain growth factors, or their receptors, that lead to apparently an almost total ablation of the mast cell lineage, are viable, although they do have several documented abnormalities and may exhibit altered inflammatory responses in a variety of tissues[2]. The viability of such animals may reflect redundancy in the murine system for specific mast cell functions, and/or that other cell types adapt to become repositories of characteristic mast cell mediators. But in any event, mast cells have long been considered to play specific roles in pathophysiology, particularly in disease states that are characterized by allergic inflammation[1-5]. In the setting of the gastrointestinal tract, release of mast cell mediators has been thought to contribute to tissue injury and inflammation, as well as alterations in epithelial and smooth muscle function, in conditions such as food allergy, systemic anaphylaxis, ulcer disease and inflammatory bowel diseases, as well as, more controversially, irritable bowel syndrome[3,5-13]. The spectrum of mast cell involvement has also been expanded by recognition that they can participate in biological events not classically related to allergic responses, such as innate immunity, the phagocytosis of bacteria and cross-talk with the peripheral and enteric nervous systems[14-16].

Mast cells are activated classically by cross-linking of membrane IgE receptors[17]. *In vivo*, this occurs when a genetically susceptible individual mounts an IgE antibody response to a foreign protein that would be seen as innocuous by the immune system of those who are not allergic. The IgE antibodies bind with great avidity to the mast cell IgE receptors. Thus, because mast cells in the tissues are also long-lived, the allergic individual becomes chronically sensitized, with mast cell IgE receptors occupied by allergen-specific IgE, priming the cell to be activated by a subsequent exposure to the allergen. Binding of allergen to adjacent IgE molecules on such primed

cells results, in turn, in apposition of the IgE receptors, thereby initiating a signal transduction cascade, involving, among other steps, mobilization of intracellular calcium and activation of protein kinases, that leads ultimately to release of mast cell mediators[17,18]. The mediators that account for the biological effects of mast cell activation may be stored in cytoplasmic granules, such as histamine and a protease known as tryptase that were studied by He and co-workers in work reported in the *Journal*[19-24]. Other potent mediators, including various cytokines and leukotrienes, are synthesized *de novo*, with delayed or rapid kinetics depending on whether gene transcription is or is not required, respectively[19]. The process of mast cell activation can be mimicked *in vitro* by artificially stimulating aspects of the signaling cascade. He and co-workers accomplished this by using antibodies directed against the IgE molecule itself, which cause allergen-independent IgE receptor cross-linking, or a calcium ionophore, which causes an increase in the levels of cytoplasmic calcium.

In addition to the immunological activation of mast cells, it has been known for many years that various other substances can initiate or potentiate mast cell mediator release[25]. These include neuropeptides, highly basic compounds, peptides from bee venom, and adenosine. The work from He *et al.*, conducted with mast cells isolated from human colonic specimens, extends this list to include histamine and proteases, including trypsin and mast cell tryptase itself[20-24]. While these and other investigators had shown that proteases can activate some mast cell populations to release histamine, it was important to demonstrate directly that they were active against human intestinal mast cells due to the known existence of substantial functional and biochemical heterogeneity among mast cells isolated from different tissue sites and from different species[26-29]. Moreover, the ability of histamine to activate tryptase release from intestinal mast cells had not previously been demonstrated; rather, in other mast cell populations, histamine has been shown to inhibit mediator release, although others have shown that histamine H_1 receptor antagonists can block mediator secretion from basophils, consistent with the findings of He *et al.*[30,31]. The work from He and co-workers also implies important autoregulatory mechanisms that almost certainly contribute to the overall level of mediator release from mast cells *in vivo*. Thus, not only are histamine and tryptase released from mast cells, but they also likely stimulate further mediator release once present in the extracellular space. The concentrations of histamine capable of activating mediator release are well within the range that might be expected in the vicinity of activated mast cells[20]. Likewise, the biological significance of the inferred effect of tryptase on mediator release is illustrated by the fact that inhibitors of the proteolytic activity of this enzyme significantly reduce mast cell mediator release evoked by IgE cross-linking[23]. Overall, these findings suggest that mast cells participate in a self perpetuating amplification mechanism that would be capable of sustaining mediator release, at least from the granule-associated pool, until released mediators had been cleared from the area by diffusion or metabolism. However, there also appear to be some "brakes" to the system that would preclude wholly uncontrolled release of the panoply of potent mast cell mediators. For histamine in

particular, the effect on mediator secretion was biphasic, with higher concentrations of the amine less effective than lower ones[20]. Thus, released histamine would amplify ongoing mediator release from the cell of origin or others in the neighborhood, but only up to a certain point. The biphasic effect of histamine may also explain differences between the findings of He *et al.* and those reported previously by others[20,30].

The authors also have begun to examine the specific receptors and other mechanisms that contribute to protease-activated mediator release from human colonic mast cells. The process is active rather than cytotoxic, and can be reproduced by peptide agonists specific for a member of a novel class of receptors, the proteinase-activated receptors, or PAR's[32]. PAR's are G-protein coupled receptors that are activated by proteolytic cleavage, revealing a tethered ligand. The prototypic member of this class is the thrombin receptor, or PAR-1[32]. In addition, PAR-2 has been shown to contribute to inflammatory reactions, including in the intestine, and is activated by both trypsin and tryptase, as well as by synthetic peptides that mimic the sequence of the tethered ligand[32-36]. He *et al.* developed evidence that mast cells are likely activated by PAR-2 ligation, such as would be stimulated by release of tryptase itself [21]. On the other hand, the receptor subtype mediating the effect of histamine on tryptase release from human colonic mast cells is not yet known.

Some minor caveats should be raised about the studies presented. First, the mast cells used for the experiments were studied as an unpurified preparation in which mast cells constituted only about 5% of the total cell number[20-24]. Thus, the effects of either histamine and proteases on mediator release could in fact be indirect, and mediated secondarily by another substance released from a contaminating cell type responsive to either agent. However, this scenario does not necessarily detract from the clinical relevance of the responses studied by He and co-workers, because mast cells are not activated in isolation *in vivo*. Likewise, the presence of PAR-2, although not histamine receptors, has been demonstrated directly on human mast cells in a variety of tissues using immunohistochemistry. Second, the authors speculate that mast cells in the gut wall might constantly be exposed to pancreatic trypsin during the normal process of digestion, and that this might evoke mediator release. However, even if a small proportion of luminal trypsin does leak across the small intestinal epithelium in intact form to encounter subepithelial mast cells, and at concentrations comparable to those needed to activate mast cells *in vitro* (which is unproven at the present time), this is unlikely to occur in the colon, and so the studies would need to be repeated using mast cells isolated from the small intestine to understand fully whether the findings have physiological or pathophysiological relevance. Finally, we know little about the persistence of mast cell mediators in the interstitium following their release. While the concentrations of both histamine and proteases capable of activating colonic mast cells are at least theoretically within the biological range immediately following degranulation, it is unknown whether these concentrations remain elevated for long enough to contribute significantly to amplifying subsequent mediator release.

The caveats notwithstanding, the studies of He *et al.* enhance our understanding of the possible roles of mast cells in initiating and/or perpetuating intestinal disorders, including inflammatory bowel diseases and peptic ulcer disease. Knowledge of the mechanisms that regulate mediator release from intestinal mast cells specifically should aid in our ability to modulate the activity of this cell type, with potential therapeutic benefits given the wide range of adverse effects of released mediators. Indeed, He and co-workers themselves suggest that proteinase inhibitors might be attractive targets for drug development, although the biological actions of such compounds would almost certainly extend beyond simply an effect on mast cell activation, given the wide distribution of PAR's[23]. Further, the findings may shed light on pathogenic mechanisms in diseases not currently appreciated as being dependent on mast cells and their mediators. For example, colon cancer cells often release novel trypsins into their environment, and this in turn could conceivably account for the fact that mast cells are often observed at the margins of tumors examined histologically, based on the possibility that such cells are chronically activated by the tumor microenvironment[37-39]. Overall, progress in this field should be expected to improve the understanding and treatment of a whole host of digestive disorders.

Abstract

Inflammatory bowel diseases (IBDs), including Crohn's disease and ulcerative colitis are chronic inflammatory disorders of gastrointestinal tract. Although the etiology is incompletely understood, initiation and aggravation of the inflammatory process seem to be due to a massive local mucosal immune response. Interleukin-10 (IL-10) is a regulatory cytokine which inhibits both antigen presentation and subsequent pro-inflammatory cytokine release, and it is proposed as a potent anti-inflammatory biological therapy in chronic IBD. Many methods of IL-10 as a treatment for IBD have been published. The new strategies of IL-10 treatment, including recombinant IL-10, the use of genetically modified bacteria, gelatine microsphere containing IL-10, adenoviral vectors encoding IL-10 and combining regulatory T cells are discussed in this review. The advantages and disadvantages of these IL-10 therapies are summarized. Although most results of recombinant IL-10 therapies are disappointing in clinical testing because of lacking efficacy or side effects, therapeutic strategies utilizing gene therapy may enhance mucosal delivery and increase therapeutic response. Novel IL-10-related cytokines, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28 and IL-29, are involved in regulation of inflammatory and immune responses. The use of IL-10 and IL-10-related cytokines will provide new insights into cell-based and gene-based treatment against IBD in near future.

INTRODUCTION

Inflammatory bowel diseases, including Crohn's disease and ulcerative colitis are chronic inflammatory and frequently relapsing diseases of the gut that ultimately lead to destruction of the intestinal tissue. Over recent decades the incidence of IBD has been rising in the world, and IBD will become increasingly common in Asia, as it has been in the last fifty years in Europe and North America[1]. The pathogenesis of IBD likely involves multifactorial interactions among genetic factors, immunological factors and environmental triggers[2].

Recent evidence suggests that a pathologic activation of the mucosal immune system in response to antigens is a key factor in the pathogenesis of IBD. In patients with IBD, a loss of immune tolerance occurs to some, but not all, commensal bacterial antigens coupled with alterations in T-cell regulation leads to relapsing chronic inflammation[3,4]. There appear to be distinct pathways of inflammation in Crohn's disease and ulcerative colitis. In patients with Crohn's disease, the patterns of cytokines expressed by mucosal lymphocytes generally tend to be consistent with a T-helper-1(Th1) response, including an early increase in the expression of interferon (IFN), IL-2, and IL-12, followed by a subsequent increase in tumour necrosis factor-α (TNF-α) and IL-18[5]. In addition, there also appears to be a compensatory increase in IL-10 and transforming growth factor-β (TGF-β) levels. In patients with ulcerative colitis, the pattern of cytokine expression differs from that seen in Crohn's disease, with an increased expression of IL-5, IL-6, IL-10, and IL-13[5].

Current therapy of IBD is neither sufficient nor disease-modifying. Long-term treatment with non-specific anti-inflammatory drugs such as aminosalicylates, corticosteroids and immunosuppressants is often accompanied by undesirable and potentially serious side effects[6]. Novel biologically-driven therapies are targeted to specific pathophysiological processes, offering the potential for better treatment outcomes. Several new therapeutic strategies are currently being tested in clinical practice, including recombinant anti-inflammatory cytokines (IFN-α, IL-10, IL-11) and inhibitors of cell adhesion molecules (ICAM), pro-inflammatory cytokines (TNF, IL-12) and their specific monoclonal antibodies or their receptors (TNFR, IL-6R)[2].

The pathogenesis of IBD is characterized by an imbalanced activation of Th1- and Th2-lymphocytes. IL-10 represents an anti-inflammatory cytokine which downregulates the production of Th1-derived cytokines. The relative deficiency of IL-10 in patients with ulcerative colitis may contribute to persistent inflammatory changes[7]. IL-10-deficient mice (IL-10(-/-)) spontaneously develop intestinal inflammation characterized by discontinuous transmural lesions affecting the small and large intestines and by dysregulated production of proinflammatory cytokines, indicating that endogenous IL-10 is a central regulator of the mucosal immune response[8]. IL-10 is in clinical trial as an anti-inflammatory therapy for IBD and various autoimmune diseases such as psoriasis, rheumatoid arthritis, and multiple sclerosis. This review describes the current state of knowledge regarding IL-10-directed biological therapies in IBD.

BIOLOGICAL CHARACTERISTICS AND FUNCTIONS OF IL-10

IL-10 was first identified in 1989 as a cytokine synthesis inhibitor produced by a subset of murine T lymphocytes termed T-helper-2 (Th2) cells. It is an 18.5 ku cytokine with a broad immunoregulatory activity. It plays the role of a Th2 cell-derived cytokine, and is produced by several cell types, including monocytes, macrophages, T lymphocytes, B cells, dendritic cells, mast cells and various tumour cell lines. Its main biological functions seem to limit and terminate the

inflammatory responses, block the proinflammatory cytokine secretion and regulate the differentiation and proliferation of several immune cells such as T cells, B cells, natural killer cells, antigen-presenting cells, mast cells, and granulocytes[9]. IL-10 acts on specific IL-10 receptors that have now been cloned, although the signal transduction pathways and kinases that lead to the widespread anti-inflammatory actions of this cytokine are not yet well understood.

Human IL-10 binds as a 2-fold symmetric homodimer to a functional tetrameric complex of two receptors[10], consisting of two α- or R1 chains which bind to IL-10, and of two CRF2-4 chains (β- or R2) which initiate the IL-10-induced signal transduction events. CRF2-4 is a member of the class II cytokine receptor family (CRF2), which includes the IFN receptors and is encoded by the CRFB4 gene on chromosome 21[11]. IL-10R generates its signals through the JAK1-STAT3 pathway and activates the SOCS-3 gene (suppressor of cytokine signalling-3) of which the expression results in inhibition of JAK/STAT-dependent signalling and the expression of many genes in the cells[12]. Some of the actions of IL-10 can be explained by an inhibitory effect on the transcription factor nuclear factor-κB (NF-κB), but this does not account for all effects as IL-10 is very effective on inhibiting IL-5 transcription which is independent of NF-κB[13].

The immunoregulatory activity of IL-10 is based upon its ability to inhibit both cytokine synthesis and antigen presentation. IL-10 inhibits the synthesis of proinflammatory cytokines (IL-1β, TNF-α, IL-6), and the Th2 cell-derived cytokines (IL-4 and IL-5)[13]. IL-10 also inhibits chemokines such as monocyte inflammatory protein-1α (MIP-1α), RANTES, IL-8 and eotaxin[14], as well as the expression of inflammatory enzymes inducible nitric oxide synthase (iNOS) and cyclooxygenase (COX-2) in macrophages, the proliferation of CD4+ T lymphocytes by inhibiting IL-2 release and reducing expression of major histocompatibility complex (MHC) class II molecules and the costimulatory molecules B7-1, B7-2, and low-affinity IgE receptors (CD23) in antigen-presenting cells, thus effectively blocking allergen presentation by mononuclear cells and dendritic cells to T cells. In addition, IL-10 also increases the expression of several anti-inflammatory proteins, including IL-1 receptor antagonist, soluble TNF-α receptor and tissue inhibitor of matrix metalloproteinases. Although many of the inhibitory effects of IL-10 on T lymphocytes are secondary to this reduction in monocyte-derived pro-inflammatory cytokines, it also has a direct regulatory effect on T-cell differentiation and proliferation by inhibiting IL-2 and IFN-γ release from activated T-cell clones[15].

However, the biology of IL-10 is highly complex. In addition to the down-regulation of immunity, both human IL-10 and murine IL-10 exert immunostimulatory effects by up-regulating MHC class II expression on B lymphocytes, and inducing cytotoxic T-cell differentiation. To complicate the issue, there is strong homology in the complementary DNA of human and murine IL-10 with an open reading frame sequence in the Epstein-Barr virus (human herpes virus type 4) genome, termed viral IL-10. Whereas viral IL-10 shares many of the immunoregulatory properties of human IL-10, it lacks immunostimulatory effects.

IL-10 THERAPY FOR IBD

Recombinant IL-10
The therapeutic experience of IL-10 in animal models of colitis is very encouraging. *In vitro* studies have shown that exogenous IL-10 can down-regulate the enhanced pro-inflammatory cytokine release from lamina propria mononuclear cells isolated from patients with Crohn's disease. Early clinical studies in untreated, as well as steroid-refractory Crohn's disease

patients, suggested that IL-10 might have strong potential in the treatment of human diseases. Colombel *et al*[16] performed a double blind controlled trial to evaluate the safety and tolerance of recombinant human interleukin 10 (IL-10, Tenovil) in subjects operated on for Crohn's disease. Tenovil treatment for 12 consecutive weeks in patients with Crohn's disease after intestinal resection was safe and well tolerated. No evidence of prevention of endoscopic recurrence of Crohn's disease by Tenovil was observed.

Unfortunately, this enthusiasm was dampened by the results of 2 multinational multicenter studies reporting the efficacy and safety of daily subcutaneous injections of recombinant human IL-10(rhuIL-10) in patients with moderately active and steroid-refractory Crohn's disease[17,18]. Fedorak *et al*[17] reported a 24-week double-blind placebo controlled study of 95 patients with moderately active Crohn's disease randomized to receive subcutaneous rhuIL-10 at 1 of 4 doses (rhuIL-10:1, 5, 10, or 20 μg/kg) or placebo daily. After a 28-day treatment period, a modest response was seen in the group receiving the 5 μg/kg dose, whereby 23.5% of patients (*n*=17) showed improvement compared with 0% of patients treated with placebo (*n*=23). Interestingly, higher doses were less effective, although there was no difference in reported adverse events between doses. During the course of a 20-week follow-up period, disease recurrence requiring therapeutic intervention occurred in 70% of placebo-treated patients compared to 55% of the rhuIL-10-treated group[17].

In the study by Schreiber *et al*[18] involving 329 therapy refractory patients with active Crohn's disease, no significant differences in the induction of clinical remission were seen between placebo and rhuIL-10 at any dose (1, 4, 8, and 20 μg/kg), although clinical improvement was achieved in 46% of patients in the 8 μg/kg group compared with 27% of patients receiving placebo (*P*=0.03). The authors also determined the nuclear levels of transcription factor NF-κB p65 and cytoplasmic concentrations of its inhibitor IκBα in ileocolonic biopsy specimens. They noticed significant differences between patients who responded to rhuIL-10 treatment and those who did not, implicating the inhibition of NF-κB nuclear translocation as one possible mechanism of the action of this therapy[18].

Recent studies linking high systemic concentrations of IL-10 with headache, fever[19], and anemia[20] have further aroused the enthusiasm for IL-10 as a therapeutic drug in treatment of IBD. Indeed, the biology of IL-10 is complex. In addition to its effects in down-regulating pro-inflammatory events, IL-10 has been shown to exert immunostimulatory effects by up-regulating MHC II expression on B lymphocytes and inducing cytotoxic T-cell differentiation. Clinical data support these immunostimulatory effects of IL-10 at high systemic doses. Tilg *et al*[19] reported that patients with Crohn's disease receiving rhIL-10 at high doses experienced a significant increase in serum neopterin and phytohaemagglutin (PHA) induced IFN-gamma production from whole blood cells. This phenomenon may be responsible for the lack of efficacy of high doses of IL-10 in the treatment of Crohn's disease[19]. In fact, the emerging picture regarding the *in vivo* effects of IL-10 is one of both the anti- and pro-inflammatory effects, depending on the local concentrations of IL-10 achieved, the types of antigens present in the microenvironment, and the activation state of the immune cells in the vicinity. It is possible that high systemic doses of IL-10 alter the balance between its immunoregulatory and immunostimulatory effects, which would explain the bell-shaped curve in therapeutic efficacy reported in the clinical trials. In addition, it is entirely possible that the pharmacodynamics of daily systemic IL-10 administration does not allow for efficient delivery of the cytokine to the local sites of inflammation. The serum half-life of IL-10 is between 1.1 and 2.6 hours, thus, the cytokine may be cleared before

reaching its target.

Treatment by lactococcus lactis secreting IL-10

IBD in humans responds to high dose of intravenous interleukin 10, but this cannot be administered orally because stomach acid destroys it. Recently, studies have been published that looked at alternative methods of delivery of IL-10. The first study used the genetically engineered bacterium, *Lactococcus lactis* (*L. lactis*), as a delivery vehicle for IL-10. Steidler *et al*[21] hypothesised that an oral delivery system that effectively bypassed the stomach might provide a treatment which would cut the dose of IL-10 required and also reduce the risk of systemic side effects. Steidler and his colleagues[21] have engineered a non-pathogenic bacterium that produces interleukin 10, an anti-inflammatory cytokine that reduces inflammatory colitis. They then established two different mice models of inflammatory bowel disease. In the first model chronic colitis was induced by feeding dextran sulphate sodium to the mice over several weeks. When the recombinant bacteria were introduced into the mice stomachs, they survived the acid environment and released interleukin 10 in the colon. The second mouse model had its interleukin 10 gene knocked out. The resultant mice were shown to develop IBD spontaneously within 8 weeks of life. When the team administered the genetically engineered *L. lactis* to these mice at 3 weeks of age, colitis did not occur in the first place. They showed that daily intragastric administration of IL-10-secreting *L. lactis* caused a 50% reduction in colitis in mice treated with dextran sulfate sodium and prevented the onset of colitis in IL-10(-/-) mice. High serum concentrations of interleukin 10 were not found, despite good uptake by inflamed cells of the gut mucosa. This approach may lead to better methods for cost-effective and long-term management of IBD in humans. Because the genetically engineered bacterium survives stomach acid, the cytokine can be delivered directly to the inflammatory target in the colon. This could reduce the dose needed and any systemic effects.

However, the release of such genetically modified organisms through clinical use raises safety concerns. Steidler *et al*[22] replaced the thymidylate synthase gene thyA of *L. lactis* with a synthetic human IL10 gene to address this problem. This thyA-hIL10+ *L. lactis* strain produced human IL-10(hIL-10), and when deprived of thymidine or thymine, its viability dropped by several orders of magnitude, essentially preventing its accumulation in the environment. The biological containment system and the bacterium's capacity of secreting hIL-10 were validated *in vivo* in pigs. This approach is a promising one for transgene containment because, in the unlikely event that the engineered *L. lactis* strains acquired an intact thyA gene from a donor such as *L. lactis* subsp. cremoris, the transgene would be eliminated from the genome.

Two technical hitches must be ironed out, however, before human trials can be considered. Human interleukin 10 is slightly different from murine interleukin 10, so the *L. lactis* has to be re-engineered. The second obstacle is that human bile is stronger than mouse bile and is likely to kill the bacteria as they pass through the stomach and duodenum[23].

Gelatine microspheres containing interleukin-10

IL-10 is an anti-inflammatory cytokine that suppresses the T helper 1 immune response and down-regulates macrophages and monocytes. The therapeutic effect of systemic administration of IL-10 for patients with IBD, however, has not been satisfactory. Several studies have indicated that active monocytes, such as macrophages and T cells, play an important role in the pathogenesis of chronic human IBD, although the etiology remains unclear. Manipulation of these cells appears essential for the treatment of patients with IBD. Recently,

considerable attention has been paid to the use of polymer microspheres for the sustained release of various drugs and the targeting of therapeutic agents to their sites of action.

Nakase *et al*[24,25] developed gelatine microspheres(GM) containing IL-10(GM-IL-10), which can be released sustainedly to a local site without losing bioactivity. They administered these microspheres to IL-10 knocked out mice rectally to investigate whether this treatment could ameliorate colitis. Colonic inflammation in mice treated with GM-IL-10 was remarkably reduced compared to those treated with IL-10 alone. Macroscopic and microscopic examination revealed marked improvement of colitis in IL-10(-/-) mice treated with GM-IL-10. mRNA expression of IL-12 in Mac-1-positive cells in GM-IL-10-treated mice was significantly decreased compared with that in the mice treated with IL-10 alone. CD40 expression in Mac-1-positive cells in GM-IL-10-treated mice was decreased more prominently than that in mice treated with IL-10 alone. The therapeutic effects of GM-IL-10 were associated with decreased expression of IL-12 mRNA and down-regulation of CD40 expression in Mac-1-positive cells. Additionally, intestinal administration of these microspheres significantly improved colitis with a decrease in histological score, myeloperoxidase activity, and nitric oxide production compared with those treated with free agents. Gene expressions of TNF-α, IL-1β, and IFN-γ were down-regulated in treated animals. Serum IL-10 levels and systemic macrophages were unchanged after treatment[26].

These data suggest that local macrophages in the intestine play a critical role in the initiation of chronic colitis in the animal model of IBD. A drug delivery system using these microspheres containing immunomodulatory IL-10(GM-IL-10) might be useful for treatment of patients with IBD.

Gene therapy

IL-10 is an endogenous anti-inflammatory and immunomodulatory cytokine that has been shown to prevent inflammation and injury in several animal studies, however clinical IL-10 treatment remains insufficient because of difficulties in the route of IL-10 administration and its biological half-life. It may be possible to use replication-deficient adenoviral vectors to deliver the IL-10 gene directly to gastrointestinal epithelial cells. This would lead to localized high level IL-10 release for a short duration that is determined by the lifetime of the infected cells. IL-10 adenoviral gene therapy has proved very successful in murine models of rheumatoid arthritis[27], a condition with many immunological similarities to Crohn's disease. Previous studies have demonstrated that adenoviral vectors, when delivered by rectal infusion, could infect intestinal epithelial cells[28]. This approach may be limited by the host anti-adenoviral immune response, that has limited gene expression and prevented re-treatment with other adenoviral vectors[29]. However, there is evidence that the delivery of immunoregulatory genes, such as IL-10, would diminish both the cell-mediated and humoral anti-adenoviral responses[30,31].

Barbara *et al*[32] reported that gene transfer was achieved by intraperitoneal injection of non-replicating human type 5 adenovirus bearing IL-10 gene, either 24 hours before or one hour after intrarectal administration of dinitrobenzene sulphonic acid in rats. Colonic damage and inflammation were assessed macroscopically and by measuring the myeloperoxidase activity and leukotriene B4 concentrations. Gene transfer increased IL-10 protein in serum for up to six days. IL-10 gene transfer prior to colitis improved colitis macroscopically and histologically, and significantly reduced colonic myeloperoxidase activity and leukotriene B4 concentrations. In contrast, IL-10 gene transfer after the onset of colitis had no beneficial effect. Lindsay *et al*[33] showed that local adenoviral vectors encoding IL-10 (AdvmuIL-10) reverse

colitis in IL-10-/- mice without systemic effects seen after intravenous administration.

Enhanced expression of MAdCAM-1 (mucosal addressin cell adhesion molecule-1) is associated with the onset and progression of IBD. Sasaki *et al*[34] reported transfection of the IL-10 vector into endothelial cell cultures significantly reduced TNF-α induction, MAdCAM-1 dependent lymphocyte adhesion (compared to non-transfected cells). IL-10 transfected endothelial cells expressed less than half (46+/-6.6%) of the MAdCAM-1 induced by TNF-α (set as 100%) in non-transfected (control) cells.

These results suggest that gene therapy strategies using plasmid IL-10 vectors or an adenovirus-IL-10 construct may prove to be a potent approach to the treatment of chronic inflammatory diseases such as Crohn's disease.

Combining regulatory T cells and IL-10

T cells, and in particular, regulatory T(Treg) cells, play a pivotal role in the control of intestinal inflammation[35,36]. Regulatory cells lacking anti-inflammatory cytokine IL-10 were unable to inhibit IBD, showing that IL-10 was required for the protective effects of lymphocytes in this setting[37].

van Montfrans *et al*[38,39] presented a novel method of IL-10 delivery to intestinal mucosal tissue by the use of transduced T cells. In these studies, the authors demonstrated that T lymphocytes could be engineered by retrovirus construct transduction to express high levels of IL-10 upon activation. With the goal of providing long-term therapy for Crohn's disease, peripheral blood mononuclear cells were obtained from healthy adults and transduced with a retroviral vector containing IL-10 and green fluorescent protein (GFP). These CD4+ T lymphocytes responded to CD3/CD28 stimulation with a 6-fold increase in IL-10 production that was shown to be biologically active. Transduced cells had high expressions of the mucosal integrin $\alpha4\beta7$, and displayed efficient binding to MAdCAM-1 expressing cells *in vivo*, suggesting that they would home to gut mucosa. Importantly, albeit *in vitro*, cells remained stably transfected for up to 4 months. In the classic CD45RB^{high} model, these IL-10 transduced CD4+ cells were able to effectively prevent the development of colitis, even when given up 14 days after the transfer of the CD45RB^{high} cells. Although circulating levels of IL-10 were not detectable, IL-10-GFP encoding messenger RNA was detected in colons of mice 15 weeks after cell transfer, and IL-10 was detected in the intestinal draining lymph nodes, spleen, and colon, indicating that the IL-10-GFP transduced CD4+ cells persisted *in vivo* and migrated into the large intestine. The mice receiving IL-10 transduced CD4+ cells exhibited a decrease in the production of TNF-α in the colon and a decreased production of IFN-γ and/or TNF-α in the intestinal draining lymph nodes. These results indicate that the transferred CD4+ cells are stimulated *in vivo* and therapeutically effective.

One of the advantages of using T cells as delivery vehicles is the likelihood that the cytokine of interest, in this case, IL-10, would primarily be released only on activation in local sites of inflammation, which would avoid the side effects known to be associated with high systemic levels and may further induce the development of immune-suppressor Treg cells in the area of inflammation. Secondly, the use of *ex vivo* transduction methodology would prevent systemic exposure to the retroviral vector, but still ensure sustained gene expression. However, the question remains, will even local delivery of IL-10 be effective in patients with IBD? IL-10 certainly exhibits potent inhibitory effect on the activation and effector functions of T cells, monocytes, and dendritic cells, all of which are key players in intestinal inflammation. However, the colon from a patient with Crohn's disease already secreted higher levels of IL-10 compared with control colons[40] and mononuclear cells

isolated from the ileum of patients with Crohn's disease appeared to be nonresponsive to IL-10[41]. These findings suggest that even if IL-10 is delivered directly to the intestinal mucosa, it may not be therapeutic in Crohn's disease. This is mirrored by effects both in the IL-10 gene-deficient mouse chronic colitis model and in the dinitrobenzene sulphonic acute model of colitis[42] where IL-10 is able to prevent the development of colitis if given before inflammation develops, but is ineffective if given either exogenously or via gene transfer, once inflammation has become established. However, although IL-10 therapy may be ineffectual in treating active diseases, there may still exist a role for such therapy as maintenance treatment in Crohn's disease. Low ileal IL-10 concentrations have been shown to predict relapse after ileocecal resection[43]. In addition, it may be that only certain subgroups of Crohn's disease patients respond to IL-10 therapy, whether it is delivered systemically or locally. It is clear that even among patients with similar clinical presentations, there exists a large diversity of patterns of immune responses to environmental and bacterial antigens[44]. It is not known how patients with these types of immune reactivities respond to different therapies.

CONCLUSION AND PERSPECTIVES

IL-10 is a pivotal cytokine in the control of intestinal inflammation. Several clinical trials[45] have demonstrated that daily systemic rhuIL-10 injections were safe and well tolerated with modest efficacy in Crohn's disease, but clinical trials with rhuIL-10 in Crohn's disease were disappointing, although some patients showed healing of intestinal mucosa. With the administered dose of IL-10 in the clinical trials, the ultimate local IL-10 concentrations in the intestine could be too low to result in downregulation of inflammation. Furthermore, higher doses of systemically administered IL-10 (which were also used in the clinical trials) might be detrimental rather than helpful[46]. But it is possible that response to IL-10 is limited to a subgroup of patients, and perhaps delivering the IL-10 in a more sustained and focused manner would prove to be effective. These may be the several reasons why this is not the end of the road for rhuIL-10 therapy in Crohn's disease[29]. Recently, some novel alternative approaches, including the use of genetically modified *Lactococcus lactis*, gelatine microsphere containing IL-10, adenoviral vectors encoding IL-10 and combining regulatory T cells, may ensure that delivery of IL-10 is indeed local, tissue-specific, and therapeutic. These therapeutic approaches caused a significant reduction in intestinal inflammation in different mouse models, and they might be useful for treatment of human IBD. However, there is still a long way to go until these approaches can be evaluated in clinical studies.

New mammalian genes that encode IL-10-related cytokines have been described as the result of experiments using cDNA subtraction cloning focusing on melanocyte differentiation (*IL24*)[47], virus-induced T-cell transformation (*IL26*)[48] or IL-9-mediated gene induction (*IL22*)[49]. The sequencing and annotation of the human genome could lead to the identification of five additional IFN- or IL-10-related genes[50-53]: *IL19*, *IL20*, *IL28A* (also known as *IFNλ2*), *IL28B* (also known as *IFNλ3*) and *IL29* (also known as *IFNλ1*). Similar to IL-10, these IL-10-related cytokines are α-helical proteins with similar cysteine localizations, whose amino acid sequences are about 20-30% identical. IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B and IL-29 are grouped together on the basis of structural homologies, indicating that these genes are derived from common ancestors[54]. All these new IL-10 supfamily member cytokines are strongly involved in immune regulation and inflammatory response, further studies will provide a better understanding of potential therapeutic utilities, some of them

may reduce adverse side effects and /or increase the efficacy typically seen in IL-10 therapy for IBD in the future.

Abstract

AIM: To investigate the surgical treatment and long-term survival for patients with carcinoma of esophagus after distal subtotal gastrectomy.

METHODS: Resections of the tumor through left thoracotomy were performed in 85 patients with esophageal carcinoma following distal subtotal gastrectomy. The procedure involved preserving the left short gastric artery and transporting the residual stomach, the spleen and tail of the pancreas into the left thoracic cavity, and using the residual stomach to reconstruct the alimentary tract.

RESULTS: The resectable rate was 91.8%, complication rate 10.3%, and no death occurred in the postoperative period. The 1-, 3-, 5-, and 10-year survival rates were 85.7%, 50.7%, 30.6% and 18.8%, respectively.

CONCLUSION: Surgical resection is the optimal management method for the patients with esophageal carcinoma after distal subtotal gastrectomy. The reconstruction of digestive tract using anastomosis of the esophagus and the residual stomach is not only simple but also can achieve a better curative effect, promoting the digestive function and improving the quality of life.

INTRODUCTION

The primary management of esophageal carcinoma is surgical resection, and the stomach is the organ most often chosen for substitution following removal of esophagus for carcinoma. However, following the resection of esophageal carcinoma after distal subtotal gastrectomy, the replacement of esophagus mostly selected other organs, such as jejunum or colon[1-11]. Since we first applied this new technique to use the residual stomach in patients all with previous distal subtotal gastrectomy in 1982[12,13], we have treated 85 patients by such approach, and will report it as follows.

MATERIALS AND METHODS

Clinical data

There were 74 men and 11 women with age ranging from 34 to 78 years (mean 60.3 years). The interval between the time of subtotal gastrectomy and the time when the patients were diagnosed having carcinoma of esophagus ranged from 7 to 29 years, averaging 15 years. According to the procedures of subtotal gastrectomy, two cases were classified as Billroth I type, 83 cases Billroth II type, including 27 cases undergoing gastrectomy posterior to colon, and 58 cases anterior to colon. The digestive functions in all of the patients were approximately normal. All the patients presented with the symptoms of dysphagia to some degree with only 42.4%(36/85) being able to take semi-fluiddiet. The average body weight of the patients was 47.7±10.2 kg. With regard to the classification of Performance Status, 30.6%(26/85) patients belonged to class 0-1, and 69.4% (59/85) to class 2-4.

In terms of the location of the tumor, 4 cases were localized in upper thoracic esophagus, 62 cases in mid thoracic, and 19 cases in lower thoracic. With regard to gross type, 60 patients belonged to medullary type, 15 ulcerative type, six constrictive type, three fungating type and one intraluminal type. All of cases received barium meal examination of gastrointestinal tract to measure the maximal diameter of residual stomach that was from the fundus to the gastrojejunal anastomosis, and no lesion was found in the residual stomach. The diameter ranged from 5 cm to 9.2 cm, mean 7.9 cm. Forty-three cases in this group were further examined by fiber-gastroscopy, which revealed nothing pathological in their residual stomachs.

All the patients underwent the resection of involved portion esophagus through left thoracotomy under the intratracheal anesthesia, except for 7 cases being found to have unresectable tumors, in which 5 cases had the local tumors infiltrating the aortic arch or / and bronchus, and two cases were found to be accompanied with metastasis of liver and extensive spread of intra-abdominal cavity.

Seventy-eight cases underwent the resection of the carcinoma of esophagus with a resectability rate of 91.8%(78/85), including 64 cases for radical resection and 14 cases for palliative resection. As for length of the involved segment of esophagus, 21 cases were shorter than 3 cm, 17 cases ranged from 3-5 cm, and 40 cases longer than 5 cm. The maximal diameters of residual stomachs measured from the fundus to the gastrojejunal anastomosis, ranged from 6 cm to 11.3 cm, mean 9.1 cm which was in contrast to X-ray examination. According to the location of anastomosis sites, 5 cases were localized in neck, 51 above aortic arch, and 22 below aortic arch. Sixty-five patients were anastomosed by handwork, 13 by mechanical anastomat, including 10 above aortic arch and 3 below aortic arch. During the operation, a silica-gel catheter with a metal guiding core was inserted into the jejunum through nostril for 30 cases[14]. Those patients were fed with mixed milk or nutritional fluid through the nasal feeding catheter one day after operation. The patients had a meal 5-10 d following operation (mean 7 d). The span of hospitalization ranged from 14 to 52 d (mean 14.6 d).

Procedure of operation

Our approach was through a left thoracotomy incision. The tumor was examined and if it appeared to be resectable, the left diaphragm was opened and the exploration of abdominal

cavity was done. After examining the operative condition of previous subtotal gastrectomy, the spleen, splenic hilus and pancreatic tail were dissociated from the back of peritoneum. Meanwhile, two to four short gastric blood vessels should be preserved to provide adequate blood supply for the residual stomach. The residual stomach, afferent and efferent loops of jejunum were mobilized from peripheral cohesion, and the previous gastrojejunal anastomosis was brought into the left thorax, the afferent loop of jejunum close to gastrojejunal anastomosis was transected and the gastric end was closed. If the part of gastrojejunal anastomosis was removed at the same time, the length of the residual stomach may be prolonged (Figure 1: C). The afferent loop is rejoined to the efferent loop 30 cm below the original gastrojejunostomy (Roux-en-Y method, Figure 2: AA'). The cardia was transected and closed (if mechanical approach was used, the cardia was not closed temporarily, Figure 1: D). The residual stomach, gastrojejunal anastomosis, efferent of jejunum, spleen, tail of pancreas were all transposed into the left thoracic cavity. The esophagus was mobilized and the upper end of esophagus resected 5 cm above the tumor as described in Sweet' s esophago-gastrostomy (Figure 2: BB'). If the staple was used, the esophagus was anastomosed to the fundus of the substitution through the cardiac, and the end of cardiac was shut soon after. The splenic ligament was fixed firmly to the thoracic wall to reduce the tension on the esophagogastric anastomosis. If the anastomosis was performed in neck, the fundus of the residual stomach could be brought up into the neck through thoracic cavity or the bed of esophagus. The approach of the operation is represented diagrammatically in Figures 1 and 2. Preoperative and postoperative barium meal examinations, postoperative roentgenogram of chest and field of operation in one of the patients are shown in Figures 3-7.

Figure 5 Field of operation, showing the spleen in the left thoracic cavity.

Figure 6 Postoperative roentgenogram of chest, showing the spleen shadow in the left thoracic cavity.

Figure 1 Resection range.   **Figure 2** Postoperative situation.

Figure 7 Postoperative barium meal examination, showing the esophagogastric anastomosis above the aortic arch, the residual stomach with previous gastrointestinal anastomosis, and the Roux-en-Y anastomosis.

Follow-up and statistical analysis

All the patients were followed up after operation. The patients failed to be followedup were deemed as death according to the last time they could be contacted. The survival rate was calculated on the basis of Kaplan-Meier procedure by statistical software SPSS10.0. The condition of eating, the body weight and the Performance Status for the patients recruited in our study 3 months after the operation. Enumeration data and measurement data were analyzed by χ^2 and t test, respectively.

RESULTS

Seventy-eight patients received resection of the tumor, including 24 cases having grade I of squamous carcinoma, 47 cases having grade II of squamous carcinoma, 4 cases grade III of squamous carcinoma, 2 cases adenocarcinoma and 1 case

Figure 3 Preoperative barium meal examination, showing mid thoracic esophageal tumor.   **Figure 4** Preoperative barium meal examination, showing residual stomach.
carcinosarcoma. There were two cases having positive resection margins. With regard to lymph node status, 34 patients were complicated with metastasis of lymph node, and 43 patients without. According to UICC1997 PTNM stage, 5 patients were classified as stage I, 30 stage II, and 43 stage III. The complication rate following operation was 10.3%(8/78), with two cases suffering from arrhythmia, two cases having pneumonia and four cases having anastomostic leakage. All these patients with complications were cured through conservative management without operation death. The follow-up rate was 91.0%(71/78), six patients lost contact. The 1, 3, 5, and 10yr survival rate were 85.7%, 50.7%, 30.6% and 18.8%, respectively (Figure 8). The patients undergoing resection could take semi-fluid diet, accounting for 92.3%(72/78). Among all the patients, 84.7%(72/85) could have 300±500 mL volume of semi-fluid diet. The mean body mass was 49.8±8.9 kg. Compared with the previous body mass, 41.0%(32/78) patients got a body weight gain after operation. In term of the grade of Performance Status, 72.9%(62/85) patients had grade 0-1, and 27.1%(23/85) grades 2-4. Apart from the body mass, the difference between the index of quality of life before operation and the comparative index after operation was statistically significant ($P<0.05$).

Figure 8 Kaplan-Meier survival curve.

DISCUSSION

Cancer of esophagus in Chaoshan region is prevalent with a high incidence, so are the gastroduodenal diseases, especially the peptic ulcer. Therefore, there are some patients with esophageal carcinoma after subtotal gastrectomy in this area. The incidence rate of these patients was 2.3%(85/3632) compared with the patients with esophageal carcinoma treated surgically in our hospital in the same period, which demonstrates the management of these patients should also be emphasized. The average interval between gastrectomy and diagnosis of esophageal carcinoma was 15 years. The mean age of the patients was 60.3 years, with no significant difference compared with other patients suffering from esophageal carcinoma without subtotal gastrectomy. So it may be suggested the development of carcinoma of esophagus is not obviously correlated with the history of surgical operation of stomach. The relationship between esophageal carcinoma and previous gastrectomy for benign ulcer disease are still not clear[9,10,15-19].

As for the influence of previous operation, the colon or jejunum is the most popular choice as a substitution in such patients. This approach is complicated and can greatly affect the postoperative quality of life[13,20,21]. For this reason, some patients were not accessible to resection, but were treated by radiotherapy. When the demand of the resection of esophageal carcinoma was met, the procedure of using the residual stomach to reconstruct the digestive tract, is the best choice, which not only facilitates the recovery of digestive function following operation, but also improves the quality of life in patients with
esophageal carcinoma after previous subtotal gastrectomy. In the process of this procedure, the residual stomach must have sufficient length for lifting, and good blood supply. The blood supply of the residual stomach originated from the short artery. Transferring spleen, tail of pancreas to thoracic cavity can provide the residual stomach with good blood supply, and benefit the lifting length of it. Amputating at the jejunal afferent loop near anastomosis, and making the jejunual Roux-Y anastomosis, fully dissociating the previous operative cohesion could also prolong the lifting length and decrease the lifting tension of the residual stomach. After being fully dissociated, the residual stomach can be lifted up by about 20 cm. Four cases were complicated with anastomotic leakage in the group, including 3 cases with thoracic leakage[13] occurring during the early application of this technique. The causes of the thoracic leakage might be related to the local infection and suturing skill. The cause of the other case with anantomotic leakage in neck probably was connected with the tension of the residual stomach. Recently, we replaced manual manipulation with mechanical anastomosis, using staple to close the cardiac and the lesser curvature of stomach. This is better for the extension of the residual stomach, reducing the traction and tension of anastomosis. At the early period after operation, the patients were offered nasal feeding nutrition, which was conducive to the rehabilitation and reduction of complications for patients after resection.

So far, there has been no clear report on the benefit of this procedure, which preserves the residual stomach and anastomoes it to esophagus, in terms of the long-term effect and quality of life for the patients with esophageal carcinoma after subtotal gastrectomy[21-29]. Compared with the management of the other patients with esophageal carcinoma in corresponding period, the difference between the means of operation and the findings of pathology in this group was not significant. The 5- and 10-year survival rates were 30.6% and 18.8% respectively. In comparison of the long-term survival rate of our group and those of the other big groups[10,30-33], no significant difference could be found. All these demonstrate that such an approach can achieve a good efficacy. The patients were satisfied with their quality of life, and the majority of them could have semi-fluid diet. Over 50% of them had a body mass gain. The grade of Performance Status of them also improved greatly. In conclusion, the above evidences further confirm that in the management of the patients with carcinoma of esophagus after previous subtotal gastrectomy, the technique, which used the residual stomach to reconstruct the alimentary tract, not only accomplished a rather good long-term survival rate, but also improved the quality of patients' life. So it is a simple operative approach with few trauma and good results.

Abstract

AIM: To investigate the immunotherapeutic potential of vaccine consisting of dendritic cells (DCs) pulsed with total RNA from MFC gastric cancer cells.

METHODS: DCs were prepared from the spleens of strain 615 mice by magnetic cell sorting (MACS). After culture for 24 h, DCs were pulsed with total RNA from MFC gastric cancer cells. Mice of one group were immunized with tumor RNA pulsed DC (RNA/DC) at the dosage of 1×10^6 on d 14 and 7 by s c inoculation before tumor implantation. Mice of another group were immunized with unpulsed DC (UDC) at the same dosage on days as the RNA/DC group. The third group of control mice was untreated. On d 0, all the mice were challenged with s c injections of 5×10^5 MFC gastric cancer cells. After inoculation, the mice were monitored closely with respect to tumor growth. Activities of NK cells in PBL and splenocytes and CTL were tested.

RESULTS: On d 21 after tumor cell inoculation, the mice of control group manifested the largest tumors with volume at a mean of 2.6323 ± 1.1435 cm^3, followed by the UDC and RNA/DC groups with mean volumes at 0.7536 ± 0.3659 cm^3 and 0.3688 ± 0.6571 cm^3, respectively. The activities of NK cells in PBL and splenocytes in RNA/DC group were 66.2% and 65.4%, respectively, higher than that in the control group. The tumor specific CTL activity in RNA/DC group was 49.5%, higher than that in the control group.

CONCLUSION: The tumor vaccine with DCs pulsed with total RNA from gastric cancer cells possesses the ability to stimulate tumor specific CTL activity and to establish anti-tumor immunity when administered *in vivo*.

INTRODUCTION

T cells, in particular CD8+ cytotoxic T lymphocytes (CTLs), are regarded as the principal effectors of anti-tumor immunity. Several studies have demonstrated that tumor-specific CTL can be induced to recognize peptide epitopes presented on the tumor cell surface in the context of MHC class I molecules. Tumors, however, have evolved various mechanisms to escape from host immune surveillance, such as loss of class I or antigen variants, secretion of immuno-suppressive agents, or development of antigen-specific T cell clonally anergy due to lack of co-stimulation[1].

The dendritic cell (DC) system of antigen-presenting cells (APCs), is the initiator and modulator of immune response[2]. DCs are efficient stimulators of B and T lymphocytes. DCs have been known to be highly specialized antigen-presenting cells and principal activators of resting or naive T cells *in vitro* and *in vivo*, capable of efficiently transporting antigens[3].

Immature DCs are capable of capturing and processing antigens extensively, they are also able to internalize apoptotic cells by binding to them via adhesion molecules[4]. After the uptake and processing of antigens, DCs leave peripheral tissues and migrate to lymphoid organs in order to present antigens to T lymphocytes. In lymph nodes, DCs form clusters with T lymphocytes by means of various adhesion molecules, in particular CD54(ICAM-1), CD102(ICAM-3) and CD58 (LFA-3), that are highly expressed by activated DCs[5]. The DC/T cell interaction is stabilized by the specific ligation of T cell receptors (TCR) of the MHC-peptide complex, which delivers the first activation signal to T lymphocytes. The second costimulatory signal is absolutely necessary to allow T cell activation and proliferation. This signal is mediated by the interaction of CD80(B7-1) and CD86(B7-2), both of which present on DC, with T cell CD28. Expression of a large amount of MHC costimulatory molecules and production of IL-12 by mature DCs turn them into very potent professional APCs[6]. DCs pulsed with tumor antigen can induce specific CTL activity[7].

The aim of the present study was to investigate the ability of DC pulsed with tumor RNA to stimulate specific CTL reaction and the potential usefulness of DC-based vaccines for the treatment of cancer patients.

MATERIALS AND METHODS

Mice and cell line

Seven to eight wk-old strain 615 mice (H-2K^k) used in these experiments, were obtained from the Chinese Academy of Medical Sciences (Beijing, China). The murine gastric carcinoma cell line MFC derived from strain 615 mouse was provided by the Chinese Academy of Medical Sciences. MFC was cultured in MPRI-1640 medium containing 100 g/L FCS.

Isolation of dendritic cells from mouse spleen

Spleen cells were prepared and treated with collagenase D. Splenocytes were labeled with mouse CD11C$^+$ DC MicroBeads (MACS, Miltenyi Biotec) according to the manufacturer's manual. In brief, 10^8 splenocytes were resuspended in 400 μL buffer and 100 μL of MACS CD11c MicroBeads was added. After thoroughly mixed, the splenocytes were incubated for

15 min at 6-12 ℃, followed by a wash with 10-20× labeling volume of buffer. Cells were resuspended in 500 μL of buffer and applied onto the MS⁺/MS⁺ column to allow removal of the negative cells. Three rinses with 500 μL of buffer were performed prior to removal of the column from the separator. The column was placed in a collection tube, and 1ml of buffer was flushed into the column to secure the positive cells. The positive cells were cultured in IMDM containing 200 mL/L FCS, 100 ng/mL IL-4, 100 ng/mL GM-CSF, 10 ng/mL TNF-α for 24 h, then examined by scanning electron microscope and flow cytometry.

Preparation of tumor total RNA

Tumor total RNA was isolated from actively growing tissue culture cells, 1×10^7 MFC murine gastric cancer cells were lysed in 1 mL of Trizol reagent (Life Technologies) prepared according to the protocol provided by the manufacturer. One mL of Trizol reagent was added to 1×10^7 of MFC cells which were well mixed well prior to incubation for 5 min at room temperature. Then 0.2 mL of chloroform was added and the mixture was thoroughly mixed and incubated for 3 min at room temperature. After centrifugation of 12 000 *g* for 15 min at 4 ℃, contents were transferred in the aqueous phase to a fresh tube, then 500 μL of isopropyl alcohol was added and mixed well, followed by incubation at room temperature for 10 min and centrifuged at 12 000 *g* for 10 min at 4 ℃. The RNA pellet was washed with 1 mL of 750 mL/L ethanol, and redissolved in RNase free water.

Pulsing DCs with tumor RNA

The procedure used for pulsing DCs with tumor RNA was described by Boszkowsk[8]. In brief, DCs were washed twice in Opti-MEM medium (GIBCO BRL). Cells were resuspended in Opti-MEM medium at $2\text{-}5\times10^6$ cells/mL and transferred into 15 mL polypropylene tubes (Falcon). The cationic lipid, DOTAP (Boehringer Manheim), was used to deliver RNA into the cells, and 25 μg of total RNA in 500 μL Opti-MEM and 50 μg of DOTAP in 500 μL Opti-MEM were mixed in 12×75 mm polystyrene tubes at room temperature for 20 min. The complex was added to the DCs and incubated at 37 ℃ for 2-4 h.

Immunization of mice using tumor RNA pulsed DCs vaccine and tumor challenge

Tumor RNA pulsed DCs (RNA/DC) and unpulsed DCs (UDC) were collected, washed twice with PBS and then resuspended in PBS. Mice from the respective treatment groups were immunized with these preparations. Each mouse received the designated dose of 1×10^6 DCs s c with an intervening period of 7 d before administration of the second dose. The mice untreated were used as control. Twelve mice were in RNA/DC group, 10 mice in UDC group, and 12 mice in control group.

Seven days after vaccination with DCs for the second and last time, each mouse in the RNA/DC group received inoculation of 5×10^5 MFC stomach cancer cells subcutaneously. The animals were closely monitored until the first palpable tumor appeared. Thereafter, two-dimensional tumor measurements were made using calipers, the measurements were recorded every 3-4 d.

Cytotoxicity and cytokine analysis

Three weeks after tumor challenge, all the mice were sacrificed. Their spleens were removed and placed in PBS. The splenocytes were depleted of red blood cells through incubation in 8.4 g/L ammonium chloride for 10 min at 37 ℃. The samples were then washed twice with PBS. The cells obtained were resuspended with RPMI-1640 containing 100 g/L FBC, 2β-

mercaptoethanol and 10 u/mL IL-2. Splenocytes were stimulated with irradiated MFC gastric cancer cells (5 000 rads) in the ratio of 10:1 (E:T). The samples were then cultured for 5 days and CTLs from each culture were tested. Cell mediated lysis was confirmed *in vitro* using standard chromium (^{51}Cr)-release assay.

When the mice were sacrificed, p40 subunits of IL-12 in serum were measured using standard ELISA (R & D).

RESULTS

DCs phenotype

DCs were cultured in IMDM containing 200 g/L FCS, 100 ng/mL IL-4, 100 ng/mL GM-CSF, 10 ng/mL TNF-α for 24 h after sorted by mouse CD11C⁺ DC MicroBeads. DCs phenotypes were detected by flow cytometry with H-2KK, I-EK, CD80, and CD 86 (Table 1).

Table 1 DCs phenotypes before and after culture

	Before culture (%)	After culture (%)
H-2K^K	92.1	91.6
I-E^K	28.1	59.2
CD80	21.0	76.4
CD86	23.1	61.3

Induction of host protective immunity against tumor by RNA pulsed DCs

To determine whether RNA pulsed DC could induce host protective immunity against MFC gastric cancer, strain 615 mice were immunized subcutaneously with RNA pulsed DCs or unpulsed DCs. Seven days after immunization, the mice were inoculated subcutaneously with 5×10^5 MFC murine gastric cancer cells. The results (Figure 1) showed that the mice in the control group (control mice) were all tumor positive on d 7, while the mice immunized with RNA pulsed DCs demonstrated a significant delay in tumor development (7 *vs* 11 d). RNA pulsed DC immunization reduced tumor incidence significantly. In the RNA/DC group, 41.7% of the mice (5/12) were free from tumor; in the UDC group, 80% of the mice (8/10) developed tumors, and all the mice (12/12)developed tumor in control group on 21 d after tumor cell inoculation. On d 21 after tumor cell inoculation, the tumor volume of the control group attained a mean of 2.6323 ± 1.1435 cm^3, followed by the UDC and RNA/DC groups with mean volumes of 0.7536 ± 0.3659 cm^3 and 0.3688 ± 0.6571 cm^3, respectively (Figure 1).

**Figure 1** Tumor growth curve. Control group mice (*n*=12) were inoculated sc with 5×10^5 MFC gastric cancer cells without any immunization. UDC group mice (*n*=10) were immunized twice with unpulsed DCS followed by inoculation sc with 5×10^5 MFC gastric cancer cells. RNA/DC group mice (*n*=12) were immunized twice with RNA pulsed DCs followed by inoculation s c with 5×10^5 MFC gastric cancer cells.

Induction of tumor specific CTL cytotoxicity by RNA pulsed DCs

Four weeks after immunization, splenocytes were restimulated *in vitro* with irradiated MFC murine gastric cancer cells for cytotoxic T lymphocyte (CTL) propagation. The results demonstrated that tumor RNA pulsed DCs induced strong tumor specific CTL production. Immunization with MFC tumor RNA pulsed DCs induced stronger lysis of MFC (Figure 2). NK cell activity in PBL or in splenocytes was examined after the mice were sacrificed, revealing that the greatest NK cell activity was seen in the RNA/DC group.

Figure 2 Cytotoxicity of NK cells and CTL. PBNK: NK cell activity in PBL, Sp-NK: NK cell activity in splenocytes, CTL-MFC: CTL activity to lyses MFC murine gastric cancer cells.

Serum IL-12 level

Three weeks after tumor challenge, IL-12 in serum was detected by ELISA. The results showed that the serum IL-12 level was the highest in the RNA/DC group among the three groups (Figure 3).

Figure 3 Serum IL-12 p40 levels in three groups of mice three weeks after tumor challenge.

DISCUSSION

In recent years, DCs have been found to play an important role in the rejection of tumors by the immune system. Their infiltration of tumors has been associated with an improved prognosis for many neoplasms[9,10].

A number of tumor antigens recognized by CD8+ CTL have been identified[11]. These defined antigens could simply be added as 9-11 mer HLA-I-restricted peptides to mature DCs[12]. So, the use of peptide-pulsed DC can obtain clearly effective results, but it requires prior knowledge of patients' HLA types and the sequence of the relevant peptide epitopes. It has been suggested that the use of longer peptides or whole proteins, which are not directly present but are endocytosed and processed, is a better way to generate a fully competent DC vaccine since it allows selection by the APC of the optimal 9-mer peptide for presentation[13]. After cloning, these tumor

antigens can also be used as cDNA in appropriate vectors to load DCs. But there are three major restrictions when defined tumor antigen is used. First, effective TSA or TAA is not identified in a large number of cancers, especially in gastric cancer. Second, it is clear that immunotherapy approaches directing against a unique antigen favor the selection of a tumor mutant that has selectively lost its ability to present efficiently to the defined antigen[14]. Third, the acquisition of antigen-specific CTL *in vitro* is not a guarantee of the development of a curative immune response *in vivo*.

To bypass these disadvantages, several alternative methodologies have been developed. Unfractionated MHC-I-presented peptides could be eluted from tumor cells and loaded onto DC [1]. DCs could also be pulsed with whole tumor antigens, such as cell lysates[15], cell extracts[16], apoptotic cells[4,17], total RNA or mRNA[7]. The method of fusing tumor cells with DCs has also been explored[18,19]. The recent demonstration of cell-contact generated by short-term coculture of DC with tumor cells without cell fusion could result in a potent immunogen and was particularly relevant[20]. DCs pulsed with tumor RNA may thus be a potential effective means to induce host T cell-mediated anti-tumor responses. Boczkowski *et al.* have recently demonstrated that vaccination with tumor RNA pulsed DCs could elicit T cell protective immunity against tumor challenge and induce immune rejection of established tumors[8].

Gastric cancer is one of the tumors with very high heterogeneity. Host immune status in patients with gastric cancer is usually poor. Up to the present, immunotherapy for gastric cancer has not been clearly effective. The use of DC-based tumor vaccine can provide a glimmer of hope for patients with gastric cancer. In this experiment, we used tumor total RNA as tumor whole antigen to pulse DCs. All the antigens were processed and selectively presented to T cells by DCs. The results following the use of tumor total RNA pulsed DCs as vaccine, indeed, induced anti-tumor immune responses by stimulating NK cells and tumor-specific CTL activity in the mouse.

For clinical trials of DC-based vaccine for cancer, other matters must be considered. The first is the source of DCs for clinical use. The second is the choice of tumor antigens and method for antigen loading of DCs. Third, the DC dose-response relationship should be determined using individual cell preparation methods. Finally, the optimal route and frequency of administration need to be determined.

Abstract

AIM: To investigate maspin expression in tumorigenesis and progression of gastric cancer and to explore its relevant molecular mechanisms.

METHODS: Formalin-fixed and paraffin-embedded tissues from normal mucosa (n=182), dysplasia (n=69), cancer (n=113) of the stomach were studied for maspin expression by immunohistochemistry. Microvessel density (MVD) in gastric cancer was labeled using anti-CD34 antibody. Maspin expression was compared with clinical parameters and MVD of tumors. Caspase-3 expression was also detected in gastric carcinoma by immunohistochemistry. The relationship between Caspase-3 and maspin expression was concerned as well.

RESULTS: The positive rates of maspin expression were 79.8%(145/182), 75.4%(52/69) and 50.4%(57/113) in normal mucosa, dysplasia and cancer of the stomach, respectively. Cancer less frequently expressed maspin than normal mucosa and dysplasia (P<0.05). Maspin expression showed a significantly negative association with invasive depth, metastasis, Lauren's and Nakamura's classification (P<0.05), but not with tumor size, Borrmann's classification, growth pattern or TNM staging (P>0.05). The positive rate of Caspase-3 was significantly lower in gastric cancer than in normal gastric mucosa (P<0.05,32.7% vs 50.4%). It was noteworthy that maspin expression was negatively correlated with MVD, but positively correlated with expression of Caspase-3 in gastric cancer (P<0.05).

CONCLUSION: Down-regulated maspin expression is a late molecular event in gastric carcinogenesis. Reduced expression of maspin contributes to progression of gastric cancer probably by inhibiting cell adhesion, enhancing cell mobility, decreasing cell apoptosis and facilitating angiogenesis. Additionally altered expression of maspin underlies the molecular mechanism of differentiation of gastric cancer and supports the different histogenetic pathways of intestinal and diffuse gastric cancers. Maspin expression can be considered as an effective and objective marker to reveal biological behaviors of gastric cancer.

INTRODUCTION

Mammary serine protease inhibitor (maspin) was identified by subtractive hybridization as a candidate tumor suppressor protein in normal mammary epithelial cells[1]. Maspin gene maps to human chromosome 18q21.3-q23, whose cDNA consists of 2 584 nucleotides encoding for a 42 ku peptide[2]. A number of findings support its inhibitory effects on tumors. Levels of maspin expression showed an inverse correlation with progression of malignancies. Mammary carcinoma cells transfected with maspin showed a reduction of tumor growth and metastasis in nude mice, the addition of recombinant maspin decreased the migration potential of breast and prostate cancer cells across a reconstituted basement membrane. More recently, maspin has been shown to inhibit angiogenesis by blocking *in vitro* migration of vascular endothelial cells and by *in vivo* inhibition of rat cornea neovascularization[1-8]. It has been documented that maspin transgene expression in mouse mammary gland inhibited Simian virus 40 (SV40) large T-antigen induced breast carcinogenesis and was correlated with increased apoptosis of mammary gland cells[9].

Gastric cancer is one of the commonest malignancies in China, and even in the world. However, the molecular aspects of carcinogenesis and progression of gastric cancer remain elusive[10-19]. The purposes of this study were to examine maspin expression in normal gastric mucosa, gastric dysplasia, gastric cancer, and to compare its expression with clinicopathological features of gastric cancer, and to analyze the correlation of maspin expression with Caspase-3 expression and MVD in gastric cancer.

MATERIALS AND METHODS

Patients and samples
Normal mucosa (n=182), dysplasia (n=69), cancer (n=113) of the stomach were collected from the Second Affiliated Hospital of China Medical University between Sept. 1996 and Feb. 2002. All tissues were fixed in 40 g/L formaldehyde, embedded in paraffin and incised into 4 μm sections. These sections were stained by hematoxylin-and-eosin method to confirm their histological diagnosis and other microscopic characteristics. All patients did not undergo chemotherapy and radiotherapy before operation.

Evaluation of clinicopathological parameters of gastric cancer
Clinicopathological staging for each gastric carcinoma was evaluated according to the TNM system. Gross appearance of the tumors was described according to Borrmann's classification. Histomorphological architecture of the tumor samples was expressed according to Lauren's and Nakamura's classifications. Growth patterns of gastric cancer were classified into mass-,

nest-, or diffuse- type. Furthermore, tumor diameter, invasive depth and metastasis were determined.

Immunohistochemistry

Representative and consecutive sections were studied with streptavidin-biotin-peroxidase immunohistochemistry (SABC kit from Boster Biotech.). Anti-maspin, anti-Caspase-3 and anti-CD34 antibodies were purchased from Novocastra, Zhongshan (China) and DAKO respectively. All procedures were implemented according to the instructions of the product. For negative controls, sections were processed as above but treated with PBS (0.01 mol/L, pH7.4) instead of primary antibodies.

Evaluation of maspin and Caspase-3 immunostaining

The immunoreactivity to maspin and Caspase-3 was localized in cytoplasms. One hundred cells were selected and counted from 5 representative fields of each section by two independent observers. The positive percentage of counted cells was graded semi-quantitatively into one of the four-tier scoring system: negative(-), 5%; weakly positive (+), 5-25%; moderately positive (++), 25-50%; and strongly positive(+++), 50%.

Microvessel density counting

CD34 antibodies were distributed in cell membranes and cytoplasms of vascular endothelial cells. Modified Weidner's method was used to calculate the microvessel density, which was described as follows. Microvessels in tumor were considered as hot points in vessel counts. Any brown staining endothelial cell or endothelial cell cluster was regarded as a single, countable microvessel. Observers selected such five areas and counted individual microvessels at 400× magnification (*i.e.* 40× objective lens and 10× ocular lens, 0.1885 mm² per field).

Statistical analysis

Statistical evaluation was performed using *chi*-square test to differentiate the rates between different groups, using Spearman correlation test to analyze the rank data, and using one-way ANOVA to differentiate means of different groups. $P<0.05$ was considered as statistically significant. SPSS 10.0 software was employed to analyze all data.

RESULTS

Maspin expression in normal mucosa, dysplasia, and cancer of the stomach

Figures 1A-D show the positive immunoreactivity to maspin in cytoplasms of epithelial, dysplasia and cancer cells of the stomach. As summarized in Table 1, the positive rates of maspin expression were 79.8%(145/182), 75.4%(52/69), and 50.4%(57/113) in normal mucosa, dysplasia and cancer of gastric cancer, respectively. Normal mucosa and dysplasia more frequently expressed maspin than cancer ($P<0.05$).

Table 1 Maspin expression in normal mucosa, dysplasia, and primary cancer of the stomach

Groups	*n*	Maspin expression		
		-	+~+++	%
Normal mucosa	182	37	145	79.8[b]
Dysplasia	69	17	52	75.4[d]
Primary cancer	113	56	57	50.4

Compared with primary cancer [b]P=0.000 (χ^2=27.589, Pearson' *r*=0.306), [d]P=0.000 (χ^2=11.075, Pearson' *r*=0.247).

Figure 1 A: Localization of maspin in cytoplasms, and strong expression in gastric epithelial cells (SABC, ×400), B: Strong immunoreactivity of gastric dysplastic cells to maspin (SABC, ×400), C: Strong immunostaining of maspin in gastric papillary adenocarcinoma cells (SABC, ×400), D: Negative expression of maspin in poorly-differentiated gastric adenocarcinoma cells(SABC, ×400).

Relationship between maspin expression and clinicopathological features of gastric cancer

Table 2 shows that maspin expression had a significantly negative association with invasive depth, metastasis, Lauren's and histological classifications ($P<0.05$), but not with tumor size, Borrmann's classification, growth pattern or TNM staging ($P>0.05$).

Relationship between maspin and Caspsae-3 expression, MVD in gastric cancer

The positive rate of Caspase-3 expression was lower in gastric

cancer than in normal gastric mucosa (*P*<0.05, 32.7% *vs* 50.4%). It was noticeable that maspin expression was positively correlated with Caspase-3 expression, but negatively with MVD in gastric cancer (*P*<0.05) (Tables 2-3, Figures 2,3).

Table 2 Relationship between maspin expression and clinico-pathological features of gastric cancer

Clinicopathological features	*n*	Maspin expression

DISCUSSION

Carcinogenesis and progression of malignancies are a complicated multistage process that requires the coordination of multiple genes, including oncogenes and tumor suppressor genes. Genomic instability is one of the driving forces for tumor development. Among all genetic alterations, inactivation of metastasis suppressor genes has been found to be an important factor because of their contribution to malignant change of normal cells and metastasis of tumor cells[20,21].

It is known that maspin is highly expressed in various kinds of normal cells and lowly expressed in cancer cells. Our data showed that maspin expression was gradually reduced from normal mucosa, through dysplasia to cancer of the stomach. The positive rate of maspin expression was lower in gastric cancer than in normal gastric mucosa and gastric dysplasia with no significant difference in the latter two. These results suggested that reduced maspin expression contributed to malignant change of gastric epithelial cells. The down-regulated expression of maspin could be considered as a late molecular event of gastric carcinogenesis. Previous reports indicated that DNA methylation, histone deacetylation or LOH was partially responsible for the silencing of maspin gene expression[22-24]. Decreased expression of maspin might be attributable to these genetic alterations in gastric carcinogenesis as mentioned above.

Our study showed that maspin expression was negatively associated with invasion and metastasis of tumors, suggesting its inhibitory effects on progression of gastric cancer. Biliran *et al*[25] found that maspin could specifically inhibit cell surface-associated urokinase-type plasminogen activator and fibrinogen-bound tissue-type plasminogen activator, which was correlated with significantly decreased cell invasion potential and motility *in vitro*. Blacque *et al*[26] reported that interaction between recombinant maspin and some collagens might contribute to cell adhesion, cell migration and angiogenesis. Seftor *et al*[27] demonstrated that maspin was able to regulate integrin expression, indicating that maspin could reduce the invasive phenotype of cancer cells by altering their integrin profile. These findings suggested that maspin expression could inhibit tumor progression *in vivo*, likely through a combination of increased cell adhesion, decreased angiogenesis, and inhibition of tumor cell migration.

Additionally, it was found that undifferentiated gastric carcinomas had a lower expression of maspin as compared with the differentiated ones, suggesting that down-regulated expression of maspin was closely associated with the differentiation of gastric cancer. Diffuse-type gastric cancers had less expression of maspin as compared with the intestinal-type ones. It supported that there were different tumorigenetic pathways between diffuse-type and intestinal-type gastric carcinomas. Diffuse-type gastric cancer, the main part of which was undifferentiated

carcinoma, displayed a diffusely invasive growth pattern. It is possible that down-regulation of maspin expression could influence mobility and adhesion of cancer cells.

Our study also showed a negative correlation between maspin expression and MVD in gastric cancer. Song *et al*[28] found that maspin-positive colonic adenocarcinomas showed less MVD than maspin-negative ones. Zhang *et al*[8] reported that maspin might act directly on vascular endothelial cells to stop their migration towards basic fibroblast growth factor and vascular endothelial growth factor and to limit mitogenesis and tube formation, which could dramatically reduce tumor-associated MVD. These *in vivo* and *in vitro* data suggest that the tumor suppressor activity of maspin may depend in large part on its ability to inhibit angiogenesis and raise the possibility that maspin and similar serpins may be excellent targets for the development of drugs that modulate angiogenesis.

Furthermore, it was found that Caspase-3 expression was increased in gastric cancer with maspin positively expressed. Jiang *et al*[29] reported that endogenous maspin expression could enhance staurosporine-induced apoptosis of carcinoma cells as judged by the increased fragmentation of DNA, increased proteolytic inactivation of poly-[ADP-ribose]-polymerase, as well as the increased activation of Caspase-8 and Caspase-3. Li *et al*[30] showed that apoptosis induced by manganese-containing superoxide dismutase was associated with elevated maspin expression level. These results indicated that it was possible that maspin expression might inhibit progression of gastric cancer by inducing apoptosis.

In summary, down-regulated maspin expression is a late molecular event in gastric carcinogenesis. Reduced expression of maspin can contribute to progression of gastric cancer by inhibiting cell adhesion, enhancing cell mobility, decreasing cell apoptosis and facilitating angiogenesis. Additionally altered expression of maspin underlies the molecular mechanism of differentiation of gastric cancer and supports the different histogenetic pathways of intestinal and diffuse gastric cancers. Maspin expression can be considered as an effective marker to reveal biological behaviors of gastric cancer.

Abstract

AIM: Most cancer cells acquire immortal capability by telomerase activation. The human telomerase reverse transcriptase gene (*hTERT*) is considered to be the major determinant of the enzymatic activity of human telomerase, and the *hTERT* promoter contains several c-Myc binding sites that mediate *hTERT* transcriptional activation. Few studies have examined the role of *hTERT* in hepatocarcinogenesis, and the relationship between c-Myc and telomerase in human hepatocellular carcinoma tissue is unknown.

METHODS: We measured *hTERT* mRNA levels and c-Myc oncoprotein expression in 57 patients with hepatocellular carcinoma using *in situ* hybridization and immunohistochemistry, respectively. The transcription regulation of *hTERT* was evaluated by transient transfection of pGL3-1375 into the human hepatocellular carcinoma cell line J5. To determine the relationship between c-Myc and the *hTERT* promoter, a 1375-bp DNA fragment encompassing the promoter was placed upstream of the luciferase reporter gene and transiently transfected into the cell line. Two additional *hTERT* promoter constructs (-776 and -100 bp region) and an *hTERT* promoter-LUC construct containing 2 c-Myc mutations (pGL3-181 MycMT) were also used for luciferase assays.

RESULTS: In 30 of 57 cases (52%), *hTERT* mRNA expression was associated with c-Myc protein expression. However, 16 of 57 cases (28%) showed strong *hTERT* mRNA detection without c-Myc protein expression, and 11 cases (19%) showed weak *hTERT* mRNA expression and strong c-Myc expression. Although luciferase activity was decreased between upstream 1 375 bp and 776 bp, there was no significant difference between upstream 776 bp and 100 bp. Finally, there was no significant decrease in activity after transfection of the *hTERT* promoter-LUC construct.

CONCLUSION: The results indicate that c-Myc does not play a major role in gene regulation of the catalytic subunit of telomerase (*hTERT*) in human hepatocellular carcinoma.

Other regulatory elements or epigenetic phenomena should be further investigated to understand *hTERT* gene regulation in human hepatocellular carcinoma.

INTRODUCTION

Telomerase is a ribonucleoprotein enzyme that synthesizes G-rich telomeric repeats using its complementary RNA sequence as a template[1,2]. Telomerase is expressed in most human cancers and immortal cell lines but is inactive in normal somatic cell lines or tissue[3-5]. Recent reports support the concept that activation of telomerase may be an important and obligate step in the development of most malignant tumors[6,7], including human hepatocellular carcinoma (HCC)[8]. The human telomerase catalytic subunit (*hTERT*) has been shown to be a rate-limiting determinant of the enzymatic activity of human telomerase[9,10]. Takakura *et al* identified the proximal 181-bp core promoter region essential for transactivation of *hTERT*[11]. Their findings suggest that *hTERT* expression is strictly regulated at the transcription machinery, and that the proximal core promoter containing an E-box which binds to Myc/Max, as well as the 3'-region containing the GC-box which binds to Sp1, is required for transactivation of *hTERT*[12]. Their findings further indicate that c-Myc and Sp1 cooperatively function as the major determinants of *hTERT* expression, and that the switching functions of Myc/Max and Mad/Max might also play roles in telomerase regulation. Wang *et al* added further support that Myc induce telomerase both in normal human mammary epithelial cells and in normal human diploid fibroblasts by introducing HPV-16, E6 protein into these cells[13]. Their findings suggest that the ability of c-Myc to activate telomerase may contribute to its ability to promote tumor formation. Further, telomerase activity in estrogen receptor-positive MCF-7 cells was upregulated by treatment with 17β-estradiol[14]. Kyo *et al* reported that estrogen activated c-Myc expression in MCF-7 cells, and that E-boxes in the *hTERT* promoter that bind to c-Myc/max played additional roles in estrogen-induced transactivation of *hTERT*.

By using TRAP assay, we previously measured telomerase activity in surgically resected specimens from 25 cases of hepatocellular and adjacent healthy tissues[15]. Telomerase activity was detected in 21 of the 25 HCC specimens from 25 different cases. This telomerase activity was correlated with human telomerase reverse transcriptase (hTERT) mRNA isoform expression but was poorly related to c-Myc expression in the hepatoma cell line J5[16]. However, the role of c-Myc in *hTERT* expression in HCC remains unresolved.

In this study, we explored the relationship between *hTERT* mRNA regulation and c-Myc expression by RNA *in situ* hybridization and immunohistochemistry stain, respectively. The methods of *in situ* hybridization and immunohistochemistry

are semiquantitative and can determine localization. In addition, to determine the cis-elements essential for transcriptional activation of *hTERT*, luciferase assays were performed with reporter plasmids with serial deletions or mutation of the core promoter using hepatoma cell line J5. The results provide evidence for a role of c-Myc in the regulation of *hTERT* in hepatoma cells.

MATERIALS AND METHODS

Cell lines

All culture media including fetal bovine serum were purchased from Gibco Laboratories (Grand Island, NY). L-glutamine and penicillin/streptomycin were obtained from Sigma (St. Louis, MO).

WI38 cells (normal human fibroblasts) were obtained from the American Type Culture Collection and grown in DMEM containing 2 mmol/L L-glutamine, 50 U/mL penicillin, 50 mg streptomycin, and 100mL/L fetal bovine serum. J5[16] was maintained in RPMI 1640 medium containing 3g/L L-glutamine and penicillin/streptomycin. All cell lines were cultivated in an atmosphere of 50mL/L CO_2 at 37 ℃.

Preparation of RNA probes

Total RNA was obtained from the HT29 cells (ATCC, Rockville, MD) by addition of TRIZOL reagent (Life Technologies, Rockville, MD) according to the manufacturer's instructions.

Ten micrograms of total RNA were used as a template for cDNA synthesis with Moloney murine leukemia virus (M-MTV) reverse transcriptase and oligo (dT)$_{12-18}$ (SUPERSCRIPT Preamplification System, Life Technologies). Subsequently, the forward primer 5' -CGG AAG AGT GTC TGG AGC AA-3' and the reverse primer 5' -GGA TGA AGC GGA GTC TGG-3' were designed for amplification of a 145-bp segment of *hTERT* spanning from nucleotide position 1 784 to 1 928 (GenBank accessory No. AF015950). Thirty-five PCR cycles were performed. For each cycle, the sample was denatured at 94 ℃ for 30 s, annealed at 55 ℃ for 60 s, and extended at 72 ℃ for 60 s. A 10 μL sample from 100 μL PCR solution was fractionated by electrophoresis on 20g/L agarose gel. Subsequently, the PCR product was eluted from the agarose gel and subcloned into the pCRII-TOPO vector (Invitrogen, Carlsbad, CA), generating the construct-designated pCRII/hTERT-145.

The sense and antisense riboprobes were synthesized from *Bam* HI- and *Eco* RV-linearized PCRII/hTERT-145 according to the manufacturer's instructions using T7 and SP6 RNA polymerase, respectively, and labeled with digoxigenin-UTP (DIG RNA Labeling Kit, SP6/T7, Roche Molecular Biochemicals, Mannheim, Germany). Moreover, the housekeeping gene *GAPDH* was used to confirm the presence of intact RNA within the slides from each sample used for ISH.

RNA in situ hybridization

Formalin-fixed, paraffin-embedded tissue sections (4-μm thick) were deparaffinized with two 10 min washes with xylene and a graded series of alcohols for 3 min each. The deparaffinized tissues were then pretreated with 20 μg/mL proteinase K (Sigma) and 40 μg/mL pronase (Roche Molecular Biochemicals) at room temperature for 30 min. The tissues were then fixed with 40g/L paraformaldehyde (Sigma) in phosphate-buffered saline at room temperature for 10 min and then acetylated with 2.5mL/L acetic anhydride in 0.1 mmol/L triethanolamine-HCl (pH 8.0) at room temperature for 10 min.

Prehybridization was carried out in hybridization solution containing 500g/L deionized formamide (Merck, Darmstadt, Germany), 5× SSC (1× SSC=150 mmol/L NaCl, 15 mmol/L sodium citrate, pH 7.2), 1g/L N-lauroylsarcosine 2g/L sodium dodecylsulfate, 20mL/L blocking solution (DIG wash and block buffer set, Roche Molecular Biochemicals) and 250 μg/mL sonicated salmon sperm DNA (Invitrogen) at 50 ℃ for 1 h.

The slides were then incubated in a moist chamber at 50 ℃ for 16 h with the hybridization solution containing 0.1 to 0.5 μg/mL digoxigenin-labeled RNA probe. The slides were subsequently washed twice with 50% formamide-2× SSC at 50 ℃ for 30 min, twice with 2× SSC at room temperature for 15 min, and twice with 0.2× SSC at room temperature for 15 min. The slides were then equilibrated with 1× washing solution for 2 min and incubated with 10mL/L blocking solution (DIG wash and block buffer set, Roche Molecular Biochemicals) for 10 min.

The tissues were incubated with a sheep monoclonal antidigoxigenin antibody (Roche Molecular Biochemicals) diluted 1:100 in 10 mL/L blocking solution at room temperature for 2 h. After washed three times with 1× washing solution (Roche Molecular Biochemicals), the color reaction was carried out by incubation with 1× nitroblue tetrazolium (NBT)/5-bromo-4-chloro-3-indolyl phosphate solution (Roche Molecular Biochemicals) at room temperature overnight. The slides were then counterstained with nuclear fast red for 5 min and then mounted with Crystal Mounting reagent (DAKO, Glostrup, Denmark).

Two independent observers evaluated the signal intensity of *hTERT* expression, which was semiquantitated as strong, moderate, weak, or no staining. Sense and antisense probes were applied to paired serial slides, and the noncoding strand detected by sense probes was used as a negative control.

Immunohistochemistry

Immunohistochemical staining was performed to determine the expression of c-Myc. The immunostaining procedure was performed using the labeled streptavidin-biotin method (LASB-2 Kit, DAKO). Briefly, the tissue was placed in a boiling citrate buffer (pH 6; ChemMate™, DAKO) twice for 5 min in a microwave oven at 750 W after deparaffinization and rehydration, as previously described. Quenching of the endogenous peroxidase activity by incubation with 30mL/L hydrogen peroxide for 10 min at room temperature was followed by incubation with mouse monoclonal antibody NCL-cMYC (Clone 9E11, Novocastra Laboratories Ltd., Newcastle-upon-Tyne, UK) diluted 1:200 at room temperature for 2 h. After washed with Tris-buffered saline containing 1g/L Tween-20, the specimens were sequentially incubated for 10 to 30 min with biotinylated anti-mouse immunoglobulins and peroxidase-labeled streptavidin. Staining was performed after 10 min of incubation with a freshly prepared substrate-chromogen solution containing 3% 3-amino-9-ethylcarbazole and hydrogen peroxide. Finally, the slides were lightly counterstained with hematoxylin, washed with water and then mounted. Two independent observers assessed the sections. Because the extent of c-Myc labeling index was heterogeneous, the scoring system included both the staining intensity and the percentage of stained cells[17]. Staining intensity was graded as no staining (0), weak (1), moderate (2), or strong (3). The percentage of tumor cells with c-Myc staining was scored as follows: 1, <5%; 2, 5-20%; 3, 21-50%; 4, >50%. The multiplication values were then grouped into 4 scores as 0 (multiplication values 0, 1), 1 (multiplication values 2, 3), 2 (multiplication values 4, 6), or 3 (multiplication values 8, 9, 12).

PCR amplification and mutation screening of hTERT promoter

One microliter of genomic DNA was obtained as DNA template for use in PCR amplification of the *hTERT* promoter. The forward primer 5' -CCC ACG CGT GCA TTC GTG GTG CCC GGA GC-3' and the reverse primer 5' -CCC AGA TCT ATC GCG GGG GTG GCC GGG GCC AGG-3' were designed on the basis of a published *hTERT* promoter sequence[11]. The PCR product was amplified in the presence of 1 μmol primers with Taq DNA polymerase (Takara Shuzo Company, Shiga, Japan) for 35 cycles of 1 min at 95 ℃, 1 min at 56 ℃, and 1 min at 72 ℃. DNA sequencing using the reverse primer was

performed directly from the gel-purified PCR product or individual PCR product subcloned into the pCRII-TOPO vector. The analysis of the DNA sequences was compared with the wild-type sequence.

Construction of luciferase reporter gene plasmids

A P-3996 construct containing 3 996 bp of sequences upstream of the ATG (with A being position 1) plus exon 1 (219 bp), intron 1 (104 bp), and 37 bp of exon 2 of *hTERT* was used (a kind gift from Silvia Bacchetti, Department of Pathology and Molecular Medicine, McMaster University, Canada)[18]. Various lengths of DNA fragments upstream of the initiating ATG codon were PCR amplified and inserted into luciferase reporter vector pGL3-Basic, a promoter- and enhancerless vector (Promega, Madison, WI) in sense orientation relative to the luciferase coding sequence at *Mlu*I and *Bgl*II sites. The sequences of primers were as follows: pGL3-1375-forward: 5'-CCCACGCGTAGACAATTCACAAACACAGC-3', pGL3-776-forward: 5'-CCCACGCGTGCCAGCAGGA GCGCCTGGCT-3', pGL3-100-forward: 5'-CCCACGCG TCCGCGCGGACCCCGCCCCGT-3' and reverse (common): 5'-CCCAGATCTATCGCGGGGGGTGGCCGGGGC CAGGGCTTC-3' with the PCR condition supported by Satoru Kyo (Department of Obstetrics and Gynecology, Kanazawa University, School of Medicine, Ishikawa, Japan)[11]. The PCR product was amplified in the presence of 1 μL primers with TaKaRa Taq DNA polymerase (Takara Shuzo Company, Shiga, Japan) for 30 cycles of 30 s at 96 ℃, 45 s at 62 ℃, and 7 min at 72 ℃, and 30 min at 72 ℃. The products were confirmed to have correct sequences by nucleotide sequencing, and their quantity and quality were routinely checked by agarose gel electrophoresis. All plasmid DNAs were purified with the QIAquick gel extraction kit (QIAGEN, Hilden, Germany).

Transfection luciferase assay

Transient transfection of luciferase reporter plasmids was performed using LipofectAMINE 2000 (LF2000, Invitrogen), according to the protocol recommended by the manufacturer. In brief, 5×10^4 cells were seeded on 24-well plates, cultured overnight, and exposed to transfection mixtures containing 2 mg luciferase reporter plasmids for 4 h at 37 ℃. Then, 0.5 ml growth media was added and cells were harvested 48 h after transfection. Luciferase assays were performed with the dual-luciferase reporter assay system (Promega) according to the manufacturer's protocols. The pGL3-control plasmid (1 mg/well, Promega) was also transfected into each cell line for better comparison among cell lines with different transfection efficiencies. The pRL-SV40 (1 ng/well, Promega) containing the *Renilla reniformis* luciferase gene was cotransfected with the *hTERT* promoter-luciferase constructs (1 mg/well) for normalization of the luciferase activity in each transfection. The MLX microtiter plate luminometer (Dynex Technologies, Chantilly, VA) was used to detect luciferase activity. All experiments were performed at least 3 times in each plasmid and represented the average relative luciferase activity.

Statistical analysis

To evaluate the relationships among paired groups, the Fisher exact test was performed using SPSS 10.0 software. Additionally, the correlation of paired groups was analyzed using chi-square test with the SPSS program. A *P* value ≤ 0.05 was considered statistically significant.

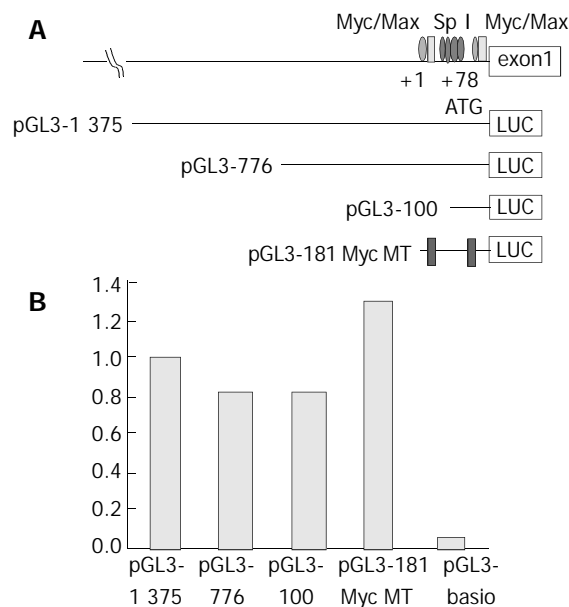
Figure 1 Corresponding distribution of *hTERT* signals and c-Myc staining in HCC tissue detected by HE staining (A, D, and G); *in situ* hybridization (*hTERT* positive, B and H; *hTERT* negative, E); and immunohistochemistry (c-Myc positive, C and F; c-Myc negative, I).


Figure 2 A: Schematic diagram of LUC reporter plasmids. Promoter fragments of decreasing size from the 5' end (1 375 bp, 776 bp, 100 bp and Myc double deletion mutant hTERT-promoter reporter plasmids of 181 bp) upstream of the initiating ATG were inserted into luciferase (*LUC*) reporter vector pGL3-Basic in sense orientation. +1, the transcription start site. Binding sites for c-Myc/Max and Sp1 are shown. B: Transcription activation of hTERT promoter. Data represent normalized relative luciferase fold activity compared with the promoterless pGL3 basic plasmid.

RESULTS

To investigate *hTERT* expression in HCC tissue, *in situ* hybridization was applied. Immunohistochemistry stain was used to observe c-Myc expression and its relationship with *hTERT* mRNA. Forty-seven of 57 cases showed weak to strong *hTERT* mRNA expression. The expression of *hTERT* mRNA was not related to tumor differentiation (*P*<0.815) (Table 1). Forty-three of 57 cases showed c-Myc expression without tumor differentiation (*P*<0.348) (Table 2).

Table 1 Comparison of *hTERT* expression and HCC differentiation

| Differentiation | *hTERT* expression | | | | Number |
	None	Weak	Moderate	Strong	
Strong	1	2	2	7	12
Moderate	7	3	4	14	28
Weak	2	4	3	8	17
Number	10	9	9	29	57

Table 2 Comparison of c-Myc expression and HCC differentiation

| Differentiation | c-Myc expression | | | | Number |
	0	1	2	3	
Strong	3	0	2	7	12
Moderate	5	7	7	9	28
Weak	6	3	2	6	17
Number	14	10	11	22	57

Thirty of 57 cases (52%) of *hTERT* mRNA expression were associated with c-Myc protein expression (30/57). However, 16 of 57 cases (28%) showed strong *hTERT* mRNA detection

with no Myc protein expression, whereas 11 of 57 cases (19%) showed weak *hTERT* mRNA expression with strong c-Myc detection (*P*<0.079) (Figure 1).

Three different-length DNA fragments (-1 375, -776, and -100 bp) encompassing the *hTERT* promoter were placed upstream of the luciferase reporter gene, as was an *hTERT* promoter-Luc construct containing 2 c-Myc mutations (pGL-181 MycMT, a gift from Kyo *et al*). All constructs were transiently transfected into HCC cell line J5 for luciferase study. Luciferase activity decreased between upstream 1 375 and 776 bp, but there was no significant difference of luciferase activity between upstream 776 and 100 bp or the 2 c-Myc mutations (Figure 2).

DISCUSSION

In a previous report, we demonstrated that telomerase activity in the HCC cell line J5 was not related to c-Myc expression[16]. To our knowledge, this is the first study to determine the role of c-Myc in *hTERT* HCC. According to *in situ* hybridization and immunohistochemistry analysis, only half of *hTERT* mRNA expression co-occurred with c-Myc protein expression. Twenty-eight percent of HCC tissue samples had strong *hTERT* mRNA detection with no or weak c-Myc protein expression, 19% of HCC tissue samples had no or weak *hTERT* mRNA expression with strong c-Myc expression. However, several studies reported that Myc expression could transactivate *hTERT* via 2 E-boxes in cooperation with Sp1 motif [12]. One of our constructs (a gift from Kyo), which encompassed 4 Sp1 and 2 c-Myc mutations, showed a high luciferase activity in the HCC cell line.

In contrast to the data of Kyo *et al*[14], pGL3-181MycMT, a double c-Myc mutant, compared with wild type pGL3-181, exhibited a 50% decreased luciferase activity when transfected to the MCF-7 breast cell line. These results implicate that c-Myc is a positive regulator of *hTERT*, though other yet undetermined regulatory elements of *hTERT* in HCC may exist. For example, hepatitis B virus pre-S2/S gene has been found to be a cis-activator of the *hTERT* promoter[19]. By transfection of *HBx* gene into the HepG2 cell line, the activity of telomerase and apoptosis were decreased[20]. Further investigation of non- c-Myc regulatory proteins in hepatoma is required in the future.

In our 16 HCC tissue specimens and 1 J5 cell line, *hTERT* promoter cis-element sequencing was performed. There was a polymorphism site (A transversion to T) just 3 bp away from the distal E-box, which might have affected the binding affinity of c-Myc[21]. This effect might explain why two E-box mutations still had a high telomerase activity. However, more evidence is required in support of this polymorphism nucleotide in 2 E-box mutation construct.

Furthermore, the presence of a large CpG island with a dense CG-rich content implicates that DNA methylation and chromatin structure may play a role in the regulation of *hTERT* expression. Devereux *et al* demonstrated that the promoter of one *hTERT*-negative fibroblast cell line, SUSM-1, was methylated at all sites examined[22]. Treatment of SUM-1 cells with the demethylating agent induced the cells to express *hTERT*, suggesting a potential role for DNA methylation in negative regulation. This epigenetic mechanism could explain why 19% of HCC samples showed strong c-Myc detection with no or weak hTERT mRNA expression. The role of GC island methylation in the regulation of *hTERT* expression merits further study.

In the Kyo *et al* report, the cis-acting effect of E-boxes and the Myc or Max requirement for transactivation varied among different cell types[12]. Deletion and mutation of the E-box resulted in significant loss of transcriptional activity in C33A cells, but not in SiHa cells. In C33A cells, expression of

Myc and Max had only marginal effects on transactivation. This diversity among different cell lineages suggests a varied role of c-Myc in *hTERT* gene regulation. The data also indicate that there are multiple levels of regulation of *hTERT* activity in human neoplasm.

In summary, in the present hepatoma tissue study, 50% of hepatomas showed c-Myc overexpression with *hTERT* transcript upregulation. Other regulator elements and epigenetic mechanisms may be involved in *hTERT* transcript regulation. The proximal c-Myc motif plays a minor role in *hTERT* gene regulation. The results of immunohistochemistry and promoter-constructed luciferase analyses suggest that, in HCC, *hTERT* regulation is not restricted to c-Myc and involves other mechanisms.

Abstract

AIM: To investigate the prognostic value of vascular endothelial growth factor messenger RNA (VEGF mRNA) in the peripheral blood (PB) of patients with hepatocellular carcinoma (HCC) undergoing curative resection.

METHODS: Using a reverse-transcription polymerase chain reaction (RT-PCR)-based assay, VEGF mRNA in the PB was determined prospectively in 50 controls and in 50 consecutive patients undergoing curative resection for HCC.

RESULTS: Among the isoforms of VEGF mRNA, $VEGF_{165}$ and $VEGF_{121}$ were expressed. By multivariate analysis, a higher level of $VEGF_{165}$ in preoperative PB correlated with a risk of HCC recurrence with borderline significance (P=0.050) and significantly with recurrence-related mortality (P=0.048); while $VEGF_{121}$ did not. Other significant predictors of HCC recurrence included cellular dedifferentiation (P=0.033), an absent or incomplete capsule (P=0.020), vascular permeation (P=0.018), and daughter nodules (P=0.006). The other significant parameter of recurrence related mortality was cellular dedifferentiation (P=0.053). The level of circulating VEGF mRNA, however, did not significantly correlate with tumor size, cellular differentiation, capsule, daughter nodules, vascular permeation, necrosis and hemorrhage of tumors.

CONCLUSION: The preoperative level of circulating VEGF mRNA, especially isoform $VEGF_{165}$, plays a significant role in the prediction of postoperative recurrence of HCC.

INTRODUCTION

Angiogenesis, known to be essential for the survival, growth, invasion, and metastasis of tumor cells, is a complex multistep process. There are extracellular matrix remodeling and binding of angiogenic factors to specific endothelial cell (EC) receptors, leading to EC proliferation, invasion of the basement membrane, migration, differentiation, and formation of new capillary tubes. Anastomosis of these new vessels develops into a vascular network[1,2].

Several factors with angiogenic activity have been identified, but one of the most potent, direct acting and specific is vascular endothelial growth factor (VEGF), also known as vascular permeability factor and vasculotropin[3].

Hepatocellular carcinoma (HCC), a leading cause of death in Taiwan and many Asian countries, is a highly vascular tumor dependent on neovascularization. Some authors have reported markedly elevated VEGF protein levels in HCC patients with remote metastases compared with those without metastasis, suggesting that VEGF may be a marker for metastasis in HCC[4-6]. Most such studies, however, depended on enzyme immunoassay to determine VEGF protein concentrations. To our knowledge, little is known about the prognostic significance of VEGF mRNA expression in the prediction of postresection recurrence of HCC. We conducted this prospective study to investigate the correlation between preoperative VEGF mRNA expression in peripheral blood (PB) and postoperative recurrence of HCC.

MATERIALS AND METHODS

Study population

From July 2001 to April 2003, 50 patients (31 men and 19 women, with a mean age of 56.2±13.3 yr) of 58 consecutive patients with HCC undergoing curative hepatectomy were enrolled in this prospective study. Patients who had previously had a hepatectomy or preoperative neoadjuvant ethanol injection or hepatic arterial chemoembolization (TACE) were excluded. The surgical procedures performed included 38 major resections (8 extended right lobectomies, 10 right lobectomies, 8 left lobectomies and 12 two-segmentectomies) and 12 minor resections (10 segmentectomies, 1 subsegmentectomy, and 1 wedge resection). A control group including 30 healthy volunteers without liver disease (15 men, 15 women, mean age 40 yr) and 20 patients with chronic liver disease but without evidence of HCC also gave PB samples.

PB samples for the detection of VEGF mRNA were obtained by forearm venipuncture one day prior to surgery from all 50 patients. After discharge, the patients were assessed regularly to detect tumor recurrence with abdominal ultrasonography (every 2-3 mo during the first 5 yr, then every 4-6 mo thereafter), serum alpha fetoprotein (AFP) and liver biochemistry (every 2 mo during the first 2 yr, then every 4 mo during the following 3 yr, and every 6 mo thereafter), abdominal computed tomography (CT) (every 6 mo during the first 5 yr, then annually), and chest X-ray and bone scans

(every 6 mo). Hepatic arteriography was obtained if the other studies suggested possible cancer recurrence. Detection of tumor on any imaging study was defined as recurrence.

Clinicopathological parameters analyzed included sex (male vs female), age, the presence of liver cirrhosis, hepatitis B virus (HBV) infection (hepatitis B surface antigen), hepatitis C virus (HCV) infection (anti-hepatitis C virus antibody), serum AFP level (<20 ng/mL vs 20 to 1 000 ng/mL vs >1 000 ng/mL), cirrhosis, Child-Pugh class of liver functional reserve (A vs B), tumor size (<3 cm vs 3 to 10 cm vs >10 cm), tumor encapsulation (complete vs incomplete or absent), presence of daughter nodules, vascular permeation (including vascular invasion and/or tumor thrombi in either the portal or hepatic vein), and cell differentiation grade (Edmondson and Steiner grades I to IV).

Detection of VEGF mRNA

Ethylenediamine tetraacetic acid (EDTA)-treated whole blood was centrifuged and the plasma fraction removed. The cellular fraction was enriched for mononuclear cells or possible tumor cells according to the method described by Oppenheim. Nucleated cells were isolated from peripheral blood using tetradecytrimethyl-ammonium bromide. Total cellular RNA was then extracted with PUREscript RNA Isolation Kits TRI-Zol (Life Technologies Inc., Gaithersburg, USA). cDNA was synthesized from 5 µg of the mRNA. The reverse transcription reaction solution contained 6 µL of 5×first strand buffer, 10 mmol/L dithiothreitol, 125 mmol/L each of dCTP, dATP, dGTP and dTTP, 0.3 µg of random hexamers, and 200 units of Superscriptase II Moloney murine leukemia virus reverse transcriptase (Life Technologies Inc.). The RNA solution was incubated at 95 ℃ for 10 min, quickly chilled on ice, then mixed with the reverse transcription reaction solution (total volume 20 µL), and incubated at 37 ℃ for 60 min. The sequences of the sense primers were 5'-AGTGTGTGCCCACTGAGGA-3' (VEGF) and 5'-AGTCAACGGATTTGGTCGTA-3' (GAPDH) and those of the antisense primers were 5'-AGTCAACGGATTTGGTCGTA-3' (VEGF) and 5'-GGAACATGTAAACCATGTAG-3' (GAPDH). The first polymerase chain reaction (RT-PCR) solution contained 5 µL of the synthesized cDNA solution, 10 µL of 10× polymerase reaction buffer, 500 mol/L each of dCTP, dATP, dGTP and dTTP, 15 pmol of each external primer (EX-sense and EX-antisense), 4 units of Thermus Brockiamus Prozyme DNA polymerase (PROtech Technology Ent. Co., Ltd. Taipei, Taiwan), and water. The PCR cycles were: denaturing at 94 ℃ for 1 min, annealing at 52 ℃ for 1 min, and primer extension at 72 ℃ for 1 min. The cycles were repeated 40 times. The PCR product was reamplified with internal primers for nested PCR to obtain a higher sensitivity. The first and second PCR components were the same, but for the primer pairs (IN-sense and IN-antisense), the final product was electrophoresed on 20g/L agarose gel and stained with ethidium bromide. Four different isoforms of human VEGF were identified, arising from alternative splicing of the primary transcript of a single gene. The majority were $VEGF_{121}$ (165 bp) and $VEGF_{165}$ (297 bp). The percentage intensity of the VEGF PCR fragment for each liver was relative to a GAPDH PCR fragment (122 bp). The intensity of bands was measured using Fujifilm Science Lab 98 (Image Gauge V3.12). The sensitivity of our assay was assessed using human hepatocytes.

A HepG2 (hepatoblastoma) cell line served as a positive control for VEGF mRNA expression. For negative controls, we used EDTA-treated water (filtered and vaporized).

Statistical analysis

A statistical software (SPSS for Windows, version 8.0, Chicago, Illinois) was employed, with Student's t-test used to analyze continuous variables and a chi-square or Fisher's exact test for categorical variables. Factors relating to the presence of postoperative hAFP mRNA in peripheral blood were analyzed by stepwise logistic regression. A Cox proportional hazards model was used for multivariate stepwise analysis to identify significant factors for predicting recurrence and mortality. Significance was taken as a P value <0.05.

RESULTS

RT-PCR analysis of VEGF transcript in peripheral blood

VEGF mRNA was expressed in the peripheral blood of 10 ($VEGF_{165}$ in 4 and $VEGF_{121}$ in 10) of 50 control patients (10/50, 20%). In the HCC group, isoform $VEGF_{165}$ was detected in 40 patients (80%) (with a concentration ranging from 0.198 to 0.7190) and isoform $VEGF_{121}$ in all 50 patients (100%) (concentration ranging from 0.2958 to 1.0356).

We did not detect isoforms $VEGF_{189}$ and/or $VEGF_{206}$ in either study or control patients

Table 1 Demographic, clinical and tumor variables of patients with HCC undergoing curative resection (n=50)

Variables		No. of patients (%)
Age (mean, years)		56.2±13
Male		31 (62)
Child-Pugh's class A		43 (86)
Serum AFP <20 ng/mL		16 (32)
20-10^3 ng/mL		18 (36)
>10^3 ng/mL		14 (28)
HBsAg (+)		36 (72)
Anti-HCV (+)		13 (26)

Correlation of VEGF mRNA expression and tumor recurrence

Sixteen patients (32%) had clinically detectable recurrence during the follow up period (median 1.5 yr, range 1 to 2.5 yr), of whom 7 died. A high preoperative level of isoform $VEGF_{165}$ mRNA correlated significantly with tumor recurrence both univariately (P=0.021) and multivariately (P=0.050). Isoform $VEGF_{121}$ levels had no such correlation. By multivariate analysis, other significant predictors of recurrence included poor cellular differentiation (P=0.033), less encapsulation (P=0.020), more vascular permeation (P=0.018) and the presence of daughter nodules (P=0.006) (Table 2).

Correlation of VEGF mRNA expression and recurrence-related death

The preoperative level of isoform $VEGF_{165}$ in PB significantly correlated with death from recurrence both univariately

(*P*<0.001) and multivariately (*P*=0.048). By multivariate analysis, a greater degree of vascular permeation significantly correlated with mortality (*P*=0.045), and poor cellular differentiation approached significance (*P*=0.053) (Table 3).

Correlation between VEGF mRNA expression and clinical and histopathologic features

There was no significant association between either isoform of VEGF mRNA and gender, age, serum AFP level, chronic HBV or HCV carriage, tumor size, coexisting cirrhosis, cellular differentiation, capsule, vascular permeation, daughter nodules, tumor necrosis, or tumor hemorrhage (all *P*>0.05).

DISCUSSION

Our study showed that a higher value of circulating VEGF mRNA isoform $_{165}$ before curative resection of HCC was significantly associated with an increased risk of postoperative recurrence and disease mortality. The presence of preoperative VEGF mRNA isoform $_{121}$ was not significantly predictive of outcomes.

The active form of VEGF was a homodimeric cytokine with molecular weight of 34-46 ku, the variation in size was due to alternative exon splicing which produces four different isoforms of 121, 165, 189 and 206 amino acids (monomeric size). The last three of those had heparin binding activity[15]. Different cancers have different expression of the isoforms. The majority of HCC could express an abundance of $VEGF_{121}$ and $VEGF_{165}$[4,7,8]. Further analysis by Ferrara indicated that $VEGF_{165}$ was the predominantly expressed form in human cDNA libraries as well as in most normal cells and tissues[8].

Several studies have revealed that the serum VEGF level is of value for predicting disease progression and prognosis in cancers of different origins, including the breast, gastrointestinal organs, kidney, urothelium, ovary, lung, and lymphoma[9-18]. However, the serum level of VEGF, which is what most other investigators have measured, might be influenced by other factors such as platelet number, associated liver cirrhosis, or coexisting infection[19-22]. For accurate measurement, citrated plasma processed within 1 h of venipuncture is better than serum.

Measuring VEGF in HCC tissue has the disadvantage of not being available until after a biopsy or resection has been done. The majority of angiogenic factors are soluble, diffusible peptides. Hence, the circulating level of angiogenic factors theoretically reflects the angiogenic activity of the tumor. Compared with expression in tumor tissue, the advantage of the measurement of circulating VEGF expression is that it can be performed without tissue specimens and repeated serially. Jinno *et al*, believed that circulating VEGF might be derived mainly from a large burden of tumor cells, but also partly from platelets activated by vascular invasion of HCC cells[20].

We chose to measure circulating mRNA expression of VEGF rather than the protein itself. According to El-Assal' s study, the level of VEGF mRNA did not always correlate with the protein concentration[23]. Immunohistochemistry could not distinguish small amounts of protein, which may partly explain the discrepancy in protein and mRNA levels.

An additional question is whether the value of circulating VEGF (either protein or mRNA) corresponds with VEGF mRNA in HCC tissue. Tokunaga noted that the circulating VEGF mRNA isoform pattern in colon cancer was not always significantly correlated with the gene expression level. The release of VEGF mRNA might be influenced by some cells other than HCC cells[24]. Warren found VEGF mRNA in hepatocytes and some Kupffer cells[25]. According to Banks, the presence of mRNA for VEGF was also described in T lymphocytes, CD34* cells, and monocytes[19,21].

There are considerable discrepancies among reports about the clinical significance of VEGF expression in HCC[20,26-34]. The high recurrence rate after resection has been found to be the main determinant for the poor outcome of HCC[35-37]. Tumor invasiveness variables correlating with recurrence include high serum AFP, hepatitis, vascular permeation, the grade of cellular differentiation, infiltration or absence of capsule, tumor size, coexisting cirrhosis, the presence of daughter nodules, and multiple lesions. Therefore, a number of studies have been done to see if VEGF correlated with any or all of those factors.

Zhou showed that high VEGF expression in HCC was associated with portal vein tumor thrombosis[28]. Li reported that VEGF mRNA in HCC correlated significantly with portal

vein emboli, poorly encapsulated tumors, and microvascular density in HCC tissues[27]. Chow found that VEGF expression was significantly associated with the PCNA index and sonographic evidence of portal vein tumor thrombosis but not with the liver biochemical profile, tumor volume, gender, severity of liver disease, or tumor grading[26].

One possible explanation for the discrepancies may be the assessment of tumors of different sizes and etiologies. The number of study patients is another possible factor. Because most of the reported investigations were performed in small series, we used 50 patients which seemed an adequate sample size compared with other studies. It is also likely that the effect of VEGF on angiogenesis depends on not only tumor cell expression of VEGF, but also on the VEGF receptors in endothelial cells.

Some have reported a correlation between increased plasma VEGF protein level in HCC patients and tumor size, number, portal vein emboli, poorly encapsulated tumors, microscopic venous invasion, metastasis, and recurrence. Yamamoto found there was a positive correlation between the increment of intratumoral MVD and serum VEGF concentrations[38].

According to our study, a higher expression of circulating VEGF mRNA was significantly correlated with tumor recurrence and recurrence-related mortality but not with the other accepted measures of invasiveness. Circulating VEGF mRNA thus appears to be an independent risk factor of postoperative recurrence. There are several possible explanations for this dissociation.

Some studies have found that the histologic grade of HCC was associated with VEGF expression in noncancerous liver cells, suggesting a complex regulatory mechanism for circulating VEGF in liver disease. Coexisting liver cirrhosis might influence VEGF expression[22,23]. About 80% of our study patients had cirrhosis. Some investigators have found that VEGF expression was significantly higher in cirrhotic livers than in noncirrhotic livers. Furthermore, it has been shown that cirrhosis itself was associated with increased angiogenic activity. El-Assal et al observed that cirrhotic livers had significantly higher VEGF expressions than noncirrhotic livers, suggesting that VEGF might be associated with angiogenesis in cirrhosis[23]. In addition, some suggested a possible involvement of VEGF in angiogenesis of the cirrhotic liver but not in angiogenesis of HCC. Akiyoshi suggested that a low serum VEGF level in liver cirrhosis might reflect the degree of liver dysfunction and might be associated with the grade of hepatocyte regeneration[22], VEGF levels were decreased with the worsening of the Child-Pugh score. However, most of our patients were Child-Pugh class A, and their resectable lesions, were unlike those studied by Akyoshi.

The stage of cancer might influence the VEGF expression[38-41]. Chao showed that a lower range of circulating VEGF levels in patients with early-stage HCC overlapped considerably with those in normal controls or in patients with chronic hepatitis or cirrhosis[30]. Therefore, serum VEGF is probably not useful for early detection of HCC. In contrast, a large quantity of VEGF may be released by the large load of HCC cells in advanced diesease (stage VI B). Because plasma VEGF level is significantly higher in stage IVB than in stage IVA, other mechanisms may be responsible, such as agglutination and activation of platelets caused by vascular invasion and circulating tumor cells. It may thus be the platelets rather than or in addition to HCC cells that are responsible for the release of VEGF into circulation. Our patients did not have such an advanced disease.

The relation between tumor size and VEGF mRNA expression might be complex and dynamic because of different vascular growth patterns[5,34,42-44]. In small hypervascular HCCs, approximately 1.0 cm in diameter in those that grow with a pattern of vessel replacement, artery-like vessels are not well developed. Capillarization of the blood spaces is present but in an incomplete form, and portal tracts often appear within cancerous nodules. These HCCs are thought to receive a predominantly portal blood supply. As tumor size increases, portal tracts decrease in number, and artery-like vessels gradually increase in number and size. Well-differentiated HCCs measuring 1.0 to 1.5 cm in diameter are in a transitional stage from portal to arterial blood supply, with the reduction in portal flow preceding the increase in arterial flow. Therefore, blood flow in HCC at this point would be low. This may be the reason why many well-differentiated HCCs are not detected on angiography, with hypervascularity seen untill nodules become larger than 2 cm in diameter.

VEGF positivity may therefore gradually decrease with increasing tumor size. According to Yamaguchi, 36.8% of nodules larger than 3.0 cm were VEGF-negative[34]. El-Assal showed that, contrary to the usual angiographic findings, HCCs larger than 5 cm in diameter were not more vascular than smaller tumors and were less vascular than medium-sized lesions[23]. However, it has been reported that the intercapillary distance increased as the tumors size or weight increased, which may be caused by the significantly different rates of endothelial (50 to 60 h) and neoplastic cell (22 h) turnover.

These complicated changes in vascularity may account for the disparate results among reported studies. Suzuki reported that VEGF mRNA levels were not correlated with the vascularity of HCCs as seen on angiography[4]. On the contrary, Mise et al. showed that the degree of VEGF mRNA expression was significantly correlated with the intensity of tumor staining in angiograms ($P<0.01$)[5]. Some have reported higher VEGF expression in small-size and well-differentiated HCCs and suggested that VEGF played its most important role in a relatively early stage of angiogenesis. In general, advanced HCCs are mainly supplied with arterial blood, and arterial angiography may reveal hypervascularity. Serum VEGF concentrations have been reported to be significantly higher in advanced stage rather than in early stage of breast and gastric cancer[9,13,14].

Neovascularization appears to be one of the crucial steps in a tumor's transition from a small, harmless cluster of mutated cells to a large, malignant growth, capable of spreading to other organs throughout the body. Because of the complex nature of the angiogenic process, however, it seems that VEGF expression is not the sole contributor to angiogenesis in HCC. Other factors involved in this process may include TGF-β, TNF-α, IL-8, etc.

It has been reported recently that VEGF mRNA expression was readily induced by hypoxia or ischemia. This is why we excluded patients who received preoperative TACE, in order to avoid ischemia-induced changes in VEGF expression.

Although tumor necrosis was present in 66% of our study patients (Table 1), circulating VEGF mRNA did not statistically correlate with it. We also did not find any correlation with fibrous capsule or septum formation, in contrast to the findings of Inoue et al[12]. The origin of the capsule and fibrous septa in HCC is unclear. Nakashima et al suggested the possibility of fibrogenesis at the interface of two tumor nodules of different properties, a process requiring fibrin deposition in the initial stage[45]. Some authors stated that a capsule or septa was formed when the HCC nodule grew to 1.5 cm or larger. It has been suggested that capsule formation is a result of compression and collagenization of the adjacent stroma. However, this mechanism has been doubted, since the tumor size did not correlate with the thickness of the capsule or the incidence of its formation. This suggests that capsules are formed by active fibrosis rather than by tumor compression on the adjacent stroma.

According to our study, circulating VEGF mRNA did not significantly correlate with the grade of cellular differentiation.

We attributed this to the possibility of different histological grades coexisting in HCC tissues. Yamaguchi examined VEGF expression immunohistochemically in HCC of various histological grades and sizes[34]. In tumors composed of a single histological grade, VEGF expression was the highest in well-differentiated, followed by moderately differentiated, and then poorly differentiated HCC. In tumors consisting of cancerous tissues of two different histological grades, the expression was less intense in the higher-grade HCC component. VEGF was also expressed in the surrounding HCC tissues in which inflammatory cell infiltration was apparent. Based on these findings, VEGF expression in HCC tissues was thought to be partly related to the histological grade but other cytokines and growth factors could also cooperatively act to enhance or influence VEGF expressions in HCC.

Solid tumors such as HCC are composed of two distinct compartments, namely the malignant cells themselves and the vascular and connective tissue stroma. The stroma provides the vascular supply that tumors require for obtaining nutrients, gas exchange, and waste disposal. Fibrin serves as a provisional stroma that is gradually replaced by granulation tissue and then by mature stroma. Human HCC is commonly surrounded by a fibrous capsule with an abundant extracellular matrix, even in the early stage. It is possible that VEGF also plays a certain role in the stimulation of regional development of the stroma in HCC.

Angiogenesis also appears to be involved in the invasion of tumors into the surrounding tissues, because this invasion requires concomitant neovascularization through the sprouting of endothelial cells in the extracellular matrix. It has been reported that VEGF induced both urokinase-type and tissue-type plasmin in endothelial cells. These are the key proteases involved in the degradation of the extracellular matrix. Thus VEGF may promote the process of vascular invasion by HCC cells.

Some authors suggested that VEGF mRNA expression in PB, which correlates well with the shift of VEGF mRNA in liver tissue, was strongly related to the development of HCC, including the progression from preneoplastic to neoplastic tissue and the potential of post-resection recurrence, the invasiveness of HCC, and poor survival[42-44]. Some stated that serum VEGF was a predictor of invasion and metastasis of HCC and a potential biomarker of metastatic recurrence after curative resection[20].

Surgery remains the best potentially curative treatment for patients with HCC. High recurrence rate limits the long term survival. Examination of preoperative VEGF mRNA in PB expression may give us information about high risk of postoperative recurrence. Addition of neoadjuvant or antiangiogenic therapy before or after surgery may be considered for such patients. Furthermore, the serial measurement of circulating VEGF mRNA during postoperative follow-up to monitor the effect of therapy or the development of recurrence needs further investigation.

From this prospective study, we suggest that circulating VEGF mRNA expression, especially isoform $VEGF_{165}$, may play a significant role in the prediction of postresection recurrence of HCC.

Abstract

AIM: To evaluate the clinical benefit of thalidomide in patients with advanced hepatocellular carcinoma (hepatoma).

METHODS: From March 2000 to July 2002, patients who had advanced hepatocellular carcinoma and failed to or were unsuited for aggressive treatment, were enrolled and took thalidomide 150 to 300 mg/d. All cases were followed till April 2003. Data collection included viral hepatitis, grade of cirrhosis, total dosage of thalidomide, side effect, stage of hepatoma by Okuda and CLIP classification, and prognosis. The subjects were divided into A and B groups, depending on 5 000 mg dosage of thalidomide. Survival time of all cases and in the two subgroups was evaluated.

RESULTS: Ninety-nine patients with hepatoma were enrolled, 81 men and 18 females with median age 58±14.1 years. Eighty-six percent had viral hepatitis and one case was alcoholism. Hepatoma was diagnosed with histology, alpha-fetoprotein (aFP) >400 ng/mL, or image examination, there were 30, 33 and 36 cases respectively. At the time of thalidomide therapy, more than 81% had cirrhotic status. Twenty-two patients were in group A (<5 000 mg) with median survival time about 25 days, for 77 cases in group B (≥5 000 mg) the median survival time was about 109 days. Six subjects had partial response. Most adverse effects were skin rush, neuropathy, somnolence, and constipation.

CONCLUSION: Several patients responded to thalidomide therapy. As a single drug therapy, thalidomide might not have good therapeutic effect for all cases, but a small ratio of patients had exciting response, the resistance or tumor escape would develop after long-term use. Up to now, no defined facts could be used to predict response. The effect of thalidomide on hepatoma might be associated with the dosage. As salvage therapy, thalidomide has its value. Combination or adjuvant therapy will be the next trial.

INTRODUCTION

Hepatocellular carcinoma (hepatoma) is a major cause of death in the world, especially in the endemic areas of viral hepatitis B and C, such as Taiwan, China. Taiwan is a high prevalence area of hepatocellular carcinoma, more than 6 900 people died of hepatocellular carcinomas at Taiwan in 2002. Although the incidence rate of small hepatoma was increased in the last few years, but most patients had severe liver cirrhosis that made them lose the opportunities to receive curative therapy. Therapy of hepatocellular carcinoma in chronic liver disease patients is challenging also. Local treatments, such as surgical resection, ethanol intratumor injection, ablation with high frequency, or transhepatic artery embolization have been improved, but these procedure might cause new problems and the curative and survival rates of these patients are still low[1]. The average survival time is shorter than 6 months if metastasis occur. However, to seek new effective therapy for hepatoma, to prolong the patient life or improve their life quality with later stage of hepatoma are major issues at Taiwan.

Anti-angiogenesis is a new concept for cancer therapy, in the 1970' s, Dr Folkman launched out the theory[2]. Neoplasm' s growth depends on angiogenesis, angiogenesis inhibitors could block the process and treat neoplasm, especially vascularized ones. Many antiangiogenic agents are developed and some are going in clinical trials. Thalidomide is one of them and has been studied for its anti-angiogenic activity in last several years.

Hepatoma is a hypervascular tumor that has been proved by angiography and histology. For this reason, antiangiogenesis therapy may be effective for hepatoma. Up to now, few papers described the antiangiogenesis therapy for hepatoma. The first success case of hepatoma treated with thalidomide, was reported in 2000. A 67- year-old man had a 6 cm large tumor. Unfortunately, the tumor continued to grow after 5FU and interferon therapy, chemoembolization and chemotherapy. Thalidomide therapy was used. The tumor was shrunk, aFP was diminished, and the patient was alive in 2000[3]. Henceforward, some might had exciting results, some were disappointed, Although a few patients would get benefit from thalidomide therapy[4-8]. No final conclusion was made. In this study, we report our experience in using thalidomide as a salvage drug for the patients with hepatoma, who were unsuitable for other managements.

MATERIALS AND METHODS

One hundred and six patients with hepatocellular carcinoma were entered into the study between Mar 2000 and July 2002. A diagnosis of hepatoma was made by histopathology, alpha fetoprotein (AFP) more than 400 ng/mL or image plus clinical manifestation. All of them were poor candidates for more aggressive treatment. Those patients were required to receive a risk-benefit counseling, to sign an informed-consent agreement, to use forms of birth control. The Institutional Ethics Committee of the Mackay Memorial Hospital and Department of Public Health in Taiwan approved the study protocol and the informed consent form.

They were given oral thalidomide table, containing 50 mg (Taiwan Tung Yang Biopharm Co. Ltd), at a dosage of 150 to 300 mg/day according to clinical reactions and adverse effects for a variable period. The drug was given 2 dosages in the morning and bedtime. The subjects were followed to April 2003. Ninety-nine patients were evaluated.

Depending the total dosage used, the patients were divided into two subgroups, group A took thalidomide less 100 tablets

(5 000 mg), and group B had more than 100 tablets. Data collected included viral hepatitis, grade of cirrhosis, total dosage of thalidomide, side effect, stage of hepatoma by Okuda and CLIP classification[9], and prognosis. The trial was prompted by the observation of response and survival times in all case and in the two subgroups. Survival time was calculated with SPSS 10 software and observation time interval was one week.

RESULTS

General data

Ninety-nine patients were valuable for evaluation (Table 1). The ratio of men and women was 81:18. The median age of the patients was 58 years (range, 21-86 years, S=14.1 years). Fifty-eight patients were chronic hepatitis B, 22 patients had hepatitis C, and five patients were infected with viral hepatitis B and C. Six cases were confirmed with non-B and non-C hepatitis. Seven cases had an underminted condition. One was alcoholic cirrhosis without viral hepatitis. Among them, another 12 patients had alcohol consumption. At the time of hepatoma diagnosed, 81%(80 cases) of the patients had cirrhosis diagnosed with histology or image studies, 14 cases had chronic parenchyma disease, and only 5 patients had normal texture of liver. The hepatoma diagnosis was dependent on either histopathology, aFP >400 ng/mL or image and clinical manifestations. There were 33, 30 and 36 cases respectively. They were followed up, with median follow-up time about 6 months (average 177 days) to April 2003 in this study. Group A had 22 patients and group B had 77 patients.

Laboratory data

The pretreatment median platelet count was $187 \times 10^3/mm^3$, leukocyte count was about 6 820/mm^3. Analyzed the liver function by Child's classification, 43, 33 and 21 patients belong to grades A, B and C, respectively. Two cases were unclassified at the beginning of medication because of incomplete data record. Both of them were grade A when hepatoma was diagnosed. One had bone and lung metastasis and one was followed up at other hospital. Fifty-two percent of the patients had alpha-fetoprotein level more than 400 ng/mL. According to hepatoma stage Okuda (Table 2) and CLIP (Table 3), the numbers of patients and survival time in the both groups are shown in Table 4 and Table 5. There were no confirmed complete responses. Although no scheduled image evaluation was done, six patients having partial response were observed, yielding a rate of 7% at least. Four responded patients had a high serum aFP initially, which was decreased after treatment.

Response and survival

Overall, the median survival time was about 80 days to Apr 2003. Twenty-one of 22 patients in group A had expired, only one survived to Dec 2000 then lost follow-up. The median survival time in group A was 25 days. Most of them had a

poor condition for aggressive treatment and died due to liver function decompensation. Thirty-six percent patients of group A has Child-pugh's grade C, compared only 16% in group B. One third patients died with hepatic failure and 4 patients died with massive esophageal varices bleeding in group A. Fifty percent cases had multiple lesions in liver or distal metastasis. Some of them liked to try TAE again and other alternative therapies. One patient had grade 3 dermatologic toxicity. These were major causes the withdrawal of thalidomide. Seventy-seven patients were group B, 61 patients died, and 16 patients experienced disease progression or partial responses. The median overall survival time in group B was 108.5 days.

Toxicity

The most common treatment-related toxic effects were skin itching, rush and urticaria. Twenty patients were relieved by antihistamine, two patients with severe dermatitis prompted discontinuation of thalidomide treatment. Other adverse effects included neuropathy, somnolence, and constipation and six had ith others side effect, such as gastrointestinal symptom. Most of them took laxative, therefore the rate of constipation was not real. Toxicity of thalidomide in our patients was tolerable.

Table 6 Response rate of hepatoma treated with thalidomide

DISCUSSION

Thalidomide was developed in the 1950's and originally marketed as a sedative but was withdrawn after its teratogenic effects were recognized in 1964. FDA approved thalidomide for erythema nodosum leprosum in 1999, which stimulated new interests[10]. Thalidomide has been shown to be effective in treating cutaneous lupus erythematosus, idiopathic oral and oropharyngeal apthous ulceration in HIV-1 positive patients. It has subsequently been used in the treatment of graft versus host disease, rheumatoid arthritis, inflammatory bowel disease, and the malignancy diseases in phase II or phase III, such as multiple myeloma, renal cell carcinoma, prostate cancer, breast cancer, ovary cancer, *etc.* The effects may come from its potent inhibitor of angiogenesis and immune response-modifying properties, which are essential to many physiologic and pathologic pathways. Thalidomide could inhibit the production of tumor necrosis factor-alpha[11,12] and alter multiple cytokines. Several other immunomodulatory effects have been reported, such as down-regulation of T-lymphocyte surface molecules, inhibition of lymphocyte proliferative responses to alloantigens and mitogens, and lowering of CD4:CD8 peripheral T-lymphocyte ratios[13,14]. It could induce a shift from T helper cell type 1(Th1) to Th2 T-cell responses and modify various cell surface receptors[15].

Hepatoma is a hypervascular tumor, blood support comes from new branch vessels of hepatic artery. Presumably, chemoembolization intercept the vessels has become one of standard treatments for hepatoma. We can speculate that anti-angiogenetic agents can inhibit hepatoma growth, such as thalidomide. Thalidomide was believed to be species-specific antiangiogenesis drug[16,17]. That is the most likely reason for its reported effectiveness against some solid tumors involving neoformation of blood vessels in early days. In addition, angiogenesis inhibitor TNP-470 can inhibit both the growth of primary tumors and the formation of liver metastases from gastric and colon cancer xenografts in nude mice. In a rat hepatoma model, it also enhanced apoptosis in hepatic metastases and improved survival[18]. Again, inhibition of tumor necrosis factor-alpha (TNF-alpha) is one important action of thalidomide, which could be used to treat human hepatoma.

To treat hepatoma with thalidomide will be feasible. Some papers have actually discussed this issue since 1999, most were reported with case studies or in academic meetings[4-8] (Table 6). The complete response was rare, partial response rate was 5% to 10%, stable disease was about 37%, the variant was depending on the duration of observation, cancer stage of patients and definition of stability. In our study, no patient had complete remission, the initial partial response was 7%.

The effect of thalidomide on cancer is still mysterious. We surmised that interaction between the drug, patient immunity and heterogeneous cancer was very complex. The impact factors of response are multiple. However, there are some other antitumor mechanisms in addition to antiangiogenesis and TNF suppression. For example, degradation of tumor necrosis factor-alpha mRNA in human monocytes was modulated by thalidomide[12]. On the contrary, TNF-alpha production in IL-1beta-stimulated or PMA-stimulated hepatocyte cultures was not altered following the addition of thalidomide[19]. Thalidomide can augment natural killer cell cytotoxicity. The number of NK cells increased in multiple myeloma after medication, but only those patients who responded to treatment showed an increase in the percentage of NK cells. Thalidomide for multiple myeloma might trigger the NK cells[20]. Same phenomena might occur in hepatoma. The exact mechanism of thalidomide is not fully clear, lot of effect wait to discover.

Why thalidomide for hepatoma does no work as a targeted therapy? Hepatoma was heterogeneous in genotype and phenotype[21]. Animal experiments showed that angioarchitecture and blood flow velocity in liver cancer were heterogeneous[22]. Adhesion molecular, E-cadherin, revealed various expressions among tumor samples[23]. These could explain why not all the solid tumors or patients had no response to thalidomide therapy, even in treatment of hepatoma. Although a few hepatomas had very good response to thalidomide beyond expectancy. At present, we still lack a landmark to select the suitable patients and specific parameters to predict the response to thalidomide treatment. Host may be another important factor affecting the response to thalidomide. All these need more researches to answer.

It seems that thalidomide may offer hepatocellular carcinoma stabilization, but has no significant antitumor activity. Most papers discussed the rate of response only. The survival time may be one of the major destinations in clinical trails of thalidomide therapy. A few phase I and II studies showed survival times slightly increased in hepatoma patient, but the survival time of those patients was also unpredictive and thalidomide did not significantly prolong the life of all patients. Our patients survived average of 25 and 108 days in groups A and B, respectively. The survival time appeared shorter than reported[9,24]. We thought the time was calculated from the day of thalidomide therapy, not the day of hepatoma diagnosed. In group A, the general condition of them was poor, they seemed not get any benefit from thalidomide therapy. All the response cases in our study were belong to group B with a large total dosage. Chen found the average survival time in patients with responded or stable disease was 269 days,

significantly longer than 74 days in the patients with progression[8]. Neben Kai reported the cumulative 3-month dosage was the remaining factor for overall survival rate in treating multiple myeloma[25]. At the same time, that might occur in HCC and the anticancer effect of thalidomide was associated with cell cycle and total dosage, as other chemotherapy. So, thalidomide might not be suitable for patients with too terminal status because they do not have chance to take enough dosage of thalidomide. It is the issue to be studied.

Besides, this study might have a worth finding. We usually think there is no drug resistance to antiangiogenetic therapy, but it did occur. We revealed a case with high aFP and lung metastasis had a good response. His serum level of aFP dropped and lung lesions became small and disappeared after thalidomide therapy. Unfortunately, the aFP increased again and lung lesion regrew after 9 months thalidomide continuous therapy. That means the resistant may develop if patients take thalidomide for enough long time. These need more case observations to confirm.

However, patients with hepatoma at later stage do not have time to wait for a new therapy. Most hepatomas develop in patients with cirrhosis. In this study, the ratio of cirrhosis was more than 80%. Lot of patients are poor candidates for aggressive treatment. Moreover, the prognosis of patients with metastatic or refractory HCC was very poor, to cure the patients was almost impossible. The aim of therapy was to improve their life quality and prolong their survival time[26]. Overall, as a single medication, thalidomide has the response rate about 5 to 10%.

At one time, thalidomide was notorious for its side effect that has been under control in last few years. Phocomelia is the most severe adverse effect that did not cause any problem in patients with hepatoma. The other adverse effects were sedation, constipation, and skin rash in our study. These effects were usually dose-related and mild, and could be treated except few patients who must discontinue medication. Peripheral axonal sensory neuropathy caused by thalidomide appeared only after a large dose accumulation. In our study, even at the later stage of cirrhosis, only few patients discontinued thalidomide. Another unusual adverse effect of thalidomide is vascular thrombosis. Deep venous thrombosis may occur, especially in patients with multiple myeloma and renal cell carcinoma, but has not seen in patients with hepatoma. Our results showed that thalidomide was tolerated in cirrhotic patients with hepatoma. Thalidomide is convenient for oral intake. It can be used as a salvage therapy before more powerful antiangionetics or other combined or adjuvant methods are developed. Several pilot studies have been on going[27], such as combination therapy of thalidomide plus interferon alfa in phase II[28]. A combination of capecitabine and thalidomide, celecoxib and escalating doses of thalidomide in patients with unresectable HCC revealed few response patients[29,30].

In conclusions, thalidomide is a drug with multifunctions, may be useful in some of patients with advanced hepatocellular carcinoma and it produces durable stability disease in approximately one third of patients, with a partial response rate not beyond 10%. Most side effects of thalidomide are minimal, it could be administered to patients with even significant liver cirrhosis and poor candidates for other therapies. However, thalidomide as a single drug formula for hepatoma is no so good, resistance will be appear after long-term use. If it is used as a salvage therapy in patients with hepatoma, some patients get benefit[27]. A controlled trial of thalidomide in selected patients with cirrhosis and hepatoma is warranted. The combination therapy with other drugs or adjuvant therapy in different stage hepatoma will be the next step studies. Thalidomide analogues have been under investigation. Hopefully, this will be the beginning of the development of a new therapeutic modality for hepatoma.

Abstract

AIM: To observe the anti-liver cancer activity of tumor
necrosis factor-related apoptosis-inducing ligand (TRAIL)
gene and its bystander effects on hepatocellular carcinoma
(HCC) cell line SMMC7721.

METHODS: Full-length cDNA of human TRAIL was transferred
into SMMC7721 cells with a binary adenoviral vector system.
Polymerase-chain reaction following reverse transcription
(RT-PCR) was used to determine the expression of TRAIL
gene. Effects of the transfected gene on proliferation of
SMMC7721 cells were measured by MTT assay. Its influence
on apoptosis was demonstrated by fluorescence-activated
cell sorting (FACS). The bystander effect was observed by
co-culturing the SMMC7721 cells with and without the
transfected TRAIL gene at different ratios, and the culture
medium supernatant from the transfected cells was also
examined for its influence on SMMC7721 cells.

RESULTS: The growth-inhibition rate and apoptotic cell
fraction in the cells transfected with the TRAIL gene, Bax
gene or only LacZ gene were 91.2%, 48.0%, 28.8% and
29.1%, 12.5%, 6.6%, respectively. The growth-inhibition
rate of transfection with these three sequences in normal
human fibroblasts was 6.1%, 45.5% and 7.6%, respectively,
indicating a discriminative inhibition of TRAIL transfection
on the cancer cells. In the co-culturing test, addition of the
transfected TRAIL to SMMC7721 cells in proportions of 5%,
25%, 50%, 75% and 100%, resulted in a growth-inhibition
of 15.9%, 67%, 80.2%, 86.4% and 87.7%, respectively.
We failed to observe a significant growth-inhibition effect of
the culture medium supernatant on SMMC7721 cells.

CONCLUSION: TRAIL gene transferred by a binary adenoviral
vector system can inhibit proliferation of SMMC7721 cells
and induce their apoptosis. A bystander effect was observed,
which seemed not to be mediated by soluble factors.

INTRODUCTION

TRAIL, first identified by searching an expressed sequence
tag (EST) database with a conserved sequence contained in
many tumor necrosis factor (TNF) family members, appears
to induce apoptotic cell death only in tumorigenic or
transformed cells and not in most of normal cells[1,2]. TRAIL
has five receptors, including two death receptors DR4 and DR5,
two decoy receptors DcR1 and DcR2, one soluble receptor
osteoprotegerin. TRAIL is expressed constitutively in many
normal tissues, which suggests that normal cells contain
mechanisms that protect them from apoptosis induced by
TRAIL. One explanation reported was that the decoy receptors
DcR1 and DcR2 and another receptor osteoprotegerin could
compete with DR4 and DR5 for TRAIL binding[3,4]. Furthermore,
TRAIL has a synergistic effect with chemotherapeutic drugs
to kill tumor cells and cause substantial tumor regression[5-7].
Much evidence have shown that repeated intravenous injection
of a recombinant, biologically active TRAIL protein could
induce tumor cell apoptosis, suppress tumor progression, and
improve the survival of animals bearing solid tumors without
any detectable toxicity in nonhuman primates[5,8]. Therefore,
it appears that TRAIL may act as a potent anticancer agent.
Furthermore, TRAIL can elicit apoptotic bystander effects on
malignant cells. However, few researches of anti-liver cancer
activity and bystander effects of TRAIL have been carried out
up to date. Here, we first transferred human TRAIL gene to liver
cancer cell line SMMC7721 with a binary adenoviral vector
system, and assessed the anti-liver cancer activity of TRAIL gene
and explored its bystander effects. In addition, we also assessed
the toxicity of TRAIL to normal human fibroblasts (NHFB).

MATERIALS AND METHODS

Cell lines and culture conditions
Human embryonal kidney cells transformed by introducing
sheared fragments of Ad5 DNA (293 cell) and human liver
cancer cell line SMMC7721 were obtained from the Key
Laboratory of Infective Diseases under Ministry of Public
Health (Zhejiang University), normal human fibroblasts
(NHFB) from normal human bone marrow were cultured; Cells
were grown in RPMI 1640 medium supplemented with 10%
fetal calf serum (NHFB with 20% fetal calf serum) in a 5%
CO_2 atmosphere at 37 ℃.

Adenoviral vectors
Adenoviral vectors Ad/GT-Bax, Ad/GT-LacZ and Ad/PGK-
GV16 were constructed as described previously[9,10]. Ad/GT-
TRAIL, an adenoviral vector expressing TRAIL, was also
constructed as described previously[9]. Amplification, titration,
and quality analysis of all of the vectors were performed as
described previously[9,10]. The titer determined by the absorbency
of dissociated viruses at $A_{260\ nm}$ (one $A_{260\ nm}$ unit=10^{12} viral
particles/ml) was used in the study, whereas the titers
determined by plaque assay were used as additive information.

Transgene expression of TRAIL
As determined in preliminary experiments, cells were

coinfected with Ad/GT-TRAIL or Ad/GT-LacZ and Ad/PGK-GV16 at a ratio of 1:1. The optimal MOI was determined by infecting each cell line with Ad/GT-LacZ +Ad/PGK-GV16 and the expression of β-galactosidase was assessed via X-gal staining. The MOI that resulted in >80% of blue stained cells were used in this experiment. These MOI were 1000 particles for SMMC7721 and NHFB. Unless otherwise specified, Ad/GT-LacZ and Ad/PGK-GV16 were used as the vector control for Ad/GT-TRAIL and Ad/PGK-GV16. Ad/GT-Bax and Ad/PGK-GV16 were used as the positive control. Cells treated with PBS only were used as a blank control.

1×10^6 SMMC7721 cells were plated on 6-well plates and infected with Ad/GT-TRAIL+ Ad/PGK-GV16 or Ad/GT-LacZ + Ad/PGK-GV16. Forty-eight hours after infection, the cells were harvested and washed in PBS. RNA was extracted from the cells using Trizol reagent (Life Technology Inc.) and reversely transcribed to cDNA. The PCR conditions for cDNA amplification were 35 cycles of at 95 ℃ for 45 s, at 58 ℃ for 45 s, at 72 ℃ for 45 s, forward primer: 5' -AGA CCT GCG TGC TGA TCG TG-3' , and reverse primer: 5' - TTA TTT TGC GGC CCA GAG CC-3' . The PCR products were separated in a 10g/L agarose gel and visualized by ethidium bromide staining.

Cell viability
Cell viability was assessed using MTT assay (Amresco) according to the manufacturer' s protocol. The 5×10^3 SMMC7721 and NHFB cells were inoculated in to 96-well plates, with 3 parallel teams. Twenty-four hours after inoculation, the cells were infected with Ad/GT-TRAIL+ Ad/PGK- GV16, Ad/GT-Bax+ Ad/PGK- GV16, Ad/GT-LacZ + Ad/PGK-GV16 at MOI of 1000, and treated with PBS. At the 1st, 3rd and 5th day after infection, the cells were incubated with 5mL/L MTT for 4 h. Then the medium was removed and 150 μl of sterilized DMSO solution was added, followed by incubation at 37 ℃ for 4 h. The absorbance of the reaction solution at 490 nm was measured. These data were used to make growth curves. The cell growth inhibition rate was (1- absorbance of experimental group/absorbance of control group)×100%.

Apoptosis
Cell apoptosis was assessed by observing morphology and using the Annexin Vkit (Immunotech, Annexin-FITC) according to the manufacturer' s protocol. The 5×10^4 SMMC7721 cells were inoculated in to 6-well plates. Twenty-four hours after inoculation, the cells were infected with adenoviruses at MOI of 1000. Then the cell morphology was observed with a reversed microscope every day. On the 4th day, the cells were harvested by trypsinization, washed in PBS and labeled with ANNEXIN V and propidium iodide (PI) according to the manufacturer' s protocol. Finally, they were subjected to flow cytometry to determine the extent of cell death.

Bystander effects
Bystander effects of the TRAIL gene were assayed by MTT as follows: 5×10^4 SMMC7721 cells were washed in PBS and plated on 80-mm dishes, cultured with fresh RPMI 1640. Twenty-four hours later, the cells were infected with adenoviruses at MOI of 1000. Another 24 h after infection, the cells were harvested as the transferred SMMC7721 cells (SMMC7721/TRAIL cells). SMMC7721/TRAIL and SMMC7721 cells were suspended in 2×10^4/ml of RPMI 1640 medium. SMMC7721/TRAIL and SMMC7721 cells were mixed with different ratios, SMMC7721/TRAIL cells accounted for 0, 5%, 25%, 50%, 75% and 100%, respectively.

Mixed cells (1×10^4) were inoculated in to 96-well plates with 3 parallel teams each ratio. Four days later the cell viability was determined by MTT assay.

Mechanism of bystander effects
In this study we tried to discover the effect of soluble factors on bystander effects of TRAIL. The 1×10^6 SMMC7721 cells were washed in PBS and plated on 80-mm dishes, cultured with fresh RPMI 1640. Twenty-four hours later, the cells were infected with Ad/GT-TRAIL+ Ad/PGK- GV16, and then cultured for another 24 h. Finally, the dishes were sent to be centrifuged and the medium was collected. This medium was filtrated with a 0.22 μm filter membrane. Other dishes of non-infected SMMC7721 cells were cultured with this filtrated medium. We made the RPMI 1640 medium as blank control and Ad/GT-TRAIL+ Ad/PGK- GV16 as positive control. Four days later, the cell viability was assessed with MTT assay.

Statistical analysis
Statistical analysis was performed with SPSS 10.0, the cells viability and the cell apoptosis ratio were determined by paired *t*-test. Statistical significance was set when $P<0.05$.

RESULTS
Virus titers
The titers of viruses determined by A_{260} were 1×10^{10}particles/mL.

Transgene expression of TRAIL
The expression of TRAIL gene with this system was confirmed *in vitro* in human liver cancer cell line SMMC7721 by RT-PCR. Treatment of cells with Ad/GT- TRAIL+ Ad/PGK-GV16 resulted in a strong TRAIL-specific band, whereas infection with control vectors resulted in undetectable expression (Figure 1). It indicated that TRAIL gene was transferred into the SMMC7721 cells and the binary adenoviral vectors were effective.

Figure 1 Expression of TRAIL tested with RT-PCR assay.

Cell viability
In cultured SMMC7721 cells, the cell viability (MTT) study showed a significant difference in cell killing effects between lines responsive to treatment with TRAIL-expression vectors versus control vectors, blank controls, even positive controls (Table 1, Figure 2). In cultured NHFB cells, the cell viability study showed a significant difference in cell killing only between TRAIL-expression vectors and Bax-expression vectors (Table 2, Figure 3). These results demonstrated that treatment with TRAIL gene could effectively elicit cell killing in cultured human liver cancer cells but not in normal human fibroblasts. TRAIL gene was more effective than Bax gene in killing cultured human liver cancer cells. Bax gene was obviously toxic to normal human fibroblasts.

Table 1 Cell growth-inhibition of SMMC7721 cells

Groups	OD(mean±SD)	Cell growth-inhibition rate (%)
PBS	1.25±0.20	0
TRAIL	0.11±0.02[ac]	91.2
Bax	0.65±0.13[a]	48.0
LacZ	0.89±0.04	28.8

[a]$P<0.05$ *vs* PBS, [c]$P<0.05$ *vs* Bax.

Table 2 Cell growth-inhibition of NHFB cells

Groups	OD(mean±SD)	Cell growth-inhibition rate (%)
PBS	0.66±0.02	0
TRAIL	0.62±0.02[c]	6.1
Bax	0.36±0.02[a]	45.5
LacZ	0.61±0.03	7.6

Figure 2 Viability of SMMC7721 cells.

Figure 3 Viability of NHFB cells.

Apoptosis

Morphologic changes of SMMC7721 cells showed cell apoptosis in cells treated with TRAIL gene versus PBS (Figure 4). NHFB cells treated with TRAIL gene and PBS showed no obvious difference in morphology (Figure 5). Assessed by FCM, the apoptosis of SMMC7721 cells infected with TRAIL gene ,Bax gene, LacZ gene and treated with PBS was 29.07%, 12.53%, 6.58%, and 2.94%, respectively. There were significant differences between SMMC7721 cells treated with TRAIL gene and Bax gene, LacZ gene and PBS (Table 3, Figure 6). It indicated that TRAIL gene had a great ability to induce apoptosis of human liver cancer cells. It was also shown that TRAIL gene was more effective than Bax gene in inducing apoptosis of human liver cancer cells.

Figure 4 SMMC7721 cells. A: uninfected with Ad/GT-TRAIL+Ad/PGK-GV16, B: infected with Ad/GT-TRAIL+Ad/PGK-GV16.

Figure 5 NHFB cells. A: uninfected with Ad/GT-TRAIL+Ad/PGK-GV16, B: infected with Ad/GT-TRAIL+Ad/PGK-GV16.

Bystander effects

The results of MTT assay showed that when transduced SMMC7721/TRAIL cells accounted for 5%, 25%, 50%, 75% and 100% of all cells, 4 days later 15.9%, 67.0%, 80.2%, 86.4%, 87.7% of all cells were killed (Table 4). It showed that partial untransfected cells were killed by bystander effects of TRAIL gene.

Moreover, we found that bystander effects could not be transferred by the medium leached transduced cell components. The viability of SMMC7721 cells cultured with the medium leached transduced cell components was 96%, similar to that

cultured with fresh RPMI 1640 (which was set to be 100%). There were no significant differences between them ($P > 0.05$, Table 5).

Table 3 Percentage of apoptotic SMMC7721 cells

DISCUSSION

Liver cancer is one of the most malignant cancers with poor prognosis, and about two thirds of patients have been in China[11]. Though many therapeutic methods have been available to its treatment, no one showed a more notable effect than operation. However, the patients who could be radically operated were less than 15%[11]. It is now considered that apoptosis plays an important role in tumorigenesis, and at the same time inducing apoptosis of malignant cells has been prevailing in tumor therapy. There have been clinical reports of primary hepatocellular carcinoma treated with wild-type

p53 gene[12].

TRAIL has become an attractive molecule for the treatment of cancer because it could kill tumor cells[5,8]. Studies of recombinant TRAIL protein have revealed that the extracellular portion of TRAIL molecule was sufficient for its antitumor activity but its homotrimerization was necessary for TRAIL protein to retain this activity[5,8], suggesting that the conformational structure of TRAIL is crucial for interaction with its receptors. In this study, we studied whether TRAIL gene could be directly transferred into tumor cells, and whether the expression of biologically active molecules could effectively kill human liver cancer cell lines rather than normal human cells *in vitro*, and whether the bystander effect exists during the process of killing.

It has been reported that a variety of malignant tumors, such as breast carcinoma[13], thyroid carcinoma[14], melanoma[15], glioma[16], multiple myeloma[17,18], colon carcinoma[19] and pancreatic carcinoma[20,21] were all sensitive to TRAIL, but few reports related to liver cancers were available. In this study, binary adenoviral vectors were used to introduce the therapeutic genes into liver cancer cell line SMMC7721 and normal human fibroblasts (NHBF) to evaluate their anti-tumor activity, toxicity and bystander effects.

It was difficult to design an adenoviral vector to transexpress proapoptotic genes because of their high proapoptotic activity and toxicity on packaging 293 cells. Arai *et al*[22] reported that they constructed an adenovirus vector containing Fas-L gene, but it required packaging 293 cells bearing resistance to Fas-L or was decorated with Caspase depressor. Okuyama *et al*[23] designed another system to achieve the transexpression of proapoptotic genes but it was too complicated. We constructed a binary adenovirus vector system, which showed that TRAIL gene had a strong proapoptotic activity on packaging 293 cells. On the other hand this system could augment transgene expressions via a GAL4 gene regulatory system. In brief, we constructed two mated vectors, Ad/PGK-GV16 and Ad/GT-TRAIL, the promoter GT was a synthetic promoter consisting of five GAL4-binding sites and a TATA box, which had a very low transcriptional activity *in vitro* and *in vivo* when it was placed in an adenoviral backbone. But the transgene activity could be substantially induced *in vitro* and *in vivo* by administering this construct in combination with an adenoviral vector (Ad/PGK- GV16) expressing a GT transactivator, the GAL4-VP16 fusion protein[24,25]. A weak promoter PGK would drive expression of the GAL4/VP16 fusion protein (GV16), which in turn would transactivate a minimal synthetic promoter, GAL4/TATA (GT), upstream of a transgene. It has been reported that this system used in CEA-positive cells treated with Ad/CEA-GV16+Ad/GT-LacZ versus Ad/CEA-LacZ had a 20- to 100- fold increase in transgene expression[24]. We determined the ratio of two vectors as 1:1 via X-gal staining with LacZ gene expression. The binary adenoviral vector system was effective for expressing high-level products of the proapoptotic gene. This has been confirmed in Bax gene study[5,26], therefore, Bax gene was used as a positive control in our study. We detected the transgene expression of TRAIL gene by RT-PCR and the result showed quite positive. Another result was that proapoptotic genes TRAIL and Bax had a high toxicity to liver cancer cells while LacZ did not by using this system.

TRAIL demonstrated its antitumor activity in a variety of tumors[1,2,5], although different tumors might vary in their sensitivity. This phenomenon was observed in this study as before[27]. SMMC7721 cells showed 29% of apoptosis. In comparison with other cell lines we tested before, HT29 had 24.6% of apoptosis[28], DLD-1, H460 and A549 had 77%, 26% and 43.5% of apoptosis[27], respectively. The mechanism underlying the differential sensitivity of malignant cells to

TRAIL treatment, as well as the differential killing of normal cells versus malignant cells, remain to be delineated. It could be partially explained by the presence of multiple receptors for TRAIL that functioned as either death-inducing or decoy receptors[4,29,30]. Some groups have proposed that expression of decoy receptors confer resistance to normal tissues[29,30], others have suggested that the level of intracellular Caspase/apoptosis inhibitors including FLIP and Bcl-X_L might result in resistance[15,31,32]. Oppositely, some other studies considered that the levels of DR4, DR5, and DcR1 could not explain this phenomenon[7,15,27,31]. Accordingly, we hold that the presence of decoy receptors is not the exclusive reason for different sensitivity of different cells. Recently, it was reported that a combined treatment with certain chemotherapy reagents could sensitize resistance to TRAIL-induced apoptosis[5,6,33]. But one of these reports also mentioned that normal cells could be sensitized to TRAIL-inducing apoptosis[7], suggesting that such a combination treatment may also increase toxicity.

Our study revealed that treatment with TRAIL gene was nontoxic to normal human fibroblasts cultured *in vitro*. This result was consistent with previous reports[5,8,27]. Recently it was reported that human hepatocytes were very sensitive to apoptosis induced by recombinant TRAIL protein[34]. But the toxicity could arise from histamine or/and leucin taken in combination with recombinant TRAIL protein[35,36]. Another report showed that Z-LEHD- FMK, one of the Caspase inhibitors, could protect hepatocytes from apoptosis induced by TRAIL, but TRAIL gene could induce apoptosis of malignant cells[37]. Now, we can transfer transgenes directly into target cells by target techniques, such as tumor specific promoter hTERT[38], to reduce the toxicity to normal cells.

One of the bottlenecks of gene therapy for malignant tumors is the low transgene efficiency. It is difficult to transfer target genes into each tumor cell. Investigators have attempted to circumvent this limitation by exploiting what was called the bystander effects based on the transfer of vector transgene products from infected to uninfected cells. Though the existence of bystander effects could not increase the transgene efficiency, it could enhance the cell killing capability. Theoretically, treatment with TRAIL may elicit bystander effects either through interaction of cell surface TRAIL molecules with receptors on the neighboring cells or through the action of soluble TRAIL from TRAIL-expression cells. It has been reported that TRAIL gene could exert proapoptotic bystander effects on cancer cells[27,39] as we demonstrated.

TRAIL is a type II membranous protein, it is speculated that membrane-bound TRAIL can be cleaved and then turned into a soluble form. Both membrane-bound TRAIL and soluble TRAIL could rapidly induce apoptosis in a wide variety of tumor cell lines via interaction with the death receptors DR4 and DR5[40,41]. Nevertheless, in our study, the cell killing effects of TRAIL gene were not transferable with the medium of TRAIL-expressing cell cultures. This result suggested that the proapoptotic activity of TRAIL gene was mainly elicited via membrane-bound TRAIL. The soluble factors contributed little to antitumor activity and to the bystander effects of TRAIL gene. One explanation is that the effects of soluble TRAIL may be dose-dependent. In previous reports, the cell killing activity of recombinant soluble TRAIL was demonstrated, but the effect was elicited by high doses of TRAIL. They could not be achieved by spontaneous cleavage of TRAIL from cultured cells.

In conclusion, we found that TRAIL gene was more effective than Bax gene in killing liver cancer cells with bystander effects TRAIL had no toxicity to normal cells. These results suggest that TRAIL gene is more effective as a therapeutic gene of malignant tumors than Bax gene.

More researches should be carried out to reveal the anti-liver cancer activity and bystander effects of TRAIL *in vivo*. It is possible that TRAIL gene will be used in clinical practices as new promoters and neoteric transgene vector systems are developed.

Abstract

AIM: To prepare thymidine kinase gene (TK gene) nanoparticles and to investigate the expression of TK gene.

METHODS: Poly(D,L-lactic-co-glycolic acid) (PLGA), a biodegradable and biocompatible polymer, was used to prepare recombinant plasmid $P^{EGFP-AFP}$ nanoparticles by a double-emulsion evaporation technique. Characteristics of the nanoparticles were investigated in this study, including morphology, entrapment efficiency, and tissue distribution. The expression of TK gene was also investigated by MTT assay, by which the viable cells were determined after the addition of ganciclovir (GCV). The enhanced green fluorescent protein (EGFP) expression in human hepatocellular carcinoma SMMC-7721 cells and normal parenchymal Chang liver cells were assessed by flow cytometry.

RESULTS: The prepared plasmid-nanoparticles had regular spherical surface and narrow particle size span with a mean diameter of 72±12 nm. The mean entrapment efficiency was 91.25%. A total of 80.14% DNA was found to be localized in the livers after 1-h injection with ^{32}P-DNA-PLGA nanoparticles in mouse caudal vein. The expression of DNA encapsulated in nanoparticles was much higher than that in naked DNA, and human hepatocellular carcinoma SMMC-7721 cells were more sensitive to GCV than human normal parenchymal Chang liver cells.

CONCLUSION: The enhanced transfection efficiency and stronger ability to protect plasmid DNA from being degraded by nucleases are due to nanoparticles encapsulation.

INTRODUCTION

In recent years, the gene delivery system has attracted much attention[1-3]. However, safe and efficient gene delivery remains a crucial barrier to successful gene therapy. Viral and retroviral vectors have been the most efficient and commonly used delivery modalities for *in vivo* gene transfer, but viral vector may provoke mutagenesis and carcinogenesis. Repeated administration of a viral vector induces an immune response which abolishes the transgene expression[4-7]. The non-viral delivery system has the potential to be non-immunogenic and stable *in vivo*[8-11]. Encapsulation of DNA in biodegradable polymer potentially offers a way to protect DNA from degradation and to control DNA release[12,13], and many examples of DNA incorporated in synthetic polymers have been developed in the micron scale. Recently, some studies have shown that intracellular biodistribution of particles with diameter less than 100 nm can be achieved[14].

Among all the present gene therapeutic protocols, combination of the administration of GCV with transfecting thymidine kinase gene of *Herpes simplex* virus (HSV-TK) into tumor cells is rather practical and potential in intra-tumoral gene therapy. The TK genes in the tumor cells can induce the metabolism of untoxicant prodrug GCV into cytotoxic parent drug, which can cause the suicide of cells. This protocol presents good potential in intra-tumoral gene therapy[15,16]. However, common TK genes (naked genes) do not have the abilities to target to specific organs and tissues, which can be harmful to the normal cells and tissues. In addition, they are easily degraded by nucleases *in vivo*.

To solve the problems mentioned above, a recombinant plasmid $P^{EGFP-TKAFP}$ was constructed, which can be specifically expressed in hepatocellular carcinoma cells. Furthermore, the plasmid was encapsulated in a biodegradable and biocompatible PLGA polymer to protect plasmid DNA from being digested by nucleases. The following characteristics of the nanoparticles were investigated, including *in vitro* anti-nuclease ability, tissue distribution in mice and the gene expression in hepatocellular carcinoma cells and normal parenchymal cells *in vitro*.

MATERIALS AND METHODS

Materials

Poly(D,L-lactic-co-glycolic acid) (PLGA; lactic-glycolic acid ratio: 75:25, M_r=30 000, batch number: 020112) was purchased from Chengdu Institute of Organic Chemistry, Chinese Academy of Science. Recombinant plasmid $P^{EGFP-TKAFP}$ was a gift from Dr. Liu Ji (Sichuan University). Human hepatocellular carcinoma SMMC-7721 cells[17] and normal parenchymal Chang liver cells[18] were provided by Shanghai Institute of Cell Biology, Chinese Academy of Science. DNase I was purchased from Chengdu Huamei Biochemicals Cooperation (Sichuan Province, China). Kunming mice, weighted 18-22 g, were provided by Experimental Animal Center of Sichuan University.

Methods

Nanoparticles preparation A double-emulsion evaporation technique[19] was used to prepare the nanoparticles. Briefly, plasmid DNA (200 μg) in 100 μL Tris-EDTA (TE) buffer was emulsified in 1 mL methylene chloride solution containing 100 mg of PLGA using a probe sonicator for 5 s. Polyvinyl alcohol (2 mL) was added to the primary emulsion and sonicated for another 5 s to form a double emulsion. The emulsion was added into the same concentration of polyvinyl alcohol and agitated by a magnetic stirrer for 3 h at room

temperature to remove methylene chloride.

Particle size and morphology analysis The PLGA nanoparticles were sized by laser diffractometry using a Malvern 2 000 laser sizer. The morphology was observed by the scanning electron microscope (JEM-100SX, Akishima, Japan). The samples were placed on to special copper grids and then stained with 20 mL/L phosphato-tungstic acid prior to visualization.

Entrapment ratio analysis The entrapment ratio was determined by measuring the total amount of added DNA and that of DNA being not encapsulated. In detail, colloid solution of DNA-PLGA nanoparticles was centrifuged at 45 000 *g* for 1 h. Then, the concentration of DNA in the supernatant was assessed by fluorescence spectrophotometry after stained with ethidium bromide. The exciting and emission wavelengths were 546 nm and 590 nm, respectively. The entrapment rate (ER) was calculated as follows: ER (%)=DNA $_{added}$-DNA $_{in\ the\ supernatant}$/DNA$_{added}$×100%

Protection from DNase The PLGA nanoparticles were incubated with DNase I (0.1 unit) at 37 ℃ in a shaking water bath. The nanoparticles were collected by centrifugation after 4, 8, and 16 h incubation, and then chloroform was added to solubilize the nanoparticles. An equal volume of PBS solution was added, and the mixture was rotated end-over-end to facilitate the extraction of DNA from the organic phase into the aqueous phase. The samples were then centrifuged at 15 000 *g* for 15 min. The resulted supernatant was transferred to another tube and DNA was precipitated with the addition of isopropanol. Precipitate was obtained after centrifugation at 5 000 r/min for 15 min. Then, the resulted pellet was rinsed with 700 mL/L ethanol and resuspended in sterile TE buffer. The purified DNA was analyzed by gel electrophoresis.

Tissue distribution One hundred Kunming mice weighed 18-22 g were randomly divided into 10 test groups and 10 control groups with 5 in each group. The nanoparticles of ^{32}P-DNA-PLGA at a dose of 10 μL/g was intravenously administered to each mouse in test groups, and ^{32}P-DNA at the same dose was intravenously administered in control groups. At predetermined intervals, mice were sacrificed for blood collection. Then, heart, livers, spleen, lungs, and kidneys were removed from mice. The radioactivity of each organ was measured by a liquid scintillation analyzer.

The cpm$_t$ was the total value of cpm in each organ (cpm$_i$) at a certain time point. The ratio of cpm$_i$/cpm$_t$×100% represented the relative content of DNA in viscera and blood.

MFI assay Human hepatocellular carcinoma SMMC-7721 cells and normal parenchymal Chang liver cells ($5×10^5$) were cultured in the DMEM medium containing 100 mL/L fetal bovine serum (FBS) in 12-well plates. The cells were transfected with plasmid DNA or nanoparticles containing DNA, and maintained at 37 ℃ in an incubator at a 50 mL/L CO$_2$ humidified atmosphere. After incubation for 12 h, the medium was removed and replaced with fresh DMEM containing 100 mL/L FBS for further 48 h incubation. The mean fluorescence intensity (MFI) of the cells was measured by flow cytometry.

Cytotoxicity assay Cells were cultured in the same way as the MFI assay. After incubation for 12 h, the medium was removed, replaced with DMEM containing 100 mL/L FBS, and incubated with 0.1, 1, or 10 μg/mL GCV. The cytotoxicity of GCV was detected by MTT assay.

RESULTS

Size and morphology

The resulted plasmid-nanoparticles had regular spherical surface (Figure 1) and a narrow size distribution with a mean diameter of 72±12 nm.

Figure 1 Transmission electron microphotography of TK-PLGA nanoparticles.

Entrapment efficiency

The mean entrapment efficiency was 91.25%, which was rather high in the nanoparticles preparation with PLGA as a carrier.

Protection from DNase

Plasmid DNA encapsulated in nanoparticles remained intact in the presence of DNase I for up to 16 h incubation. On the other hand, control plasmid DNA was completely digested within 1 h incubation with the equal amount of DNase I. This result demonstrated that PLGA nanoparticles could protect encapsulated plasmid DNA from nuclease digestion (Figure 2).

Figure 2 Agarose gel electrophoresis of DNA extracted from nanoparticles after treatment with sonication and Dnase I. Lane 1 represented untreated control plasmid DNA, lane 2 represented plasmid DNA incubated with Dnase I at 37 ℃ for 1 h, and lane 3, 4, 5, 6 indicated DNA extracted from PLGA nanoparticles incubated with Dnase I at 37 ℃ for 0, 4, 8, or 16 h, respectively.

Measurement of DNA in blood and viscera of mice

The tissue distribution of DNA-PLGA nanoparticles was investigated by the technique of gamma scintigraphy. The results showed that 1 h after injection with ^{32}P-DNA-PLGA nanoparticles in mouse caudal vein, the ratio of radioactivity in livers against total radioactivity was more than 80%, which was 1.5-fold of that after injection with ^{32}P-DNA alone (Table 1 and Table 2).

Cytotoxicity assay and MFI assay

The EGFP expression in human hepatocellular carcinoma SMMC-7721 cells and normal parenchymal Chang liver cells were assessed by flow cytometry. The expression of TK gene was also investigated by MTT assay, by which the viable cells were quantitated after the addition of parent drug GCV. The results showed that the EGFP and TK expression in human hepatocellular carcinoma SMMC-7721 cells was much higher than that in human normal parenchymal Chang liver cells ($P<0.05$) (Table 3). It also showed that plasmid DNA encapsulated in nanoparticles could enhance the expression of TK or EGFP gene compared with naked plasmid DNA ($P<0.05$) (Table 4).

DISCUSSION

Recombinant plasmid P[EGFP-AFP] was constructed, which could be specifically expressed in hepatocellular carcinoma cells because of alpha-fetoprotein-albumin (AFP-alb) promoter[20-27]. Meanwhile, EGFP as the reporter gene of plasmid DNA, can be assessed by confocal laser scanning microscopy and flow cytometry[28-32]. A polymer, PLGA, was selected due to its biocompatible and biodegradable properties, which was already approved for *in vivo* applications[33-39]. Non-toxicity of the carrier may permit repeated administration of the nanoparticles to compensate for transient transgene expression.

Our results showed that plasmid DNA could be encapsulated in PLGA nanoparticles without compromising its structural and functional integrity. Additionally, PLGA nanoparticles could protect plasmids from nuclease degradation, and therefore offer an effective approach for gene delivery *in vivo*. However, the relatively low transfection efficiency was obtained in comparison with viral vector, which still remains to be a problem.

The DNA nanoparticles probably permeate the cells through endocytotic mechanism due to their small size and negative charged surface[40]. The encapsulation of plasmid DNA in cationic liposomes offers another choice to be protected from DNases. However, cationic liposomes may be toxic to cells due to an excess of positive charge[41,42], and can be easily influenced by the substances in plasma. In recent years, nanoparticles attract more and more attention because of many advantages, including high stability at room temperature, favorable safety, the ability to deliver plasmid DNA at a controllable rate, and easy adaptability. Unlike most viral vector, there is no limit on the size of plasmids encapsulated into the nanoparticles[43,44].

Abstract

AIM: To investigate the inhibitory effect of hepatitis C virus internal ribosome entry site (HCV IRES) specific inhibitor RNA (IRNA) on gene expression mediated by HCV IRES *in vivo*.

METHODS: By using G418 screening system, hepatoma cells constitutively expressing IRNA or mutant IRNA (mIRNA) were established and characterized, and HCV replicons containing the 5′ untranslated region (5′ UTR) were constructed by using the same method. Cotransfection of pCMVNCRluc containing HCV 5′ UTR-luc fusion genes and eukaryotic vector of IRNA into human hepatic carcinoma cells (HepG2) was performed and the eukaryotic expression plasmid of IRNA was transfected transiently into HCV replicons. pCMVNCRluc or pCDNA-luc was cotransfected with pSV40-β Gal into IRNA expressing hepatoma cells by using lipofectamine 2000 *in vitro*. Then the reporting gene expression level was examined at 48 h after transfection by using a luminometer and the expressing level of HCV C antigen was analysed with a confocal microscope.

RESULTS: Transient expression of IRES specific IRNA could significantly inhibit the expression of reporter gene and viral antigen mediated by HCV IRES by 50% to 90% *in vivo*, but mIRNA lost its inhibitory activity completely. The luciferase gene expression mediated by HCV IRES was blocked in the HHCC constitutively expressing IRNA. At 48 h after transfection, the expression level of reportor gene descreased by 20%, but cap-dependent luciferase gene expression was not affected. IRNA could inhibit the HCV replicon expression 24 h after transfection and the highest inhibitory activity was 80% by 72 h, and the inhibitory activity was not increased until 7d after transfection.

CONCLUSION: IRNA can inhibit HCV IRES mediated gene expression *in vivo*.

INTRODUCTION

Hepatitis C virus (HCV) is the primary causative agent of parenterally transmitted non-A, non-B hepatitis and affects a significant part of the world population. HCV infection frequence leads to chronic hepatitis, cirrhosis of the liver, and hepatocellular carcinoma. The genome of HCV is a single-stranded, plus-polarity RNA. The 5' untranslated region (UTR) of HCV RNA is approximately 340 nt long, and contains multiple AUG codons. The 5' UTR is highly conserved among different strains of HCV. Nucleotides 40 to 370 of the 5' UTR of HCV have been shown to contain an internal ribosome entry site (IRES)[1-3]. The presence and stability of IRES play an important role in virus life cycle, so the region has become the target of antivial gene therapy[4-16]. Coward and Dasgupta found that gene expression mediated by polio virus (PV) IRES was inhibited by one 60 nt long RNA which is called inhibitor RNA (IRNA). Because HCV and PV IRES elements bound to similar polypeptides[16-20], it was reasoned that IRNA might also interfere with HCV IRES-mediated translation. Using transient transfection of hepatoma cells and a hepatoma cell line consititutively expressing IRNA, we demonstrated specific inhibition of HCV IRES-mediated translation by IRNA *in vivo*.

MATERIALS AND METHODS

Materials
Vectors pcRz-IRNA and pcRz-mIRNA were constructed by our laboratory, which introduced the sequences of 5' and 3' *cis*-self cleavage ribozyme into both sides of IRNA or mIRNA sequence[21]. pCMVNCRluc contain full sequence of HCV 5' UTR and 66 nt core gene, and was fused with lucferase gene (generous gift of professor Alt). pcHCVcluc was constructed by our laboratory containing full sequence of HCV 5' UTR and partial sequence of core region, and could express in cells stably.

Methods
Cell culture Human hepatocarcinoma cell (HHCC) HepG2 was grown in RPMI1640 medium supplemented with 100 mL/L newborn calf serum.
Plasmid construction By using subcloning methods, IRNA and mIRNA sequence were cloned into the pcDNA3 vector, yielding pcRz-IRNA and pcRz-mIRNA which introduced the ribozyme sequence over both sides of IRNA and mIRNA to generate the correct side of IRNA and mIRNA[16]. In brief, by using PCR methods the sequences of target RNA were generated from pGRz-IRNA or pGRz-mIRNA which was constructed by our laboratory. Then the PCR product was cloned into the *BamH*I-*Apa*I sites of the pcDNA3 vector.
Establishment of stable hepatoma cell line expressing IRNA or cloning HCV replicon Plasmids pcRz-IRNA, pcRz-mIRNA, pcDNA3 and pcHCVcluc were transfected into HHCC respectively by using Lipofectamine 2000 reagent (GIBCO) and screened for neomycin resistance with 300 μg/mL of geneticin (G418) (Invitrogen) per milliliter for 4 weeks. The antibiotic-resistant cell clones were harvested and further screened by dilution titer.

Detection of IRNA in cell lines IRNA or mIRNA expression in the cells was measured by isolating total RNA from these cells and IRNA or mIRNA were detected by reverse transcriptase (RT)-mediated PCR (RT-PCR) by using IRNA or mIRNA specific oligonucleotide primers. One to 2 μg of total RNA isolated from the IRNA or mIRNA expressing cells, and 2 μg total RNA from HHCC control cells were reversely transcribed by murine leukemia virus RT using random hexamer primers in 20 μL reaction mixture according to the TaKaRa RNA PCR kit protocol. Twenty pmol of each primer (corresponding to 5' nt 1 to 20 and 3' nt 1 to 20 of the IRNA or mIRNA sequence) was used to amplify the 60-nt fragement in 100 μl PCR reaction. The cycling parameters were as follows: denaturation at, 95 ℃ for 1 min, annealing at, 65 ℃ for 1 min, extension at, 72 ℃ for 1 min, a total of 50 cycles, then total extrension at, 72 ℃ for 10 min. Twenty microliters of each reaction product were loaded onto 20 g/L gel and visualized by ethidium brominde staining.

Detection of HCV core protein expression in HHCC HCV core protein was detected by using indirect immune fluorescence method. HCV replicon cells were plated on a cover glass and fixed with pure ethanol for 10 min. Monoclonal antibody of HCV core protein was properly diluted (1:100) and covered on the glass with HCV replicon cells for 1 h at 37 ℃, and then the glass was washed 3 times with PBS (10 min each). Then FITC labeled second antibody was covered on the glass at 37 ℃ for 1 h and the glass was washed 3 times again with PBS. At last the cells were examined by using fluorescence microscopy or laser confocal microscopy.

DNA transfection For each transfection assay, 1×10^6 HHCC cells in 30-mm-diameter plates were transfected with 15 μL of lipofectin (GIBCO) and 2 to 5 μg of plasmid DNA. At 16 h post transfection, cell lysates were prepared according to the luciferase assay kit protocol (Promega) and assayed for both β-galactosidase (β-Gal) and luciferase expression.

RESULTS

Inhibitor effecty of IRNA transient expression on HCV IRES-mediated translation

To test the possibility that IRNA interfered with HCV IRES-mediated translation, human hepatocellular carcinoma cells (HepG2) were transiently cotransfected with three plasmids: a reporter gene expressing luciferase programmed by the HCV IRES element (pCMVNCRluc), pSV-β-galactosidase to measure transfection efficiency, and the plasmid expressing IRNA (pcRz-IRNA). All transfections were done in triplicate and contained equal amounts of the luciferase reporter and β-Gal plasmid. Increasing concentrations of plasmid pcRz-IRNA were used in various reactions, and the total amount of DNA in each reaction was kept constant by addition of an appropriate amount of a nonspecific DNA(pcDNA3). Following transfection, luciferase activity was measured in cell extracts at 48 h. At the lowest concentration of the IRNA plasmid, inhibition of luciferase activity from plasmid pCMVNCRluc was approximately 50% compared to the control. However, at the highest concentration, 92% of luciferase activity was inhibited. Translation of luciferase from

a control plasmid (pCDNA-luc) without HCV IRES was not significantly inhibited by IRNA, ($P>0.05$, Table 1).

In order to determine the inhibitor effect of IRNA on HCV IRES-mediated translation further, the HHCCs were transfected with pCMVNCRluc or cotransfected with pcRz-IRNA and pCMVNCRluc. Following transfection, the HCV core protein programmed by HCV IRES was detected by using laser confocal microscopy. HCV core protein could express efficiently in the HHCC cells as shown in Figure 1. But IRNA plasmid cotransfection could inhibit HCV core protein expression. The pels density of HCV core protein was different between the two groups (58.05 ± 42.24 *vs* 15.56 ± 8.54). The inhibitory rate was plotted by 1- pels density of IRNA transfection group/pels density of control ×100%.

Figure 1 Stable expression of IRNA and mIRNA in HHCC cells. 1: DL2000 DNA marker; 2, 3: IRNA RT-PCR; 4: mIRNA RT-PCR; 5: IRNA PCR.

Construction of hepatoma cell line expressing IRNA or mIRNA

To determine the long-term effect of RNA expression in HepG2, the cell line constitutionally expressing IRNA was generated by using a pcDNA-based vector as described in Material and Methods. In order to obtain both the correct and stable sites of the expressed IRNA, ribozyme sequences were introduced into both sides of IRNA and mIRNA. IRNA or mIRNA was examined by RT-PCR using appropriate primers. IRNA and mIRNA were expressed stably in the stable cell lines as shown in Figure 2.

Figure 2 Inhibitory effect of IRNA on luciferase expression mediated by different mechanism.

Table 1 Inhibitory effect of IRNA on HCV IRES mediated gene translation

Sample pcRz-IRNA μg	Activity of luciferase programmed by cap-dependent mechanism (IU/U)	Activity of luciferase programmed by HCV IRES (IU/U)	Inhibitory rate (%)	
			pcDNA-luc	pCMVNCRluc
0	55.5±3.11	52.49±2.31		
2	60.1±2.31	27.0±0.740	0	50
4	58.3±1.89	14.7±0.380	0	72
6	52.4±2.12	4.03±0.120	4	92

HCV IRES-mediated gene expression in IRNA expressing HepG2 cells

IRNA or mIRNA expressing HepG2 cells and empty vector pcDNA3 expressing cells or control cells were cotransfected with pCMVNCRluc and transfection efficiency control plasmid pSV-β-Gal. At 48 h post-transfection cell extracts were used to measure the activities of both luciferase and β-galactosidase. The result was plotted as percent of control after normalized for β-Gal activity and protein concentration. The pcRz-IRNA cells showed approximately 80% inhibition of luciferase activity compared to the control. Both pcRz-mIRNA cells and pcDNA3 cells showed less than 5% inhibition activity. No significant inhibition of cap-dependent translation from the pCDNA-luc construct was observed in cell lines expressing IRNA, (P=0.05, Figure 3).

Figure 3 Inhibitory effect of IRNA on HCV Core expression mediated by HCV IRES(A: 40×10 *vs* B: 25×10). A: HCV Core protein of pCMVNCRluc transfection group, B: HCV Core protein of pcRz-IRNA and pCMVNCRluc cotransfection group.

Construction of HCV replicon containing HCV IRES

The results demonstrated that HCV core programmed by HCV IRES was positive in about 90% of HHCC cells (Figure 4).

Figure 4 Detection of HCV core protein in HHCC lines stably expressing pcHCV Cluc (25×10).

Interference of IRNA with HCV replicon translation

To confirm the result obtained in IRNA expressing cells, HCV replicon containing HCV IRES was transfected with IRNA expressing plasmid, and luciferase activity was determined at different time following transfection. The result was that at 24 h HCV IRES-mediated luciferase gene translation decreases by 15% compared to the control HHCC cells, and along with time extending, the inhibitory effect of IRNA on HCV IRES-mediated luciferase gene translation increased and reached 80% at 72 h. On d 7, the inhibitory effect was still 80%. But mIRNA and nonspecific short RNA did not show any inhibitory effect on HCV IRES-mediated gene translation (Figure 5).

Figure 5 Interference of IRNA with HCV replicon translation.

DISCUSSION

IRES-dependent protein translation mechanism was first discovered in picornavirues, including PV, rhinovirus and hepatitis A virus, as well as certain flavivirues, such as hepatitis C virus[23-28]. Although there is very little sequence homology between these different IRES elements, structural similarity does appear to exist. In fact, in order to keep the activity of IRES, it was more important to maintain the secondary structure than to maintain the integrality of certain genome sequences[1-3,7,8]. IRES is the key structure for some viral RNA replication, so it has become the target for antiviral infection. We have constructed the self-cleavage plasmid of IRNA, and affirmed that IRNA can inhibit IRES-dependent protein translation *in vitro*[22]. In order to further confirm the effect of long-term expressing IRNA on cellular protein and viral protein translation, we established a HHCC line stably expressing IRNA, and confirmed that long-term expressing IRNA could significantly inhibit IRES mediated protein translation compared to the control cells and mIRNA expressing cells. Das *et al* prepared the human hepatoma (Huh-7) cell lines expressing IRNA by using the similar methods. They found that HCV IRES-mediated cap-independent translation was markedly inhibited in cells constitutively expressing IRNA compared to control hepatoma cells[29].

Alt *et al* designed the vector pCMVNCRluc fusing the luciferase gene to HCV core gene 66 nt site, and the gene expression was mediated by HCV 5' UTR, so we could dertermine the inhibitor effect of new strategies on HCV 5' UTR by examining the activity of luciferase. In this study, three plasmids pCMVNCRluc, pcRz-IRNA expressing IRNA and transfection efficiency control plasmid pSV-βGal were cotransfected into HHCC cells and luciferase activity (light units) was expressed as percentage of the control after normalized for β gal activity. When the effect of transfection efficiency and transient expression efficiency where excluded, the results of this study showed that IRNA could specifically inhibit HCV IRES mediated gene expression *in vivo*. The results of our study suggested that HCV 5' UTR-mediated translation was specifically inhibited by IRNA transient expression in hepatoma cells (50% to 92%), whereas cap-dependent translation of luciferase from the control plasmid

lack of HCV IRES element was not significantly affected by IRNA. To confirm the result obtained by using transient transfection, the vector containing HCV IRES was transfected into human hepatoma cells expressing IRNA constitutively and the results demonstrated that stably expressing IRNA could inhibit HCV IRES-mediated translation. By using a bicistronic construct containing CAT and luciferase genes flanked by the HCV 5' UTR Das *et al* found that IRNA could significantly inhibit HCV IRES-mediated gene expression *in vitro*. Further, they studied the IRNA effect *in vivo* and obtained the similar result to our study[29,30].

In order to determine the IRNA inhibitor effect *in vivo* further, we used the HCV replicon containing the full length of HCV 5' UTR to investigate the IRNA activity; the results demonstrated that IRNA could inhibit HCV 5' UTR mediated gene expression *in vivo*, but IRNA could not completely block HCV 5' UTR mediated gene expression.

To rule out the nonspecific effect of nonspecific short RNA regiment on HCV IRES –mediated gene expression, plasmids pCDNA3 and pCMVNCRluc were cotransfected into human hepatoma cells and the results showed that nonspecific RNA regiment didn't have the inhibitor effect on HCV IRES-mediated translation.

In summary, IRNA can significantly inhibit HCV IRES-mediated translation.

Abstract

AIM: The eradication rate of *Helicobacter pylori* (*H pylori*) shows variation among countries and regimens of treatment. We aimed to study the eradication rates of different regimens in our region and some factors affecting the rate of eradication.

METHODS: One hundred and sixty- four *H pylori* positive patients (68 males, 96 females; mean age: 48±12 years) with duodenal or gastric ulcer without a smoking history were included in the study. The patients were divided into three groups according to the treatment regimens. Omeprazole 20 mg, clarithromycin 500 mg, amoxicillin 1 g were given twice daily for 1 week (Group I) and 2 weeks (Group II). Patients in Group III received bismuth subsitrate 300 mg, tetracyline 500 mg and metronidazole 500 mg four times daily in addition to Omeprazole 20 mg twice daily. Two biopsies each before and after treatment were obtained from antrum and corpus, and histopathologically evaluated. Eradication was assumed to be successful if no *H pylorus was* detected from four biopsy specimens taken after treatment. The effects of factors like age, sex, *H pylori* density on antrum and corpus before treatment, the total *H pylori* density, and the inflammation scores on the rate of *H pylori* eradication were evaluated.

RESULTS: The overall eradication rate was 42%. The rates in groups II and III were statistically higher than that in group I (*P*<0.05). The rates of eradication were 24.5%, 40.7% and 61.5% in groups I, II and III, respectively. The eradication rate was negatively related to either corpus *H pylori* density or total *H pylori* density (*P*<0.05). The median age was older in the group in which the eradication failed in comparison to that with successful eradication (55 yr *vs* 39 yr, *P*<0.001). No correlation between sex and *H pylori* eradication was found.

CONCLUSION: Our rates of eradication were significantly lower when compared to those reported in literature. We

believe that advanced age and high *H pylori* density are negative predictive factors for the rate of *H pylori* eradication.

INTRODUCTION

Eradication treatment for *H pylori* infection has been generally accepted since the relation between *H pylori* and peptic ulcer disease was established[1,2]. Furthermore, this treatment approach has gained importance since the eradication of *H pylori* was found to reduce the recurrence of duodenal and gastric ulcer[3,4]. The eradication rate of *H pylori* has reached high levels with combined use of antibiotics and proton pump inhibitors (PPIs), being 60-90% in Turkey[5]. Different treatment protocols have been used for *H pylori* eradication. The rate of *H pylori* eradication was higher than 85% with the combination of drugs consisting of two antibiotics and a PPI[6]. We aimed to study the rates of *H pylori* eradication in Cukurova region with regard to different treatment regimens and the effects of patient age, sex, and *H pylori* density on *H pylori* eradication rates.

MATERIALS AND METHODS

One hundred and 64 patients (68 males, 96 females; mean age 48±12 yr, range 17-78 yr) with gastric or duodenal ulcer and *H pylori* detected at endoscopy were included in the study. Two biopsies from antrum and two from corpus were taken. *H pylori* density and gastric inflammation in both antrum and corpus were assessed based on Sydney classification (normal=0, mild=1, moderate=2, marked=3)[7]. The patients were randomly divided into three groups and each group was treated with one of the protocols as follows. Group I received Omeprazole (0) 20 mg, Clarithromycin (C) 500 mg, amoxicillin (A) 1 000 mg, twice daily for 7 d. Group II received the same drugs as in group I for 14 d. Group III received Omeprazole 20 mg twice daily, Bismute subsitrate (BS) 300 mg 4 times daily, tetracycline (T) 500 mg 4 times daily, metronidazole (M) 500 mg 4 times daily for 10 d. There were 53, 59 and 52 patients in the 3 groups, respectively. Antibiotics, PPIs, and H_2 receptor blockers were used for at least one month. Smoking, pregnancy and lactation, past history of gastric surgery, renal or liver failure, diabetes mellitus and irregular use of drugs in the eradication regimens were accepted as exclusion criteria. Endoscopy was repeated and two biopsies each from corpus and antrum were obtained after 45-60 d of treatment. Eradication was accepted to be successful if *H pylori* were not found in any of the 4 samples. Total bacterial density was calculated semi quantitatively by addition of antrum and corpus *H pylori* density[8]. None of the patients had atrophy in histologic evaluation. The relations of *H pylori* densities in

different locations before treatment, age, and sex with the rate of *H pylori* eradication were analyzed.

Statistical analysis

Data were expressed as medians with interquartiles. Mann-Whitney-*U* test or χ^2 test was used to assess significant differences between values in various groups of patients. $P<0.05$ was considered statistically significant. Data were analyzed using the SPSS for Windows (version 9.05; SPSS, Inc., Chicago, Illinois, USA).

RESULTS

Out of 164 patients who completed the study, 69 (42%) had eradication of *H pylori* infection, and 151 (91.4%) showed ulcer healing. Eradication could not be achieved in 10 of 13 patients without ulcer healing. The eradication rate in group I, II, and III was 24.5%(13/53), 40.6%(24/59), and 61.5%(32/52), respectively. The rate of eradication in group III was higher than group I and II (P<0.03). There was a difference between groups I and II, which did not reach statistical significance (P=0.07). The ulcer cure was 45/53, 55/59, and 51/52, respectively in the 3 groups. *H pylori* density in antrum before treatment or severity of inflammation was not statistically related to its eradication. Corpus and total *H pylori* densities were higher in patients who failed the eradication treatment when compared to those who showed successful eradication (P<0.01 and P<0.05, respectively for corpus and total densities) (Table1). The median patient age was higher in the group in which eradication failed. (55 *vs* 39 yrs, P<0.001). The distribution of age, sex and *H pylori* density of corpus in the patient groups were summarized in Table 2.

Table 1 Rates of *H pylori* eradication and ulcer healing in various treatment regimens

Group	n	Age	F/M	Eradication (%)	Ulcer healing[d] (%)
I	53	49±12	30/23	13 (24.5)[a,b]	45 (84.9)
II	59	48±11	35/24	24 (40.7)[c]	55 (93.2)
III	52	45±12	31/21	32 (61.5)	51 (98)
Total	164	48±12	96/68	69 (42)	151(92.1)

[a]P=0.07 *vs* Group II; [b]P<0.01 *vs* Group III; [c]P<0.03 *vs* Group III; [d]P=N.S. among the three groups.

DISCUSSION

The discovery of *H pylori* by Marshall and Warren has been considered as a revolution[9]. As the role of this microorganism in gastric pathologies is fully understood, the treatment principles of some of the gastro-duodenal lesions have been changed[10].

Nowadays, *H pylori*-positive peptic ulcer disease is accepted as an infectious process, and combination of drugs, including the same antibiotics were used in all of the treatment protocols[11-13]. No standard therapy for *H pylori* eradication has been underlined. An ideal *H pylori* treatment must be safe, cheap, easy and tolerable with more than an 80% eradication rate and must have a low rate of antibiotic resistance[14,15].

PPIs are commonly used in the combined regimens as a result of significant *in vivo* and *in vitro* effects on *H pylori*. Many treatment regimens including PPls were still hard to eradicate *H pylori*[16-19].

In Europe and in the USA despite resistance to metronidazole, clarithromycin, and tetracycline was 30-40%, 2-10% and <1%, respectively, the eradication rate of the combined treatment with clarithromycin, PPl and amoxicillin or metronidazole for 7-14 d was 87-100% in metronidazole sensitive group and 57-88% in metronidazole resistant group. In 10-12 d of PPl-A-C regimens, 88-96% eradication rate was maintained in clarithromycin sensitive group and 50% in the resistant group. These findings showed the importance of antibiotic resistance in unsuccessful eradication trials[20]. Several studies, in which the antibiotic resistance was analyzed as one of the independent parameters that can be predictors of eradication failure, supported the same suggestion[21-23]. In Turkey, Boyanova *et al* found the resistance to M 37.9%, to C 9.5%, and to A 0.9%, respectively. The double drug resistance (M+C) was 6.1%[24]. In a former study we found C and M resistance rates were 5.2% (1/19) and 36.8% (7/19) in a group of 19 patients (data unpublished). These observations suggested that antibiotic resistance could not explain completely the low eradication rate as we observed in the present study. The resistance in our patients was similar to that detected in the Western world whereas the rate of eradication was markedly lower when compared to Western population.

The effect of combination therapies on *H pylori* eradication rates varied according to the differences in treatment duration. Some studies which showed that 14 d trials were more successful than 7 d trials, whereas other studies showed no difference. In our study the rate of *H pylori* eradication was higher in prolonged treatment but did not reach any statistical significance[25].

The reported higher rates of *H pylori* eradication with either OCA or OCM combination in early studies in our country as compared to recent ones suggested the development of resistance was due to irregular and unsubscribed use of antibiotics in our population[17]. The possible differences in the production process of drugs by various manufacturers may play a role in the bioavailability of active compounds. We could not find any study regarding to this issue. However, Kim *et al.* from South Korea have found similar benefits in *H pylori* eradication rate of three drug combinations with two different Omeprazole preparations[26]. If similar studies can be made for antibiotics, questions on this matter can be answered.

Patient incompliance to treatment is another factor contributing to eradication failure. Graham *et al* have found that the eradication rate was about 96% in patients who used

Table 2 The distribution of age, sex and *H pylori* density of corpus in the patient groups

Group	Eradicated				Non-eradicated			
	n	Age[a]	F/M	Density	n	Age[a]	F/M	Density
I	13	35.3 ±11.7[a]	9/4	1.31±0.95[b]	40	54.0±9.1[a]	21/19	2.17±0.87[b]
II	24	40.04±9.3[a]	13/11	1.92±0.8[b]	35	54.94±8.8[a]	21/14	2.37±0.77[b]

60% or more of their drugs and 69% in those who used less than 60% of drugs[27]. We tried to eliminate this factor via good questioning and follow-up throughout the study. Patient incompliance did not seem to be a determinant factor for *H pylori* eradication failure in our study.

The response to combination of four drugs was around 87-100% in several studies. Nelson *et al.* found that the ulcer cure and eradication rate of *H pylori* with BSOMT in a 2 d and 7 d regimen were 95.7% and 76.1%, and 98% and 100%, respectively[11]. In studies using BSTMO combination, the eradication rate of *H pylori* was 96% in the metronidazole sensitive group and 82% in the metronidazole resistant group[28]. The rate of *H pylori* eradication with the same protocol in our study was much lower compared to previous trials, but significantly higher than two other protocols we used. This shows the necessity for studying some geographic factors.

Smoking; one of the parameters of antibiotic resistance in literature, was restrained during the inclusion phase of this study. We studied two other factors associated with *H pylori* eradication failure, namely the grade of *H pylori* density and gastritis. Our findings suggested that the eradication was more difficult in patients who had high total or corpus *H pylori* density. Georgopoulos *et al* found no relation between eradication and *H pylori* density or the severity of gastritis[21]. Yang *et al* reported a lower total bacterial density in the eradicated group[8]. In our study corpus and total (sum of *H pylori* density in antrum and corpus) *H pylori* densities were higher in patients with eradication failure compared to the successfully eradicated group. Consequently, the factors affecting *H pylori* density can be expected to affect the eradication rate. Some studies on this issue showed that some factors related with host or bacteria could affect *H pylori* density in gastric mucosa[21,29-31].

The patients' lifetime exposure to several kinds of antibiotics could cause resistance and this might partly explain the difference noted in the age groups with respect to *H pylori* eradication rate[32].

Another factor that can contribute to the resistance to antibiotic treatment is intracellular settling of bacteria. The examples of this fact were some chronic infections such as tuberculosis and brucellosis for which a long term use of antibiotics was required[33,34]. The difficulty in eradication treatment of *H pylori* may in part be due to intracellular location of these bacteria since *H pylori* has been shown to penetrate into cells in cell cultures[35]. This suggestion was firmly supported when 14 d regimens were shown to be more effective than 7 d regiments as reported in this and previous studies.

The rate of eradication we encountered was significantly lower than those in literature, which suggests further studies concerning the mechanisms underlying the eradication failure in our community should be designed.

Abstract

AIM: To evaluate the relationship of *Helicobacter pylori* infection to reflux esophagitis (RE), Barrett's esophagus (BE) and gastric intestinal metaplasia (IM).

METHODS: RE, BE and gastric IM were determined by upper endoscopy. Patients were divided into 2 groups; those with squamocolumnar junction (SCJ) beyond gastroesophageal junction (GEJ) ≥3 cm (group A), and those with SCJ beyond GEJ <3 cm (group B). Biopsy specimens were obtained endoscopically from just below the SCJ, gastric antrum along the greater and lesser curvature. Pathological changes and *H pylori* infection were determined by HE staining, Alcian blue staining and Giemsa staining.

RESULTS: The prevalence of *H pylori* infection was 46.93%. There was no difference in the prevalence between males and females. The prevalence of *H pylori* infection decreased stepwise significantly from RE grade I to III. There was no difference in the prevalence between the two groups, and between long-segment and short-segment BE. In distal stomach, prevalence of *H pylori* infection was significantly higher in patients with IM than those without IM.

CONCLUSION: There is a protective role of *H pylori* infection to GERD. There may be no relationship between *H pylori* infection of stomach and BE. *H pylori* infection is associated with the development of IM in the distal stomach.

INTRODUCTION

The incidence of adenocarcinoma in the esophagus and gastroesophageal junction (GEJ) is increasing, whereas the incidence of distal gastric cancer is falling for the two decades in North America, Europe, Japan and China. In China, the incidence of adenocarcinoma at the GEJ is increasing even more significantly[1-3].

The adenocarcinomas at the esophagus and GEJ differ from those in the stomach[4]. They share epidemiological characteristics with each other, and often originate from segments of Barrett's esophagus (BE). It has therefore been proposed that both of them can be called "esophagocardia adenocarcinoma"[5]. BE is a well-defined premalignant condition for esophageal adenocarcinoma and most of adenocarcinomas at GEJ[6,7]. Neoplastic progression of BE has been shown to involve multiple steps with intestinal metaplasia and dysplasia serving as histopathologic markers[5]. It is considered that the absence of specialized intestinal metaplasia in many patients with adenocarcinoma at the GEJ may be due to the complete replacement of the metaplastic epithelium by the tumor, and in these tumors, IM usually is confined to ultrashort segments that may easily be overgrown by the tumor[8].

Gastro-esophageal reflux disease (GERD) can give rise to BE, and reflux symptoms are important indicators that a patient is at risk of having Barrett's metaplasia. Recently, interest has focused on the relationship between *H pylori* infection and GERD as well as BE, but controversial findings have been obtained Several retrospective studies have examined the association of Barrett's adenocarcinoma with gastric *H pylori* infection, yielding discordant results. It has been known that the prevalence of *H pylori* infection in China is high. It is necessary to clarify whether *H pylori* infection is the causally associated with BE or whether it has a protective effect on BE. In addition, further investigations are also required to clarify the relationship between *H pylori* infection and GERD. Therefore, the aim of this prospective study was to evaluate the relationship between gastric *H pylori* infection and reflux esophagitis (RE), BE, and gastric IM in China.

MATERIALS AND METHODS

Patients

Consecutive patients undergoing esophagogastroendoscopy at Second Hospital, Xi'an Jiaotong University, Xi'an, China from August 1, 2000 to the end of August 1, 2001 were included in the study. Exclusion criteria included previous gastric or esophagus resection, contraindication to performing biopsies, prior history of *H pylori* eradication therapy, and/or use of bismuth-containing compounds or antibiotics within the previous 4 weeks.The study was approved by the Ethics Committee of the hospital, and informed consents were obtained from all patients before entry.

Endoscopy and biopsy

Endoscopy was performed in a standardized manner by experienced endoscopists. The appearance of the squamoucolumnar junction (SCJ) was carefully studied in the prograde view after insufflation of air and after retroversion in the stomach. According to the length from the GEJ to SCJ, patients were divided into two groups; those with velvety red gastric-like mucosa lining the distal esophagus for 3 cm or over (group A) and those with velvety red gastric-like mucosa lining the distal esophagus for less than 3 cm (group B). Endoscopic esophagitis was graded as I, mucosal erythema; II, non-circumferential mucosal breaks or erosions; III,

circumferential erosion or ulcer.

Four-quadrant biopsies were taken from the area immediately distal to the SCJ. Additional targeted biopsies were also taken from erosions, nodules or ulcers. For assessment of *H pylori* status biopsies were taken from antral greater curvature (two), and lesser curvature (two).

Biopsy specimens were fixed in 40 g/L buffered formaldehyde, embedded in paraffin, serially sectioned, and then stained with hematoxylin and eosin. BE was defined as the presence of distended, barrel-shaped goblet cells, indicative of intestinal metaplasia[6,31,32], which was further confirmed by staining with Alcian blue pH 2.5.

In addition, BE was divided into long-segment Barrett's esophagus (LSBE, the segments of IM more than or equal to 3 cm in length) and short-segment Barrett's esophagus (SSBE, the segment of IM less than 3 cm in length).

The presence of gastric *H pylori* infection was defined when one or more of Giemsa-stained gastric biopsy specimens demonstrated typical *H pylori*-like organisms.

The gastric IM was defined by the presence of barrel-shaped goblet cells.

Statistical analysis
Statistical analyses were performed using the χ^2 test.

RESULTS
Altogether, 391 patients were recruited. Of these patients, 253 had esophageal disorders; 103 with RE (39 grade I, 35 grade II and 29 grade III), 120 with BE (26 LSBE and 94 SSBE), 12 with dysplasia (seven low–grade and five high-grade), 17 with adenocarcinoma at the GEJ and one with adenocarcinoma at lower esophagus (Table 1). Males were more likely to have esophageal disorders than females. The average age ranged from 52.41 to 62.64 years old, with and increased progressively from RE→BE→LGD→HGD→adenocarcinoma.

Table 1 Clinic features of study population

		No.	Mean age (yr)	Male: Female
No. Of patients		391	52.41	211:180
RE	I	39	52.12	26:13
	II	35	53.67	26:9
	III	29	55.56	24:5
BE	SSBE	94	54.71	62:32
	LSBE	26	58.66	20:6
Low-grade dysplasia		7	59.57	5:2
High-grade dysplasia		5	62.00	3:2
Adenocarcinoma at GEJ		17	62.64	14:3

Status of *H pylori* infection was available for 375 patients. The prevalence *of H pylori* infection was 46.93% (176/375). There was no significant difference in the prevalence between males and females (males, 48.71% and females, 45.00%) (*P*>0.05) (Table 2). The prevalence of *H pylori* infection in Group A was 41.84% (41/98), which was slightly lower than that 48.73% (135/277) in group B (*P*>0.05), The prevalence of *H pylori* infection decreased stepwise significantly from RE Grade I (51.72%), grade II (28.57%) to grade III (20.68%) (*P*<0.05) (Table 2).

The prevalence of IM in group A (LSBE) (26.53%) was slightly lower than that in group B (SSBE) (33.94%) (*P*>0.05). In groups A and B the prevalence of *H pylori* infection (46.15% and 51.06%, respectively) in patients with IM was slightly higher than that (40.27% and 47.54%, respectively) in those without IM (both *P*>0.05) (Table 3). The prevalence of *H pylori* infection of LSBE (46.15%) is slightly lower than that of SSBE

(51.06%) (*P*>0.05). However, in the distal stomach, the prevalence of *H pylori* infection in patients with IM (56.29%) was significantly higher than that in those without IM (37.89%) (*P*<0.05) (Table 3).

Table 2 Comparisons of *H pylori* status among patients with sex, length of SCJ, grade of RE

Comparision of *H pylori* status between LSBE (IM+ in group A) and SSBE (IM+ in group B), *P*=0.658, (χ^2=0.196); Comparision of *H pylori* status between IM "+" and IM "–" in group A, *P*=0.603, (χ^2=0.271); Comparision of *H pylori* status between IM "+" and IM "–" in group B, *P*=0.579, (χ^2=0.308); Comparision of *H pylori* status between IM "+" and IM "–" in distal stomach, *P*=0.000, (χ^2=12.14).

DISCUSSION
Since the isolation of *H pylori* from gastric mucosa by Warren and Marshall in 1983, there has been renewed interest in a possible bacterial cause of upper gastrointestinal diseases[9]. *H pylori* is now widely accepted as a major cause of antral gastritis and peptic ulcer disease[10,11]. Epidemiological evidence for an association with gastric carcinoma has also been reported[12,13]. In addition, gastric mucosa-associated lymphoid tissue (MALT) lymphoma has been linked to *H pylori* infection[14,15]. The relationship of *H pylori* to GERD and BE is less clear. Some groups have reported a lower prevalence of *H pylori* infection in individuals with GERD, and have postulated that infection may reduce the risk of reflux esophagitis[16-18]. However, other epidemiological studies have found little or no association between *H pylori* infection and GERD[19-21]. With regard to Barrett's esophagus the majority of studies have found no association with *H pylori* infection[22,23]. However, there is also evidence to the contrary[18]. Our prospective study tried to evaluate the relation between gastric *H pylori* infection and RE, BE, and gastric IM in Chinese.

H pylori infection can be diagnosed by a variety of noninvasive or invasive tests. Histological examination with special staining of gastric biopsy specimens is accepted as the gold standard for *H pylori* diagnosis[24,25]. Gastric antrum is the most common place for *H pylori* colonization[26,27]. Modified Giemsa staining, which has been shown to have a high specificity and sensitivity[25,28], was used to detect *H pylori* status in this study.

In early studies, BE was defined as the presence of specialized IM in a columnar-lined mucosa encompassing more than 3 cm proximal to GEJ or a LSBE[29]. Any columnar-lined mucosa less than 3 cm above the GEJ was thought to be a

normal variant. However studies over the past years have indicated that there is a spectrum of involvement that includes the distal 3 cm of esophagus or a SSBE[30,31]. What is important is the presence of IM relating to adenocarcinoma. It has been shown that a patient with LSBE has a higher risk to develop dysplasia or cancer[32]. It also has been shown that the development of LSBE is more closely related to gastresophageal reflux[33]. Therefore, in our study, patients were divided into two groups; those with a velvety red gastric-like mucosa lining the distal esophagus for 3 cm or over and those with a velvety red gastric-like mucosa lining the distal esophagus for less than 3 cm. Because esophageal hiatal hernia is often complicated by GERD and BE, many researchers think that to define an esophageal hiatal hernia, the presence of a velvety red gastric-like mucosa lining the distal esophagus for 2 cm should be considered as normal. In our study, therefore, we referred to this definition; the length from the GEJ to SCJ for esophageal hiatal hernia reduced 2 cm[34,35].

Altogether, 391 patients were evaluated over the course of the study (Table 1), The presence of IM was confirmed in 26 cases of the 98 patients suspected of having LSBE, and in 94 cases of the 277 patients suspected of having SSBE. Seven BE cases with dysplasia, 103 RE and 17 adenocarcinoma at GEJ were diagnosed. The average age of patients increased gradually with the sequence of RE, BE, LGD, HGD and adenocarcinoma at GEJ from 52.41 to 62.64 years old. Males were more likely to have the diseases. Cameron et al reported that the age after 40 had a high incidence of BE, and development of adenocarcinoma from BE required about 20 years[36].

Of the entire study population, 375 subjects received histological examination for H pylori infection, with a prevalence of H pylori infection of 46.93%. There was no significant difference between males and females. These results are similar to the report by Hui et al about H pylori infection in the same area of China[37].

The first change in BE, is the replacement of the normal stratified epithelium with metaplastic columnar epithelium in the distal esophagus, making the SCJ rising upward above the GEJ. It is accepted that BE is an acquired condition, and is related to gastro-esophageal reflux. An excellent overview and hypothesis detailing the role of H pylori infection in the pathogenesis of duodenal ulcer, gastric cancer, and GERD has been given by Graham and Yamaoka[38,39]. H pylori infection has been shown to decrease acid secretion in patients with body-predominant H pylori colonization[40]. With less acid production, the offensive potency of the refluxate may be reduced. An additional mechanism could be neutralization of acid by ammonia produced by H pylori, with subsequence reduction in intragastric acid load and in the reflux of acid into the esophagus, as proposed by Bercik et al[41]. Ammonia may also promote protective adaptation of the esophageal mucosa[42]. So, if H pylori infection can decrease the offensive potency of the refluxate, we could infer indirectly whether H pylori infection has the protective effect in GERD and BE by comparing the RE grade and the prevalence of H pylori infection in different length from the GEJ to the SCJ (i.e. between group A and group B). In our study there was no significant difference in the prevalence of H pylori infection between group A (41.84%) and group B 48.73%. Furthermore, the prevalence of H pylori infection decreased stepwise significantly from RE Grade I (51.72%), grade II (28.57%) to grade III (20.68%) (P=0.032). These findings suggest that there is no relationship between gastric H pylori infection and GERD, although gastric H pylori infection had an apparent protective effect against the progression of GERD.

Barrett' s metaplasia is precancerous lesion of esophageal adenocarcinoma and most of adenocarcinoma at the GEJ. Progression from metaplasia, LGD, HGD to invasive cancer

occurs in a stepwise process. It is unquestionably BE, especially LSBE, is linked with gastresophageal reflux. Our study shows that H pylori infection has the protective effect in GERD. But how about BE? The present study demonstrated that there was no significant difference in IM prevalence between group A and group B. Marian et al reported that the prevalence of LSBE was higher than that of SSBE and the prevalence of IM is directly proportional to the length of column-lined esophagus[33]. This finding, which is different from ours, may explain the reason why the incidence of esophageal adenocarcinoma is on the increase in North America and Europe. However, in our study, the prevalence of SSBE was higher than that of LSBE, which may explain the reason why the incidence of adenocarcinoma at the GEJ is more common than that at the esophagus in China. There was no significant difference in the prevalence of H pylori infection between patients with and without IM in both group A and group B. Similarly, there was no significant difference in the prevalence of H pylori infection between LSBE and SSBE. However, in distal stomach, the prevalence of H pylori infection in patients with IM (56.29%) is much higher than that in those without IM (37.89%) (P<0.001), which is in agreement with previous observations[22,23,43]. It is suggested that H pylori infection is associated with IM in the distal stomach, but may have no protective effect in BE. The distal gastric IM is thought to be less dangerous to progress to gastric carcinoma, and thus it is not suggested to supervise routinely the patients with distal gastric IM[44]. However, patients with BE has an overrated risk, about 30 to 125 times to progress to adenocarcinoma than patients without BE[45, 46].

In conclusion, H pylori infection may have a protective role in GERD. There is no relationship between gastric H pylori infection and BE. H pylori infection is associated with IM in the distal stomach.

Abstract

AIM: To study whether vascular endothelial growth factor messenger RNA (VEGF mRNA) in the hepatocellular carcinoma (HCC) tissues obtained after curative resection has a prognostic value.

METHODS: Using a reverse-transcription polymerase chain reaction (RT-PCR)-based assay, VEGF mRNA was determined prospectively in liver tissues of 50 controls and in HCC tissues of 50 consecutive patients undergoing curative resection for HCC.

RESULTS: Among the isoforms of VEGF mRNA, $VEGF_{165}$ and $VEGF_{121}$ were expressed. By multivariate analysis, a higher level of $VEGF_{165}$ in HCC tissue correlated with a significant risk of HCC recurrence ($P=0.038$) and significantly with recurrence-related mortality ($P=0.045$); while $VEGF_{121}$ did not. Other significant predictors of HCC recurrence included cellular dedifferentiation ($P=0.033$), an absent or incomplete capsule ($P=0.020$), vascular permeation ($P=0.018$), and daughter nodules ($P=0.006$). The other significant variables of recurrence related mortality consisted of vascular permeation ($P=0.045$), and cellular dedifferentiation ($P=0.053$). The level of VEGF mRNA in HCC tissues, however, did not significantly correlate with tumor size, cellular differentiation, capsule, daughter nodules, vascular permeation, necrosis and hemorrhage of tumors.

CONCLUSION: The expression of VEGF mRNA, especially isoform $VEGF_{165}$, in HCC tissues, may play a significant and independant role in the prediction of postoperative recurrence of HCC.

INTRODUCTION

Angiogenesis, the establishment of a neovascular blood supply from preexishing blood vessels, known to be essential for the survival, growth, invasion, and metastasis of tumor cells, is a complex multistep process. The process may include the extracellular matrix remodeling and the binding of angiogenic factors to specific endothelial cell (EC) receptors, leading to EC proliferation, invasion of the basement membrane, migration, differentiation, and formation of new capillary tubes and developing into a vascular network[1-10].

One of the most potent, direct acting, and specific factors with angiogenic activity is vascular endothelial growth factor (VEGF)[11,12].

Hepatocellular carcinoma (HCC), a leading cause of death in Taiwan and many Asian countries, is a highly vascular tumor dependent on neovascularization. Some authors have suggested that VEGF may be a marker for metastasis in HCC because they found markedly elevated VEGF protein levels in HCC patients with remote metastases compared with those without metastasis[13-15]. However, most such studies determined VEGF protein concentrations by enzyme immunoassay. To our knowledge, in the prediction of postresection recurrence, little is known about the prognostic significance of VEGF mRNA expression in tumor tissues. We conducted this prospective study to investigate the correlation between VEGF mRNA expression in HCC tissues and postoperative recurrence of HCC.

MATERIALS AND METHODS

Study population

Fifty patients (31 men and 19 women, with a mean age of 56.2 ± 13.3 yr) of 58 consecutive patients with HCC undergoing curative hepatectomy from July 2001 to April 2003, were enrolled in this prospective study. Patients who had previously had a hepatectomy or preoperative neoadjuvant ethanol injection or hepatic arterial chemoembolization (TACE) were excluded. Surgical procedures performed included 38 major resections (8 extended right lobectomies, 10 right lobectomies, 8 left lobectomies and 12 two-segmentectomies) and 12 minor resections (10 segmentectomies, 1 subsegmentectomies, and 1 wedge resection). HCC tissues were obtained from all 50 patients after resection. A control group including 10 healthy volunteers without liver disease (5 men, 5 women, mean age 40 yr) and 20 patients with chronic liver disease but without evidence of HCC also received liver biopsy during laparotomy on them for other reasons. All these HCC tissues and liver biopsy tissues (from control group patients) were examined for VEGF mRNA.

After discharge, the patients were assessed regularly to detect tumor recurrence with abdominal ultrasonography (every 2-3 mo during the first 5 yr, then every 4-6 mo thereafter), serum alpha fetoprotein (AFP) and liver biochemistry (every 2 mo during the first 2 yr, then every 4 mo during the following

3 yr, and every 6 mo thereafter), abdominal computed tomography (CT) (every 6 mo during the first 5 yr, then annually), and chest X-ray and bone scans (every 6 mo). Hepatic arteriography was obtained if the other studies suggested possible cancer recurrence. Detection of tumor on any imaging study was defined as clinical recurrence.

Clinicopathological variables analyzed included age, sex (male *vs* female), the presence of liver cirrhosis, Child-Pugh class of liver functional reserve (A *vs* B), hepatitis B virus (HBV) infection (hepatitis B surface antigen), hepatitis C virus (HCV) infection (anti-hepatitis C virus antibody), serum AFP level (<20 ng/mL *vs* 20 to 1 000 ng/mL *vs* >1 000 ng/mL), tumor size (<3 cm *vs* 3 to 10 cm *vs* >10 cm), tumor encapsulation (complete *vs* incomplete or absent), presence of daughter nodules, vascular permeation (including vascular invasion and/or tumor thrombi in either the portal or hepatic vein), and cell differentiation grade (Edmondson and Steiner grades I to IV).

Detection of VEGF mRNA

It included extraction of RNA, reverse transcription and amplification of cDNA of VEGF and GAPDH by PCR.

VEGF mRNA of liver tissue

Extraction of RNA We homogenized resected tissues completely in 1 mL of RNA–bee^{TM}, and added 0.2 mL chloroform and shaked vigorously for 15-30 s. We stored the sample on ice for 5 min and centrifuged at 12 000 *g* for 15 min. We transferred the supernatant to a new 1.5 mL eppendorf tube and precipitated it with 0.5 mL of isopropanol. Precipitation could be as short as 5 min at 4 ℃. We centrifuged it at 12 000 *g* for 5 min at 4 ℃. We removed the supernatant and washed the RNA pellet with 1 mL of 750 mL/L ethanol, it dislodged the pellet from the slide of the tube by shaking. We centrifuged at 7 500 *g* for 5 min at 4 ℃ and carefully removed ethanol. We removed the supernate and dissolved RNA in DEPC-H$_2$O (usually between 50-100 μL) and store at -80 ℃.

Reverse transcription We heated the RNA sample at 55 ℃ for 10 mimutes and chilled it on ice. We added the following components: (1) 4 μL 5×RT butter containing 50 mmol/L Tris-HCl (pH 8.3), 75 mmol/L KCl, 3 mmol/L MgCl$_2$ and 10 mmol/L DTT(dithiothreitol), (2) 3 μL 10 mmol/L dNTP, (3) 1.6 μL Oligo-d(T)$_{18}$ and 0.4 μL random hexamers (N)6 (1 μg/μL), (4) 0.5 uL RNase inhibitor (40 units/μL), (5) 3 μL 25 mmol/L MnCl$_2$, (6) 6 μL RNA in DEPC-H$_2$O, (7) 0.5 μL DEPC-H$_2$O. We incubated it at 70 ℃ for 2 mimutes, chilled it to 23 ℃ to anneal primers to RNA. We added 1 μL of M-MLV RTase (moloney murine leukemia virus reverse transcriptase, 200 units/μL, Promega). We incubated it for 8 min at 23 ℃ followed by 60 min at 40 ℃. We heated the reaction at 94 ℃ for 5 min, chilled it on ice and stored cDNA at -20 ℃.

Amplification of cDNA of VEGF and GAPDH by PCR The sequences of the sense primers were 5'-AGTGTGTGCCCA CTGAGGA-3' (VEGF) and 5'-AGTCAACGGATTTGGT CGTA-3' (GAPDH) and those of the antisense primers were 5'-AGTCAACGGATTTGGTCGTA-3' (VEGF) and 5'-GGAACATGTAAACCATGTAG-3' (GAPDH). The first polymerase chain reaction (RT-PCR) solution contained 5 μL of the synthesized cDNA solution, 10 μL of 10× polymerase reaction buffer, 500 moi/L each of dCTP, dATP, dGTP and dTTP, 15 pmol of each external primer (EX-sense and EX-antisense), 4 units of Thermus Brockiamus Prozyme DNA polymerase (PROtech Technology Ent. Co., Ltd. Taipei, Taiwan) and water. The PCR cycles were denaturing at 94 ℃ for 1 min, annealing at 52 ℃ for 1 min, and primer extension at 72 ℃ for 1 min. The cycles were repeated 40 times. The PCR product was reamplified with internal primers for nested PCR to obtain a higher sensitivity. The first and second PCR components were the same, but for the primer pairs (IN-sense

and IN-antisense), the final product was electrophoresed on 20g/L agarose gel and stained with ethidium bromide. Four different isoforms of human VEGF were identified, arising from alternative splicing of the primary transcript of a single gene. The majority were VEGF$_{121}$ (165 bp) and VEGF$_{165}$ (297 bp). The percentage intensity of the VEGF PCR fragment for each liver was relative to a GAPDH PCR fragment (122 bp). The intensity of bands was measured using Fujifilm Science Lab 98 (Image Gauge V3.12). The sensitivity of our assay was assessed using human hepatocytes.

A hepatoblastoma cell line (HepG2) served as a positive control for VEGF mRNA expression. For negative controls, we used EDTA-treated water (filtered and vaporized).

Statistical analysis

A statistical software (SPSS for Windows, version 8.0, Chicago, Illinois) was employed, with Student's *t*-test used to analyze continuous variables and a chi-square or Fisher's exact test for categorical variables. Parameters relating to the presence of postoperative hAFP mRNA in peripheral blood were analyzed by stepwise logistic regression. A Cox proportional hazards model was used for multivariate stepwise analysis to identify the significant variables for predicting recurrence and mortality. Significance was taken as a *P* value <0.05.

RESULTS

RT-PCR analysis of VEGF transcript in liver tissues

VEGF mRNA was expressed in the liver tissues of 10 (VEGF$_{165}$ in 10 and VEGF$_{121}$ in 6) out of 30 control patients. In the HCC group, isoform VEGF$_{165}$ was detected in all the 50 patients (100%) (with a concentration ranging from 0.1860 to 0.7240) and isoform VEGF$_{121}$ in 40 patients (80%) (with a concentration ranging from 0.2849 to 1.0298).

We did not detect isoforms VEGF$_{189}$ and/or VEGF$_{206}$ in either HCC tissues or control liver tissues.

Table 1 Demographic, clinical and tumor variables of patients with HCC undergoing curative resection (*n*=50)

Variables	No. of patients (%)
Age (mean, years)	56.2±13
Male	31 (62)
Cirrhosis	40 (80)
Child-Pugh's class A	43 (86)
Serum AFP <20 ng/mL	16 (32)
20-10^3 ng/mL	18 (36)
>10^3 ng/mL	14 (28)
HBsAg (+)	36 (72)
Anti-HCV (+)	13 (26)
Size of HCC <3 cm	12 (24)
3-10 cm	13 (26)
>10 cm	25 (50)
Edmondson-Steiner's Grade I	4 (8)
Grade II	12 (24)
Grade III	18 (36)
Grade IV	16 (32)
Absent or incomplete capsule	31 (62)
Vascular permeation	29 (58)
Daughter nodules	31 (62)
Tumor necrosis	33 (66)
Tumor hemorrhage	29 (58)

AFP: serum alpha fetoprotein, HBsAg (+): positive hepatitis B surface antigen, Anti-HCV(+): positive hepatitis C virus antibody, Edmondson Steiner grade: differentiation grade.

Correlation of VEGF mRNA expression and clinical recurrence

During the follow up period (median 1.5 yr, range 1 to 2.5 yr), 16 patients (32%) had clinically detectable recurrence, of whom 7 died. A higher level of isoform $VEGF_{165}$ mRNA in HCC tissue correlated significantly with clinical recurrence both univariately (P=0.022) and multivariately, (P=0.038). Isoform $VEGF_{121}$ levels had no such correlation. By multivariate analysis, other significant predictors of recurrence included poor cellular differentiation (P=0.033), less encapsulation (P=0.020), more vascular permeation (P=0.018) and the presence of daughter nodules (P=0.006) (Table 2).

Table 2 Predictors of HCC recurrence

Variable	P values	
	UV	MV
Sex	0.895	-

Tumor necrosis	0.373	-
Tumor hemorrhage	0.306	-
Tissue $VEGF_{165}$ mRNA	0.018	0.045
Tissue $VEGF_{121}$ mRNA	0.744	-

UV: univariate analysis, MV: multivariate analysis, AFP: serum alpha fetoprotein, HBsAg (+): positive hepatitis B surface antigen, Anti-HCV(+): positive hepatitis C virus antibody, Edmondson Steiner grade: differentiation grades I, II vs III, IV, n.s: not significant.

Correlation of VEGF mRNA expression and recurrence-related death

The level of isoform $VEGF_{165}$ in HCC tissue significantly correlated with death due to recurrence both univariately (P=0.018) and multivariately (P=0.045). By multivariate analysis, a greater degree of vascular permeation significantly correlated with mortality (P=0.045), and poor cellular differentiation approached significance (P=0.053)(Table 3).

Correlation between VEGF mRNA expression in HCC tissues and clinical and histopathologic features

There was no significant association between isoform of VEGF mRNA and gender, age, serum AFP level, chronic HBV or HCV carriage, tumor size, coexisting cirrhosis, cellular differentiation, capsule, vascular permeation, daughter nodules, tumor necrosis, or tumor hemorrhage (P>0.05).

DISCUSSION

Our study revealed that a higher value of VEGF mRNA isoform $_{165}$ in resected HCC tissues was significantly associated with an increased risk of postoperative recurrence and disease mortality. The value of VEGF mRNA isoform $_{121}$ in HCC tissues was not significantly predictive of the outcome.

VEGF is also known as a vascular permeability factor and vasculotropin. Its active form is a homodimeric cytokine with molecular weight 34-46 ku. The variation in size due to alternative exon splicing might produce four different isoforms of 121, 165, 189 and 206 amino acids (monomeric size). The last had heparin binding activity[11,12]. Different cancers might have different expression of the isoforms. The majority of HCC expressed an abundance of $VEGF_{121}$ and $VEGF_{165}$[13-15]. According to Ferrara's finding, $VEGF_{165}$ was the predominantly expressed form in human cDNA libraries as well as in most normal cells and tissues[12].

Some authors have shown that the VEGF level in serum or in tissue is of value for predicting disease progression and prognosis in different cancers, such as the gastrointestinal origins, breast, lung, urothelium, ovary, and lymphoma[16-26]. Compared with expression in tumor tissue, the advantage of measurement of serum VEGF level is that it can be performed without tissue specimens and repeated, but it may be influenced by some factors such as coexisting liver cirrhosis, associated infection and platelet activation[27-32].

In addition, the expression of VEGF mRNA in serum might not always correlate significantly with the gene expression level of tumors[33]. Therefore, we used liver tissue instead of serum in this study. Warren found VEGF mRNA in hepatocytes and in some Kupffer cells[34]. However, release of VEGF mRNA might also be influenced by some cells other than HCC cells[34]. The presence of mRNA for VEGF has also been described in T lymphocytes, CD34* cells, and monocytes[27, 30].

For more accuracy, we chose to measure mRNA expression of VEGF in liver tissue rather than the protein itself. The level of VEGF mRNA did not always correlate with the protein concentration[32]. Immunohistochemistry could not distinguish small amounts of protein, which may partly explain the discrepancy in protein and mRNA levels.

The high recurrence rate after resection is the main determinant for the poor outcome of HCC[35-40]. Tumor invasiveness variables correlated with recurrence include high serum AFP, hepatitis, vascular permeation, grade of cellular differentiation, infiltration or absence of capsule, tumor size, coexisting cirrhosis, presence of daughter nodules, and multiple lesions. Therefore, a number of studies have been done to see if VEGF correlated with any or all of those factors.

Among reports about the clinical significance of VEGF

expression in HCC, there are considerable discrepancies[13-15,28,41-48]. Li found that VEGF mRNA in HCC correlated significantly with portal vein emboli, poorly encapsulated tumors, and microvascular density in HCC tissues[42]. Zhou reported that high VEGF expression in HCC was associated with portal vein tumor thrombosis[43]. Chow showed that VEGF expression was significantly associated with portal vein tumor thrombosis (sonographic evidence) but not with liver function, tumor volume, gender, severity of liver disease, or tumor grading[41]. In addition, the correlation between increased VEGF protein level in HCC and tumor size, number, microscopic venous invasion, metastasis, and recurrence has also been reported.

However, according to our study, a higher expression of VEGF mRNA was significantly correlated with tumor recurrence and recurrence-related mortality but not with the other parameters of tumor invasiveness. VEGF mRNA in HCC tissue thus appears to be an independent risk factor of postoperative recurrence. There are several possible explanations for this dissociation.

The number of study patients is one possible factor. Because most of the reported investigations were performed in small series, the 50 patients we used seemed a more adequate sample size compared with other studies. Another possible explanation for the discrepancies may be the assessment of tumors of different sizes and etiologies.

The relation between tumor size and VEGF mRNA expression might be complex and dynamic because of different vascular growth patterns[14,48-52]. If HCCs are about 1.0 cm in diameter, artery-like vessels are not well developed. Capillarization of the blood spaces is present but incomplete, and portal tracts may appear within cancerous nodules. These HCCs are thought to receive a predominantly portal blood supply. As tumor size increases, portal tracts decrease in number, and artery-like vessels gradually increase in number and size. Well-differentiated HCCs measuring 1.0 to 1.5 cm in diameter are in a transitional stage from portal to arterial blood supply, with reduction in portal flow prior to the increase in arterial flow. Therefore, blood flow in HCC at this point would be low and may not be detected on angiography. Hypervascularity becomes easily seen when nodules are larger than 2 cm in diameter. However, with increasing tumor size, VEGF positivity may gradually decrease. According to Yamaguchi, 36.8% of nodules larger than 3.0 cm were VEGF-negative[48]. El-Assal showed that, HCCs larger than 5 cm in diameter were less vascular than smaller or medium-sized lesions[32]. However, it has been reported that the intercapillary distance increased as the tumor size or weight increased, caused by the significantly different rates of turnover of endothelial cells and neoplastic cells. These complicated changes in vascularity may account for the disparate results among reported studies.

Suzuki reported that VEGF mRNA levels were not correlated with the vascularity of HCCs as seen on angiography[13]. On the contrary, Mise *et al* showed that the degree of VEGF mRNA expression was significantly correlated with the intensity of tumor staining in angiograms ($P<0.01$)[14]. Because of the complex nature of the angiogenic process, however, it seems that VEGF expression is not the sole contributor to angiogenesis in HCC. Other factors involved in this process may include TGF-β, TNF-α, IL-8, *etc*.

The stage of cancer might also influence VEGF expression[53-55]. VEGF concentrations have been reported to be significantly higher in advanced rather than early stages of breast, colon and gastric cancer[16-18,21]. Chao showed that a lower range of VEGF levels in patients with early-stage HCC overlapped considerably with those of normal controls or patients with chronic hepatitis or cirrhosis[45].

Coexisting liver cirrhosis may influence VEGF expression.

About 80% of our study patients had cirrhosis. Some investigators have found that VEGF expression was significantly higher in cirrhotic liver than in noncirrhotic liver. Furthermore, it has been shown that cirrhosis itself was associated with increased angiogenic activity. According to El-Assal, cirrhotic livers had significantly higher VEGF expressions than noncirrhotic livers[32]. In addition, some suggested a possible involvement of VEGF in angiogenesis of cirrhotic liver but not in angiogenesis of HCC[31,32]. Akiyoshi suggested that a low serum VEGF level in liver cirrhosis might reflect the degree of liver dysfunction and be associated with the grade of hepatocyte regeneration and VEGF levels decreased with the worsening of Child-Pugh score[31]. Whereas, most of our patients belonged to Child-Pugh class A, with resectable lesions, unlike those studied by Akyoshi.

According to the cell differentiation, the regulation of VEGF may be complex. In our study, VEGF mRNA did not significantly correlate with the grade of cell differentiation. We attribute this to the possibility of different histological grades coexisting in some HCC tissues. Yamaguchi examined VEGF expression immunohistochemically in HCC with various histological grades and sizes[48]. In tumors composed of a single histological grade, VEGF expression was the highest in well-differentiated, followed by moderately differentiated, and then poorly differentiated HCC. In tumors consisting of cancerous tissues of two different histological grades, the expression was less intense in the higher-grade HCC component. VEGF was also expressed in the surrounding HCC tissues in which inflammatory cell infiltration was apparent. Based on these findings, VEGF expression in HCC tissues was thought to be partly related to the histological grade, but other cytokines and growth factors could also cooperatively act to enhance or influence VEGF expressions in HCC.

We also found no correlation between VEGF and the absence or presence of fibrous capsule or septum formation, which was in contrast to the findings of Suzuki *et al*[13]. The origin of the capsule and fibrous septa in HCC is unclear. Nakashima *et al* suggested the possibility of fibrogenesis at the interface of two tumor nodules with different properties, a process requiring fibrin deposition in the initial stage when the HCC nodule grows to 1.5 cm or larger[52]. However, this mechanism has been doubted, since the tumor size did not correlate with the thickness of the capsule or the incidence of its formation.

In our study, a higher level of VEGF mRNA in tumor tissue correlated with more postresection recurrences. We attribute it to two possible mechanisms. One is that the higher angiogenesis may have more invasive nature of cancer to spread into the surrounding tissues. This invasion requires concomitant neovascularization through the sprouting of endothelial cells in extracellular matrix. It has been reported that VEGF could induce both urokinase-type and tissue-type plasmin in endothelial cell, which are the key protease involved in the degradation of the extracellular matrix. The other mechanism is that a shift of VEGF mRNA occurred in liver tissue, which is strongly related to the development of HCC. The progression from preneoplastic to neoplastic tissue would contribute to recurrence.

Surgery remains the potentially curative treatment for patients with HCC. High recurrence rate limits the long term survival. Examination of VEGF mRNA expression in resected HCC tissue may give us information on the risk of postoperative recurrence. Addition of neoadjuvant antiangiogenic therapy after surgery may be considered for such patients. Furthermore, serial measurement of circulating VEGF mRNA during postoperative follow-up to monitor the effect of therapy or the development of recurrence should be further investigated[56,57].

In conclusion, expression of VEGF, especially isoform

VEGF$_{165}$, in HCC tissues may play a significant role in the prediction of postresection recurrence of HCC.

Abstract

AIM: To investigate the effect of acupuncture and moxibustion on epithelial cell apoptosis and expression of Bcl-2, Bax, fas and FasL proteins in rat ulcerative colitis.

METHODS: A rat model of ulcerative colitis was estabelished by immunological methods and local stimulation. All rats were randomly divided into model control group (MC), electro-acupuncture group (EA), herbs-partition moxibustion group (HPM). Normal rats were used as normal control group (NC). Epithelial cell apoptosis and expression of Bcl-2, Bax, fas and FasL proteins were detected by TUNEL and immunohistochemiscal method respectively.

RESULTS: The number of epithelial cell apoptosis in MC was significantly higher than that in NC, and was markedly decreased after the treatment with herbs-partition moxibustion or electro-acupuncture. The expression of Bcl-2, Bax, fas and FasL in colonic epithelial cells in MC was higher than that in NC, and was markedly down- regulated by herbs-partition moxibustion or electro-acupuncture treatment.

CONCLUSION: The pathogenesis of ulcerative colitis in rats involves abnormality of apoptosis. Acupuncture and moxibustion can regulate the expression of Bcl-2, Bax, fas and FasL proteins and inhibit the apoptosis of epithelial cells of ulcerative colitis in rats by Bcl-2/Bax, fas/FasL pathways.

INTRODUCTION

Ulcerative colitis (UC) is a non-specific inflammatory intestinal disease. The pathogenesis of ulcerative colitis involves abnormality of apoptosis which is affected by a variety of factors[1-3]. At present, increasing evidence suggests that acceleration of apoptosis of epithelial cells and inhibition of apoptosis of inflammatory cells (such as neutrophil) are closely associated with colonic tissue injury and immunological abnormality in ulcerative colitis.

Apoptosis is determined by the relative expression of serial genes involved in the regulation of apoptosis. Fas/FasL is one of the important pathways of epithelial cell apoptosis in UC. In tissues of UC, the number of FasL positive cells is significantly increased, resulting in apoptosis. FasL expression increases in the focal region of active UC, which directly promotes apoptosis of Fas expressing colonic epithelium. The apoptosis promoting gene bax also plays an important role in apoptosis. The ratio of bax/bcl-2 determines whether apoptosis occurs or not. Excessive expression of bax promotes apoptosis.

In the present study, a rat model of UC was established by immunological method and local stimulation. After the treatment with electro-acupuncture and herbs-partition moxibustion, the number of colonic epithelial cell apoptosis and the expression of Bcl-2/Bax and Fas/FasL proteins were detected by TUNEL and immunohistochemistry respectively for elucidating the mechanism of acupuncture and moxibustion underlying colonic epithelial cell apoptosis in rat UC.

MATERIALS AND METHODS

Experimental animals and materials
Two hundred male SD rats (weighting 200±20 g) were provided by Experimental Animal Center of Shanghai University of TCM. TUNEL kits was purchased from Boehringer Mannheim (Germany). Bax, Bcl-2 and FasL kits were from Dako (Denmark). Fas was from Santa-cruz (USA).

Methods
Animal model and therapeutic methods Establishment of animal model: According to Experimental Methodology of Pharmacology[4], UC rat model was established by immunological method and local stimulation. Colonic mucosa was prepared from human fresh surgical colonic specimens, homogenized by adding appropriate amount of normal saline and centrifuged for 30 min at 3 000 r/min. The supernatant was removed for the measurement of protein concentration and then mixed with Freund adjuvant. The antigen fluid was first injected into the plantar pedis of the model group rats, then into the plantar pedis, dorsum, inguen and abdominal cavity (no Freund adjuvant in the last injection) on the tenth, seventeenth, twenty-fourth and thirty-first day respectively. When a certain titer of serum anti-colonic antibody was reached, 3 mL 3% formalin and 2 mL antigen fluid (no Freund adjuvant) were administered by enema successively. The rats in NC were administrated with normal saline as the same procedure of MC.

Treatment: After the ulcerative colitis rat model was built, the animals were randomly divided into model control group (MC 8), electro-acupuncture group (EA 8), herbs-partition moxibustion group (HPM 8) and normal control group (NC 6). HPM: Moxa cones made of refined mugwort floss were placed on the medicinal formula (medicinal formula dispensing: *Radix Aconiti praeparata, cortex Cinnamomi, et al*) for Qihai (RN

6) and Tianshu (ST 25, bilateral) and ignited. Two moxa cones were used for each treatment once a day and 14 times as a course. EA: Tianshu (bilateral) and Qihai were acupunctured and then stimulated by intermittent pulse with 2HZ frequency, 4 mA intensity for 20 minutes once a day and 14 times as a course.

After treatment, four gronp rats were killed simultaneously. The distal 6 cm long colons were dissected and reserved in formaldehyde solution.

TUNEL analysis Formalin fixed specimens were embedded in paraffin using standard procedures. Deparaffinised and rehydrated sections were immersed in 3mL/L H_2O_2 for 30 min at room temperature and digested with proteinase K for 20 min at 37 ℃. The sections were immersed in 1g/L Triton-100 and then incubated with TUNEL mixture for 1 hour at room temperature, with streptavidin-HRP(1:400) for 30 min at 37 ℃. The sections were stained with 0.4g/L DAB and treated with 3mL/L H_2O_2 for 10 min and with hematoxylin for 1 min. The results were observed with light microscopy. Positive reaction was shown by brown color. The apoptotic cells were counted as the mean of cells in 3 visual fields of one section. The data were analysed by q test, using statistical package SPSS.

Immunohistochemistry Formalin fixed specimens were embedded in paraffin using standard procedures. Sections attached on carry sheet glass were autoclaved at 58 ℃ for 24 h. Deparaffinised and rehydrated sections were immersed in 10mL/L H_2O_2 for 20 min and washed three times, each time for 3 min with PBS. Sections were preincubated with 10mL/L normal goat anti rabbit serum for 20 min at room temperature and then incubated with the first antibodies diluted for 18 h at 4 ℃ and Envision reagent for 30 min at 37 ℃. Sections were stained by 0.4g/L DAB with 0.3mL/L H_2O_2 for 8 min and hematoxylin for 30 s. The results were observed under light microscope.

Positive specimens were used as positive controls. The result of PBS instead of the first antibody was used as negative control. The positive reactions showed brown particles. The positive cells expressing Bcl-2, Bax, fas and FasL were counted as the mean of cells in 3 visual fields of one section. The data were analysed by q test, using statistical package SPSS.

RESULTS

The effect of acupuncture and moxibustion on epithelial cell apoptosis in UC rats is shown in Table 1 and Figure 1(A-D).

Table 1 Results of epithelial cell apoptosis in different groups

Group	n	Number of apoptotic cells (mean±SD)
NC	6	20.61±1.99
MC	8	66.21±8.51[b]
HPM	8	33.58±3.59[bd]
EA	8	34.29±2.70[bd]

[b]$P<0.01$ *vs* NC; [d]$P<0.01$ *vs* MC.

Table 1 shows that the number of epithelial cell apoptosis in MC was significantly increased compared with that of NC ($P<0.01$). The number of epithelial cell apoptosis in EA and HPM was remarkably decreased compared with that of MC ($P<0.01$), but was not as low as that of NC ($P<0.01$).

The effect of acupuncture and moxibustion on Bax expression in colonic epithelia of UC rats is shown in Table 2 and Figure 2(A-D)

Table 2 Bax expression in colonic epithelia of different groups (mean±SD)

Group	n	Area of expression	Intensity of expression
NC	6	35 905.06±2 987.97	0.1683±0.0105
MC	8	52 451.13±3 174.10[b]	0.2558±0.0142[b]
HPM	8	39 561.50±1 382.94[d]	0.1900±0.0047[d]
EA	8	38 477.79±3 309.19[d]	0.1796±0.0117[d]

[b]$P<0.01$ *vs* NC; [d]$P<0.01$ *vs* MC.

Table 2 shows that the area and intensity of Bax expression in the colonic epithelia of MC were significantly increased compared with that of NC ($P<0.01$). The area and intensity

Figure 1 A: Epithelial cell apoptosis in NC ×200, B: Epithelial cell apoptosis in MC ×200, C: Epithelial cell apoptosis in EA ×200, D: Epithelial cell apoptosis in HPM ×200.

of Bax expression in the colonic epithelia of PHM and EA were markedly decreased compared with that of MC, but showed no significant difference when compared with that of NC.

The effect of acupuncture and moxibustion on Bcl-2 expression in the colonic epithelium of UC rats is shown in Table 3 and Figure 3(A-D)

Table 3 shows that the area and intensity of Bcl-2 expression in the colonic epithelia of MC were significantly increased compared with that of NC ($P<0.01$). The area and intensity of Bcl-2 expression in the colonic epithelia of PHM and EA were markedly decreased compared with that of MC, but which were not as low as that of NC.

The effect of acupuncture and moxibustion on Fas expression in the colonic epithelium of UC rats is shown in Table 4 and Figure 4(A-D)

Table 4 shows that the area and intensity of Fas expression in the colonic epithelia of MC were significantly increased compared with that of NC ($P<0.01$). The area and intensity of Fas expression in the colonic epithelia of PHM and EA were markedly decreased compared with that of MC($P<0.01$), but still had a significant difference compared with that of NC ($P<0.05$).

Figure 2 A: Bax expression in colonic epithelia of NC ×200, B: Bax expression in colonic epithelia of MC ×200, C: Bax expression in colonic epithelia of EA ×200, D: Bax expression in colonic epithelia of HPM ×200.

Figure 3 A: Bcl-2 expression in colonic epithelia of NC ×200, B: Bcl-2 expression in colonic epithelia of MC ×200, C: Bcl-2 expression in colonic epithelia of EA ×200, D: Bcl-2 expression in colonic epithelia of HPM ×200.

Table 3 Bcl-2 expression in colonic epithelia of different groups (mean±SD)

Group	n	Area of expression (μm²)	Intensity of expression
NC	6	30 863.61±2 273.44	0.1539±0.0114
MC	8	44 757.67±28.1.53[b]	0.2242±0.0196[b]
HPM	8	40 061.63±4 937.84[be]	0.1979±0.0177[bd]
EA	8	39 219.04±3 449.84[db]	0.1875±0.0133[bd]

[b]$P<0.01$ *vs* NC; [d]$P<0.01$ *vs* MC; [e]$P<0.05$ *vs* MC.

Table 4 Fas expression in colonic epithelia of different groups (mean±SD)

Group	n	Area of expression (μm²)	Intensity of expression
NC	6	33 764.67±4 422.37	0.1722±0.0153
MC	8	50 262.08±4 780.34[b]	0.2500±0.0212[b]
HPM	8	37 992.29±3 239.23[de]	0.1825±0.0200[d]
EA	8	38 913.21±4 669.80[de]	0.1850±0.0138[d]

[b]$P<0.01$ *vs* NC; [d]$P<0.01$ *vs* MC; [e]$P<0.05$ *vs* NC.

Figure 4 A: Fas expression in colonic epithelia of NC ×200, B: Fas expression in colonic epithelia of MC ×200, C: Fas expression in colonic epithelia of EA ×200, D: Fas expression in colonic epithelia of HPM ×200.

**Figure 5** A: FasL expression in colonic epithelia of NC ×200, B: FasL expression in colonic epithelia of MC ×200, 5: FasL expression in colonic epithelia of EA ×200, D: FasL expression in colonic epithelia of HPM ×200.

The effect of acupuncture and moxibustion on FasL expression in the colonic epithelium of UC rats is shown in Table 5 and Figure 5(A-D)

Table 5 FasL expression in colonic epithelia of different groups (mean±SD)

Group	n	Area of expression (μm^2)	Intensity of expression
NC	6	33 063.56±3 347.24	0.1561±0.0080
MC	8	44 566.58±4 637.23[b]	0.2600±0.0105[b]
HPM	8	38 825.58±2 495.51[bd]	0.1838±0.0156[bd]
EA	8	38 553.29±3 489.38[bd]	0.1850±0.0108[bd]

[b]$P<0.01$ *vs* NC; [d]$P<0.01$ *vs* MC.

Table 5 shows that the area and intensity of FasL expression in the colonic epithelia of MC were significantly increased compared with that of NC($P<0.01$). The area and intensity of FasL expression in the colonic epithelia of PHM and EA were markedly decreased compared with that of MC($P<0.01$), which had a significant difference compared with that of NC($P<0.01$).

DISCUSSION

UC is a non-specific inflammatory intestinal disease. The incidence of UC in our country has an increasing trend yearly. The pathogenesis of ulcerative colitis in rats involved in the abnormality of apoptosis[5-8]. Increasing evidence showed that acceleration of epithelial cell apoptosis and inhibition of inflammatory cell apoptosis were closely associated with colonic tissue injury and immunological abnormality in ucerative colitis[9-11].

Studies showed that cell proliferation, differentiation and apoptosis of epithelial cells in intestines mucosa were a dynamic equilibrium process, and neonate epithelial cells migration along crypt villi from pit cells became mature villous epithelial cells. In physiological condition, apoptosis only occurred on superficial epithelial cells of intestine. In pathologic status, this sequence was destructive. For example, at the area of active inflammation, the apoptotie rate of neonate epithelial cells is accelerated and pit cells were superproliferative[12-14]. This alteration would lead to destruction of epithelial barrier of colon and imbalance of intestinal function of absorption and excretion.

Apoptosis is a procedure of death adjusted by a flock of apoptotic genes, the cell apoptosis was determined by the relative gene expression level of a series of apoptosis genes[15-17]. The bcl-2 gene kindred is an important apoptosis adjusting gene, the position of Bcl-2 protein is at mitochondrial membrane, endoplasmic reticulum and nuclear membrane. As it could prolong the life of cells, it has been generally accepted as an antiapoptosis gene[18-23]. Bax is a new member of bcl-2 gene kindred, it could form a dimer with bcl-2 to inhibit its function[24-27]. The relative expression ratio of bcl-2 and bax determines whether apoptosis happens in cells or not. When expression of bax gained advantage, apoptosis would occur and when the expression of bcl-2 gained advantage, the cells would continue to exist[28-32]. Many studies have shown that abnormal apoptosis in ulcerative colitis could be affected by many agents[33-36].

This study showed that persistent inflammation resulted in the abnormal increase of epithelial cell apoptosis in UC rats. Meanwhile, the area and intensity of Bcl-2 and Bax expression in colonic epithelia of MC were significantly increased compared with that of NC, suggesting that epithelial cell apoptosis is abnormally active. The upregulation of Bcl-2 and Bax expression in colonic epithelia increased the number of

apoptotic cells, which might be one of the important mechanisms of colonic pathological changes in UC. After the treatment with electro-acupuncture and herbs-partition moxibustion, the ulceration of colonic tissues in both groups was markedly improved and the tissue structure was well restored. The number of apoptotic cells in colonic tissues in EA and HPM was significantly decreased compared with that of NC. The area and intensity of Bcl-2 and Bax expression in colonic epithelia of PHM and EA were markedly decreased compared with that of MC. Especially, Bax expression was much downregulated. The above results showed that electro-acupuncture and herbs-partition moxibustion could inhibit colonic epithelial cell apoptosis of UC rats by decreasing Bcl-2 and Bax expression. The extent of Bcl-2 and Bax expression in colonic epithelia of UC rats downregulated by acupuncture and herbs-partition moxibustion was different, thus the raletive ratio of Bcl-2 and Bax expression in colonic epithelia was changed due to the inhibition of the abnormal increase of epithelial cell apoptosis in UC. The above results showed that down-regulation of the inflammatory reaction of colonic epthelia in UC rats, inhibition of the injurious effect of a variety of proinflammatory cytokines on colonic tissues, decrease of Bcl-2 and Bax expression of epithelial cells and regulation of the relative ratio of Bcl-2 and Bax expression could change the active state of colonic epithelial cell apoptosis due to its decrease. This is one of the important mechanisms of acupuncture and moxibustion in regulating apoptosis and treating UC.

Many studies[37-39] have shown Fas/FasL is an important pathway of epithelial cell apoptosis in UC. Fas is also named Apo-1 or CD95, belongs to tumour necrosis factor receptor (TNFR) kindred, it has comprehensive expressions in various histocytes and can bind anti-Fas antibody or FasL to change the constitution of cell surface. So it can transmit signals in cells to switch on apoptosis mechanism, leading to apoptosis of cells that express Fas. The function of Fas/FasL is to maintain immune stablity of body and balance of body's apoptosis[40-44]. Normally colonic epithelium could express Fas, and a small quantity of cells could express FasL in the site where the number of apoptosis cells was markedly increased. When UC occurred, because of stimulation by inflammation, the increase of FasL expression would cause apoptosis[45,46]. The high expression of FasL in active UC could cause apoptosis of cells expressing Fas[47-49], this would accelerate migration and activity of neutrophils and lymphocytes, causing progressive mucosal lesion of UC[50-52]. Therefore, the study of epithelial cell apoptosis may develop a new effective therapeutic approach to UC.

The study showed that the area and intensity of Fas and FasL expression in colonic epithelia of MC were significantly increased compared with that of NC as apoptosis increased, suggesting that the high expression of Fas and FasL plays an important role in epithelial cell apoptosis in UC. After the treatment with electro-acupuncture and herbs-partition moxibustion, Fas and FasL expressions in colonic epithilia of both groups were markedly downregulated compared with MC, and the number of apoptosis cells was also decreased. The above results showed that regulating the abnormal expression of Fas and FasL in colonic tissues of UC rats and decreasing its epithilial cell apoptosis might be one of the important mechanisms of acupuncture and moxibustion in treating UC. Our previous study showed that acupuncture and moxibustion could markedlly inhibit the expression of proinflammatory cytokines such as IL-1β and IL-6[53-56]. It is suggested that acupuncture and moxibustion can regulate Fas and FasL expression in colonic tissues of UC rats, and may be associated with the inhibition of the activation of macrophages in colonic epithilia and decrease of the expression of proinflammatory cytokines such as IL-1β and IL-6. Further activation of

macrophages in the blocked initial cascade reaction of inflammation and immunity in colonic epithilia can be effectively controlled. Stimulation of inflammatory cytokines on colonic tissues is relieved and stability of immunological function in UC rats is restored.

Abstract

AIM: To evaluate the effect of tumor necrosis factor (TNF), endothelin (ET) and nitric oxide (NO) on hyperdynamic circulation (HC) of rats with acute and chronic portal hypertension (PHT).

METHODS: Chronic portal hypertension was induced in Wistar rats by injection of carbon tetrachloride. After two weeks of cirrhosis formation, L-NMMA (25 mg/kg) was injected into one group of cirrhotic rats via femoral vein and the experiment was begun immediately. Another group of cirrhotic rats was injected with anti-rat TNFα (300 mg/kg) via abdominal cavity twice within 48 h and the experiment was performed 24 h after the second injection. The blood concentrations of TNFα, ET-1 and NO in portal vein and the nitric oxide synthase (NOS) activity in hepatic tissue were determined pre-and post-injection of anti-rat TNFα or L-NMMA. Stroke volume (SV), cardiac output (CO), portal pressure (PP), superior mesenteric artery blood flow (SMA flow) and iliac artery blood flow (IAflow) were measured simultaneously. Acute portal hypertension was established in Wistar rats by partial portal-vein ligation (PVL). The parameters mentioned above were determined at 0.5 h, 24 h, 48 h, 72 h and 120 h after PVL. After the formation of stable PHT, the PVL rats were injected with anti-rat TNFα or L-NMMA according to different groups, the parameters mentioned above were also determined.

RESULTS: In cirrhotic rats, the blood levels of TNFα, NO in portal vein and the liver NOS activity were significantly increased ($P < 0.05$) while the blood level of ET-1 was not statistically different ($P > 0.05$) from the control animals (477.67±83.81 pg/mL *vs* 48.87±32.79 pg/mL, 278.41±20.11 µmol/L *vs* 113.28±14.51 µmol/L, 1.81±0.06 u/mg· prot *vs* 0.87±0.03 u/mg· prot and 14.33±4.42 pg/mL *vs* 8.72±0.79 pg/mL, respectively). After injection of anti-rat TNFα, the blood level of TNFα was lower than that in controls (15.17±18.79 pg/mL *vs* 48.87±32.79 pg/mL). The blood level

of NO and the liver NOS activity were significantly decreased, but still higher than those of the controls. The blood level of ET-1 was not significantly changed. PP, SV, CO, SMAflow and IAflow were ameliorated. After injection of L-NMMA, the blood level of NO and the liver NOS activity were recovered to those of the controls. PP and CO were also recovered to those of the controls. SV, SMAflow and IAflow were ameliorated. In PVL rats, the blood levels of TNFα, NO in portal vein and the liver NOS activity were gradually increased and reached the highest levels at 48 h after PVL. The blood level of ET-1 among different staged animals was not significantly different from the control animals. PP among different staged animals (2.4±0.18 kPa at 0.5 h, 1.56±0.08 kPa at 24 h, 1.74±0.1 kPa at 48 h, 2.38±0.05 kPa at 72 h, 2.39±0.16 kPa at 120 h) was significantly higher than that in controls (0.9±0.16 kPa). After injection of anti-rat TNFα in 72 h PVL rats, the blood level of TNFα was lower than that in controls (14±14 pg/mL *vs* 48.87±32.79 pg/mL). The blood level of NO and the liver NOS activity were significantly decreased, but still higher than those of the controls. The blood level of ET-1 was not significantly changed. PP was decreased from 2.38±0.05 kPa to 1.68±0.12 kPa, but significantly higher than that in controls. SV, CO, SMAflow and IAflow were ameliorated. After injection of L-NMMA in 72 h PVL rats, the blood level of NO and the liver NOS activity were recovered to those of the controls. PP, SV, CO, SMAflow and IAflow were also recovered to those of the controls.

CONCLUSION: NO plays a critical role in the development and maintenance of HC in acute PHT and is a key factor for maintenance of HC in chronic PHT. TNFα may not participate in the hemodynamic changes of HC directly, while play an indirect role by inducing the production of NO through activating NOS. No evidence that circulating ET-1 plays a role in both models of portal hypertension has been found.

INTRODUCTION

Associated with hyperdynamic circulatory syndrome (HCS), the portal hypertension (PHT) is characterized by systemic vasodilatation, increase of plasma volume, cardiac output and regional blood flow[1-8]. Although it is most likely initiated by vasodilatation resulted from an increase of vasodilator activity[9], the etiology of HCS is still controversial. Two potent vasodilators, endogenous nitric oxide (NO) and tumor necrosis factor (TNF) may play important roles in the pathogenesis of hemodynamic changes of PHT[1,10]. As a powerful vasoconstrictor, endothelin (ET) could influence the

pathogenesis of hemodynamic changes of PHT as well[5,11-15]. Since ET has contradictory effect on blood vessels in comparison with the former two, it is hard to imagine that they synergistically take part in the hemodynamic changes. It is thus necessary to find out what kind of role the three factors play in the pathogenesis of HCS, respectively.

MATERIALS AND METHODS

Reagents
Carbon tetrachloride was purchased from Chongqing Chemical Reagents Factory (Chongqing, China). A rabbit anti-rat TNFα antibody was purchased from PharMingen Company (USA). N^G-methyl-L-arginine (L-NMMA) and endothelin EIA kit were purchased from Cayman Company (USA). Rat TNFα ELISA kit was purchased from Endogen Company (USA). NO and NOS determining kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Animal model of acute PHT (aPHT)
Partial portal vein ligation (PVL) was performed to establish the aPHT model as described previously[10]. In brief, male Wistar rats (220-280 g, offered by the Animal Center of Chongqing University of Medical Sciences) had free access to water and standard rat chow. After fasted overnight, the rats were anesthetized with pentobarbital intra- abdominally at a dose of 60 mg/kg. The portal vein was isolated and two ligatures were placed around both the portal vain and a 16-gauge blunt-end needle. One ligature was placed 1 mm distal to the bifurcation of portal vein and the other ligature was placed 1-2 mm to the input point of splenic vein. The needle was ligated together with the portal vein and immediately removed to allow the portal vein to expand to the limit imposed by the ligature. The abdomen was closed. In sham-operated rats, surgery consisted of dissection and visual inspection of the portal vein without ligature.

Animal model of chronic PHT (cPHT)
Carbon tetrachloride induced cirrhosis was made as the cPHT model. Male Wistar rats (150-200 g, provided by the Animal Center of Chongqing University of Medical Sciences) had free access to standard rat chow and 100mL/L alcohol. Cirrhosis model was established by injection with 600mL/L carbon tetrachloride mixed with paraffin liquid subcutaneously at a dose of 0.3 mL/100g at the lateral abdomen of both sides, twice a week for 17 times. The rats were allowed to stabilize for 2 weeks.

Determination of hemodynamic indexes
Stroke volume (SV) and cardiac output (CO) Ultrasonic probe of HEWLETT PACKARD 5500 type ultrasonic instrument (USA) was placed on the parasternum of rats at the left ventricle long axis and mitral valve level and then exchanged by M type ultrasonic image. The inner computer system of this instrument would calculate and display the data we needed.
Superior mesenteric artery (SMA) and iliac artery (IA) blood flow SMA and IA were isolated and embraced by a cuff of electromagnetic flowmeter (NIHON KHDEN, Japan) respectively. Its blood flow was determined while blood passed a photoelectric sensor.
Portal pressure (PP) and right atrial pressure (RAP) A 7 gauge needle was penetrated into portal vein in the direction of liver and a catheter was inserted through the internal jugular vein into the right atrium and connected to a pressure transducer respectively. PP and RAP were recorded with a four-channel physiometer (NIHON KOHDEN, Japan).

Mean arterial pressure (MAP) Rat's tail was placed in a photoelectric channel and MAP was determined with an RBP-1 type blood pressometer.
Calculation of superior mesenteric artery vascular resistance (VR_{SMA}) and iliac artery vascular resistance (VR_{IA}) VR_{SMA} and VR_{IA} were calculated according to the following formula reported by Colombato et al[16].

$$VR_{SMA}(kPa/L \cdot min) = \frac{MAP\text{-}PP}{SMA\text{-}flow}$$

$$VR_{IA}(kPa \cdot /L \cdot min) = \frac{MAP\text{-}RAP}{IA\text{-}flow}$$

Serum levels of TNFa, ET-1 and NO and hepatic activity of NOS
Blood was obtained from the portal vein at the time of sacrifice. Hepatic tissue was obtained from the left lobe of rat's liver. Serum level of TNFα was measured by ELISA according to the manufacturer's instructions (Phar Mingen Co., USA). Serum samples were analyzed for ET-1 content by EIA according to the manufacturer's instructions (Cayman Co., USA). Serum samples and hepatic tissues were analyzed for NO content and NOS activity according to the manufacturer's instructions by Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Experimental protocol
The rats involved in this experiment were divided into experimental group, treated group and control group. Fifty aPHT(PVL) rats were divided into five staged subgroups (0.5 h, 24 h, 48 h, 72 h and 120 h after PVL, 10 rats each group) and 10 cPHT rats were used as the experimental group. Twenty cPHT rats and 20 aPHT rats were divided into two groups (10 rats each group) respectively as the treatment group, and the method of treatment was as following. Ten cPHT rats were injected with anti-rat TNFα twice within 48 h and the experiment was performed 24 h after the second injection and 10 aPHT rats were injected with anti-rat TNFα at 0.5 h and 48 h after PVL respectively and the experiment was performed at 72 h after PVL (one dose of 300 μg/kg, via intra-abdominal cavity). The other 10 aPHT rats and 10 cPHT rats were injected with L-NMMA (25 mg/kg) through femoral vein 72 h after PVL and the experiment was performed immediately. Ten normal rats and 10 sham operated rats were used as the cPHT and the aPHT control groups respectively. The following parameters were determined, namely the hemodynamic indexes, serum levels of TNFα, ET-1 and NO, hepatic NOS activity.

Statistical analysis
Data were expressed as mean±SD and analysis of variance was performed using SPSS 8.0 software. Differences between groups were analyzed using t-test. One-way analysis of variance was used for multiple comparisons, and Newman-Keuls test was used for intra-group comparisons. $P<0.05$ was considered statistically significant.

RESULTS

Hemodynamic change
In PVL rats, SV, CO, PP, SMAflow and IAflow were significantly increased from 0.16±0.04 mL/s, 0.058±0.008 L/min, 0.9±0.16 kPa, 8.24±1.16 ml· min^{-1} and 10±0.89 ml· min^{-1} to 0.27±0.02 mL/s, 0.113±0.004 L/min, 1.74±0.1 kPa, 17.58±0.7 mL/min and 20.42±1.07 mL/min respectively at 48 h after PVL($P<0.05$). VR_{SMA} and VR_{IA} were significantly decreased from 15.57±2.75 kPaL/min and 13.58±2.19 kPaL/min to 5.96±0.35 kPaL/min and 5.62±0.33 kPaL/min respectively at 48 h after PVL($P<0.05$).

These hemodynamic variables no matter increased or decreased, all reached a maximal level at 72 h after PVL($P<0.05$) and did not change thereafter ($P>0.05$). In cirrhotic rats, SV, CO, PP, SMAflow and IAflow were significantly increased from 0.162±0.04 mL/s, 0.058±0.017 L/min, 0.91±0.16 kPa, 8.42±1.16 mL/min and 10±0.89 mL/min to 0.59±0.06 mL/s, 0.159±0.031 L/min, 2.26±0.39 kPa, 27±3.19 mL/min and 27.33±1.21 mL/min respectively at the time of cirrhosis formation ($P<0.05$). VR_{SMA} and VR_{IA} were significantly decreased from 15.57±2.74 kPaL/min and 13.58±2.19 kPaL/min to 4.07±0.43 kPaL/min and 4.44±0.13 kPaL/min respectively at the time of cirrhosis formation ($P<0.05$).

Alteration of serum TNFa, ET-1 and NO and hepatic NOS activity

Serum TNFα and NO levels and NOS activity were significantly increased at 24 h compared with those of control ($P<0.05$) and reached a maximal level at 48 h after PVL and did not change thereafter. An increase of serum ET-1 levels was also observed at different time points post PVL, however, all of them did not reach the significant level as compared with control ($P>0.05$). The serum TNFα and NO levels were significantly increased compared with control in cirrhotic rats ($P<0.05$) and their increment was markedly greater than those rats 48 h after PVL ($P<0.05$). The NOS activity was also markedly increased ($P<0.05$) and the serum ET-1 level was slightly increased, but did not reach the significant level ($P>0.05$) compared with control in cirrhotic rats (Table 1).

Effects of anti-rat TNFa and L-NMMA on serum TNFa, ET-1 and NO and hepatic NOS

The serum level of TNFα was markedly decreased and lower than that of controls in both rat models, and the serum level of NO and hepatic NOS activity were significantly decreased,

but still markedly greater than those of controls. Injection of anti-rat TNFα had no effect on the level of ET-1. The serum level of NO and hepatic NOS activity were significantly decreased to the levels of the controls in both rat models after injection of L-NMMA (Table 2).

Table 1 Serum levels of TNFα, ET-1 and NO and hepatic NOS activities in PVL and cPHT rats

Groups	TNFα (pg/min)	ET-1 (pg/min)	NO (µmol/L)	NOS (u/mg· prot)
Control aPHT	48.67±32.79	8.72±0.79	113±15	0.9±0.03
PVL0.5 h	50±15	13.4±2.6	128.64±18.29	0.86±0.14
PVL24 h	328±100[ac]	12.8±5.7	169.40±21.07[ac]	1.45±0.17[ac]
PVL48 h	428±69[a]	13.5±2.6	223.71±35.44[a]	1.7±0.12[a]
PVL72 h	416±48[a]	13.1±3.2	215.49±12.75[a]	1.67±0.16[a]

[a]$P<0.05$ *vs* control, [c]$P<0.05$ PVL 24 h group compared with PVL 48 h, 72 h, 120 h and cPHT groups respectively, [e]$P<0.05$ cPHT group compared with PVL 48 h, 72 h, 120 h groups respectively.

Effects of anti-rat TNFa and L-NMMA on hemodynamic variables

In both rat models, SV, CO, PP, SMAflow and IAflow were significantly decreased, but were still markedly higher than those of the controls. However, VR_{SMA} and VR_{IA} were significantly increased but still markedly lower than those of the controls after injection of anti-rat TNFα. In PVL rats, SV, CO, PP. SMAflow, IAflow, VR_{SMA} and VR_{IA} were all recovered to the levels of the controls after injection of L-NMMA. In cPHT rats, CO and PP were exclusively recovered to the levels of controls. SV, SMAflow, IAflow, VR_{SMA} and VR_{IA} were markedly increased or decreased, but still significantly different from those of the controls after injection of L-NMMA (Table 3).

Table 2 Effects of anti-rat TNFα and L-NMMA on levels of TNFα, ET-1 and hepatic NO and NOS activity in PVL and cPHT rats

DISCUSSION

In our study, HCS was observed in rats with acute and chronic PHT, and characterized by the increase of SV, CO, regional blood flow and PP, as well as the decrease of peripheral and splanchnic vascular resistance. This agreed with a lot of literature[1-8]. Lopez-Talavera et al[9,10] studied the correlation between hemodynamic changes and TNFα on days 5, 13 and 14 after PVL, and found that TNFα might play a role in HCS of portal hypertension. In this study, we found that the serum level of TNFα in portal vein was markedly increased at 24 h, reached a peak at 48 h and maintained stable thereafter in PVL rats. Whereas, the obvious hemodynamic changes occurred at 48 h and HCS was induced at 72 h, about 24 h later than the obvious increase in TNFα level. The serum level of TNFα was much more higher in cPHT rats than that in rats 48 h after PVL. There was no obvious difference between the hemodynamic indexes of both groups. Therefore, we speculated that TNFα might play a role in the early stage of HCS, and that overproduction of TNFα might have a mild effect on hemodynamic changes. In the anti-rat TNFα experiment, we found that the serum level of TNFα was lower than that of the controls and the effect of TNFα was completely inhibited by the injected anti-rat TNFα. Although the hemodynamics was significantly changed, it still had a remarkable difference in comparison with the controls. In other words, HCS was improved and a new HCS balanced on a lower basis formed. At the same time, the NO levels and hepatic NOS activity in rats with hepatic cirrhosis and PVL were decreased by 20-25% and 15-30%, respectively. Kaviani et al[17] revealed that after gastric strips from PVL rats were incubated with TNFα neutralizing antibody, inducible NOS mRNA expression was significantly decreased by 40%, 70%, and 80% after 1, 2, and 6 h. This suggested that the vasoactive effect of TNFα itself on the development and formation of HCS in portal hypertension was little, and that corresponding hemodynamic changes after injection of TNFα antibody were due to the elimination of TNFα activation on NOS and the decreased production of NO. This conclusion disagreed with the report of Lopez-Talavera et al[9] that anti-rat TNFα treatment of rats after PVL significantly inhibited hyperdynamic circulation and reduced portal pressure. It was also inconsistent with the report of Munoz et al[18]. In their experiment, anti-TNFα polyclonal antibodies were injected into rats before and 4 days after portal vein stenosis (PVS) (short-term inhibition) and at 24 h and 4, 7, 10 d after PVS (long-term inhibition). After a short-term inhibition or a long-term inhibition, portal pressure kept unchanged. Tabrizchi[19] found that cardiac output, blood pressure and mean circulatory filling pressure were significantly reduced, but the arterial resistance increased following treatment with TNFα in anaesthetized rats. This, obviously, did not accord with the features of HCS at PHT, and also suggested that TNFα did not directly take part in the hemodynamic changes at PHT.

In our study, we found the serum NO level and hepatic NOS activity in the two animal models with portal hypertension were decreased by 20-25% and 15-30% respectively after injection of anti-rat TNFα antibody. This suggested that the increase of serum NO level was stimulated by the combination of TNFα and other media such as IL-6 and INFα,etc., which agreed with what was reported[10,20,21]. Wiest et al[21] reported that upregulation of eNOS release and increase of NO by SMA endothelium occurred before the development of hyperdynamic splanchnic circulation, suggesting a primary role of NO in the pathogenesis of arterial vasodilatation. But the results reported by Albornoz et al[22] disagreed with those of ours. Their results showed that dexamethasone (an inhibitor of the expression of the iNOS) administration did not modify

systemic and splanchnic hemodynamic parameters in endotoxemic cirrhotic rats and suggested that stimulation of iNOS might not play a role in increasing NO production in portal hypertension. We found that the NO level in portal vein and the liver NOS activity were significantly decreased to the level of controls by injecting L-NMMA in cirrhotic rats and in rats 72 h after PVL. In PVL rats, the hemodynamics was recovered to the controls. In cirrhotic rats, the PP was also recovered to the control. But the SV was still significantly greater than that of control and the systemic vasodilatation was not recovered to the state of control. These results suggested that NO played a critical role in the development and maintenance of HCS in acute PHT and was a key factor in maintenance of HCS in chronic PHT. This conclusion was consistent with those of most authors[1,5-7,23-26]. In patients with chronic portal vein hypertension, since the tissue structure of vascular wall was changed due to the long term dilatation of systemic blood vessels, the dilated blood vessels would be hard to recover, even if the effect of vasodilators had been completely eliminated.

Elevated ET-1 level in blood and its active role in portal hypertension in cirrhotic patients and a variety of animal models have been reported by many authors[13-16,27-29]. Nevertheless, Poo et al[30] reported that the liver paracrine ET system did not play a major role in the pathogenesis of portal hypertension, but took part in the development of liver fibrogenesis. Varagic et al[31] reported that circulating endothelin-1 did not play a role in spontaneously hypertensive rats. In this study, the blood level of ET-1 in portal vein was mildly increased but not significantly higher in comparison with the controls in cirrhotic and PVL rats. This finding suggested that ET-1 might not play a role in the development of hemodynamic abnormalities in PHT. It might keep the tension of blood vessels and antagonize the effect of vasodilators. Therefore, ET-1 may have a regulating effect on the vasodilatation and vascular refilling. Our finding was consistent with Poo et al[30], but inconsistent with the other authors[12-15,27-29].

Based on the result of a combination study of TNFα, NO and ET, we draw a conclusion that TNFα may not directly participate in the hemodynamic changes of HCS, while exert an indirect effect by inducing the production of NO. NO is the primary factor for forming and maintaining HCS at PHT. ET does not directly take part in the hemodynamic changes of PHT either, while keeps the tension of blood vessel and prevents it from overdilating under the effect of vasodilatation factors.

Abstract

AIM: Taurine has been shown to be an effective scavenger of hypochlorous acid (HOCl). The role of HOCl is well established in tissue damage associated with inflammation and injury. In the present study, the effect of HOCl on nuclear nucleoside triphosphatase of hepatocytes and the ability of taurine to prevent this effect were investigated.

METHODS: Isolated hepatic nuclei from rat liver were exposed to HOCl with or without taurine. The NTPase activity on nuclear envelope was assayed using ATP and GTP as substrates, respectively.

RESULTS: The first series of experiments evaluated the toxicity of HOCl and the efficacy of taurine to protect NTPase. HOCl at 10^{-9}-5×10^{-6} mol/L reduced nuclear NTPase activities in a concentration dependent manner (ATP and GTP as substrates) ($P<0.01$). HOCl at 10^{-6} mol/L reduced the NTPase activity by 65% (ATP as substrate) and 76% (GTP as substrate). Taurine (10^{-7} to 10^{-4} mol/L) was tested for protection against HOCl at 10^{-6} mol/L and the nuclei treated with 5×10^{-4} mol/L taurine exhibited only 20% and 12% reduction in NTPase activities compared to untreated controls. A second study was performed comparing taurine to glutathione (GSH). GSH and HOCl at 10^{-6} mol/L exhibited 46% and 67.4% reduction in NTPase activities compared with control. GSH (10^{-4} mol/L) which was incubated with the nuclei and HOCl still exhibited 44.2% and 44.8% reduction in NTPase activities of untreated control. Taurine with HOCl only exhibited 15.2% and 17.1% reduction in NTPase activities, which provided more powerful protection against HOCl than GSH. The third experiment was undertaken to evaluate the specificity of taurine against HOCl. Incubation of rat hepatic nuclei with Fe^{3+}/H_2O_2 (1 m mol/L vs 5μ mol/L) resulted in a decrease in nuclear NTPase activities ($P<0.01$). When hepatic nuclei were incubated with Tau (10^{-4} mol/L) and Fe^{3+}/H_2O_2 (1m mol/L vs 5μ mol/L), nuclear NTPase activities were only slightly increased as compared with that of incubation with Fe^{3+}/H_2O_2 alone. However, GSH failed to alter the NTPase activities induced by Fe^{3+}/H_2O_2.

CONCLUSION: The present findings indicate that HOCl can act as an inhibitor of nuclear NTPase. Taurine can antagonistically reduce the toxicity of HOCl to NTPase.

INTRODUCTION

The mechanism of mRNA transport involves two major steps: the recognition of RNA molecules to be transported and their transfer through the nuclear pore. The latter step is an important rate-limiting step in protein expression[1]. The nucleocytoplasmic transport of mRNA is an energy-consuming process. The energy requirement is associated with the functioning of a nucleoside triphosphatase (NTPase). The nuclear NTPase activity exhibits a broad substrate specificity toward nucleotides and divalent metal cations[2,3]. The recent data demonstrated that the activity of the NTPase was strikingly inhibited by cholesterol oxidase treatment, which indicated that oxidation of nuclear membrane cholesterol could inhibit NTPase activity[4]. These results have implications for mRNA flux across the nuclear membrane during conditions where lipid peroxidation may be expected.

Hypochlorous acid (HOCl) is a major oxidant produced by neutrophils and monocytes, via the myeloperoxidase-catalyzed oxidation of chloride by hydrogen peroxide[5]. HOCl is a potent oxidant capable of damaging host tissue during inflammation. The strong oxidizing species HOCl plays a highly significant role in the bactericidal function of the neutrophil. However, inappropriate and/or excessive activation of neutrophils leads to oxidative stress and collateral damage to surrounding tissues. Cysteine and methionine residues in proteins and reduced glutathione (GSH) appear to be the main targets for HOCl[6], thereby altering the structure and function of proteins and lowering antioxidant status in the cell. In the literature, taurine, a 2-amino ethanesulfonic acid, is characterized as an antioxidant, a membrane protector, or a regulator of calcium ion homeostasis. It is the major free intracellular amino acid that presents in many tissues[7,8] and possibly acts physiologically as a trap for HOCl[8]. In the present study, we explored the possible action of HOCl on hepatic nuclear NTPase activity and the protective effect of taurine on the changes of NTPase activity induced by HOCl.

MATERIALS AND METHODS

Materials

Male Sprague-Dawley (SD) rats were supplied by the Animal Center, Health-Science Center, Peking University. Taurine and GSH were purchased from Sigma Chemical Co (St. Louis, MO, USA). The term HOCl was used to cover the equilibrium mixture with OCl^- present at neutral pH. The following reagents were freshly prepared. Phenylmethylsulfonyl fluoride (PMSF), sodium salt of nucleotides (ATP and GTP); DS/PMSF buffer

(mmol/L): 250 sucrose, 50 Tris/HCl pH 7.4, 5 MgCl$_2$, 1 PMSF; STM/ Buffer (mmol/L): 2 100 sucrose, 50 Tris/HCl pH 7.4, 5 MgCl$_2$, 1 PMSF, 1 EDTA, l DTT, and l μ mol/L leupeptin. All the reagents were analytically pure.

Isolation of rat hepatocytes
Rat hepatocytes were isolated according to Berry and Friend methods[9]. Briefly, under anesthesia with urethane (1 g/kg *i.p.*), male SD rats (220-250 g) were in situ liver-perfused at 37 ℃ via portal vein, with Ca^{2+}-free Hanks' solution containing 5 mg/L collagenase and 1 mg· L^{-1} hyaluronidase bubbling of 950 ml/L O$_2$-50 ml/L CO$_2$. After 20 min perfusion, the liver was removed, transferred to a beaker containing 200 mL of enzyme medium, broken up with a blunt spatula, and shaken at 37 ℃ for 15 min in an atmosphere of air. The suspension was filtered through nylon mesh and the cells were separated from debris by centrifuging at 50 *g* for 2 min. The cells were resuspended in Hanks' solution at 4 ℃. Cell viability tested by trypan blue exclusion was higher than 90%.

Isolation and chracterization of hepatic nuclei
Isolation of rat liver nuclei was performed according to the method described by Kaufmann *et al*[10] with modification. Suspended cells were homogenized in Teflon (10 strokes), sedimented at 800 *r/min* for 10 min. The nuclei were suspended in DS/PMSF buffer, layered over cushions of this buffer, and sedimented at 70 000 *g* for 60 min. Isolated nuclei were resuspended in STM/PMSF buffer, again layered over cushions of DS/PMSF buffer, and sedimented at 70 000 *g* for 30 min. The final pellet was resuspensed with STM/PMSF to 1 mg protein/mL, and stored at -70 ℃.

Nuclear membrane NADH pyrophosphorylase activity and microsome- NADPH cytochrome-C reductase activity were determined to test the purification of the freshly isolated hepatocyte nuclei.

Protocol for treatment of isolated nuclei with hypochlorous acid and taurine
Isolated purified nuclei (0.25 mL) were incubated with different chemicals (dissolved in 0.25 mL) for 10 min at 30 ℃. The reaction was stopped by cold (4 ℃) centrifugation on microcentrifuge for 2 min, and the nuclei pellet was washed once and then resuspended in STM/PMSF to obtain a final protein concentration of 1 mg/mL.

Protocol 1: incubation with buffer alone (control) and sodium hypochlorite (10^{-9} to 5×10^{-6} mol/L), respectively. Protocol 2: Incubation with buffer alone (control), taurine (10^{-6}, 10^{-5} and 10^{-4} mol/L), sodium hypochlorite (10^{-6} mol/L), sodium hypochlorite (10^{-6} mol/L) plus taurine (10^{-7} to 10^{-4} mol/L), respectively. Protocol 3: Incubation with sodium hypochlorite (10^{-6} mol/L), sodium hypochlorite (10^{-6} mol/L) plus glutathione (GSH, 10^{-6} to 10^{-4} mol/L), respectively. Protocol 4: Incubation with buffer alone (control), taurine (10^{-4} mol/L), GSH (10^{-4} mol/L), H$_2$O$_2$/FeSO$_4$ (1m mol/L/5 μ mol/L), H$_2$O$_2$/FeSO$_4$ (1 mmol/L/5 μ mol/L) plus taurine (10^{-6} to 10^{-4} mol/L), H$_2$O$_2$/FeSO$_4$ (1 m mol/L/5 μ mol/L) plus GSH (10^{-6} to 10^{-4} mol/L), respectively.

Assay of nuclear NTPase activity
NTPase activity was assayed as described by Tiffany[11] and Ramjiawan[12] with modification. Nuclear suspension (1 μg protein/μL) was preincubated for 10 min at 30 ℃. Addition of 1.0 mmol/L ATP or 1.0 mmol/L GTP initiated the reaction. Ten minutes after 30 ℃-incubation, the reaction was stopped by addition of 100g/L SDS and placing the test tube on ice bath, and inorganic phosphate was measured according to the method of Raess[13], which was expressed as nmol/mgPr per 10 min.

Preliminary experiments showed a linear relationship of NTPase activity with incubation time of nucleoside triphosphate within 30 min. The values were normalized to protein content.

Data analysis
Separated six experiments were performed in duplicate. All results were expressed as mean±SD. Statistical analysis of the data was performed using one-way analysis of variance followed by Student-Newman-Keuls tests. *P*<0.05 was accepted as statistically significant.

RESULTS
Characterization of hepatic nuclei
The level of NADH pyrophosphorylase activity (as marker enzyme for nuclear envelope) in prepared nuclei from rat hepatocytes was 7-fold that in homogenate of whole cells (25.77±1.26 *vs* 3.68±0.27 nmol/mg Pr per min, *P*<0.01), but NADPH cytochrome C reductase activity (marker enzyme for microsome) was only 28% of that in hypatocytes homogenate (2.88±0.22 *vs* 10.27±0.87 nmol/mg Pr per min, *P*<0.01). While the activity of mannose-6-phosphatase existing in both microsomes and nuclei, was 4-5 times that in cell homogenate (412±22 *vs* 91±6 nmol/mg Pr per min, *P*<0.01). It showed that the isolated hepatic nuclear fraction was of high purity and little contaminated by other organelles.

Inhibitory effect on hepatic nuclear NTPase of hypochlorous acid
HOCl (at mol/L: 10^{-9}-5×10^{-6}) could significantly depress NTPase activity of hepatic nuclei in a concentration- dependent manner, regardless ATP or GTP as a substrate (Figure 1). After incubation of hepatic nuclei with 5×10^{-6} mol· L^{-1} HOCl, the hepatic nuclear NTPase activities were decreased by 70.0% (ATP as substrate) and by 76.3% (GTP as substrate), compared with those of control groups (both *P* values less than 0.01) respectively.

Figure 1 Inhibitory effect of hypochlorous acid on hepatic nuclear NTPase activity. ATP and GTP were used as reaction substrates, respectively. Mean±SD, *n*=6. ªP<0.05, ᵇP<0.01 compared with control.

Effects of taurine on hepatic nuclear NTPase activity
The effect of taurine on NTPase activity is shown in Table 1. After incubation of hepatic nuclei with different concentrations of taurine (10^{-6}, 10^{-5} and 10^{-4} mol/L), the NTPase activities on nuclear envelope were increased in a concentration-dependant fashion, either using ATP or GTP as a substrate (all *P* values <0.05 as compared with those of controls). When taurine was at 10^{-4} mol/L, the NTPase activities were increased by 18.1% (ATP as substrate) and 27.3% (GTP as substrate), respectively. All *P* values were less than 0.01 as compared with those of their controls.

Table 1 Effects of taurine on hepatic nuclear NTPase activity

Groups	NTPase activity (nmol/mg Pr per 10 min)	
	ATP as substrate	GTP as substrate
Control	127±7	150±9
Taurine 10^{-6} mol/L	136±9 (+7.1%)	168±10(+12.0%)[a]
Taurine 10^{-5} mol/L	148±7 (+16.5%)[b]	179±11(+19.3%)[b]
Taurine 10^{-4} mol/L	150±8 (+18.1%)[b]	191+12 (±27.3%)[b]

ATP and GTP were used as reaction substrates, respectively. The increases of the enzyme activities are indicated in parentheses as percentage of the control. Mean±SD, n=6. [a]P<0.05, [b]P<0.01 compared with control.

Effect of taurine on OCl-induced inhibition of hepatic nuclear NTPase activity

The abilities of HOCl to depress NTPase were confirmed by detecting NTPase activities. Incubation of hepatic nuclei with HOCl at 10^{-6} mol·L^{-1} resulted in an obviously lower nuclear NTPase activity than that with buffer alone. The hepatic nuclear NTPase activities were decreased by 65.4% (ATP as substrate) and by 76.0%(GTP as substrate), compared with the control groups respectively (P<0.01).

The reduction of NTPase activities induced by HOCl was antagonized by taurine (as shown in Figure 2), even at a very low concentration (10^{-6} mol/L) (ATP and GTP as substrates). The antagonistic effect of taurine on HOCl was in a concentration dependent manner. When the nuclei were incubated with HOCl (10^{-6} mol/L) and taurine (5×10^{-4} mol/L), the NTPase activity reached 80.3% (ATP as substrate) and 88.7% of control group (GTP as substrate), respectively (all P values less than 0.01).

Figure 2 Effect of taurine on OCl-induced inhibition of NTPase activity in hepatic nuclei. ATP and GTP were used as reaction substrates, respectively. Mean±SD, n=6. [a]P<0.05, [b]P<0.01 compared with OCl (10^{-6} mol/L) group. [c]P<0.05, [d]P<0.01 compared with control.

Effect of glutathione on OCl-induced inhibition of hepatic nuclear NTPase activity

Incubation of hepatic nuclei with HOCl at 10^{-6} mol/L resulted in an obviously lower nuclear NTPase activity. The hepatic nuclear NTPase activities were decreased by 51.2% (ATP as substrate) and by 101.3% (GTP as substrate), compared with the control groups respectively (P<0.01). The reduction of NTPase activities induced by HOCl was antagonized by taurine (10^{-4} mol/L, ATP and GTP as substrates). Incubation of taurine increased the NTPase activity by 92.6% (ATP as substrate) and 154% (GTP as substrate) compared with HOCl incubation (as shown in Figure 3). GSH incubation attenuated the depressive effect of HOCl in a concentration- dependent manner. When the nuclei were incubated with HOCl (10^{-4} mol/L)

and GSH (10^{-4} mol/L), the NTPase activity was increased by 27% (ATP as substrate) and 38.5% (GTP substrate) of HOCl incubation group, respectively (all P values less than 0.01). It was showed that the effect of GSH on HOCl-induced depression of NTPase was smaller than that of taurine (F value: 5.3, P<0.01).

Figure 3 Effects of glutathione on OCl-induced inhibition of NTPase activity in hepatic nuclei. ATP and GTP were used as reaction substrates, respectively. Mean±SD, n=6. [b]P<0.01 compared with control group (OCl^{-1} 10^{-6} mol/L). [a]P<0.05, [c]P<0.01 compared with (10^{-6} mol/L OCl^{-1}+10^{-4} mol/L taurine).

Effect of taurine and GSH on ·OH-induced inhibition of hepatic nuclear NTPase activity

The ability of the Fe^{3+}-H_2O_2 system to produce ·OH was confirmed by detecting NTPase activities. Incubation of hepatic nuclei with Fe^{3+}-H_2O_2 at 1 m mol/L/5 μ mol/L resulted in a lower nuclear NTPase activity as compared with buffer alone. The NTPase activities on nuclear envelopes were decreased by 70% (ATP as substrate) and by 76.7% (GTP as substrate), compared with control group respectively (Table 2).

The reduction of NTPase activities induced by Fe^{3+}-H_2O_2 was antagonized by taurine. When taurine was at 10^{-4} mol/L (ATP as substrate), the decreases of NTPase activities induced by Fe^{3+}-H_2O_2 (1 m mol/L/5 μ mol/L) were slightly reversed (from 29.8±8.2 to 46.5±8.7, P<0.05). Whereas, GSH, at all concentrations used in our experiment, had no significant effect on Fe^{3+}-H_2O_2 -induced depression of NTPase activity (Table 2).

Table 2 Effect of taurine and glutathione on ·OH -induced inhibition of NTPase activity in hepatic nuclei

Groups	NTPase activity (nmol/mg Pr per 10 min)	
	ATP as substrate	GTP as substrate
Control	100.0±9.9	151.8±9.9
Tau (10^{-4} mol/L)	138±14.6	175.5±5.9
GSH (10^{-4} mol/L)	95±12.2	150.0±9.8
·OH	29.8±8.2[b]	35.3±7.8[b]
·OH+Tau (10^{-6} mol/L)	35.6±6.1	36.2±8.8
·OH+Tau (10^{-5} mol/L)	40.8±8.8	32.7±7.3
·OH+Tau (10^{-4} mol/L)	46.5±8.7[a]	43.3±7.2
·OH+GSH (10^{-6} mol/L)	32.0±8.2	43.2±11.8
·OH+GSH (10^{-5} mol/L)	32.1±9.7	41.2±9.6
·OH+GSH (10^{-4} mol/L)	44.3±6.2	39.8±5.9

ATP and GTP were used as reaction substrates, respectively. ·OH was produced by Fenton chemistry (Fe^{3+}-H_2O_2: 1 m mol/L/ 5 μ mol/L). Mean±SD, n=6. Tau: taurine, GSH: glutathione. [b]P<0.01 compared with control group (OCl^{-1} 10^{-6} mol·L^{-1}). [a]P<0.05 compared with ·OH (Fe^{3+}-H_2O_2: 1 mmol/L/5 μ mol/L) group.

DISCUSSION

Nuclear NTPase, a nuclear membrane-associated enzyme, provides energy for poly (A)+mRNA export through the nuclear pore. Many factors may play a modulatory role in NTPase activity. Extracellular biological active molecules, such as insulin, epidermal growth factor and nuclear membrane cholesterol, could affect NTPase activities through the individual cellular signal transduction system[14]. In addition, oxygen derived free radicals of nuclear membrane cholesterol could inhibit nucleoside triphosphatase activity[4]. Thus, export of poly (A) mRNA from the nucleus via the nuclear pore complex was influenced, which plays a crucial role in protein synthesis[1-3, 14].

In this present study using nuclei purified from rat hepatocytes, HOCl was confirmed to be a very efficient inhibitor of nuclear NTPase activity. Hepatic nuclear NTPase activity was depressed by incubation of hepatic nuclei with HOCl in a concentration dependent manner, regardless of using ATP or GTP as substrate. It was suggested that NTPase was one of the favorite targets of HOCl. The inhibition of this enzyme might probably be caused by oxidation of an amino acid critical for enzyme function. It is difficult to determine the exact concentration of HOCl that can be reached *in vivo* since it is formed locally and HOCl is very reactive. Concentrations of the drugs in the present study were not quite inadequately used. In our experiments, taurine and GSH were present which might repair the oxidative damage to the NTPase. Therefore the inhibition of nuclear NTPase activity *in vitro* was reversible. Furthermore, taurine has been found to be an activator for nuclear NTPase, since it could stimulate hepatic nuclear NTPase activity in a concentration dependent manner. Taurine and thiol group-containing compounds could play a protecting role during inflammatory processes.

The mechanisms of the effect of HOCl were not concerned in the present studies. It has been shown that HOCl is highly reactive with a wide range of biological molecules[15,16]. Of these, thiols are among the most reactive and crucial targets for oxidation in a cell. The deleterious effects of HOCl could be prevented by incubating the nuclei with thiol group-containing compounds as glutathione in the present study. This was in perfect agreement with Pullar *et al*[6] who reported that HOCl could react rapidly with thiol groups. The initial product of oxidation of thilos by HOCl was sulfinyl chloride[17]. It could react with additional thiols to give disulfide[17]. Oxidation of sulfhydryl groups in proteins might affect their functional properties. Formation of protein disulfides, mixed disulfides with GSH, or sulfinic acids could result in changes in enzymatic activity, conformation or affinity toward other molecules. Such changes could contribute to the cell damage caused by oxidative stress[18].

As an antioxidant, taurine could effectively antagonize the toxic effect of HOCl on NTPase. However, the mechanism of this effect remains unclear. More recent information has revealed that taurine could interact with peroxide anions to form stable products TauCl[8]. The latter was the product formed through the sequestration of taurine with HOCl and has been found to be an exceptionally stable and long-lived compound with cytoprotective properties due to its ability to preserve cellular function in response to physiologic stress[7]. In the present study, taurine greatly inhibited the suppression of hepatic nuclear NTPase activity induced by OCl-, indicating the important protective role of taurine against OCl- attack.

It has been found that oxygen free radical species such as H_2O_2 and O_2 are produced in mammalian cells during normal aerobic metabolism[19,20]. However, O_2 or H_2O_2 dose not directly act under physiologically relevant conditions. It has been proposed that much of the toxicity of these species in living

organisms be due to the iron-dependent generation of ·OH, and /or other powerful oxidants, by Fenton chemistry[21]. Once it oxidizes Fe^{2+}, the reactive ·OH is produced. Incubation of hepatic nuclei with Fe^{3+}-H_2O_2 in the present study resulted in the decrease of NTPase activities in a concentration dependent manner both using ATP and GTP as substrates, which was coincident with that of Ramjiawan' s work[4]. The results of this *in vitro* study demonstrated that neither taurine nor GSH could directly prevent the reduction of nuclear NTPase activity caused by the ·OH producing Fe^{3+}/H_2O_2 system, even if very high concentrations of them (10^{-4} mol· L^{-1}) were used regardless of using ATP or GTP as substrate. These results therefore suggested that taurine could protect NTPase from HOCl specifically.

It has been found that HOCl is produced under aerobic and pathophysiological conditions such as oxidative stress and inflammation[22]. Under most circumstances, HOCl is likely to be the major strong oxidant produced by neutrophils, and contributors to oxidative damages associated with a variety of diseases in which inflammatory cells participate[23]. Impairment of NTPase on hepatic nuclei by HOCl might result in default of RNA nucleocytoplasmic transport. Taurine could antagonize the toxic effect of HOCl on NTPase. This observation could be a part of the global machinery, which acts as a cytoprotective factor in liver inflammation and oxygen stress.

In summary, our results showed that HOCl could cause a decrease in nuclear NTPase activities, which was most likely the result of decreased breakdown of NTPase. This pointed toward HOCl as an inhibitor of this enzyme. Nuclear NTPase can be effectively protected by taurine against HOCl driven oxidative injury, a consequence of direct drug scavenging capacity towards HOCl. Interaction of taurine with HOCl can also protect nuclear NTPase activity. Therefore, taurine treatment would have a beneficial effect on some diseases relating to protein synthesis.

Abstract

AIM: To explore the methods of hepatocytes culture in a collagen gel mixture or between double layers of collagen sandwich configuration and to examine the functional and cytomorphological characteristics of cultured hepatocytes.

METHODS: A two-step collagenase perfusion technique was used to isolate the hepatocytes from Wistar rats or newborn Chinese experimental piglets. The isolated hepatocytes were cultured in a collagen gel mixture or between double layers of collagen sandwich configuration respectively. The former was that rat hepatocytes were mixed with type I rat tail collagen solution till gelled, and the medium was added onto the gel. The latter was that swine hepatocytes were seeded on a plate precoated with collagen gel for 24 h, then another layer of collagen gel was overlaid, resulting in a sandwich configuration. The cytomorphological characteristics, albumin secretion, and LDH-release of the hepatocytes cultured in these two models were examined.

RESULTS: Freshly isolated rat hepatocytes were successfully mixed and fixed in collagen gel, and cultured in the gel condition. During the culture period, the urea synthesized and secreted by rat hepatocytes was detected throughout the period. Likewise, newborn experimental piglet hepatocytes were successfully fixed between the double layers of collagen gel, forming a sandwich configuration. Within a week of culture, the albumin secreted by swine hepatocytes was detected by SDS/PAGE analysis. The typical cytomorphological characteristics of the hepatocytes cultured by the above two culture models were found under a phase-contrast microscope. There was little LDH-release during the culture period.

CONCLUSION: Both collagen gel mixture and double layers of collagen sandwich configuration can provide cultural conditions much closer to *in vivo* environment, and are helpful for maintaining specific hepatic functions and cytomorphological characteristics. A collagen gel mixture culture may be more eligible for the study of bioartificial livers.

INTRODUCTION

Isolated and cultured hepatocytes *in vitro* are an important tool for hepatic disease study, and have been extensively used in basic researches of liver disease, pathophysiology, pharmacology and other related subjects[1-5]. Furthermore, they are a core material of bioartificial liver system which has been developed rapidly in recent years[6-10]. However, normal culture condition of hepatocytes *in vitro* differs greatly from the environment *in vivo*, and is difficult to maintain the physiological function of hepatocytes, leading to restriction of their extensive uses. Along with the advancs in the research of bioartificial liver support system and its related fields, a highly active hepatocyte culture system is urgently required to meet the quality requirement of cultured hepatoctyes in these studies[11-15].

It has been discovered that collagen is one kind of important matrix of hepatocytic basal membrane. Type I rat tail collagen is usually used as a coated material for hepatocyte culture. It promotes attachment and growth of hepatocytes. The effect of culture is much better than that without collagen coating, indicating that collagen matrix might be an important condition for long-term hepatocyte culture[16-18]. Based on this idea, we performed the collagen mixture culture for rat hepatocytes and the collagen sandwich culture for new-born Chinese experimental piglet hepatocytes, in order to improve the effect of hepatocyte culture, and provide experimental data for bioartificial liver.

MATERIALS AND METHODS

Animal

Wistar rats (both sexes, less than one month old) and newborn Chinese experimental piglets (both sexes, one week old) were provided by the Experimental Animal Center, Third Military Medical University. All studies were performed with the approval of Experimental Animal Committee in our university. The animals were fed under standard conditions and fasted for 4 h before the experiment.

Reagents

Type IV collagenase, type I mouse collagen (collagen VII) and epidermal growth factor (EGF) were purchased from Sigma. DMEM medium, RPMI1640 medium and FBS were from Gibco. Acrylamide, N,N' -methylene-bis-acrylamide, sodium dodecyl sulfate (SDS), Coomasie blue were from Shengong Biothech Company (Shanghai, China).

Cell isolation

Hepatocytes were harvested using a two-step collagenase perfusion technique described previously[19,20]. Breifly, an animal was anesthetized by pentobarbital sodium (30 mg/kg), followed by sterilizing the skin, opening the abdomen, exposing the portal vein, and heparin sodium (100-150 u) was injected into the portal vein. When the liver was isolated at liver hilus, it was first perfused with calcium and magnesium-free Hank' s buffer at 80-100 mL/min for 10-15 min. The liver was then perfused with 0.5g/L collagenase solution at 50-70 mL/min for

10 min. The two perfusion systems were kept at 37-38 ℃. After perfusion, the liver capsule was incised. The thick fibrous connective tissue was discarded, and cell suspensions were harvested. The cell suspensions were further digested at 37 ℃ for 10-15 min in case. When RPMI 1640 medium was used for cessation of digestion, the released cells were filtered through three-layer sterilized gauze and washed via three centrifugations (50 g). The hepatocyte viability greater than 95% as determined by trypan blue exclusion was used for culture.

Collagen mixture gel culture

The collagen mixture consisted of a 4:1 ratio of rats tail collagen and 4× DMEM brought to a pH of 7.2 using 1mol/L NaOH, 1×10^6 isolated rat hepatocytes were mixed with collagen solution and plated in a flask. The height of hepatocyte-collagen mixture was 0.3-0.4 cm. The mixture was incubated in a 37 ℃ incubator for 2 h until the collagen mixture was gelled, resulting in hepatocyte-collagen mixture gel. After washed 2-3 times with PBS, RPMI1640 medium containing 100mL/L FBS and EFG was added and the cells were cultured in normal conditions. The medium was changed daily and the culture was over on day 9. The normal single layer culture was used as control, the seeding density and medium were the same as collagen gel mixture culture.

Collagen sandwich culture

The collagen solution was prepared as described above, and coated on a 6-well plate. Collagen solution (1.2 mL) was added into each well and incubated in a 37 ℃ incubator for 2 h until the collagen was gelled. Freshly isolated hepatocytes (10^6) were plated on a 6-well plate precoated with collagen gel and cultured with serum free RPMI 1640. After 24 h, the culture medium was replaced by 1.2 mL/well collagen solution, and incubated in an incubator for 1 h until the collagen was fixed. The hepatocytes were cultured under the above conditions. The medium was changed daily and the culture was over on day 7.

Morphological and functional observations of cultured hepatocytes

Supernatant of the medium was collected every day during the rat hepatoclytes-collagen gel culture, and BUN was measured using a biochemical autoanalyzer (Model 7020, Hitach Co., Tokyo, Japan). Twenty-five μl of the supernatant of serum free medium with piglet hepatocyte sandwich culture was harvested on days 1, 2, 5, and 7 respectively, and separated on a 120 g/L SDS-PAGE, resulting in porcine albumin bands. The gel was stained with 5g/L Coomasie blue, and the images were analyzed with the gel documentation-analyzing systems (Gel DocTM 2000, Bio-Rad, USA). LDH-release in the supernatants of the two kinds of hepatocyte culture media was analyzed by ultraviolet dynamic method. Morphological changes of hepatocyes in both collagen gel mixture and sandwich cultures were observed under a phase-contrast microscope.

RESULTS

Morphology of rat hepatocytes cultured in collagen gel mixture
When freshly isolated hepatocytes were mixed with collagen and seeded on the culture plate, spherical hepatocytes were mixed in a slightly transparent collagen solution. When the collagen solution was gelled, the heptocytes were uniformly fixed within. After cultured for 24 h, most hepatocytes remained spherical in shape with part of the cells transformed into polygonal shape. The majority of hepatocytes adhered to each other presenting a fascicular growth (Figure 1). After cultured for 48 h, the majority of hepatocytes reconstructed their cellular polarity presenting a typical and even polygonal

morphology. Binuclei were observed in the majority of hepatocytes, the hepatic plate structure was gradually formed, and the boundary between hepatocytes was perfectly clear and bright, illustrating the formation and participation of bile canaliculi (Figure 2). Such cytomorphological characteristics remained till the end of culture. The rat hepatocytes via an ordinary single layer culture quickly sank and attached to the bottom of culture plate after seeding. Their cytomorphology changed from freshly isolated spherical morphology to a monolayer flat polygon. The cells became flat 48-72 h later and gradually lost their typical polygonal characteristic, and eventually, the hepatocytes were in conjunction with each other and grew in patches.

Figure 1 Morphology of rat hepatocytes in collagen gel mixture culture at 24 h (phase-contrast microscope ×200).

Figure 2 Morphology of rat hepatocytes in collagen gel mixture culture at 72 h (phase-contrast microscope ×200).

Morphological changes of hepatocytes cultured in sandwich configurations

After freshly isolated piglet hepatocytes were seeded on a single layer of collagen gel, the hepatocytes soon attached to the culture plates and their spherical morphology changed quickly to polygonal morphology. After 4 h of culture, the hepatoctyes exhibited colonial and fascicular growth, showing typical, uniform polygonal morphology (Figure 3).

Twenty-four hours after overlaying the upper-layer of the gel, the cells still remained polygonal in shape. Over the culture period, polygonal characteristics were much more typical, and showed unique nuclei, most of which were binuclei. Another unique appearance was that the cellular border was clear and bright among the cells, indicating formation of bile canaliculi. The reconstructed hepatocytes had a cellular polarity and a plate-like structure, and maintained their characteristics till the end of culture (Figure 4).

Urea synthesis by rat hepatocytes cultured in collagen gel mixture

Figure 5 shows the BUN level in supernatant of the medium

by dynamic measurement. The BUN level in collagen gel mixture culture group was higher than that in the normal culture group throughout the period, and was significantly higher on d 3, 4, 5,7 and 8 (*n*=5, *P*<0.05).

**Figure 3** Morphology of piglet hepatocytes cultured on a single layer of collagen gel at 4 h (phase-contrast microscope ×200).

Figure 4 Morphology of piglet hepatocytes cultured in sandwich configurations on d 5 (phase-contrast microscope ×200).

**Figure 5** BUN level in supernatant of medium.

Figure 6 Albumin secretion in cultured piglet hepatocytes by SDS-PAGE analysis. M: Low-range protein molecular weight markers; lanes A, B, C, D are culture media on days 1, 3, 5, 7.

Albumin secretion of piglet hepatocytes

Porcine albumin released from piglet hepatocytes was detected by SDS-PAGE during the procedure of sandwich culture and high rates of urea biosynthesis were maintained throughout this period (Figure 6).

LDH-release

The amount of LDH released from hephatocytes cultured in collagen gel was detected to be an average of 106±17.4 U/L by dynamic measurement in supernatant of the medium. The amount of LDH in supernatant of the medium with sandwich culture fluctuated between 24.8-58.6 U/L, and was not significantly different (*P*>0.05) at various batches. LDH release was declined both in collagen gel mixture and in sandwich culture and remained at a similar low level towards the end of culture.

DISCUSSION

Along with the improvement in the techniques of enzyme-digested hepatocyte isolation in recent years, hepatocyte culture has been applied extensively. However, since the complexity of liver structure and function as well as the existence of specificity of hepatocytes *in vivo*, isolating hepatocytes *in vitro* reguires very strict conditions. Monolayer attachment culture model is not suitable for hepatocytes *in vivo*, it only meets the general experimental requirements so far. In order to overcome this difficulty, enormous researches have been carried out to improve the media, supplements, growth factors, matrix or culture methods in hepatocyte culture. A series of methods have been developed, such as specified medium, addition of traceelements, transferrin, insulin, HGF, EGF, coated specific matrix, and the use of microcarrier as well as mixed culture[21-28]. However, a mature technique meeting the specific requirements of research in bioartificial liver supporting system requires a large scale of high density, high activity, and long-term hepatocyte culture. This has not been developed so far. Therefore, the exploration of hepatocyte culture with high activity becomes an important subject in this research field.

It is known that normal hepatocytes appear as a three dimensional structure arranged in the liver lobules. There exists a complicated connection between hepatocytes, parenchymal-nonparenchymal cells, and hepatocytes-extracellular matrix. Among them, the matrix has been found to play an important role in maintaining hepatocytic functions. A large number of researches have shown that using collagen to fix hepatocytes in the manner of sandwich configuration could create a matrix environment close to that *in vivo*, and availed thus, hepatocytes of growth and their specific function. In this study, freshly isolated hepatocytes from newborn Chinese experimental piglets were cultured between double layers of collagen sandwich configuration, and the hepatocytes were found to have good functions of protein secretion and maintained their cytomorphological characteristics with little LDH-leakage. This illustrated that double layers of collagen sandwich configuration could provide a fairly good cultural and growth condition to piglet hepatocytes with high activity. Even though the double layers of collagen sandwich configuration technique could be used in highly active hepatocyte culture, it is still a monolayer attachment culture, the liver plate so formed is still unlike the normal three dimensional structure of hepatocytes *in vivo*, and also lacks connections with other kinds of cells in the liver. In addition, the cell density is not high, and operation is not convenient, requiring digestion twice. Thereby, the double layers of collagen sandwich technique might not be suitable for the study of bioartificial liver supporting system and hepatocyte transplantation.

Collagen gel mixture is a novel gel immobilizing technique. In this method, the hepatocytes, collagen and medium are mixed and gelled after seeding. The medium was added on its top. Our study showed that rat hepatocytes cultured by such a method could uniformly mix in collagen gel, showing high-density and a three dimensional structural characteristic. During the culture period, the urea synthesizing ability of rat hepatocytes cultured by collagen gel mixture was obviously superior to that of hepatocytes cultured ordinarily and the LDH-release reflecting the hepatocyte activity was close to that of hepatocytes cultured ordinarily. This illustrated that collagen gel mixture could provide fine hepatocytes culture and growth with high density and high activity. The greatest advantage of this culture method is that the structure of cultured hepatocytes is closer to the normal three dimensional hepatocyte structure *in vivo* with the characteristics of high density and more extensive connections between hepatocytes and other cells. Therefore, collagen gel mixture immobilization may become one of the effective methods for hepatocytes culture in the bioartificial liver supporting system.

Abstract

AIM: To study the therapeutic effects of anti-fibrosis herbs and selenium on hepatic fibrosis induced by carbon tetrachloride (CCl_4) in rats and the underlining molecular mechanisms.

METHODS: Fifty-three Wistar rats were randomly divided into: normal control group, model control group, colchicine group, anti-fibrosis herbs group (AF group) and anti-fibrosis herbs plus selenium group (AS group). The last four groups were administered with CCl_4 at the beginning of experiment to induce hepatic fibrosis. Then colchicine, anti-fibrosis herbs and selenium were used to treat them. The normal control group and the model control group were given normal saline at the same time. At the end of the 6th week, rats in each group were sacrificed. Blood and tissue specimens were taken. Serum indicators (ALT, AST, HA, LN) were determined and histopathological changes were graded. Lymphocyte CD_4 and CD_8 were examined by flow cytometry. Expression of TGF-β_1 and NF-κB was detected by immunohistochemistry and expression of TGF-β_1 mRNA was detected by semi-quantified RT-PCR.

RESULTS: Histological grading showed much a smaller degree of hepatic fibrogenesis in AS group and AF group than that in colchicine group and model control group. The serum content of ALT, AST, HA and LN in AF group and AS group were significantly lower than that in colchicine group (ALT: 65.8±26.5, 67.3±18.4 and 96.2±20.9 in AF, AS and colchicine groups respectively; AST: 150.8±34.0, 154.6±27.3 and 215.8±24.6 respectively; HA: 228±83, 216±58 and 416±135 respectively; LN: 85.9±15.0, 80.6±18.6 and 106.3±14.2 respectively) ($P<0.05$). The level of CD_4 and CD_4/CD_8 ratio in AF group and AS group was significantly higher that those in cochicine group (CD_4: 50.8±3.8, 52.6±3.4 and 40.2±2.1 in AF, AS and colchicine groups respectively; CD_4/CD_8 ratio: 1.45, 1.46 and 1.26, respectively) ($P<0.05$). The expression level of NF-κB and TGF-β_1 in the liver tissues of AF and AS treatment groups was markedly decreased compared with that in cochicine group, and TGF-β_1 mRNA was also markedly decreased (1.07±0.31 and 0.98±0.14 *vs* 2.34±0.43, $P<0.05$).

CONCLUSION: Anti-fibrosis herbs and selenium have beneficial effects on hepatic fibrosis in rats by enhancing immunity and inhibiting NF-κB and TGF-β_1 expressions.

INTRODUCTION

Hepatic fibrosis is a common pathological process of chronic hepatic disease, leading to the development of irreversible cirrhosis[1-3]. The incidence of hepatitis is high in China[4-8]. If treated properly at fibrosis stage, cirrhosis could be prevented[9]. However, there are no effective antifibrosis drugs to date. Chinese herbs, which are well known for their long history of proven therapy of various diseases with low cost and few side effects, have particular potentials in the treatment of hepatic fibrosis[10-18]. In addition, some studies have indicated that selenium is closely related to the inhibition of hepatic fibrosis[19,20]. In the present study, we first established a rat model of chronic liver injury - hepatic fibrosis-cirrhosis and then tested the therapeutic effects of Chinese herbs and selenium on hepatic fibrosis. An array of indexes in proteins and mRNA levels were evaluated in order to understand the mechanism underlying the effects observed.

MATERIALS AND METHODS

Reagents

TGF-β_1 mRNA primers were purchased from Sangon Biological Technology Company, China. Anti-TGF-β_1 monoclonal antibody and anti-NF-κB polyclonal antibody were purchased from Santa Cruz Biological Technology Company, USA. Streptomycin avidin peroxidase immunohischemistry kit for immunohistochemistry and RNA isolation kit were purchased from Boster Biological Technology Ltd, China. Anti-CD_4 and CD_8 polyclonal antibodies were purchased from Caltag Biological Technology Company, USA. Serum activities of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were determined by the Laboratory Department of 4th affiliated hospital, Hebei Medical University, China. Serum hyaluronic acid (HA) and laminin (LN) concentrations were measured radioimmunologically using a commercial kit (Shanghai Navy Medical Institute, China).

Preparation of Chinese herbs

The anti-fibrosis herbs included Salvia miltiorrhiza, Sparganium stoloniferum, Angelica sinensis, Amyda sinensis, Curcuma aromatica, Carex phacota. These were purchased from Shijiazhuang Lerentang Pharmacy, China. The herbs were boiled with water and extracted by alcohol: put 95% alcohol in liquid of anti-fibrosis herbs, mixed the alcohol and herbs, filtrate the protein and amylum, then heat the liquid at 90-95 ℃ to evaporate the remained alcohol.

Establishment of animal model

Wistar rats, half males-half females, weighing 180-200 g were obtained from Experimental Animal Center of Hebei Medical

University, China. The rats were housed 5 heads per cage and subjected to 12 h-d/12 h-night cycle with free access to basic food and water. All animals were treated humanely according to the national guideline for the care of animals in the country.

Hepatic fibrosis was induced in rats by carbon tetrachloride (CCl_4). Wister rats were randomly assigned to normal control group (10), model control group (13), Colchicine group (10), anti-fibrosis herbs group (AF group, 10) and anti-fibrosis herbs plus selenium group (AS group, 10). On the first day of experiment, the rats in model group, colchicine group, AF group and AS group were given hypodermic injection of bean oil solution containing 400g/L CCl_4 (0.5 mL/100 g body mass), followed by injection of the same solution (0.3 mL/100 g body mass) every 4 d. The rats in normal control group received hypodermic injection of bean oil at the same dose and frequency. Fourteen times after CCl_4 administration, 3 rats in model control group were sacrificed to evaluate the liver histological change, which indicated the development of chronic hepatitis. Then colchicine group was given colchicine orally at a dose of 0.01 mg/100 g body weight daily, AF group was given anti-fibrosis herbs (2.11 g/mL) orally at a dose of 0.5 mL/100 g body mass daily, AS group was given orally anti-fibrosis herbs containing sodium selenite ($Na_2SeO_3.5H_2O$) at 3 µg/mL daily. Normal control group was given saline orally at a dose of 0.5 mL/100 g body mass daily. All the administrations lasted for 6 weeks.

Collection of specimens

At the end of the 6th week of the administration, rats in each group were sacrificed by amobarbital sodium anesthesia. Midline laparotomy was performed. Livers and thymus were excised and blood was collected through cardiopuncture.

Histological grading
